Another alternative method that has been proposed by chiropractors is spinal manipulation therapy. This method uses the concept that parasympathetic and sympathetic pelvic nerve pathways are closely associated with the spinal vertebrae, and therefore, mechanical dysfunction in these vertebrae results in disruption of the sympathetic nerve supply to the blood vessels supplying the pelvic viscera. This disruption causes dysmenorrhea due to vasospasm and constriction. With spinal manipulation spinal mobility is improved, the autonomic nerve function improves, and the resultant blood supply improves (Proctor et al., 2003). Alternatively, the theory behind how spinal manipulation therapy works has been explained by assuming dysmenorrhea is referred pain that originally arises from the musculoskeletal structures that share the same pelvic nerve pathways (Proctor et al., 2003). A review of recently published studies concluded that there is no evidence this technique is any more effective than sham manipulation, but it may be more effective than no treatment (Proctor et al., 2003).

Some final techniques are magnetic field therapy and photographic reinforcement during postoperative counseling after diagnostic laparoscopy. A randomized, double-blind placebo-controlled study out of the University of Tennessee Health Sciences Center and Mount Sinai School of Medicine, looked at 51 patients with chronic pelvic pain who had completed 2 to 4 weeks of treatment with either active (500 G) or placebo magnets applied to abdominal trigger points for 24 hours a day (Brown et al., 2002). The study used the McGill Pain Questionnaire, Pain Disability Index, and Clinical Global Impressions Scale as outcome measures. The authors concluded that there was a significant improvement in disability and pain after 4 weeks of continuous use. A randomized trial of photographic reinforcement evaluated 233 women who were randomly assigned to either see or not see a Polaroid print taken of the pelvis during diagnostic laparoscopy concluded that there were no significant differences in pain improvement between these two groups (Onwude et

al., 2004). In addition, the authors stated that the patients and the doctors did not feel that the photograph benefited communication regarding intraoperative findings as compared to controls.

The reader can access ACOG for its chronic pelvic pain definitions and guidelines (Williams et al., 2004).

Urologic Pain

Hossein Sadeghi-Nejad, MD, Carin V. Hopps, MD, and Allen D. Seftel, MD

UPPER URINARY TRACT PAIN (RENAL COLIC)

Renal colic is a severe paroxysmal pain that occurs from obstruction of the ureter at any point along its course. The most common cause of ureteral obstruction is a kidney stone that formed within the calyceal system of the kidney, became dislodged, and has been passed along the path of urine flow. In attempting to do so, however, the stone becomes wedged within the ureter somewhere along its course between the point at which the ureter joins the collecting system of the kidney (ureteropelvic junction) and the point at which the ureter enters the bladder (ureterovesical junction). It is estimated that approximately 12% of the population is expected to have urinary stone disease at some time in their lives (Sierakowski, Finlayson, Landes, Finlayson, & Sierakowski, 1978). In 55.4% of these individuals, it has been found that at least one first-degree relative had experienced renal stones, demonstrating that a hereditary component plays a significant role in urolithiasis (Ljunghall et al., 1985). The natural cumulative recurrence rate of calcium oxalate renal stones is approximately 14% within 1 year, 35% within 5 years, and 52% within 10 years (Uribarri, Oh, & Carroll, 1989). The gravity of this pathophysiological process is reflected in the cost incurred to the U.S. economy in 1993 that totaled $1.7 billion, including indirect costs from loss of productivity (Menon & Resnick, 2002). Although discussion of all causes of ureteral obstruction is beyond the scope of this chapter, the etiologies are multiple and diverse: they may be intrinsic or extrinsic, including, for example, congenital anomalies such as ureteral stricture and ureterocele; neoplastic processes such as primary or metastatic carcinomas of the ureter; inflammatory processes such as tuberculosis, schistosomiasis, or endometriosis; and other pathologic processes such as retroperitoneal fibrosis and pelvic lipomatosis.

Obstruction of the upper urinary tract may occur acutely or chronically and it may be complete or partial. Acute obstruction is typically accompanied by sudden onset, severe, colicky pain in the flank that radiates to the groin or to the ipsilateral thigh, occurring usually at night or in the early morning hours while at rest. Following acute obstruction, the kidney continues to produce urine, which in turn leads to distention of the renal pelvis (hydronephrosis) and ureter (hydroureter) proximal to the site of obstruction. Stretching of the renal capsule, which contains splanchnic innervation, with hydronephrosis, may cause nausea, vomiting, and chills (Teichman, 2004). For this reason, acute renal colic may be confused with an acute abdominal process such as appendicitis or gastroenteritis, or a pelvic process such as salpingitis. As the stone descends down the ureter, the location of the pain may course laterally and anteriorly along the individual's abdomen with radiation into the groin and testicle in the male and the labia majora and round ligament in the female. Visceral pain is transmitted by the autonomic nervous system, making localization of the source difficult (Menon & Resnick, 2002). Further descent of a stone toward the ureterovesical junction is associated with irritative voiding symptoms such as frequency, urgency, and dysuria. Patients with renal colic typically cannot position themselves comfortably and, if riding in a car, complain of severe exacerbation of pain with each bump in the road. On physical examination, the individual with acute ureteral obstruction will have severe costovertebral angle (CVA) tenderness such that pressing on the CVA is barely tolerated.

While the symptoms of acute complete obstruction are severe, the symptoms of partial unilateral obstruction may be subtle. For example, partial obstruction may only become symptomatic when the patient consumes a large fluid volume followed by a diuresis, which causes temporary exacerbation of upper tract distention and subsequent pain until diuresis subsides.

Following acute obstruction, the diameter and length of the ureter increase as pressure within the renal pelvis and ureter increases (Biancani, Zabinski, & Weiss, 1976). This is accompanied by pyelolymphatic and pyelovenous urine backflow wherein urine extravasates into lymphatic and small venous channels associated with the kidney (Stenberg et al., 1988). Despite this physiologic pop-off valve, however, the pressure may continue to rise acutely until rupture of the upper tract occurs at the fornix (the location at which the papillae of the kidney converge with the calyx of the collecting system). Rupture of the upper tract may cause a rapid diminution and possibly even complete resolution of pain, as urine may freely drain into the retroperitoneal space and pressure within the upper tract rapidly decreases.

MANAGEMENT OF RENAL COLIC

Fewer than 10% of patients with a newly diagnosed ureteral stone require hospitalization for pain management and treatment (Menon & Resnick, 2002). The majority of ureteral stones smaller than 4 to 5 mm pass spontaneously. Patients without evidence of severe obstruction, renal deterioration, or infection proximal to the site of obstruction may be treated conservatively as outpatients if they do not have nausea and if the renal colic responds to oral medication. Parenteral administration of pain medication may be necessary in the nauseated patient with refractory pain. Both narcotics and nonsteroidal anti-inflammatory drugs (NSAIDs) can be used in the treatment of renal colic. The benefits of narcotics include low cost, titratability, and potency, and the disadvantages include nausea and sedation. In addition, liberal use of narcotics in patients with renal colic may foster drug dependency and possible drug-seeking behavior. NSAIDs are non-narcotic analgesics that have a direct effect on the mechanism of pain through inhibition of cyclooxygenase, which results in decreased eicosanoid production subsequently reducing sensitization of pain receptors. NSAIDs are, however, not titratable and are associated with gastrointestinal bleeding and renal failure. Inhibition of cyclooxygenase also limits vasodilatation, thereby lowering renal blood flow and lessening diuresis, and decreases ureteral smooth-muscle stimulation. Limiting diuresis with an obstructive calculus will limit the extent to which the collecting system becomes distended and therefore the extent to which the patient experiences pain. Ketorolac tromethamine, an NSAID, was found to significantly

decrease ureteral pressure and renal blood flow within 15 minutes of administration in a canine model of unilateral ureteral obstruction, which in addition to the analgesic effect of ketorolac synergistically contributed to lessened pain (Perlmutter et al., 1993). However, the rapid decrease in blood flow to an obstructed kidney may adversely affect renal function, and therefore NSAIDs should be used with caution in this patient population.

The first study to compare an NSAID with morphine administered by intravenous (IV) titration evaluated rectally administered indomethacin with IV morphine for analgesia of renal colic in a randomized, double-blind, double-dummy, two-period crossover study and showed that IV morphine produced more rapid analgesia than rectally administered indomethacin, although at 20 and 30 minutes, no significant difference existed between the two groups (Cordell, Larson et al., 1994). A prospective, controlled, randomized, double-blind trial conducted in an academic emergency department comparing the efficacy of intramuscular ketorolac and meperidine (opioid) demonstrated that ketorolac was significantly more effective than meperidine in reducing renal colic at 40, 60, and 90 minutes, and patients who were treated with ketorolac left the hospital significantly earlier than those treated with meperidine, concluding that intramuscular ketorolac as a single agent for renal colic is more effective than meperidine and promotes earlier discharge of renal colic patients from the emergency department (Larkin, Peacock, Pearl, Blair, & D'Amico, 1999). When the analgesic efficacy and safety of IV ketorolac was compared with IV meperidine and with a combination of the two agents for renal colic in a double-blind, randomized, multicenter clinical trial, by 30 minutes, 75% of the ketorolac group and 74% of the combination group had a 50% reduction in pain scores, compared with 23% of the meperidine group, indicating that IV ketorolac, alone or in combination with meperidine, was superior to IV meperidine alone in moderate and severe renal colic, suggesting that clinicians may choose to initiate treatment with a ketorolac–meperidine combination (Cordell, Wright et al., 1996).

To determine the relative efficacy, benefits, and disadvantages of NSAIDs and opioids for the management of acute renal colic, Holdgate and Pollock (2004) performed a rigorous analysis of 20 randomized controlled trials that compared any opioid with any NSAID. The authors found that while both NSAIDs and opioids can provide effective analgesia in acute renal colic, opioids are associated with a higher incidence of adverse events (particularly vomiting observed especially with pethidine), prompting the recommendation that if an opioid is to be used it should not be pethidine. The new generation of NSAIDs, cycolooxygenase-2 (COX-2) inhibitors, does not inhibit cycooxygenase-1, which is located within gastrointestinal mucosa and is responsible for prostaglandin production that maintains gastrointestinal (GI) mucosal integrity. Thus, the use of

TABLE 31.1
Medications Commonly Used to Treat Renal Colic

Class and Name of Drug	Adult Dose
NSAIDs	
Ketorolac	30–60 mg IV or IM loading dose, then 15 mg IV or IM every 6 hours
	Oral continuation dose: 10 mg PO every 4–6 hours (maximum 40 mg/day), not to exceed 5 days
Diclofenac	50 mg PO 2 or 3 times/day
Cyclooxygenase-2 Inhibitors	
Rofecoxib	50 mg PO once/day
Narcotics	
Meperidine	1 mg/kg of bodyweight IM every 3–4 hours
Morphine sulfate	0.1 mg/kg IM or IV every 4 hours
Narcotic Combinations	
Acetaminophen with codeine	300 mg acetaminophen with 30 mg codeine, 2 tablets PO every 4–6 hours

Note: IM = Intramuscular; IV = Intravenous; PO = Orally. Appended from "Clinical Practice. Acute Renal Colic From Ureteral Calculus," by J. M. Teichman, 2004, *New England Journal of Medicine, 350*(7), pp. 684–693.

COX-2 inhibitors for the treatment of renal colic may provide clinical efficacy as has been observed with other NSAIDs while providing a reduced risk of GI toxicity. Teichman (2004) has made suggestions for different medications commonly used to treat renal colic which are detailed in Table 31.1 along with their dosages.

Alternatively, a prospective randomized study performed to compare the effect of acupuncture and an intramuscular narcotic analgesic analogue for the treatment of renal colic showed that acupuncture was as effective in relieving renal colic as the narcotic and had a more rapid analgesic onset in the absence of side effects, whereas 43.8% of the patients in the narcotic group had side effects including paralytic ileus, suggesting that acupuncture can be an excellent alternative for the treatment of renal colic (Atala, Amin, Harty, Liu, & Keeling, 1992). α-Adrenergic and β-adrenergic receptors have been identified in the human ureter, where α-adrenergic receptors are quantitatively predominant (Malin, Deane, & Boyarski, 1970). The efficacy of the α1-adrenergic antagonist tamsulosin in patients with renal colic secondary to a ureterovesical stone was compared with floroglucine-trimetossibenzene (a spasmolytic agent) in a nonblinded randomized trial (Dellabella, Milanese, & Muzzonigro, 2003). Although the mean stone size in this study was statistically larger in the tamsulosin group, the stone expulsion rate was significantly greater and the mean hours to expulsion, the mean number of diclofenac (NSAID) injections, the rate

of hospitalization, and the need for endoscopic stone removal were all lower in the tamsulosin group, suggesting that tamsulosin is effective in hastening the passage of juxtavesical ureteral stones and in decreasing both the severity and duration of renal colic.

BLADDER PAIN

Interstitial Cystitis

Interstitial cystitis (IC) is one of the most enigmatic disease entities in the field of urology. The earliest documented description of this disorder was made in 1808 by Philip Syng Physick, who described an inflammatory condition of the bladder comparable to an ulcer that produced lower urinary tract symptoms similar to a bladder stone (Parsons, 2004). He later expanded his description to include a chronic frequency, urgency, and pain syndrome in the absence of demonstrable etiology which was called tic douloureux of the bladder (Parsons, 2004). Although the disease entity has been recognized for nearly 200 years, the etiology and pathology of the disease remain elusive. IC is characterized by urinary frequency, urgency, and pain in the absence of identifiable inciting factors such as infection, malignancy, radiation, or medication. Pain may be present in the suprapubic area, lower abdomen, lower back, medial thighs, inguinal area, urethra, vagina or vulva in women, or scrotum or testis in men (Parsons, Zupkas, & Parsons, 2001). It is important to remember that the symptoms of IC exist on a spectrum from tolerable to severe, and patients find themselves anywhere between the two ends of the spectrum with alternating exacerbations and remissions.

Recent reports have demonstrated that the prevalence of IC is much greater than was previously thought. The prevalence of IC was calculated to be 8 to 16 per 100,000 female patients in the Netherlands in a study based on a questionnaire administered to urologists (Bade, Rijcken, & Mensink, 1995). The prevalence of IC in 184,583 female participants in the patient questionnaire-based U.S. Nurses' Health Study was between 52 and 67 per 100,000 women (Curhan, Speizer, Hunter, Curhan, & Stampfer, 1999). The disparity observed between these two studies may reflect different diagnostic criteria, detection rates, and study design. While the majority of individuals diagnosed with IC are women, chronic pelvic pain syndrome (CPPS) in men, formerly classified as prostatodynia and nonbacterial prostatitis (see below), shares features similar to IC, and the diagnosis of IC should be considered in patients with CPPS (Dunn, Miller et al., 1995). Early studies report that men make up only 10% of patients with IC (Cristol, Greene, & Thompson, 1944), although contemporary studies suggest that IC in men is underdiagnosed and is commonly misdiagnosed as prostatitis (Forrest & Vo, 2001).

Diagnosis of Interstitial Cystitis

In 1987, the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) first developed consensus criteria for the diagnosis of IC, which have subsequently undergone revision. These criteria, detailed in Table 31.2, were not intended to define IC, but rather to standardize criteria for the purpose of patient inclusion in clinical trials (Gillenwater & Wein, 1988). Glomerulations (small, punctate, red lesions) seen within the bladder mucosa at the time of cystoscopic hydrodistention under general anesthesia (technique described below) are essential for the

---

TABLE 31.2

Consensus Criteria for Diagnosis of Interstitial Cystitis from the National Institute of Arthritis, Diabetes, and Digestive and Kidney Diseases Workshop on Interstitial Cystitis

Automatic Exclusion:

Age <18 years
Benign or malignant bladder tumors
Radiation cystitis
Tuberculous cystitis
Cyclophosphamide cystitis or any other chemical cystitis
Vaginitis
Urethral diverticulum
Uterine, cervical, vaginal, or urethral carcinoma
Active genital herpes infection
Diagnosis of bacterial cystitis or prostatitis within a 3-month period
Bladder or ureteral calculi
Waking frequency <8 times per day
Absence of nocturia
Symptoms relieved by antimicrobials, urinary antiseptics, anticholinergics, or antispasmodics
Duration of symptoms <9 months
Bladder capacity >350 cc on cystometry
Absence of an intense urge to void with bladder filled to 150 cc of H_2O during cystometry, using fill rate of 30–100 cc/min
Involuntary bladder contractions demonstrated on cystometry

Automatic Inclusion:

Hunner's ulcer

Positive Factors:

Pain on bladder filling relieved by emptying
Pain (suprapubic, pelvic, urethral, vaginal, or perineal)
Glomerulations on cystoscopy
Decreased bladder compliance on cystometrogram

Y. Gillenwater, & A. J. Wein, 1988, *Journal of Urology, 140*(1), pp. 203-206; and "Interstitial Cystitis: An Introduction to the Problem," by A. J. Wein, P. M. Hanno et al., in *Interstitial Cystitis* (pp. 13–15), edited by P. M. Hanno, D. R. Staskin, R. J. Krane, & A. J. Wein, 1990, London: Springer-Verlag.

---

diagnosis of interstitial cystitis. However, examination with cystoscopy and bladder hydrodistention of 20 asymptomatic women undergoing tubal ligation demonstrated bladder mucosal lesions that are characteristically observed in patients diagnosed with interstitial cystitis (Waxman, Sulak, & Kuehl, 1998). Conversely, not all patients with IC develop glomerulations with hydrodistention (Awad, MacDiarmid, Gajewski, & Gupta, 1992). Given these findings, the diagnosis of IC is commonly one of exclusion. In 1915, Hunner (1915) described red, bleeding areas within the bladders of patients with IC, and while these were at one time thought to be pathognomonic for IC, they are actually very rare, observed in fewer than 5% of patients (Hanno, 2002).

While the exact etiology of IC has not been determined, multiple factors are thought to play a role in the pathogenesis of disease. Changes in urothelial permeability, increased mast cell activity, neuroimmune abnormalities, neuroplasticity of the nervous system, and infectious etiologies have all been implicated (Butrick, 2003). The bladder mucosa is lined by a mucus layer containing glycosaminoglycans (GAGs). This layer forms a physical barrier that prevents small molecules from diffusing through the urothelium into the submucosal tissue containing muscle and nerves (Lilly & Parsons, 1990). Potassium is present in high concentration in urine and normally does not penetrate healthy urothelium. However, individuals with IC, who have defects in the GAG layer, may be subject to potassium diffusion through the urothelium causing depolarization of sensory nerves (C-fibers) in the bladder muscle effecting the symptoms of IC (Parsons, 2004). The intravesical Potassium Sensitivity Test (PST) was developed to detect disruption of urothelial integrity. The PST was found to be positive in 78% of patients with clinical IC and in 0% of controls, suggesting that a positive PST correlates with the presence of an abnormal bladder epithelium (Parsons et al., 2001).

To perform the PST, 40 ml of sterile water is first instilled into the bladder over 2 to 3 minutes followed 3 to 5 minutes later by patient assessment of pain and urgency using a numerical scale from 0 to 5 (0 = none; 5 = severe; Parsons, 1996). The patient voids and 100 ml of a KCl solution (400 mEq/L) is instilled into the bladder over 2 to 3 minutes followed 3 to 5 minutes later by patient assessment of pain and urgency using the numerical scale. The patient voids and the bladder is thoroughly rinsed with water. If the patient experiences severe symptoms, 10,000 to 20,000 units of heparin in 20 cc of 1% lidocaine may be instilled into the bladder until the patient needs to void. Analgesics may be necessary as well. If the patient experiences no pain with instillation of water but scores ≥ 2 on assessment of pain or urgency, then the test indicates aberrant epithelial permeability.

Parsons et al. (2002) designed a self-administered, eight-item pelvic pain and urgency/frequency (PUF)

symptom scale that gives balanced attention to urinary urgency/frequency, pelvic pain, and symptoms associated with sexual intercourse. Answers to the eight-item questionnaire result in a score from 0 to 35; a high score is associated with a high likelihood of having IC. When validated by the PST, high PUF scores correlated with a high likelihood of a positive PST in urologic patients suspected of having IC and in gynecologic patients with pelvic pain, suggesting that the PUF is a valid tool for detecting IC (Parsons et al., 2002). The PUF is also useful in assessing symptoms that the patient is having but does not recognize as abnormal. The symptom complex of an individual with IC usually begins with frequency followed by the development of urgency and finally pain, ultimately prompting the patient to see a physician (Parsons, 2004). IC is associated with significant inter- and intraindividual variation in symptoms, resulting in common misdiagnosis of recurrent urinary tract infection and delay in the correct diagnosis for up to 4 to 7 years before being correctly diagnosed (Butrick, 2003). It is a progressive disease that can result in severe, unremitting pain with time in the absence of treatment to the extent that an end-stage bladder develops, requiring cystectomy with urinary diversion. Prompt identification of IC and timely treatment can lead to improved therapeutic success.

Pathophysiology of Interstitial Cystitis

The symptoms of IC are likely caused by persistent toxic insult on a molecular level that results in tissue injury. The bladder is the most densely innervated organ in the pelvis and has particularly rich innervation by silent afferent fibers (C-fibers) that transmit pain when activated by repeated abnormal noxious stimuli (Cervero, 1994). These fibers transmit a signal to the dorsal horn, which when persistent and repetitive causes activation of N-methyl-D-aspartate (NMDA) receptors in the spinal cord (Bennett, 1999). Subsequently, cells within the dorsal horn undergo neuroplastic changes, causing exaggerated and prolonged pain. The stimulus necessary to induce severe pain is thus significantly reduced; this augmented sensory processing is referred to as non-nociceptive pain, which is characterized by four features (Markenson, 1996):

1. The description of pain seems inappropriate in comparison with the degree of tissue pathology, or no tissue pathology is discernable.
2. Noxious stimuli result in a pain experience that is greater and more unpleasant than would normally be expected (hyperalgesia).
3. Normally non-noxious stimuli may result in pain (allodynia).
4. The extent of the pain boundary is greater than would be expected on the basis of the site of the original tissue pathology.

Neurogenic inflammation may occur as a result of activation of sensory nerves through release of neuropeptides such as substance P, neurokinin A, and calcitonin gene-related protein (Brookoff, 2000). These substances contribute to vascular permeability and mast cell degranulation with release of histamine and other mediators of inflammation causing injury and increased permeability of epithelial surfaces (Elbadawi & Light, 1996).

Increased concentrations of mast cells have been detected in patients with IC. Mast cells have been predominantly located within the detrusor muscle in these individuals and also within the lamina propria, the bladder epithelium, and bladder washings, whereas in control subjects mast cells have been found both in the lamina propria and detrusor muscle, but not in the epithelium nor in bladder washings, suggesting that the mucosal mast cell-IgE system is not only involved in the pathogenesis of IC but also that mast cells in patients with IC migrate across the epithelium (Aldenborg, Fall, & Enerback, 1986, 1989). Bladder washings from patients with ulcerative IC contained well-preserved mast cells and histamine, while only occasional mast cells and traces of histamine were found in washings from patients with non-ulcerative IC (Aldenborg et al., 1989). Mast cells secrete proinflammatory mediators in response to activation by IgE+antigen, acetylcholine, anaphylotoxins, substance P, chemicals, contrast agents, cytokines, opioids, antihistamines, exercise, hormones, viruses, and bacterial toxins (Hanno, 1994; Lagunoff, Martin, & Read, 1983).

Substances that cause mast cell secretion may be released by neurons that innervate the bladder. Investigation of the nerve population within the bladder wall using immunohistochemical stains demonstrated a significantly greater concentration of nerve fibers within the suburothelial and detrusor muscle layers in chronic IC when compared with controls and individuals with chronic bacterial cystitis and systemic lupus erythematosus cystitis, suggesting a specific association between nerve fiber proliferation and IC (Christmas, Rode, Chapple, Milroy & Turner-Warwick, 1990).

Mast cells and neurogenic inflammation may together promote defects in urothelial permeability, all of which contribute together to a cycle of persistent noxious stimulus to the bladder. Tight junctions between urothelial cells provide a barrier between the lumen of the bladder and submucosal tissue. It is suggested that GAGs line the bladder mucosa, providing a continuous physical barrier that prevents small molecules from reaching the underlying tight junctions and cell membranes and, hence, make up a major permeability barrier (Lilly & Parsons, 1990). Different types of GAGs include hyaluronic acid, heparin sulfate, heparin, chondroitin 4-sulfate and chondroitin 6-sulfate, dermatan sulfate, and keratan sulfate. Not only does the GAG layer provide a barrier to permeability but it also provides an antiadherence mechanism. The

increased bacterial adsorption that occurs when the bladder is denuded of the GAG layer was prevented by the instillation of heparin (Hanno, Fritz, Wein, & Mulholland, 1978). Parsons et al. (Parsons, Housley, Schmidt, & Lebow, 1994) demonstrated in a rabbit model that the ability of the bladder GAG layer to impair movement of both charged and uncharged small molecules is inhibited by protamine sulfate (heparin antagonist). This protamine effect can be reversed by a treatment with exogenous GAG (heparin), thus demonstrating that the GAG layer plays an important role as a bladder permeability barrier in modulating ion movement (Lilly & Parsons, 1990). Patients with IC were shown to have a leaky epithelium by placing a solution of concentrated urea into the bladder and measuring absorption (Parsons, Lilly, & Stein, 1991). In this study the control subjects absorbed 4.3% in 45 minutes, while the patients with IC absorbed 25%, a difference that was highly significant. Chronic self-administered intravesical heparin was studied to determine if replacement of GAG into the bladder would control the symptoms of IC, and in more than half of patients studied, intravesical heparin controlled the symptoms of IC with continued improvement even after 1 year of therapy (Parsons, Housley, Schmidt, & Lebow, 1994).

While the theory of aberrant epithelial permeability is attractive, not all studies support this mechanism in the etiology of IC. Patients with IC do appear to have a defect in epithelial permeability, but whether this is a primary defect or a result of a separate phenomenon such as mast cell degranulation or neurogenic inflammation is unclear. Likely, the pathogenesis is based on a cycle of events that escalates and in its persistence contributes to chronicity of the disease.

Treatment of Interstitial Cystitis

Hydrodistention

One of the first therapeutic approaches described for the treatment of IC was hydrodistention of the bladder with the patient under anesthesia. In addition to providing therapeutic benefit, hydrodistention also provides information that may facilitate diagnosis as described above. The literature has detailed variable techniques for hydrodistention in terms of pressure and duration of distention. In an early study of 25 patients with IC, treatment by bladder distention was performed at a pressure that was similar to systolic blood pressure for a period of up to 3 hours (Dunn, Ramsden, Roberts, Smith, & Smith, 1977). While 16 patients were symptom-free at a mean follow-up of 14 months, bladder rupture occurred in 2 individuals. Although this study suggested that prolonged bladder distention had a role for the treatment of IC, it also demonstrated that care must be taken to avoid morbidity. Hanno (2002) recommends initial cystoscopy, bladder washings for cytology, and distention of the bladder for 1 to 2 minutes at a pressure of 80 cm H_2O, followed by emptying of the bladder and refilling to assess for the presence of glomerulations or ulceration. A therapeutic distention is then performed for 8 minutes, and if a biopsy is necessary, it is performed following therapeutic distention. In patients with bladder capacity less than 600 ml, therapeutic response was excellent in 26% and fair in 29%, while in patients with larger bladder capacities, response was excellent in 12% and fair in 43% (Hanno & Wein, 1991). Overall, responses were brief, but those patients with a therapeutic benefit lasting 6 months are excellent candidates for repeat hydrodistention. It is thought that therapeutic benefit is secondary to damage of mucosal afferent nerve endings (Dunn, Ramsden et al., 1977).

Conservative Measures

Patients with IC may experience a spectrum of symptoms with alternating exacerbations and remissions. Some may have relatively mild symptoms with nocturia twice per night and a daytime urinary frequency of 2 to 3 hours. These patients may wish to defer medical treatment and instead utilize conservative measures while possible. It is thought that reduction from the diet of acidic foods such as caffeine, alcohol, and juices that acidify the urine may diminish severity of symptoms, although this theory has not been substantiated in clinical trials. Calcium glycerophosphate is a nutraceutical that is marketed for the treatment of IC to neutralize dietary acid, although clinical evidence demonstrating therapeutic benefit of the supplement and supporting its use is lacking. Similarly, the use of potassium citrate as a urinary alkalinizing agent has not been supported by clinical trials. The Interstitial Cystitis Association (www.ichelp.org) is a nonprofit health organization dedicated exclusively to providing a full range of programs, support services, and research funding necessary to help those who suffer with IC. Organizations such as this can be invaluable to individuals with IC in terms of education, which itself can eliminate a great deal of anxiety about the disease process. Awareness regarding the disease history and different types of treatment options as well as a connection not only to other patients with IC, but also to experts in the field may provide some degree of emotional relief.

Oral Medications

Oral medications used in the treatment of IC include tricyclic antidepressants, antihistamines, and pentosan polysulfate sodium (PPS; Elmiron™; Ortho-McNiel Pharmaceuticals, Rantan, NJ).

Tricyclic antidepressants. The most common oral agent used in the treatment of IC is amitriptyline, which may regulate neurological activation. Tricyclic antidepressants have several inherent properties that may benefit patients with IC:

- Anticholinergic actions decrease urinary frequency.
- Reuptake inhibition of serotonin and norepinephrine provide both analgesia and alleviation of potential depression associated with a chronic disease.
- Sedative effects (perhaps mediated by blocking H1-histaminergic receptors) improve sleep.

A clinical trial of amitriptyline for treatment of IC demonstrated that in 28 of 43 (65%) patients who could tolerate the medication for 3 weeks at a dosage of 25 mg that was titrated up to 75 mg over 2 weeks, 18 (64%) had complete remission of symptoms with a mean follow-up of 14.4 months (Hanno, 1994). The most common side effect limiting tolerability of the medication was sedation. Imipramine, a tricyclic antidepressant with general pharmacological properties similar to those of amitriptyline may also be used for the treatment of IC. A starting dose of 25 mg/day of amitriptyline or imipramine at bedtime is recommended (Parsons, 2004). The daily dose is increased to 50 mg/day after 1 to 2 months.

Antihistamines. As described above, mast cell degranulation is thought to be an etiologic factor in IC. Hydroxyzine, a piperazine H1-receptor antagonist, has been shown to inhibit neurogenic stimulus-induced bladder mast cell activation (Minogiannis, El-Mansoury, Betances, Sant, & Theoharides, 1998). An open-label, nonconsecutive case series of patients treated by their local physicians with oral hydroxyzine found that 90 of 140 patients that returned case-report forms reported a 40% reduction in symptom scores, while this rose to 55% in patients with a history of allergies, demonstrating that hydroxyzine is a useful drug for the symptomatic treatment of IC, especially in patients with documented allergies and/or evidence of bladder mast cell activation (Theoharides & Sant, 1997). It is recommended that patients with IC with a history of allergies stay on a continuous regimen of hydroxyzine, beginning with 25 mg/day at bedtime and increasing to 50 to 100 mg/day during allergy seasons (Parsons, 2004).

Pentosan polysulfate sodium. PPS was the first oral drug to receive regulatory agency approval for use in the treatment of IC in the United States in 1996. It is a synthetic sulfated polysaccharide sodium pentosanpolysulfate, a heparin analogue. Heparin sulfate is the predominant GAG located on the bladder surface. The mechanism of action is based on oral administration of a GAG that is then excreted in the urine, with subsequent repair of the GAG layer of the bladder, thereby eliminating the symptoms of IC. To determine the efficacy of 100 mg PPS three times per day in patients with IC, a randomized, prospective, double-blind, placebo-controlled study was conducted at seven clinical centers on 148 patients (Parsons et al., 1993). Of the patients on drug therapy, 32% showed significant improvement compared with 16% of those on placebo, and more drug patients showed a mean increase of greater than 20 ml in voided volume than did placebo patients. Long-term efficacy and safety of PPS in relieving recurring symptoms of IC were investigated in a long-term, open-label physician's usage study, which demonstrated overall improvement in symptoms in 62% of patients who received therapy for 6 to 35 months (Hanno, 1997). Most patients continued to show improvement over 1 to 2 years, demonstrating that the rate of response to PPS increases with duration of treatment. Adverse events were reported by fewer than 4% of subjects, most commonly reversible alopecia, diarrhea, nausea, headache, and rash. The recommended dosage of PPS is 100 mg given three times per day. In general a trial of PPS lasting up to 6 months is necessary to observe symptom improvement.

Intravesical Treatment

DMSO. Treatment of IC with intravesical agents has the potential benefit of rapid improvement in symptoms when compared with oral agents, as agents instilled into the bladder may locally affect the bladder mucosa directly, thereby effecting a rapid response. Dimethylsulfoxide (DMSO), a derivative of lignin, received regulatory agency approval for treatment of IC in the United States in 1978 (Abber, Lue, Luo, Juenemann, & Tanagho, 1987). DMSO has multiple pharmacological actions including anti-inflammation, analgesia, muscle relaxation, collagen dissolution, and enhancement of drug penetration (Bornman, Franz, Jacobs, & Pretorius, 1986). For treatment, 50 ml of a 50% DMSO solution is instilled into the bladder through a urethral catheter and is retained in the bladder for 15 minutes after which the patient voids to empty the bladder (Parkin, Shea, & Sant, 1997). For patients with difficulty voiding, the catheter may be kept in place and clamped for 15 minutes followed by drainage of the bladder and removal of the catheter. Typically, one instillation is performed once per week for up to 8 weeks, and maintenance therapy may then be instituted once every 2 weeks. Instillation should not be performed sooner than 2 to 3 weeks following a bladder biopsy and urine culture should be proved negative prior to treatment. A review of intravesical DMSO for treatment of IC demonstrated that with this regimen, the overall response rate is 50 to 90% in patients with non-ulcerative disease and 50 to 70% in patients with ulcerated, small-capacity bladders (Parkin et al., 1997). In addition, an overall relapse rate of 35 to 40% with a 4 to 8 week course of DMSO treatment occurred, although 50 to 60% of these patients responded to additional treatment with intravesical DMSO. The most common side effects included chemical cystitis (10%), initial worsening of symptoms (10 to 15%), and transient garlic breath (20 to 40%). Belladonna and opium suppositories, oral anticholinergics, and/or analgesics may be beneficial for patients who develop cystitis following DMSO instillation.

Heparin. Intravesically administered heparin, an exogenous GAG, has been shown to provide an epithelial permeability barrier in bladders injured with protamine, a heparin antagonist (Nickel, Downey, Morales, Emerson, & Clark, 1998). Intravesical heparin is given at a dose of 10,000 to 40,000 IU/day in 10 ml of water held within the bladder for 30 to 60 minutes for chronic therapy, or for maintenance this dose can be given three times/week (Parsons, 2004). To determine the effectiveness of intravesical heparin in treatment of IC, 48 patients underwent intravesical heparin therapy (10,000 units in 10 ml sterile water, three times per week for 3 months), and at 3 months 27 of 48 patients (56%) attained good clinical remissions (Parsons et al., 1994). In this study, the majority of responders that continued with treatment for up to 1 year observed continued improvement.

Pentosan polysulfate sodium. PPS, a semisynthetic GAG, may be dissolved and administered intravesically. To evaluate the therapeutic efficacy of intravesical PPS, a small, double-blind, placebo-controlled study was performed in which 10 patients received intravesical PPS (300 mg in 50 ml of 0.9% sodium chloride) instilled twice per week for 3 months and 10 patients received placebo (Bade, Laseur, Nieuwenburg, van der Weele, & Mensink, 1997). Four patients in the PPS group gained significant symptomatic relief compared with only two receiving placebo, while at 18 months from the start of the study, symptoms were relieved in eight patients still receiving PPS instillations and in four without treatment, suggesting that intravesical PPS provides some benefit in the treatment of IC.

Hyaluronic acid. Hyaluronic acid is a GAG marketed as Cystistat™ (Bioniche Live Sciences, Belleville, Ontario, Canada) in Canada and in Europe that is used intravesically as well. For treatment, 40 mg of hyaluronic acid dissolved in 40 ml of normal saline is instilled weekly for 4 to 8 weeks and monthly thereafter. A 3-year follow-up study of an initial open, nonrandomized trial of Cystistat demonstrated that 58% of patients observed significant long-term improvement in pain and urinary frequency, while approximately 20% of patients recovered to the extent that further treatment was unnecessary (Nordling, Jorgensen, & Kallestrup, 2001). Placebo-controlled, double-blinded investigation of hyaluronic acid for the treatment of IC is in progress.

Lidocaine hydrochloride. Lidocaine is a local anesthetic that belongs to the amide group and is associated with rapid onset of pharmacologic activity. Lidocaine has an anti-inflammatory effect including blockage of mast cell degranulation and inhibition of histamine release, which may contribute to improvement in symptoms of the patient with IC. Because intravesical lidocaine alone is not sufficiently absorbed by human bladders to achieve significant serum levels, it must be administered with sodium bicarbonate to promote absorption (Henry et al., 2001). Henry et al. demonstrated a significant decrease in

acute pain scores in a group of patients with IC treated with 5 mg/kg of 5% lidocaine mixed with 8.4% sodium bicarbonate daily for 3 days, indicating that a concentration of local anesthetic within the bladder wall was achieved that was sufficient to block the sensory neurons within the submucosal plexus. For patients with severe IC, Parsons (2004) recommends supplementation of oral pentosan polysulfate with intravesical heparin and lidocaine instillations performed once or twice per day (heparin 40,000 IU in 10 cc 1% lidocaine, or 16 cc 2% lidocaine if 1% is ineffective, and 3 ml of 8.4% sodium bicarbonate). Bupivacaine, an amide group local anesthetic with a longer half-life than lidocaine may have a role in intravesical treatment of IC as well.

Neurotoxins. Capsaicin is a pungent crystalline alkaloid found in chili peppers that acts as a neurotoxin by desensitization of C-fiber afferent neurons. A pilot study of intravesical capsaicin therapy performed on five female patients diagnosed with IC was performed to study the safety and efficacy of this agent (Fagerli et al., 1999). Topical anesthesia (30 ml of 0.5% bupivacaine) was instilled intravesically for 30 minutes prior to each weekly treatment with capsaicin in increasing concentrations of 10, 50, 100, and 250 μM solutions in 1% ethanol given as tolerated by the patient. Four of the five patients experienced subjective improvement in both symptom and pain score with no complications, suggesting that intravesical capsaicin is a safe and promising treatment for IC, potentially functioning through desensitization of bladder C-fiber afferents, which presumably initiate painful sensations in patients with IC. Resiniferatoxin, an ultrapotent analogue of capsaicin, was evaluated for the treatment of IC in a pilot study in which five female patients received a prolonged infusion of a saline solution containing 10 nM of resiniferatoxin at a flow rate of 25 μl/hour through an infusion pump connected to a 5 Fr suprapubic catheter for 10 days (Lazzeri et al., 2004). Patients were evaluated 30 days and >3 months from the end of infusion and showed a significant decrease in frequency, nocturia, and pain score without side effects, demonstrating that the prolonged intravesical instillation of resiniferatoxin by an *in situ* drug delivery system shows promise in the treatment of patients with IC. Clearly, additional investigation is necessary to determine the benefit of neurotoxins in this patient population.

Multimodal Treatment

As no single agent is curative for all patients with IC, a multimodal approach may be necessary. Therapy is directed at the different etiologic mechanisms that have been proposed in IC. Parsons (2004) has made several recommendations for multimodal therapy. Function of the lower urinary tract epithelium may be improved with administration of pentosan polysulfate in a dose of 100 mg given three times per day, or in very difficult to treat

patients, the dose may be doubled, although a dose greater than 300 mg per day represents an off-label use of the drug. Intravesical heparin may also help to restore urothelial function, given as frequently as once or twice daily instilled into the empty bladder at a dose of 40,000 IU in 10 cc 1% lidocaine with 3 ml of 8.4% sodium bicarbonate held within the bladder for 30 minutes. If the 1% formulation of lidocaine is ineffective, then 16 cc of 2% lidocaine can be substituted. Alternatively, heparin can be replaced by pentosan polysulfate in this formulation. The PPS capsules can be opened and the contents (100 to 200 mg) dissolved in 10 cc buffered normal saline (Parsons, 2004). Parsons and Davis (2003) report that 85% of patients who used the above intravesical solution three to seven times per week for 2 weeks or longer observed sustained pain relief. Parsons (2004) notes that patients with severe IC may realize improvement with these measures only after long-term treatment (up to 2 years) and therefore treatment with these GAGs should not be discontinued prior to this time period.

To diminish or, ideally, to reverse neural activation, amitriptyline may be added to the treatment regimen at a dosage of 25 mg per day at bedtime. This dosage can be increased to 50 mg after a period of 1 to 2 months as tolerated.

Control of the proposed allergic component of IC can be attempted with administration of hydroxyzine at a starting dose of 25 mg per day at bedtime, increased to 50 to 100 mg as needed and as tolerated. A broad approach to the multiple pathological mechanisms thought to be causative in the development of IC may best benefit the patient when a solitary treatment approach fails.

Nerve Stimulation

Up to 10% of patients with IC are unresponsive to oral or intravesical therapy (Webster & Galloway, 1987), and may benefit from neuromodulation with percutaneous sacral nerve stimulation (PNS). While previously surgical intervention has been considered for patients with refractory IC, PNS may offer a line of therapy prior to implementation of radical surgery. This technique employs electrical nerve stimulation to the third sacral nerve root with a wire electrode that is inserted into the foramen and is connected to an external pulse generator on a temporary basis to assess efficacy, followed by implantation of a permanent device if the trial is successful. The efficacy of PNS in treatment of patients with IC refractory to oral and intravesical treatments who would otherwise have been candidates for surgical intervention was assessed in a multicenter study that included 30 patients wherein statistically significant improvements were seen in frequency, pain, average voided volume (from baseline of 92 ± 73 ml to test average 134 ± 106 ml), maximum voided volume, and in symptom scores, suggesting that PNS is effective in reducing symptom severity and increasing voided volumes in patients with IC previously unresponsive to standard

therapy (Whitmore, Payne, Diokno, & Lukban, 2003). Implementation of sacral neuromodulation for treatment of severe IC provides a reversible option that holds significant promise in this patient population for which the only remaining alternative may be major surgery.

Surgical Therapy

The last resort for end-stage IC remains surgical therapy, although success rates with this approach are variable. While radical surgery is an option, it must be decided on only after prolonged consideration especially because IC is a nonmalignant process with the possibility of temporary remission and does not cause mortality (Hanno, 2002). Transurethral resection of Hunner's ulcers, which are observed in the minority of patients with IC, has been attempted. Complete transurethral resection of visible lesions in 30 patients resulted in initial disappearance of pain in all and a decrease in urinary frequency in 21; 10 patients experienced a relapse in pain at a mean of 10.2 months postoperatively (Fall, 1985).

Laser ablation of Hunner's ulcers may be performed as well. A prospective series of 24 patients who underwent ablative therapy of Hunner's ulcers using a neodymium (Nd):YAG laser showed that all patients had a significant decrease in pain scores, mean urgency score, and nocturia, and a significant increase in mean voiding interval was observed over a mean follow-up of 23 months, though relapse in 11 patients required one to four additional treatments (Rofeim, Hom, Freid, & Moldwin, 2001). This study demonstrated that Nd:YAG laser ablation of Hunner's ulcers represents a minimally invasive method of treating IC that offers patients an opportunity to achieve symptomatic improvement for an extended period and may be repeated as necessary. However, this procedure must be approached with caution, as laser scatter through the thin bladder wall may result in bowel injury.

Supratrigonal cystectomy, in which the majority of the diseased bladder is removed and the remaining bladder is augmented with a large patch of bowel, has been attempted for treatment of IC, and multiple studies investigating the success of this technique are reported in the literature with disparate success rates. Of 13 patients with refractory IC who underwent supratrigonal cystectomy and ileocystoplasty (augmentation of the bladder with ileum), all 10 patients with ulcerative IC experienced relief of symptoms, while 3 patients with non-ulcerative IC had persistent pain (Peeker, Aldenborg, & Fall, 1998). In these latter patients, trigonal resection and urinary diversion with a Koch pouch was performed with resolution of symptoms, suggesting that supratrigonal cystectomy with ileocystoplasty is unsuitable for non-ulcerative disease. Conversely, of 23 patients with IC refractory to conservative therapy treated with subtotal cystectomy and orthotopic bladder substitution with an ileocecal pouch, 20 patients were completely symptom-free at a mean follow-

up of 31.5 months, demonstrating that this technique offers significant benefit to the patient with refractory IC (Linn et al., 1998). Review of a series of 100 intestinocystoplasties revealed that 57 had postoperative complications, and of those, 27 patients required either early or late surgical intervention, while 30 were managed non-operatively (Khoury, Timmons, Corbel, & Webster, 1992). The high complication rate of partial cystectomy with bladder reconstruction using bowel must be weighed against the potential benefit.

Alternatively, urinary diversion with or without cystourethrectomy may be performed. If urine is diverted with an ileal loop conduit and the bladder remains *in situ*, complications such as pyocystis, hemorrhage, and pain or spasm may occur potentially requiring eventual cystectomy, and for this reason, cystectomy is recommended at the time of urinary diversion (Adeyoju et al., 1996). In conjunction with cystectomy, continent diversion of the urine (with a catheterizable, continent reservoir created with bowel) or total bladder replacement with creation of a neobladder has been described in the literature for treatment of refractory IC, as well with disparate results. Although the surgical procedure may be technically successful, 40 to 50% of patients can develop "pouch" pain (pain within the urinary diversion) or phantom pain within the pelvis, despite removal of the bladder (Broderick, Gordon, Hypolite, & Levin, 1994; Parsons, 2000). While surgical intervention for the patient with IC for whom all other treatment options have failed may be successful in relieving the patient of debilitating symptoms, surgical complications are not uncommon and no guarantee can be issued that an individual's symptoms will be cured. Surgical intervention for IC must therefore be approached with reservation.

BLADDER CANCER

A study performed by the American Cancer Society estimated that in the year 2000, 53,200 new cases of bladder cancer would be diagnosed in the United States and that, of those, 72% would be detected in men (Greenlee, Murray, Bolden, & Wingo, 2000). For perspective, according to the U.S. Census Bureau, the population of the United States on April 1, 2000, was 281,421,906. In men, bladder cancer is the fourth most commonly diagnosed cancer after prostate, lung, and colorectal carcinomas, representing 6.2% of all newly diagnosed cancers, while in women, bladder cancer is the eighth most commonly diagnosed cancer after breast, lung, colorectal, uterine, ovarian, non-Hodgkins lymphoma, and melanoma, representing 2.5% of newly diagnosed cancers (Greenlee et al., 2000).

While bladder cancer can occur at any age, it is usually detected in middle age or later; the median age at diagnosis for women is 71 years and for men 69 years of age (Lynch & Cohen, 1995). The most common symptom with which a patient with bladder cancer presents is painless hematuria (macroscopic or microscopic blood in the urine), which occurs in up to 80% of patients with bladder cancer (Schoenberg, 2002). The second most common symptom is one or more of a complex of irritative voiding symptoms including dysuria (pain with urination), frequency, and urgency (Schoenberg, 2002). This type of presentation may be observed with carcinoma *in situ* or invasive bladder cancer. It is unusual for patients with bladder cancer who present with this symptom complex not to have hematuria, although if irritative voiding symptoms are present in the absence of hematuria and in the absence of infection, full evaluation for bladder cancer must be performed. The urinary tract is typically assessed with renal ultrasound to evaluate the renal parenchyma and with intravenous pyelogram and cystoscopy or retrograde pyelogram and cystoscopy to assess the entirety of the urothelium from collecting system within the kidney to the bladder.

Superficial bladder cancer is treated with transurethral resection of the tumor and possible intravesical chemotherapy, while muscle invasive bladder cancer is treated with cystectomy. Although the majority of bladder cancers are painless, large tumors infiltrating the pelvic viscera such as the prostatic stroma, rectum, uterus, or vagina (Stage T4a) or the pelvic sidewalls or abdominal wall (Stage T4b) may cause severe pelvic pain. While rarely curative, locally invasive tumors can be treated with radiation or chemotherapy for palliation, although if refractory to these measures, cystectomy and/or tumor debulking may remain the only alternative for pain relief. Bladder tumors may also have a mass effect on the ureter or extend directly into the ureter resulting in ureteral obstruction. If ureteral obstruction occurs gradually, the patient may not experience renal colic and with chronic obstruction a painless loss of renal function can occur.

PROSTATITIS AND PELVIC PAIN SYNDROMES

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Adult men of all ages may be affected by prostatitis, a condition that results in more physician visits in the United States than benign prostatic hypertrophy (BPH) or prostate cancer. (Lobel & Rodriguez, 2003; Roberts, Lieber, Bostwick, & Jacobsen, 1997). A national survey of physician visits in the 1990s revealed that more than 2 million office visits per year were attributed to the diagnosis of prostatitis (Collins, O'Leary, & Barry, 1998). In a letter addressed to the editor of the *Journal of Urology* in 1978, Drach, Fair, Meares et al. outlined a scientific and systematic approach to the management of patients with symptoms of prostatitis. In 1995, a National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) workshop on prostatitis classified the prostatitis syndromes: (I) acute bacterial prostatitis, (II) chronic bacterial prostatitis, (III)

chronic prostatitis/chronic pelvic pain syndrome (CPPS), and (IV) asymptomatic inflammatory prostatitis (Schaeffer et al., 2002). More recently, Krieger et al. (Krieger, Nyberg, & Nickel, 1999) outlined new recommendations for patient evaluation and classification based on the U.S. National Institutes of Health consensus recommendations. The authors recommended patient classification and evaluation based on the segmented urinary specimens (including the seminal fluid) and evaluation of symptoms. The new recommendations expanded the concept of nonbacterial prostatitis by including the seminal fluid in the evaluation and permitted inclusion of seminal inflammation or other urogenital organ abnormalities as potential factors in the etiology of the patients' symptoms (Krieger et al., 1999). In a study of the demographic and clinical characteristics of the chronic prostatitis cohort, Schaeffer et al. (2002) reported that the majority of patients with chronic prostatitis are white, affluent, and well educated. The same investigators noted that lower socioeconomic status, younger age, and lower education were correlated to more chronic pelvic pain symptoms. Furthermore, it is unknown whether decreased income and disability are *caused* by CPPS or whether those who have disability and lower incomes are more prone to developing CPPS (Schaeffer et al., 2002).

The exact pathophysiology of prostatitis has not been clearly elucidated. The presence in prostatic calculi of constituents found only in urine and not in prostatic secretions led Kirby to suggest that inflammatory prostatitis may arise secondary to intraprostatic ductal reflux (Kirby, Lowe, Bultitude et al., 1982). Nickel has nicely summarized the hypotheses based on the concept of intraprostatic ductal urine reflux as follows: Intraductal reflux of urine causes an immunologically mediated inflammatory response in the prostate. Presence of pathogenic bacteria in various segments of the urethra will send the bacteria and the refluxing urine into the prostate, an event that is followed by a quick antibody response resulting in acute bacterial prostatitis *if* the bacterial antigens have not been previously introduced into the prostate (Nickel, 1995). This scenario typically yields to proper antimicrobial therapy and resolution of the acute febrile illness. In a different scenario, recognition of the pathogen by the prostate will result in a slower and milder inflammatory process (chronic bacterial prostatitis). Recurrence of infection occurs because the bacterial microfilm adherent to the ductal epithelium protects these bacteria from host defenses and antibiotics. Given the presence of intraductal reflux, even complete elimination of the bacteria leaves the system open to reinfection with different bacterial strains in the future (Nickel, 1995).

Acute Bacterial Prostatitis

From a purely clinical standpoint, it is important to consider that only a minority of the patients seen in clini-

cians' offices with complaints of pelvic pain have demonstrable "bacterial prostatitis" in the acute or chronic form. Acute bacterial prostatitis is a sudden-onset, febrile illness that results from acute infection of the prostate by aerobic Gram-negative rods, predominantly *Escherichia coli* and *Pseudomonas* spp., that are also commonly encountered in urinary tract infections (UTIs). The latter species, as well as other resistant organisms such as *Enterococcus faecalis* and *Staphylococcus aureus*, are typical causative organisms in bacterial prostatitis that is caused in hospitalized patients whereas nonhospitalized prostatitis is typically caused by coliforms (Meares, 1991). The role of other than enterococci has been questioned in prostatitis. Most Gram-positive organisms (with the exception of enterococcus and possibly *S. aureus*) cannot be reproducibly localized to the prostate in men with prostatitis and do not cause recurrent UTI in untreated patients (Meares, 1991).

Chronic Bacterial Prostatitis

The clinical hallmark of this condition is recurrent UTIs caused by identical bacterial strains due to persistence of the pathogen within the prostate. The recurrence of infections with the same pathogen has been attributed to poor penetrability of most antimicrobials into the prostate and hence reemergence of the unaltered pathogen after cessation of antibiotic therapy. Improved prostate penetration of newer-generation antibiotics such as the fluoroquinolones may result in a gradual decline in the prevalence of chronic bacterial prostatitis in the future. Prostate stones are commonly found in adult men and may be infected. It has been suggested that unrecognized infected prostate stones may account for some cases of persistent chronic bacterial prostatitis despite prolonged antimicrobial therapy (Meares, 1991).

Chronic Prostatitis/Chronic Pelvic Pain Syndrome (Category III)

This syndrome is a broad group that composes the largest segment of symptomatic patients and may be inflammatory (subcategory A) or non-inflammatory (subcategory B). Men in a variety of demographic subgroups may be affected and the disorder has a serious negative impact on the quality of life. Chronic prostatitis/CPPS has a poorly understood etiology that is refractory to most medical therapies and is further characterized by low correspondence of symptoms and objective findings, and association with psychosocial dysfunction, shared features among many chronic pain syndromes (Turner et al., 2002). The primary objective feature of this condition is genitourinary pain of at least 3 months duration in the absence of documented uropathogenic bacteria using standard microbiological procedures. The inflammatory subcategory of this

condition is distinguished by the presence of leukocytes in the expressed prostatic secretions (EPS), semen, or prostatic massage urine whereas no bacteria are detected in the non-inflammatory subcategory (Lobel & Rodriguez, 2003). Some investigators are skeptical of the accuracy or clinical significance of this newer National Institutes of Health (NIH) classification and cite lack of a cutoff point for the degree of leukocytosis and the possible pooling in the current system of patients with an autoimmune mechanism responsible for chronic pelvic pain as some of the potential pitfalls of this newest classification (Maake & John, 2003).

The role of cytokines, immunological causes, prostate tissue pressure, and bladder neck morphologic or functional alterations are among the more recent areas of focus. It has been suggested that alterations of the bladder neck may be observed in patients with CPPS. A recent study by Hruz et al. (Hruz, Danuser, Studer, & Hochreiter, 2003) from Germany found that among 48 patients who fulfilled the criteria for NIH classification of non-inflammatory chronic pelvic pain syndrome (III-B), 60% had bladder neck hypertrophy documented in endoscopic studies. The same authors speculated that in those patients with this diagnosis in whom bladder neck hypertrophy may not be visually documented, a functional obstruction in the form of detrusor/internal sphincter dyssynergy may be responsible for the symptoms. An active inflammatory process in the genital tract has been inferred from a number of publications that have shown elevated levels of cytokines — interferon-gamma (IFNγ), interleukin-2 (IL-2), IL-10, tumor necrosis factor-alpha (TNF-α), IL-6, IL-8 — in the seminal plasma or prostatic secretions of men with CPPS (Miller, Fischer, Goralnick et al., 2002; Orhan, Onur, Ilhan, & Ardicoglu, 2001). An adaptive immune response directed against a genital tract antigen(s) (autoimmunity) has been proposed as a possible mediator of this inflammatory reaction. (Batstone, Doble, & Batstone, 2003) Another mediator of an autoimmune process may be a bacterial inflammatory event. This view is supported by demonstration of increased levels of bacterial 16S ribosomal DNA in the prostates of men with chronic prostatitis compared with controls (Krieger & Riley, 2002). The role of increased intraprostatic pressure in the pathophysiology of CPPS has been evaluated by Mehik et al. (Mehik, Alas, Nickel, Sarpola, & Helstrom, 2003) who demonstrated statistically significant elevations of intraprostatic pressure in patients with both the inflammatory and non-inflammatory subtypes of CPPS. The association of rheumatological conditions with CPPS in as many as 21% of patients with prostatitis is suggestive of an immunological process, and the presence of rheumatological disorders in patients with prostatitis is associated with worse quality-of-life scores (but not with more severe symptoms) in questionnaires (Schaeffer et al., 2002). Another support for an autoimmune cause for CPPS comes from Batstone

et al. (Batstone, Doble, & Gaston, 2002), who show that the patient's peripheral T cells proliferate to the seminal plasma and propose a T-cell-mediated response to a seminal plasma antigen as the root cause of CPPS.

Asymptomatic Inflammatory Prostatitis

This category is characterized by lack of subjective symptoms in patients in whom white blood cells are found in prostatic tissue or in prostate secretions during evaluation or treatment of other disorders (Schaeffer et al., 2002).

Parsons (2003) has suggested that prostatitis, IC, chronic pelvic pain, and urethral syndrome share a common pathophysiology in lower urinary dysfunctional epithelium and potassium recycling. His group has devised the PST to test for bladder epithelial dysfunction and to test for the hypothesis that potassium cycling is responsible for generating symptoms. He reports that the rate of positive PSTs in men with category IIIA-IIIB CPPS is 84%, similar to the rate found in patients with IC and female patients with pelvic pain (Parsons, 2003).

DIAGNOSIS OF PROSTATITIS

Acute bacterial prostatitis (*category I*) presents with an acute bacterial urinary tract infection that may manifest with a variety of localized or systemic symptoms. The typical patient will give a history of sudden chills, fever, and low back and/or perineal pain as well as possible irritative or obstructive voiding dysfunction (Meares, 1991). Other reported symptoms include evolving arthralgias, myalgias, and general weakness. In this condition, the prostate is typically swollen, warm, and tender to palpation on digital rectal examination. Evaluation of the prostatic secretions reveals heavy growth of the bacterial pathogen. Numerous white blood cells (WBCs) as well as macrophages that are packed with fat droplets may be demonstrated on microscopic evaluation. Prostate massage is not recommended during the acute phase of the infection because the examination is universally uncomfortable and the responsible uropathogen is readily cultured from the voided urine without the need for prostate massage (Meares, 1991).

Most patients with *chronic bacterial prostatitis* (*category II*) will complain of nonspecific perineal or lower abdominal pain without systemic signs and symptoms. Prostate examination findings are variable and range from completely normal to indurated or boggy. Diagnosis depends on a culture of a standard uropathogen in the postprostatic massage-voided bladder specimen or in the expressed prostatic secretions that is at least 1 log greater in colony-forming units than the preprostate massage urine specimens as per the Stamey–Meares localization procedure guidelines (Batstone et al., 2003; Meares & Stamey, 1968).

Chronic pelvic pain syndrome/chronic nonbacterial prostatitis: The diagnosis of CPPS relies heavily on the patient's history. Patients frequently complain of prostatic tenderness and pain between the rectum and testes, highlighting the likely role of the prostate in CPPS pathophysiology; however, various socioeconomic influences in the prevalence of this disorder in different groups as well as family histories and IC-like overactive bladder symptoms in a number of these patients suggests the possibility of other organ system (e.g., bladder) involvement (Schaeffer et al., 2002). Because a "gold standard" diagnostic test for chronic prostatitis/CPPS does not exist, CPPS is in some ways a diagnosis of exclusion and all other pathology must be excluded first (Batstone et al., 2003. Perineal and suprapubic pain are the major complaints of patients with chronic prostatitis/CPPS, and it is the presence of pain, particularly post-ejaculatory pain, that differentiates lower urinary tract symptoms (LUTS)/BPH from prostatitis (Nickel, 2003). For accurate follow-up and establishing a reproducible measure of the patient's progress, it is recommended that the Chronic Prostatitis Symptom Index, developed in 1999, be used (Potts, 2003). Potts (2003) and others have suggested that because of the overlapping nature of symptoms in CPPS and many other illnesses, it is critical to complete a thorough review of systems and include potential psychological factors among the possible etiologies for this disorder. Similarly, formal psychological/psychiatric counseling and stress reduction measures should be among the armamentarium of interventions considered in this group. A study of 357 men with CPPS revealed that only 36% were presenting with their first episode of pelvic pain and highlighted the persistent and recurrent nature of this disease as well as the possible beneficial role of cognitive-behavioral and self-management interventions as long-term strategies for symptom control (Turner et al., 2002). Objective differentiation of categories IIIA (inflammatory) and IIIB (non-inflammatory) is made by finding inflammatory cells in the semen, voided bladder specimen (postprostate massage), or the EPS (Batstone et al., 2003. A group of patients with CPPS may have tenderness of the pelvic floor muscles, which may be secondary to inflammation, prostatic infection, or muscle spasm; these patients may benefit from pelvic muscle physiotherapy (Schaeffer et al., 2002).

TREATMENT OF PROSTATITIS

Acute Bacterial Prostatitis

As in most infectious processes, the mainstay of therapy in acute bacterial prostatitis is the administration of antimicrobials. This is a serious bacterial infection that may be potentially fatal and requires immediate attention and antibiotic therapy. Hospitalization for general supportive measures including bed rest, intravenous fluid adminis-

tration, antipyretics, and pain management may be required for the very ill and those who cannot tolerate oral fluids/medications. The severe inflammatory nature of this disease allows excellent accumulation of antibiotics at therapeutic levels in the prostatic secretory system, stroma, and interstitium with usually prompt clinical response (Meares, 1991). Outpatient management may be started with fluoroquinolones (pending final culture and sensitivity results) for those who can tolerate fluids and are not critically ill. The clinician should be aware of the possibility of prostatic abscess formation in cases refractory to antibiotic therapy. Transperineal or transurethral drainage of the abscess may be employed after sonographic or CT scan documentation, but transurethral instrumentation is not recommended during the acute, febrile phase of the disease (Gurunadha Rao Tunuguntla, & Evans, 2002). For the systemically ill patient, hospitalization and initial treatment with intravenous ampicillin and an aminoglycoside, quinolone, or third-generation cephalosporin may be employed and later followed with an appropriate oral agent for a minimum of 4 weeks once the culture and sensitivity results are obtained (Nickel, 1995). Alpha blocker therapy may decrease the chance of urinary retention, and the patient may benefit from alpha blocker combination with a NSAID to subside the inflammatory process in the prostate/bladder neck area. In case of urinary retention, a punch suprapubic cystostomy is recommended to avoid possible epididymitis or prolongation of the infection as a result of urethral catheterization (Gurunadha Rao Tunuguntla & Evans, 2002).

Chronic Bacterial Prostatitis

An extended period of antibiotic therapy forms the backbone of treatment for chronic bacterial prostatitis. Chronic prostatitis due to coliforms is more responsive to therapy than *Pseudomonas aeruginosa* or enterococcal CBP (Lobel & Rodriguez, 2003). In general, antibiotics with lipid solubility and a high pKa such as quinolones, sulfas, macrolides, tetracyclines, and aminoglycosides have the best prostate permeability. However, bacteriologic "cure" may not translate into symptom relief in chronic bacterial prostatitis and, in one study of antibiotics in chronic prostatitis, Nickel et al. (Nickel, Downey, Johnston et al., 2001) demonstrated the least symptom benefit among those patients who had positive cultures (Shoskes, 2003). Furthermore, the particular anatomic and morphological processes affecting the prostate in chronic bacterial prostatitis (i.e., microabscess formation, stasis and obstruction in prostatic ducts and ascini, prostatic calculi, and biofilm-enclosed bacterial colonies) prevent optimal efficacy of even those antibiotics such as fluoroquinolones and trimethoprim-sulfamethoxazole (TMP-SMX) that have been demonstrated to have superior prostate permeability (Nickel, 1995). Consequently, a characteristic of chronic

bacterial prostatitis is frequent relapses with the same organism and low-dose. Chronic suppressive antibiotic therapy with nitrofurantoin or TMP-SMX to control the symptoms and prevent bacteriuria is indicated, although even prolonged therapy often does not eradicate the bacteria and symptoms will recur after cessation of therapy (Meares, 1991). Despite a paucity of data pertaining to long-term recurrence and symptom eradication rates, the results of therapy with quinolones appear to be superior to TMP-SMX (Lobel & Rodriguez, 2003). A trial of alpha-blockers or repetitive prostatic massage may be appropriate in patients who fail to respond to antibiotics alone (Barbalias, Nikiforidis, & Liatsikos, 1998; Nickel, Alexander, Anderson et al., 1999; Shoskes, 2003). For those experiencing reflux of a new pathogen into the prostate after eradication of the original bacteria, low-dose prophylactic antibiotic therapy is recommended (Nickel, 1995). Meares (1986) reported success in curing refractory chronic bacterial prostatitis by means of antibiotic therapy combined with "radical" transurethral prostatectomy, but this approach is a "last ditch" effort that is not widely used.

Chronic Pelvic Pain Syndrome/Chronic Nonbacterial Prostatitis

A wide variety of treatment regimens have been proposed for this most common and controversial category of prostatitis. General supportive measures offered by most clinicians caring for the CPPS patients include sitz baths, avoidance of spicy foods, and increased or decreased sexual activity/ejaculation as the last has been shown to alleviate *or* exacerbate symptoms in various groups of patients (Shoskes, 2003; Yavaskaoglu, Oktay, Simsek, & Ozyurt, 1999). Anti-inflammatory medications are also commonly prescribed as more publications have pointed to an autoimmune and inflammatory etiology of CPPS (Batstone et al., 2003; Maake & John, 2003; Orhan et al., 2001).

Therapy directed at relief of pain and spasm of the pelvic floor muscles has been reported through the use of biofeedback and bladder retraining as well as amitriptyline and gabapentin alone or in combination (Shoskes, 2003; Ye et al., 2003).

Despite lack of strong scientific evidence and the fact that complete bacterial localization studies are rarely performed, most clinicians will treat chronic prostatitis/CPPS with an initial trial of antibiotics and use the rationale that cultures may be inconclusive due to "difficult-to-culture bacteria" such as chlamydia, ureaplasma, and mycoplasma and that empiric therapy is easier than performing extensive and inconclusive cultures (Shoskes, 2003). Furthermore, Nickel et al. (2001) have shown that up to 57% of patients with chronic prostatitis/CPPS will respond to empiric antibiotic therapy and that the response to antibi-

otics is independent of culture results, white blood cell count, or antibacterial antibody status.

In 1981, Osborn et al. (Osborn, George & Rao, 1981) demonstrated the beneficial effects of the nonselective alpha blocker, phenoxybenzamine, in the treatment of the symptoms of prostatodynia. Since then, a number of publications have addressed the possible benefits of different alpha blockers in the management of prostatitis and concomitant relief of voiding symptoms. Mehik et al. (2003) reported on the use of alfuzosin in prostatitis and found that 6 months of alfuzosin therapy for chronic prostatitis/CPPS is safe and well tolerated. Compared with placebo and standard/traditional treatments listed above, the NIH-Chronic Prostatitis Symptom Index (CPSI) showed a modest improvement, particularly in the pain domain, after alfuzosin therapy. The authors further reported that the beneficial effect is not seen until after several months of treatment and disappears when treatment is discontinued. In a nonrandomized study, resolution of symptoms was seen in 76% of patients with prostatodynia after 1 month of alpha-blocker therapy with terazosin and 58% remained asymptomatic 3 months later (Neal & Moon, 1994). Overall, there are four small, placebo-controlled trials addressing the use of alpha blockers in chronic prostatitis/CPPS and this therapy has become increasingly popular among urologists, but there is no consensus regarding the mechanism of action of the alpha blockers' beneficial effects in prostatitis (Nickel, 2003).

The role of prostate massage alone or in combination with antibiotics and other remedies has received renewed attention in a number of publications. Patients who are most likely to benefit are those who have symptom relief with the first massage and have large volume EPS (Nickel et al., 1999; Shoskes, 2003).

Possible anti-inflammatory or 5-alpha reductase inhibitory properties have led to the use of the pollen extract, Cernilton, for treatment of chronic prostatitis/CPPS. An open trial with Cernilton in a group of patients with chronic prostatitis and prostatodynia demonstrated either complete and lasting relief of symptoms or a marked improvement in 13 of 15 patients (Buck, Rees, & Ebeling, 1989). Similarly, Rugendorff et al. (Rugendorff, Weidner, Eberling, & Buck, 1993) reported the results of a prospective study with Cernilton N in 90 patients and found a 78% response rate (36% cure; 42% significant improvement) in those without complicating factors (i.e., urethral strictures, prostatic calculi, bladder neck sclerosis). The same authors reported an overall excellent tolerability (97%) as well as a very poor response in those with the above-mentioned complicating factors. However, rigorous evaluation of these compounds is lacking and they are not widely recommended as standard therapy for chronic prostatitis/CPPS.

A number of investigators have published their findings pertaining to the use of transurethral microwave ther-

motherapy (TUMT) and prostatic temperature elevation for the treatment of chronic prostatitis/CPPS (Choi, Soh, Yoon & Song, 1994; Gurunadha Rao Tunuguntla & Evans, 2002; Montorsi et al., 1993; Nickel & Sorensen, 1994. Nickel (Nickel & Sorensen, 1996) has demonstrated the beneficial effect of TUMT with lasting results (up to 21 months) compared with sham therapy in a randomized, double blind study using validated questionnaires. Although this mode of therapy, now increasingly popular for treatment of LUTS due to BPH, appears to be potentially effective and safe, its real efficacy and durability of the response have yet to be confirmed with further randomized double-blind, sham-controlled trials before it is routinely adopted.

Based on his ideas pertaining to lower urinary tract dysfunctional epithelium (LUDE), Parsons (2003) advocates the addition of therapies such as hydroxyzine (Atarax™) aimed at suppressing mast cell activity and histamine release, as well as heparinoid therapy with intravesical heparin, intravesical PPS, or oral PPS (Elmiron) to the usual regimen of therapies for prostatitis. The positive effect of Elmiron may also be related to its anti-inflammatory properties (Shoskes, 2003). It should be mentioned that while this approach to therapy is more widely accepted in the treatment of IC, most urologists have not adopted this strategy in the management of prostatitis syndromes.

Among the newer experimental developments, the use of a high-frequency electrostimulation device that can be self-administered is noteworthy. John et al. (2003) reported on a prospective study of urethro-anal high-frequency electrostimulation in 88 patients with non-inflammatory chronic pelvic pain syndrome (Cat IIIB CPPS) and found excellent tolerability, no urethral or anal complications, and improvement of the pain syndrome in 83%.

Finally, Chen and Nickel (2003) reported on the use of acupuncture in 12 men diagnosed with chronic prostatitis/CPPS pain syndrome (NIH criteria) who were refractory to standard therapy (antibiotics, alpha-blockers, anti-inflammatories, phytotherapy) with an average follow-up of 33 weeks. The authors reported that 83% had a sustained greater than 50% decrease in NIH-CPSI at final visit without any adverse events.

PRIAPISM

EPIDEMIOLOGY AND PATHOPHYSIOLOGY OF PRIAPISM

Priapism is defined as a pathological prolonged engorgement or erection of the penis or clitoris that is unrelated to sexual arousal. The word *priapism* is derived from Priapus, a minor god of fertility and luck, and the deity of gardens and fields in Greek mythology (Papadopoulos & Kelami, 1988). Hinman (1914) classified priapism as either mechanical or nervous in etiology in the early 20th

century and suggested corporal vein thrombosis as the cause of "mechanical" priapism. The condition is more common in men and typically involves the paired corpora cavernosa, although rare exceptions with involvement of the corpus spongiosum and sparing of the cavernosal spaces have been reported (Taylor, 1980).

Priapism is generally classified as low flow (ischemic) or high flow (arterial and non-ischemic). Low-flow priapism and the associated severe decrease in venous drainage from the corpora cavernosa is a potential medical emergency and may lead to irreversible ischemic tissue changes. High-flow priapism is less commonly encountered and involves unregulated inflow that is typically secondary to some form of arterial trauma. Unlike the ischemic subtype, arterial priapism is not considered an emergency: spontaneous resolution is the likely outcome in more than half the cases and the patient does not have pain. Therefore, the majority of the discussion in this segment is dedicated to the ischemic, low-flow variant of priapism. Hauri and co-workers (Bruhlmann, Pouliadis, Hauri, & Zollikofer, 1983) were some of the first investigators to suggest that the prognosis of the veno-occlusive (low-flow) priapism is far less favorable than arterial priapism.

The overall incidence rate of priapism in the general population has been estimated to be 1.5 per 100,000 person-years (2.9 per 100,000 person-years in men 40 years old and older; Eland, van der Lei, Stricker, & Sturkenboom, 2001). Because not all patients with priapism will seek medical care, the reported data may underestimate the actual rate in the general population. The incidence of priapism in special "at risk" subpopulations such as those with a history of cocaine drug use or advanced pelvic or hematologic malignancy, and those on antipsychotic medications is much higher (Altman, Seftel, Brown, & Hampel, 1999; Compton & Miller, 2001; Steinhardt & Steinhardt, 1981; Suri et al., 1980). A study of 230 single case reports in the literature revealed the following priapism etiologies: idiopathic causes composed one third of the cases while 21% were attributed to alcohol abuse or medications, 12% to perineal trauma, and 11% to sickle cell anemia (SCA) (Pohl, Pott, & Kleinhans, 1986).

Another "at risk" group of patients are those with erectile dysfunction (ED) who are on intracorporal injection therapy. The incidence range of priapism episodes in this population ranges from 1% for those on prostaglandin E_1 (PGE_1) to 17% for patients who receive intracorporal injections of papaverine (Linet & Ogrinc, 1996). Avoidance of overdosage by gradual upward titration of the dose will help decrease this adverse event.

Most cases of priapism associated with sickle cell disease are classically described as ischemic, although rare exceptions (unknown etiology) of high-flow priapism in association with SCA have been reported (Ramos, Park, Ritchey, & Benson, 1995). SCA-related priapism is unusual before puberty with a reported 6% prevalence

(Fowler, Koshy, Strub, & Chinn, 1991; Tarry, Duckett, & Snyder, 1987). However, the probability of experiencing priapism in patients with homozygous SCA (Hb SS) and sickle cell beta(0)-thalassemia (Hb S-beta(0)) by age 20 is as high as 89% (Mantadakis, Cavender, Rogers, Ewalt, & Buchanan, 1999).

A variety of medications, most commonly related to the antihypertensive drugs guanethidine, prazosin, and hydralazine as well as psychotropic medications, have been implicated as etiologic factors in priapism (Rubin, 1968). Among psychotropic medications, trazodone (Desyrel™), thioridazine, and chlorpromazine have been associated with priapism (Ankem et al., 2002). This effect has been attributed to the alpha-adrenergic antagonist properties of these medications (Abber et al., 1987). Antipsychotics that have been reported to cause priapism on rare occasions. The exact pathophysiology has not been elucidated, but is likely multifactorial and may be related to the ratio of alpha-adrenergic blockade to anticholinergic activity. Atypical antipsychotics that have been reported to cause priapism on rare occasions include risperidone, olanzapine, and clozapine (Compton & Miller, 2001).

The recreational drug ecstasy has been associated with episodes of priapism (Dubin & Razack, 2000). More importantly, because trazodone is commonly employed as a hypnotic and is often chosen for polysubstance abusers due to its low abuse potential, it is important to consider that trazodone and cocaine may have synergistic effects in promoting priapism (Myrick, Markowitz, & Henderson, 1998). Cocaine-induced priapism has been reported in association with topical application to enhance sexual performance, as well as intranasal and intracavernous injections (Fiorelli, Manfrey, Belkoff, & Finkelstein, 1990; Mireku-Boateng & Tasie, 2001; Rodriguez-Blaquez, Cardona, & Rivera-Herrera, 1990).

Priapism in patients with degenerative stenosis of the lumbar canal, the cauda equina syndrome (following degenerative stenosis of the lumbar canal and lumbar arachnoiditis), herniated disc, or blockage of the central inhibitory influences such as that seen during general or regional anesthesia are examples of neurologically induced priapism.

Priapism has been reported in patients on high concentration (i.e., 20% rather than 10%) fat emulsion total parenteral nutrition and in a variety of systemic illnesses such as amyloidosis, glucose phosphate isomerase deficiency, and Fabry's disease (glycosphingolipid lipidosis) presenting with a combination of renal insufficiency and priapism (Bschleipfer et al., 2001; Goulding, 1976; Hebuterne, Frere, Bayle, & Rampal, 1992; Lapan, Graham, Bangert, Boyer, & Conner, 1980; Wilson, Klionsky, & Rhamy, 1973; Zimbelman et al., 2000). Table 31.3 lists the important etiologic factors in ischemic (low-flow) priapism.

TABLE 31.3
Etiologic Factors in Low-Flow Priapism

Total parenteral nutrition (high fat content)
Thrombophilia states (lupus, protein C)
Vasculitis
Hematologic
Warfarin/heparin-induced
Fabry's disease
Dialysis
Hemoglobinopathies and sickle cell disease
Malignancies including bladder/prostate cancer and metastatic (e.g., renal) tumors
Psychotropics and antidepressants (chlorpromazine, trazodone, risperidol)
Antihypertensives (guanethidine, hydralazine, prazosin)
Erectogenic agents (intracavernosal vasoactives; sildenafil; intraurethral PGE_1)
Spinal cord stenosis
Amyloidosis
Glucose phosphate isomerase deficiency
Alcohol
Androgens/testosterone

PATHOPHYSIOLOGY

Priapism may be regarded as a failure of erectile regulatory control causing an imbalance between arterial inflow and outflow (Burnett, 2003). Dysregulation of the veno-occlusive mechanism, arterial inflow, or neurogenic processes that can affect inflow or outflow, or malfunction of the normal contractile activities of cavernosal smooth muscle cells may be implicated as causative factors in priapism. The low-flow, ischemic variant of priapism that is the focus of this section is considered a medical emergency. This most common form of priapism is characterized by a painful rigid erection, absent cavernosal blood flow, and severely acidotic corpora. Immediate attention to the problem and decompression of the "compartment syndrome" minimize the chances of long-term adverse events such as penile fibrosis and ED. Trabecular interstitial edema and ultrastructural changes in trabecular smooth muscle cells including functional transformation to fibroblast-like cells may result from the combination of venous outflow obstruction, high pressure chambers, and poor-to-absent inflow. Severe cellular damage and widespread necrosis may occur in cases lasting more than 24 hours (Spycher & Hauri, 1986). Irreversible ED may be caused in cases lasting beyond 48 hours where destruction of the endothelial lining, formation of blood clots within the corpora, and widespread transformation of the smooth muscle cells to fibroblast-like cells or necrosis may be observed (Spycher & Hauri, 1986). These irreversible "late" changes underscore the importance of early intervention and patient education in high-risk groups.

Broderick et al. (1994) have demonstrated that anoxia can eliminate spontaneous and drug-induced contractile activity in an animal model, suggesting a likely explanation for the failure of penile injection of alpha-adrenergic agonists to reverse prolonged ischemic priapism when the penis is in its maximal rigid state. Failed alpha-adrenergic neurotransmission, endothelin deficit, or inactivation of intracellular cofactors of smooth muscle contraction due to hypoxia and/or hypercarbia have been suggested as factors affecting the absence of proper detumescence in low-flow priapism (Broderick et al., 1994). Seftel et al. (Seftel, Haas, Brown et al., 1998) have reported on two cases of veno-occlusive priapism refractory to conventional therapy who later developed high-flow priapism. The high-flow state observed after treatment of veno-occlusive priapism may represent a variant of non-ischemic priapism or, alternatively, may represent the pathophysiology of recurrent idiopathic priapism.

Inheritance of one or two genes coding for an abnormal S hemoglobin may result in sickle cell hemoglobinopathy, which is manifested in 0.15% of black Americans in the form of sickle cell disease (homozygous for hemoglobin S) and in 8% as sickle cell trait (heterozygous for hemoglobin S). Inheritance of a combination of a hemoglobin S gene and a second gene coding for an abnormal hemoglobin (e.g., B$^+$ thalassemia or C hemoglobin) is possible and, as in the homozygous type, may result in ischemic complications (Fowler et al., 1991). SCA-induced priapism likely results from decreased oxygen tension and pH developing in stagnant blood within the corporal sinusoids, which in turn leads to a cycle of erythrocyte sickling and sludging followed by even more hypoxemia and acidosis (Siegel, Rich, & Brock, 1993).

DIAGNOSIS

A thorough history and physical examination are prerequisites to diagnostic accuracy.

Many patients with priapism experience significant anxiety and fear in addition to severe penile pain and discomfort. During the initial encounter, often in the emergency room setting, the clinician should make a genuine effort to alleviate the patient's apprehension. The sexual and medical history should especially focus on medications, trauma, and predisposing comorbidities. Presence or absence of pain is a fairly reliable predictor of low-flow versus high-flow priapism, respectively. A history of penile or perineal trauma further suggests high-flow priapism. Absence of pain in arterial priapism frequently results in less patient anxiety and discomfort as compared with veno-occlusive priapism. Consequently, those with arterial priapism may present days or even weeks after the original injury. The fundamental aim of the initial phase of assessment is to distinguish arterial from ischemic pri-

apism. The American Foundation for Urologic Disease (AFUD) panel recommendations for the management of priapism are illustrated in Figure 31.1 and follow a step care model that has been modified and refined over the years (Berger et al., 2001; Jacob & Herschler, 1986; Sadeghi-Nejad, Dogra, Seftel, & Mohamed, 2004).

Physical examination of the penis is critical and will typically reveal firm corpora cavernosa and a soft glans, indicating sparing of the corpus spongiosum in low-flow priapism. Findings in high-flow states usually reveal a partial to full erection and sparing of the corpus spongiosum in most cases (as in low-flow states). Urine toxicology screening for psychoactive drugs and metabolites of cocaine are recommended among the general laboratory diagnostic tests and are especially helpful if the diagnosis is unclear (Altman et al., 1999; Berger et al., 2001). A reticulocyte count, urinalysis, CBC, platelets and differential WBC as well as urologic consultation should be obtained. Men with SCA will typically have an elevated reticulocyte count, but it should be emphasized that hemoglobinopathies are not restricted to African-American men. Other groups, especially those of Mediterranean descent, may be affected (i.e., thalassemia or sickle-thalassemia). The sickledex test and examination of the peripheral smear are less time-consuming than hemoglobin electrophoresis and may be more appropriate for the emergency room setting (Montague et al., 2003).

The corporal blood flow status should be assessed to differentiate low-flow from high-flow priapism. This may be done with a corporal aspirate and visual inspection by color and consistency *or* corporal blood gas including pH, PO_2, and PCO_2 *or* penile duplex Doppler ultrasound (Berger et al., 2001). Low oxygen, high carbon dioxide, and low pH in the blood gas analysis of the aspirate are typical findings in low-flow priapism, whereas a high-flow state is suspected based on the bright red appearance or high oxygen content in the blood gas analysis of the corporal aspirate. In these cases, duplex Doppler sonography may identify a dilated cavernosal artery or pseudocapsule formation at the site of arterial sinusoidal fistula and will be helpful if superselective arterial embolization is performed (Pautler & Brock, 2001). Unlike veno-occlusive priapism, penile aspiration has mainly a diagnostic role in the management of arterial priapism, and nonischemic priapism resolution after aspiration or irrigation is only rarely observed (Berger et al., 2001; Koga, Shiraishi, & Saito, 1990; Montague et al., 2003; Rudick, 2002).

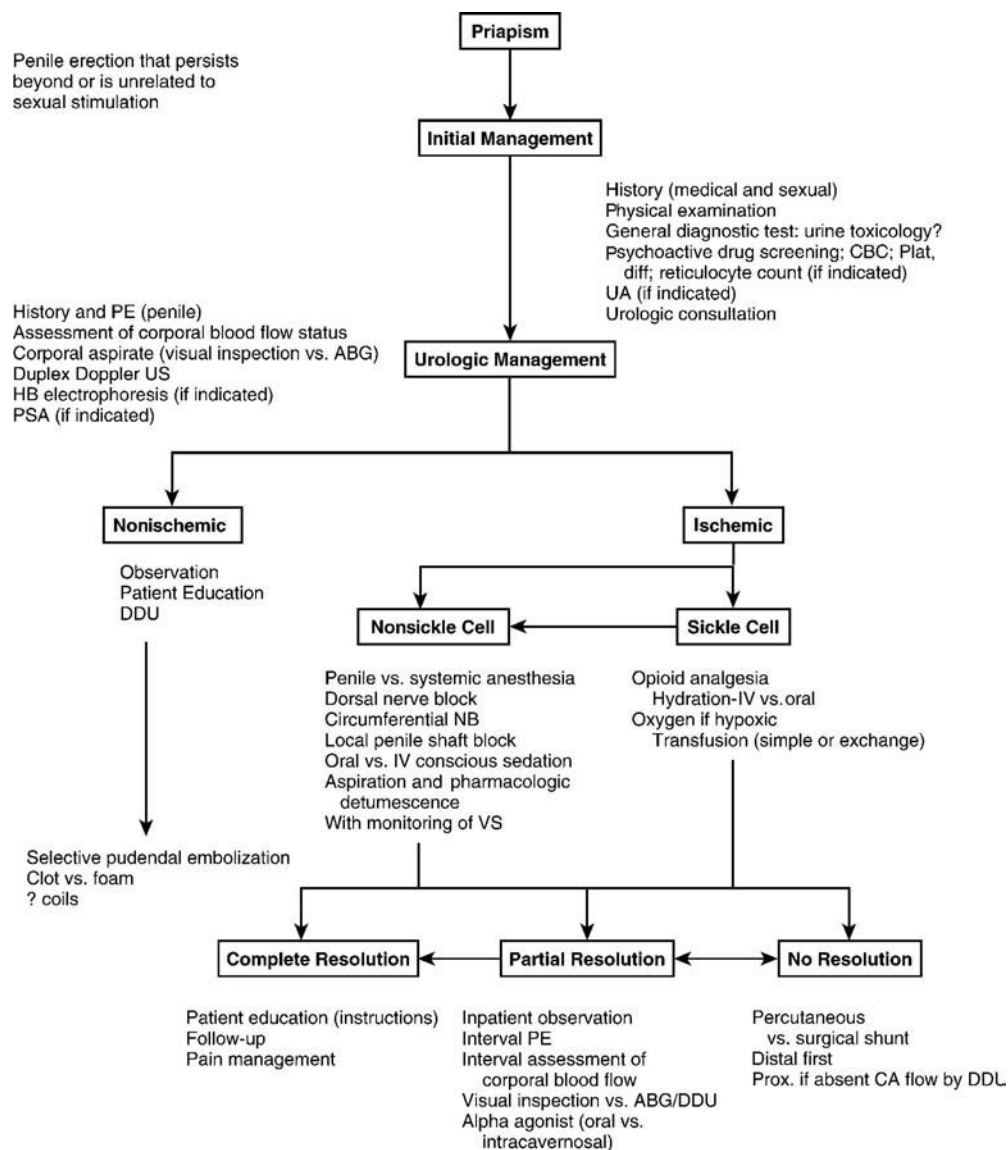
If conventional corporal irrigation and intracavernosal sympathomimetics (i.e., phenylephrine) fail to resolve the initial veno-occlusive priapism, sonography should be considered to identify those patients presenting with refractory low-flow priapism who later convert to a high-flow state. Although this is a very small group of patients with priapism, the distinction is important


FIGURE 31.1 The American Foundation for Urologic Disease (AFUD) panel recommendations for the management of priapism. ABG = arterial blood gas; CA = cavernosal artery; CBC = complete blood count; DDU = duplex Doppler ultrasound; HB = hemoglobin; IV = intravenous; NB = nerve block; PE = physical examination; PSA = prostate specific antigen; UA = urinalysis; US = ultrasound; VS = vital signs.

because the management of the low-flow and high-flow states is radically different and the high-flow group is usually managed conservatively (Sadeghi-Nejad et al., 2004; Seftel, Haas, Brown et al., 1998.

TREATMENT

Most cases of veno-occlusive priapism treated without excessive delay (<12 hours) will respond to alpha agonist therapy. Failure of resolution after 20 minutes of injection (0.1 ml/min of a 500 µg/ml phenylephrine solution for a total infused dose of 1 mg) is an indication for alternative strategies for management as these patients are unlikely to respond to further injection therapy (Paut-

ler & Brock, 2001). Aspiration and irrigation of the corpora are performed as first-line treatments even in low-flow priapism of more than 4 hours duration; however, these therapies have not shown a benefit in preserving potency when priapism has persisted beyond 72 hours (Berger et al., 2001). Failure of resolution after conservative measures as described will move the "step care" process to the surgical level. A number of different surgical shunts for diversion of blood away from the corpus cavernosum have been described. The consensus among authorities is that, in general, distal corporospongiosal shunts should be undertaken before proximal shunts; however, there is no consensus regarding the choice of percutaneous versus open surgical shunts. We prefer to

start with a transglandular Winter shunt (corporoglandu-lar) using a biopsy gun device to create multiple channels between the corpus spongiosum and the corpora (Nelson & Winter, 1977). If this technique is not successful, a larger communication between the corpora cavernosal and the corpus spongiosum may be created by a modified Al-Ghorab shunt in which the distal tunica albuginea of the corpora cavernosa is removed through a transglan-dular incision. Proximal shunts are rarely performed and are recommended if distal shunts fail and absent caver-nosal artery flow is assessed by Doppler sonography (Berger et al., 2001; Sacher, Sayegh, Frensilli, Crum, & Akers, 1972). A few authors have advocated early use of penile prostheses in cases of refractory or recurrent priapism associated with corporal fibrosis and ED (Sundaram, Fernandes, Ercole, & Billups, 1997).

In patients with SCA, initial efforts are directed at relief of pain and anxiety, as well as hydration with hypo-tonic fluids at 1.5 times maintenance. Intravenous hydra-tion and parenteral narcotic analgesia are started while preparing for aspiration and irrigation, supplemental oxy-gen, and possible exchange transfusion (Berger et al., 2001). The utility of red cell transfusion in this group of patients has been questioned by Powars and Johnson (1996) who hypothesize that in the static, hypoxic, and acidotic corporal environment, it is unlikely that red cells can reach the target area. Because there is an increased risk of cerebrovascular accident, coma, and intracranial hemorrhage, the blood volume and viscosity must be closely monitored in patients undergoing exchange trans-fusion or rapid single unit transfusion. Lack of priapism resolution after conservative measures calls for more inva-sive measures following an algorithm that is very similar to that described for non-SCA priapism. Rutchik et al. (Rutchik, Sorbera, Rayford, & Sullivan, 2001) have reported on a single case of refractory veno-occlusive priapism (failure of response to intracavernosal alpha adr-energic injection/irrigation and recurrence after an Al-Ghorab surgical shunt) that responded to intracavernosal injection of 15-mg tissue plasminogen activator. The authors resorted to this therapy due to severe penile con-gestion and risk of penile necrosis with further shunting. However, it must be emphasized that experience with this approach is very limited. Methylene blue, a guanylate cyclase inhibitor, has been used as a novel approach for treatment of priapism in a small group of patients. De Holl et al. (de Holl, Shin, Angle, & Steers, 1998) describe the use of methylene blue in 11 patients with priapism and report immediate detumescence in 67%. A possible expla-nation for the success of this therapy is blockage of cyclic GMP-induced muscle relaxation following the initial aspi-ration attempts. Recently, successful treatment of recur-rent idiopathic priapism with oral baclofen has been reported in two patients (Rourke & Jordan, 2002).

PENILE FRACTURE

Fracture of the penis, *faux pas du coit*, was first reported by Abul Kasem in Cordoba more than 1,000 years ago and follows trauma to the erect penis during coitus or penile manipulation/masturbation (Eke, 2002). This acute condition is a medical emergency that presents with a sudden cracking sound (due to the rupture of the corpora cavernosa) that is accompanied by localized penile pain and immediate detumescence. Many patients present hours (or even days) after the actual injury due to embar-rassment. Penile swelling due to hematoma formation at the site of rupture may result in voiding difficulties includ-ing possible urinary retention, as well as penile swelling, bruising, and deviation that is often described as an "egg-plant" deformity (Cumming & Jenkins, 1991). Some reports have indicated that the condition may be as uncom-mon as 1 in 175,000 hospital admissions in the United States, but this is likely to be a low estimate due to the stigma associated with penile injury sustained during sex-ual activity (Farah, Stiles, & Cerny, 1978). Eke (2002) have reviewed a total of 183 publications pertaining to penile fracture from various countries and reported a total of 1,642 cases, but the condition is undoubtedly highly underreported and is commonly seen in most emergency rooms at least a few times per year.

PATHOPHYSIOLOGY

Penile fracture occurs as a result of trauma to the erect penis and has been reported in association with inter-course and penile manipulation including forced bending of the phallus to achieve detumescence (Zargooshi, 2000). The acute bending of the penis has been described in association with a variety of situations including reverse coitus with the woman-on-top position or abrupt female rotation during intercourse, as well as accidental injury due to rollover during nocturnal tumescence (Mohapatra & Kumar, 1990; Pruthi, Petrus, Nidess, & Venable, 2000; Seftel, Haas, Vafa, & Brown, 1998; Zar-gooshi, 2000).

DIAGNOSIS AND TREATMENT

The diagnosis is based on history and physical examina-tion; radiological studies such as MRI or ultrasound, and more invasive measures such as cavernosography are rarely, if ever, required to confirm the diagnosis. A history of acute penile pain after penile trauma and a description of the classic popping sound followed by detumescence is characteristic. The site of injury is often palpable as a distinct defect in the tunica albuginea of the corpus cav-ernosum, but may be difficult to appreciate if it is covered by a large hematoma. In severe cases, the rupture may involve the corpus spongiosum and urethra with resultant

gross hematuria and a possible butterfly-shaped perineal hematoma (Lee et al., 2000).

Treatment of penile fracture consists of surgical repair with evacuation of the hematoma and closure of the cavernosal tunical defect. In comparison with conservative management, immediate repair is associated with faster recovery and lower morbidity (Kalash & Young, 1984; Zargooshi, 2000). Depending on the location of the tunical defect, a circumcising, an inguino-scrotal, or transverse scrotal (with "eversion" of penis) incision may be used to access the site of injury for repair. Both absorbable as well as non-absorbable sutures may be used for tunical closure, but the latter may be associated with long-term discomfort, as the patients can often feel the knots below the skin (Asgari, Hosseini, Safarinejad, Samadzadeh, & Bardideh, 1996; Zargooshi, 2000). Although most authorities recommend aggressive surgical management of penile fracture (especially in the acute setting), those presenting late or refusing therapy will find comfort in knowing that conservative management may also be associated with good long-term outcomes in select cases. Mydlo et al. (Mydlo, Gershbein, & Machia, 2001) reported a series of five patients suspected of having penile fracture who had refused aggressive surgical therapy and who suffered no serious complications (12-month follow-up) as a result of conservative management (Mydlo et al., 2001).

SCROTAL PAIN

In its acute form, scrotal pain is a medical emergency that requires prompt attention to rule out testicular torsion. A full history including the patient's age, sexual history, duration, severity, and onset (gradual vs. sudden) of pain are necessary to focus the clinician's attention on the correct diagnostic path. Contrary to traditional teaching, a few recent reports have shown that the incidence of epididymo-orchitis (EO) is equal to that of testicular torsion and has a peak incidence in infants (McAndrew, Pemberton, Kikiros, & Gollow, 2002). Depending on the study, torsion of the testicular appendages has been reported to peak in 7- to 13-year-old children, whereas testicular torsion is most common in neonates and boys aged 15 years (Marcozzi & Suner, 2001; Van Glabeke, Khairouni, Larroquet, Audry, & Gruner, 1999). The physical examination should be complete and must include a careful evaluation of the abdomen and the inguinal region to assess possible herniation. This section focuses on the acute and non-acute urological causes of scrotal pain.

The physician should be aware of the nonurologic causes of acute scrotal pain (peritonitis, incarcerated hernia, ruptured abdominal aortic aneurysm) as well as referred scrotal pain. Because sensory fibers from both the upper ureter and testis go through the spinal cord segments T11 and T12, upper ureteral distension (e.g., due to a ureteral stone) may cause referred pain to the testis and

lower ureteral distension may result in ipsilateral scrotal pain (Hayden, 1993). The differential diagnosis of scrotal pain also includes Henoch-Schonlein purpura (HSP), a systemic vasculitis that typically affects patients younger than 20 years of age and has a peak incidence at 4 or 5 years of age. This entity may involve the scrotum in 2 to 38% of cases and be misdiagnosed as diseases that require surgical intervention such as testicular torsion or an incarcerated inguinal hernia (Ben-Sira, 2000). HSP has distinct sonographic features (marked edema of the scrotal skin and contents with intact vascular flow in the testicles, epididymal enlargement, and a hydrocele) that allow distinction from testicular torsion in many cases and prevent unnecessary surgical exploration (Ben-Sira, 2000; Laor, Atala, & Teele, 1992). Testicular tumors most often present as a painless scrotal mass, and the teaching that "a painless scrotal mass is testicular cancer until proven otherwise" still holds. However, the astute clinician must be aware that a rapidly growing testicular mass may present with scrotal pain.

When all other causes of chronic scrotal pain described below have been ruled out, low back strain and the resultant radiculitis due to sensory nerve root irritation at the T10 to L1 level may be the source of the discomfort. Holland et al. (Holland, Feldman, & Gilbert, 1994) have proposed that idiopathic orchalgia or "phantom orchalgia" follows an abnormal neural processing where referred scrotal pain is caused by a noxious stimulus. In these cases, the authors recommend correction of bad posture, avoidance of heavy strain or lifting, and use of a scrotal support for 6 weeks. Other recommendations include spermatic cord anesthetic infiltration at the pubic tubercle with lidocaine 1% and bupivacaine 0.5%, physiatrist referral for neuromuscular evaluation, and a possible trial of transcutaneous electrical nerve stimulation unit. Selective ilio-inguinal/genitofemoral blocks or paravertebral nerve root blocks at T10 to L1 may also be attempted in refractory cases (Holland et al., 1994).

Testicular torsion may be intravaginal or extravaginal (typically neonatal and prior to complete testicular descent and scrotal wall fusion) and follows rotation of the spermatic cord with resultant ischemia. The degree of testicular rotation strongly affects the possibility of salvage after torsion and the time until necrosis occurs. *Torsion of the testicular appendages* may present very similarly to testicular torsion, accounts for 24 to 46% of acute scrotal presentations, and is often present in 7- to 13-year-old children (Knight & Vassy, 1984; Marcozzi & Suner, 2001).

Diagnosis

The patient suffering from testicular torsion will typically present with acute-onset, unilateral scrotal pain. As in prostatitis and other parenchymal inflammatory processes, the

edema and resultant capsular stretching increase the intensity of the pain (Gerber & Brendler, 2002). Previous episodes of scrotal pain may be related to prior ischemic episodes with spontaneous resolution, and the patient may also complain of systemic symptoms such as nausea and vomiting. A "high riding" testis due to shortening of the cord is often a hallmark of testicular torsion, and the testis may also have an abnormal (e.g., transverse) position in the scrotum (Marcozzi & Suner, 2001). In the pediatric population, the absence of the cremasteric reflex is also characteristic of torsion (Rabinowitz, 1984). The normal reflex is elicited by extra gentle stroking of the inner thigh whereupon elevation of the ipsilateral testis and contraction of the cremasteric muscle is observed; this finding is very rarely seen in a patient with testicular torsion. As in all other causes of painful scrotum, a urinalysis and scrotal ultrasound are helpful in confirming the diagnosis. The presence of hematuria or leukocytosis is more typical of EO as the cause of the acute scrotum. Absence of testicular blood flow on color Doppler ultrasonography is a helpful clinical tool. However, this modality is highly operator dependent and may be subject to false interpretation in young children or neonates with small testicular vessels (Herbener, 1996). Although torsion usually occurs around puberty, whereas epididymitis typically affects sexually active men after age 20, the age distribution may be clinically misleading and should not be relied upon for a definitive diagnosis.

Patients with appendicular torsion (appendix testis or appendix epididymis) rarely have systemic complaints and typically describe a gradual-onset, unilateral scrotal pain that is lesser in intensity compared with testicular torsion and that is localized to the superior pole of the testis (Burgher, 1998). Careful examination of the scrotal skin early in the course of presentation may reveal the "blue dot sign" due to the nonviable appendage.

Treatment

When torsion is suspected, immediate surgical intervention with scrotal exploration, detorsion, and orchidopexy is required. In a review of 543 surgical explorations for acute scrotal pain in boys, Van Glabeke et al. (1999) found a 16.6% incidence of testicular torsion and a 46% incidence of appendage torsion. The authors recommend surgical intervention in all male children complaining of acute scrotal pain. When immediate operative intervention is not possible, manual detorsion in the emergency room setting after adequate analgesia may be attempted. It is helpful to recall that torsion typically occurs in a medial direction, and detorsion should therefore be initially tried in a clockwise direction on the left and counterclockwise on the patient's right side (Marcozzi & Suner, 2001). Although surgical exploration is not strictly required for appendicular torsion, the distinction from testicular torsion is not always possible unless unequivocal testicular

blood flow is demonstrated on color Doppler sonography, in which case surgical intervention may be necessary.

EPIDIDYMITIS

Epididymitis is another common cause of the acute scrotum that must be differentiated from torsion of the testis or testicular appendages. This clinical condition is a painful, parenchymal inflammatory process that results in epididymal swelling and may also affect the testicles (epididymoorchitis). Epididymitis typically results from the spread of microorganisms from the urethra, prostate, or seminal vesicles, but may occur due to hematogenous spread in conditions such as tuberculosis. *Chlamydia trachomatis* and *Neisseria gonorrhea* are the most common causative agents in sexually active men younger than 35 years, whereas Gram-negative enteric epididymitis associated with urinary tract infections is usually seen in older patients, those who have undergone recent genitourinary tract surgery, and those with anatomical abnormalities (Marcozzi & Suner, 2001; Morbity and Mortality Weekly Report [MMWR], 1998). Rarely, fungal agents such as candida have been reported to cause epididymitis (Hori & Tsutsumi, 1995). It has been suggested that the association of infantile epididymitis with other urogenital abnormalities mandates further diagnostic evaluation (Hamdan, 1991). However, Anderson et al. (Anderson, Giacomantonio, & Schwarz, 1989) assessed 48 boys for acutely painful scrota and noted that two of three boys with bacteriuric epididymitis had known predisposing genitourinary anomalies, but boys with sterile urine and epididymitis did not have anatomic abnormalities noted on renal and pelvic ultrasonography or voiding cystourethrography and therefore did not require additional studies. The use of the antiarrhythmic agent amiodarone has been associated with sterile epididymitis in up to 11% of adult patients and, rarely, in children. The pathophysiology of amiodarone-induced epididymitis is unknown, but may be related to high concentration in testicular tissue (Hutcheson, Peters, & Diamond, 1998).

Diagnosis

Unlike the acute nature of the pain experienced by most patients with testicular torsion, epididymitis usually presents as a gradually increasing, dull, unilateral scrotal pain. Possible involvement of the vasa may result in exquisite pain that affects not only the entire hemiscrotum, but the spermatic cord as well. However, milder cases with localized involvement of the epididymis may also be observed. Attempts to distinguish epididymitis from torsion may be frustrated due to this variable presentation, although a history of prior genitourinary tract procedure, sexual activity, and a normal cremasteric reflex on examination are more suggestive of epididymitis. Physical examination reveals a tender and swollen epididymis. A

urinalysis and urine culture as well as urethral cultures (for identification of *C. trachomatis or N. gonorrhea*) must be performed. When positive, these tests or an elevated white blood cell count favor a diagnosis of epididymitis, but do not exclude torsion. The inflammatory nature of epididymitis causes increased blood flow to the scrotum and its contents. This feature is very helpful in differentiating epididymitis from torsion when interpreting color Doppler ultrasound or nuclear scintigraphy findings. Tuberculous epididymitis has gradually declined in incidence in the western hemisphere. When present, it manifests between the ages of 20 and 50 years in the sexually active years, and more than two thirds of the patients give a history of previous tuberculosis. Scrotal swelling, pain, discharge from draining scrotal sinuses in combination with sterile pyuria are common presenting symptoms (Heaton, Hogan, Michell, Thompson, & Yates-Bell, 1989). Tuberculous orchitis is considered to be a rare entity that may follow tuberculous epididymitis and represents a more severe end of this clinical spectrum.

TREATMENT

When the constellation of clinical findings points to epididymitis, empiric antibiotic therapy until the final culture results are available is recommended. In the younger (less than 35 years old) population in whom a sexually transmitted condition is the more likely etiology of epididymitis, empiric therapy should be started with ceftriaxone and doxycycline or oflaxacin, whereas in the older population, oral fluoroquinolones are recommended (Marcozzi & Suner, 2001). Symptomatic pain relief is achieved with bed rest, scrotal elevation, analgesics, and NSAIDs. A cord block may be used when the pain is severe.

Recognition of amiodarone-induced epididymitis in children and a reduction in dosage or temporary cessation of the drug may result in rapid resolution of the epididymitis and avoidance of unnecessary surgical intervention in a high risk population (Hutcheson et al., 1998).

The patient should be advised that, although the pain and edema usually subside in 7 to 10 days, the epididymal induration may be present for a few weeks despite good response to antimicrobials. An early follow-up (3 days) is advised when the symptoms do not improve within 3 days. Similarly, more unusual organisms (tuberculous or fungal) should be suspected in symptomatic cases that persist 6 to 8 weeks after completion of antimicrobial therapy (Marcozzi & Suner, 2001).

POST-VASECTOMY PAIN

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

A questionnaire-based outcome study of non-oncological post-vasectomy complications revealed that pain after vasectomy is the most common adverse event affecting the patients' quality of life after this operation (Choe & Kirkemo, 1996). Chronic scrotal discomfort is seen in up to one third of men after vasectomy and half of these men consider the pain bothersome and may seek further therapy for relief (McMahon et al., 1992; West, Leung, & Powell, 2000. In one study of 13 patients with post-vasectomy pain, mean time to pain onset after vasectomy was 2 years and the presenting symptoms included testicular pain in 9 cases, epididymal pain in 2, pain at ejaculation in 4, and pain during intercourse in 8 (Nangia, Myles, & Thomas, 2000). The same authors reported the physical examination findings in the same cohort and noted tender epididymides in 6 men, full epididymides in 6, a tender vasectomy site in 4, and a palpable nodule in 4.

The pathophysiology of this condition is not entirely known, but tender sperm granuloma, nerve entrapment, or nerve proliferation at the site of vasectomy, perineural fibrosis, and mechanical duct obstruction with epididymal congestion have been suggested as possible causes (Nangia et al., 2000; Sweeney, Tan, Butler, McDermott, Grainger, & Thornhill, 1998). Epididymal engorgement, complex cystic disease, and chronic epididymitis are the main histological findings in post-vasectomy patients with scrotal pain (West et al., 2000). Other investigators, however, have observed no differences in vasectomy site histological features in patients with the post-vasectomy pain syndrome and matched controls, and no difference in histological findings in patients with the post-vasectomy pain syndrome who did and did not become pain-free postoperatively (after microsurgical vasectomy reversal) (Nangia et al., 2000).

TREATMENT

Some investigators have reported that the incidence of post-vasectomy pain may be significantly reduced by the injection of 1 ml of 0.5% bipuvicaine into the vasal lumen at the time of vasectomy (Paxton, Huss, Loughlin, & Mirakhur, 1995). Inhibition of excitability at the dorsal horn of the spinal cord caused by nociceptive impulses from the injured tissue has been suggested as a possible explanation for the benefits of preemptive bupivacaine anesthesia (Woolf & Chong, 1993).

Conservative measures such as NSAIDs, scrotal elevation, and various analgesics are typically used as first-line therapy. When ineffective, a cord block may be tried, but this requires multiple and possible lifelong therapies and may not be a practical option. A few authors have suggested epididymectomy when surgical intervention is contemplated (Sweeney et al., 1998; West et al., 2000). West et al. (2000) report initial improvement in 14 of 16 patients and lasting symptom relief in 9 of 10 patients who were interviewed 3 to 8 years after epididymectomy. Furthermore, they cite atypical symptoms such as testic-

ular or groin pain, erectile dysfunction, and normal sonographic appearance of the epididymis as poor prognostic indicators (West et al., 2000). Although this option precludes ipsilateral vasectomy reversal in the future, the availability of high-level assisted reproductive techniques in combination with testicular sperm retrieval provide the potential for future fatherhood. Finally, a number of studies have reported on microsurgical vasectomy reversal for the treatment of post-vasectomy pain syndrome (Bruning, 1997; Edwards, 1997; Myers, Mershon, & Fuchs, 1997; Nangia et al., 2000). In one of these publications, Bruning (1997) reported relief of post-vasectomy pain in 24 of 32 men who underwent a single microsurgical vasectomy reversal and in 3 of 6 with recurrent pain who had undergone a second procedure.

VARICOCELE

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Varicocele, an abnormal dilation of the spermatic veins, is a common anatomical abnormality that has an incidence of 10 to 20% in the United States (Meacham, Townsend, Rademacher, & Drose, 1994; Saypol, 1981). In the absence of (or malfunction of) vein valves, retrograde flow of blood from the internal spermatic and cremasteric veins into the veins of the pampiniform plexus in the spermatic cord and scrotum causes varicoceles. Absence of the valve at the left renal–internal spermatic vein and absent/incomplete valves along the internal spermatic vein have been demonstrated by a number of investigators (Ahlberg, Barley, Chidekel, & Fritjofsson, 1966; Comhaire, Kunnen, & Nahoum, 1981; Coolsaet, 1980; Kohler, 1967). Varicoceles can affect various seminal parameters and most authors agree that surgical therapy of varicoceles is an accepted intervention in the treatment of male factor infertility. The varicocele pain is typically reported as a dull, aching, and throbbing sensation in the scrotum without sharp or radiating components (Peterson, Lance, & Ruiz, 1998). Long periods of standing and the resultant increased hydrostatic pressure in the valveless veins of the pampiniform plexus may exacerbate the dull ache. The diagnosis is made by a careful physical examination of the scrotum and spermatic cord after the patient has been standing in a warm room (to allow cremasteric relaxation) for a few minutes. Varicoceles are traditionally classified as grade I (palpable during a Valsalva maneuver), grade II (visible in the standing position during a Valsalva maneuver), or grade III (visible in the standing position through the scrotal skin without increased intra-abdominal pressure). Decreased diameter of the spermatic cord in the recumbent position in comparison with the standing position suggests the presence of varicoceles. Sonographic diagnosis of a clinical varicocele is made when a minimal diameter of 3.5 mm

is demonstrated in the veins of the pampiniform plexus (Meacham et al., 1994).

TREATMENT

It has been estimated that 2 to 10% of men with varicoceles have pain secondary to varicoceles, but surgical intervention for relief of pain is controversial (Peterson et al., 1998). A number of recent studies have published the results of varicocelectomy performed for relief of pain. A large study from Turkey evaluated 119 men who underwent subinguinal microsurgical varicocele ligation for painful varicocele diagnosed based on the findings of both physical examination and color Doppler ultrasound (Yaman, Ozdiler, Anafarta, & Gogus, 2000). Of the 82 patients who were evaluable at the end of this study, 72 (88%) reported complete resolution of pain, 4 patients (5%) partial resolution, 5 patients (6%) no change, and 1 patient (1%) epididymal discomfort that resolved with conservative measures. Similarly, Peterson et al. (1998) (60%) reviewed records from 58 patients who underwent varicocele ligation to establish success of surgical ligation of the painful varicocele and obtained follow-up on 35 of the 58 (60%) patients with painful varicocele in whom initial conservative measures had failed. The authors report resolution of pain postoperatively in 86% and partial resolution in 1 patient, while 4 patients (11%) had persistent or worse symptoms. The excellent results in the two aforementioned studies are corroborated by at least two other recent studies that report 82.8 and 84.5% complete resolution of pain, but are in contrast to the 48% improvement reported by Biggers and Soderdahl in 1981. It should be noted that the diagnostic modalities and follow-up methods are not identical in these reports.

Rheumatologic Pain

Thomas Romano, MD, PhD

INTRODUCTION

Pain can be defined as an unpleasant sensation that is thought to originate from a particular body part and that is usually associated with processes capable of causing damage to body tissue. Pain can be acute, such as one might experience in the case of a fractured bone. If pain persists beyond the customary time it takes the affected part to heal or recuperate, the pain is termed " chronic." Acute pain typically occurs when a noxious stimulus activates sensitive peripheral endings of primary afferent nociceptors. The noxious stimulus is then turned into a form of electrochemical energy by a process called *transduction*, whereupon the message is then transmitted via peripheral nerves to the spinal cord and then on to the brain, where the inputs are modulated and pain is consciously perceived (Fields, 1987). It is clear that pain is more than just a sensation. It has two components: (1) sensory and (2) affective. Regardless of the cause of the pain, both of these components must be considered.

No greater interplay between the sensory and affective aspects of pain can be found than in the rheumatic diseases. Not only is the central nervous system of a patient suffering from arthritis bombarded by afferent signals from inflamed swollen tissue, but the conscious (or unconscious) interpretation of the significance of the painful stimuli (perhaps the harbinger of crippling, loss of independence, etc.) may influence pain perception, as can other factors such as the development of a secondary fibromyalgia syndrome (FS) or psychiatric/psychological problems that may complicate the course of a patient with chronic (i.e., incurable and probably progressive) disease.

Rheumatologists are concerned with many problems and/or potential problems that affect the clinical course of the patients under their care. Patients need to be kept ambulatory, or at least their ability to care for themselves has to be maximized to prevent progressive joint and spine deformity. Physicians want to minimize or eliminate the chance that the patient's underlying disease, such as systemic lupus erythematosus (SLE) and rheumatoid arthritis (RA), will affect the internal organs, for example, nephritis in SLE and Felty's syndrome (splenomegaly and neutropenia) in RA, and optimize the length and quality of the patient's life.

When the vast majority of patients first present for consultation and treatment, it is the complaint of pain, above all other symptoms, that dominates the initial patient–physician encounter. Certainly, the fear of having a potentially crippling disease or of not being able to perform certain tasks because of weakness, stiffness, or loss of dexterity comes to the fore after the impact of the illness is explored. However, it is the worsening of pain or the fear of increased pain that has brought the patient to see the rheumatologist at that particular time although other symptoms may have been present for months or even years.

To better appreciate how the rheumatologist approaches the problem of pain and to gain an understanding of the role of pain control in the rheumatic diseases, one must first understand the training of a rheumatologist and what concerns the rheumatologist when confronted with a patient who is in pain, and who often has other symptoms/problems. Frequently, the rheumatologist's patient is confused regarding the diagnosis and prognosis, often having seen numerous other health professionals before consulting the rheumatologist.

A rheumatologist typically treats many types of musculoskeletal diseases. The spectrum of rheumatologic disease is vast, and classifications are constantly being

updated. The most recent classification can be found in the latest *Primer on Rheumatic Disease* (Schumacher, 1997). The rheumatologist typically encounters patients with inflammatory conditions, such as RA, SLE, and the like, or degenerative joint disease such as osteoarthritis, or other conditions such as myofascial pain syndromes and fibromyalgia. These latter two conditions are very common problems and each is the subject of a separate chapter in this text.

The rheumatologist is also confronted with musculoskeletal problems that arise out of or complicate other diseases. Infectious disease (e.g., AIDS, tuberculosis, and rheumatic fever), endocrine abnormalities (e.g., diabetes mellitus, thyroid disease, and hyperparathyroidism), malignancy, and other pathologic conditions may first manifest themselves as painful neuromuscular or musculoskeletal problems. Therefore, the rheumatologist must use his or her acumen as an internist to understand and treat patients thus afflicted.

It would be easier to understand the treatment of rheumatologic diseases by establishing general categories and analyzing them separately. For purposes of clarity and trying to follow general pathophysiologic guidelines, this author proposes dividing rheumatologic disorders into four main groups: (1) degenerative conditions, (2) inflammatory diseases, (3) soft tissue problems (e.g., myofascial pain syndrome, fibromyalgia syndrome), and (4) other cause of rheumatologic pain (e.g., infectious, neoplastic, endocrine, congenital).

Naturally, there may be considerable overlap, and any one patient may have several of the above conditions, but these distinctions should prove useful in systematically analyzing and treating patients with either simple or complex problems. Conspicuous in its absence in the above format is the impact of psychological forces that may play a part in the suffering of patients with rheumatologic diseases. Although rheumatologists do not primarily treat psychological disease, its presence is recognized in some patients. Therefore, problems such as depression and anxiety are discussed in terms of their impact on specific diseases, as opposed to creating a separate category.

DEGENERATIVE DISEASES

The category of degenerative diseases contains, but is not limited to, degenerative joint disease; degradation of joint, bone, and other connective tissue by repeated trauma or inflammation; and low back pain that usually arises from a combination of factors.

Degenerative arthritis or osteoarthritis (OA) (also referred to as osteoarthrosis) is probably the most common rheumatic disease affecting bones and joints (Creamer & Hochbery, 1997). It may be primary (idiopathic) or secondary to other diseases (Table 32.1). It is characterized by the narrowing of joint space by progressive loss of

---

TABLE 32.1
Possible Causes of Seconday Osteoarthritis

Joint damage due to:
   Infectious (septic arthritis)
   Hemophilia
   Neuropathy (Charcot joint)
   Gout and other crystal-induced arthritis
   Rheumatoid or other inflammatory arthritis
Multiple epiphyseal dysplasia
Congenital dislocation of the hip
   Slipped capital epiphysis
Inherited metabolic disorders
   Wilson's disease
   Hemochromatosis
   Alkaptonuria
   Morquio's disease
Paget's disease of bone
Acromegaly
Other processes that damage articular cartilage

---

articular cartilage, usually accompanied by reactive changes at the joint margins and underlying subchondral bones. Many patients describe a " bone-on-bone" sensation in weight-bearing joints, such as the knees and/or hips, especially during exercise or simply upon ambulation. It must be remembered that OA is a disease of the joints and has no systemic component (Bergstrom, 1985; Forman, Malamet, & Kaplan, 1983).

The prevalence of OA increases with age and some form of OA is present in almost all patients 65 or older. Many times, the patient experiences transient and/or mild to moderate discomfort and does not see a pain practitioner. Often, over-the-counter analgesics combined with resting of the affected area tend to provide sufficient relief. However, acetaminophen alone may not be effective in providing adequate pain relief in OA (Case et al., 2003). Many patients have more prolonged symptoms or have more severe pain than they can control themselves, so they initially seek relief from their family doctor. Many such patients obtain relief with the chronic use of nonsteroidal anti-inflammatory drugs (NSAIDs). Many NSAIDs in comparatively low doses are available over the counter. These include ibuprofen, naproxen, and ketoprofen. More potent preparations such as indomethacin (Indocin®, Indocin SR®), diclofenac (Voltaren®), and piroxicam (Feldene®) are available by prescription. These have been amply reviewed (Fowler & Arnold, 1983; Fries, Williams, & Boch, 1991) and their effectiveness has been established. A word of caution: if a patient with OA on an NSAID obtains objective improvement (e.g., decreased swelling, redness, warmth) but still complains of pain, a secondary myofascial pain or fibromyalgia syndrome should be considered. Many patients with OA also suffer from regional (e.g., anserine bursitis) or generalized (e.g.,

fibromyalgia) soft tissue pain syndromes. Unless these are addressed separately and treatment initiated, the patient will continue to complain of pain, which is the main reason he or she sought medical attention in the first place, despite a good response to OA treatment. These are the types of patients the rheumatologist is apt to see. The OA sufferers who do well with NSAID or other therapy prescribed by their family doctor have no reason to visit a rheumatologist's office. While NSAIDs are excellent medications, their use in a cavalier fashion should be discouraged due to potentially severe and even life-threatening side effects. The potential gastrointestinal toxicity of these medications is very well known (Huskisson et al., 1976) as are the effects of these drugs on renal plasma flow (Brezin et al., 1979) and platelet aggregation (Roth & Majerus, 1975). These effects are the result of prostaglandin inhibition and seem to affect patients in direct proportion to their age and the presence of another disease such as peptic ulcer disease, liver disease, and kidney disease.

One way to prevent the untoward effects of prostaglandin inhibitors is the use of anti-inflammatory medications that are selective prostaglandin inhibitors such as nonacetylated salicylate (e.g., salsalate or choline magnesium trisalicylate). Misoprostol (Cytotec®) was introduced to prevent NSAID gastropathy (Graham, Agranval, & Roth, 1988) because it is a synthetic prostaglandin E analogue that allows the stomach to proceed with its endogenous cytoprotective mechanisms even in the presence of NSAID-induced prostaglandin inhibition. It is generally prescribed to patients who are elderly or who have had upper gastrointestinal problems in the past. Patients using nonacetylated salicylates do not need to use misoprostol. Recently, a new class of NSAIDs has been approved for use for arthritis sufferers (Osiri & Moreland, 1999). Celecoxib (Celebrex®) (Simon et al., 1999) and rofecoxib (Vioxx®) (Langman et al., 1999) selectively inhibits cyclooxygenase-2 (COX-2), thus minimizing potential adverse effects on the gastrointestinal tract. The most recently introduced coxib, valdecoxib (Bextra®), has good anti-inflammatory activity and is reported to be relatively safe (Chavez & DeKorte, 2003). Care must be taken when prescribing celecoxib or valdecoxib for patients who are allergic to sulfonamide preparations as such patients may also experience allergic reactions if they are treated with either medication.

Merck, the manufacturer of Vioxx™ (rofecoxib) voluntarily withdrew medication wordwide on September 30, 2004 because of possible adverse reactions. Committees of the FDA met from February 16, 2005 to February 18, 2005. The panel voted unanimously to advise the FDA that all three COX-2 inhibitors could cause heart problems, but the majority of the panel advised against taking them off the market, provided that adequate safety warnings be published.

As adjunct therapies, topical capsaicin (McCarthy & McCarty, 1992) and topical preparations of NSAIDs (Ginsburg & Famaey, 1991; Russell, 1991) have been shown to be effective in relieving symptoms in patients with OA. Often, the combination of such topical therapies and oral NSAIDs is not enough to relieve the pain in a particular joint. In such cases, the use of intra-articular injections of a local anesthetic–corticosteroid mixture can provide prompt, dramatic relief (Hollander, 1972). While the relief is usually temporary, lasting from weeks to months, it can aid the patient in taking advantage of exercise or physical therapy, which previously may have been difficult to endure. The long-term safety and efficacy of intra-articular steroid injections have been recently described (Raynauld et al., 2003). An alternative to intra-articular steroid therapy is the injection of viscous/elastic intra-articular preparations composed of mixtures of hyaluronic acid and saline such as sodium hyaluronate (Hyalgan®; Altman & Moskowitz, 1998) or Synvisc®. These have been employed to treat painful knee OA. While these viscosupplementation medications are superior to oral NSAID treatment alone (Kahan, Lleu, & Salin, 2003), their role in the long-term management of OA has still to be determined, especially because these preparations may be no better than intra-articular corticosteroids (Leopold et al., 2003). Other regimens to help reduce pain and relieve mechanical stress on affected (especially weight-bearing) joints are weight loss, muscle strengthening, use of orthotic (e.g., cane, walker, crutches), and local heat/massage.

A word of warning: NSAIDs should be given with great caution in patients taking oral anticoagulants, sulfonylurea antidiabetes medication, or other highly protein-bound drugs because NSAIDs compete with such medication for plasma protein-binding sites and often displace a sufficient amount of the drug in question to cause untoward effects (e.g., a further prolongation of the prothrombin time or an exaggerated hypoglycemic response). In addition, NSAIDs can interfere with diuretic therapy, and adjustments in type or dosage of these medications may need to be made (Day et al., 1984).

When the pain or deformity of OA becomes overwhelming, consideration should be given to orthopedic consultation, especially if the patient has symptoms involving a weight-bearing joint such as the hip or knee. The technology for the replacement of these joints is superior to that for other joints, and orthopedists generally have more experience with this type of replacement. Significant improvement in pain, function, and quality of life has been documented after total knee (Hawker et al., 1998) or hip (Chang et al., 1996) arthroplasty. Surgery needs to be timely as delays in performing necessary surgery can result in a worse outcome (Fortin et al., 1999).

However, not every patient with recalcitrant knee OA needs total knee replacement. High tibial osteotomy and

other corrective procedures may be more appropriate in selected patients.

Often, patients with OA develop associated painful conditions, such as carpal tunnel syndrome, fibromyalgia, or a local myofascial pain syndrome, all of which need to be identified and treated (Romano, 1996).

Joints under increased mechanical stress would seem to be likely candidates for the development of OA, although the medical literature is far from clear on this issue, as illustrated in recent papers regarding runners (Lane et al., 1986; Panush et al., 1986).

Some studies have found that there is a relationship between prolonged stress and OA, for example, spine OA in coal miners (Schlomka, Schroter, & Ocherwal, 1955) and shoulder OA in bus drivers (Lawrence, 1969), while other studies have not found this to be the case (Burkle, Fear, & Wright, 1977; Puranen, et al., 1975).

Each patient's problem must be evaluated individually, and aggravating factors minimized or removed if and when they are identified. This is particularly true for patients with back problems.

Back pain may come from a single problem or a combination of pathologic processes. Spinal OA is a disease of the apophyseal joints. It is frequently associated with disc disease often described by the terms *degenerative disc and joint disease*, or *spondylosis*. While anatomic changes may be well defined by an x-ray or computed tomography (CT) scan showing osteophytic lipping and sclerosis, often these correlate poorly with the clinical picture. The development of spondylosis is probably inevitable in most patients with microtrauma where everyday activities contribute to the symptoms. However, preventive measures, such as the maintenance of ideal weight, good posture, moderate exercise, and proper methods of lifting and carrying, can do much to ease symptoms. The use of NSAIDs as well as adequate rest and the use of heat or cold applications to the affected areas may be helpful. In some patients, traction and/or bracing may be needed (Lee et al., 1989). If the cervical spine is involved, the use of a cervical pillow (preferably a four-in-one cervical pillow or Wal-Pil-O, Los Angeles, CA), which prevents neck flexion and hyperextension, is helpful in relieving night pain. Using a chair with a headrest and avoidance of reading or watching television while recumbent can also help. Posterior neck muscles can be strengthened by using isometric exercises (Thiske, 1969). The patient tightens the muscles in the back of the neck and makes a double chin (military posture) to the count of five; this is repeated 10 times. Patients are encouraged to do this exercise four or five times per day.

As far as the lumbar area is concerned, pain in the buttocks, thighs, and legs can be caused by a combination of entrapment of nerve roots by discs, apophyseal joints, and adjacent soft tissue, which may contribute to foraminal stenosis. There is often a long-standing history of recurrent low back pain related to a congenital narrowing of the neural canal. Aging and degenerative changes bring on further narrowing and the clinical syndrome of spinal stenosis.

Spinal stenosis, especially of the lumbar spine, most commonly occurs in elderly patients with spondylosis with encroachment of osteophytes into the spinal canal or neural foramina. This may manifest as a phenomenon known as *neurogenic claudication* in which the patient experiences calf and/or thigh/buttock pain while walking. Relief typically occurs when the patient sits down, which helps to differentiate the problem from vascular claudication. The symptoms of vascular claudication are often alleviated when ambulation ceases, but sitting down is not usually necessary for relief. The presence of the above history in an elderly patient (or one who suffers from Paget's disease) with strong distal pulses, should make the clinician very suspicious. A CT or magnetic resonance imaging (MRI) scan of the spine should be taken and, if stenosis is present, orthopedic or neurosurgical consultation should be obtained. Corrective surgery often gives dramatic relief. Age alone should not be a deterrent in cases of spinal stenosis, especially because medical management of this condition is far from ideal and the quality of life can be greatly enhanced by a relatively safe and effective procedure.

For those patients who are not surgical candidates and/or have such severe pain that the above remedies are simply inadequate, the use of opioids is, indeed, appropriate. The pain can be so severe that sleep may be adversely affected (Drewes, 1999). Several long-acting preparations such as extended release morphine (Avinza®; Caldwell et al., 2002), controlled-release oxycodone (OxyContin™; Lacouture et al., 1996) and transdermal fentanyl (Duragesic patch™; Milligan et al., 2001) are FDA-approved for moderate to severe pain. While used extensively in the treatment of terminally ill patients with pain related to underlying malignancy, they can be used with success in patients with moderate to severe pain of musculoskeletal origin such as osteoarthritis (Schug et al., 1991). The dose of such medications should be determined by the unique needs of each individual patient (Galer et al., 1992).

The use of short-acting opioids such as oxycodone/acetaminophen (Percocet®) or hydrocodone/acetaminophen (Vicodin®) combinations can be used when pain increases due to weather changes, increased physical activity, or other causes. A word of caution: because of the abuse potential of opioid preparations and regulatory scrutiny, it is prudent for those pain practitioners who prescribe such medications to enter into a formal pain management agreement with each patient receiving such prescriptions. The agreement should clearly specify that the patient must be seen at regular intervals (usually monthly), obtain opioid prescriptions from only one practitioner, and act in a responsible manner. The agreement may call for urine drug

screening or other methods, such as random pill counts to test compliance. If the patient fails to abide by the terms of the agreement, no further opioid prescriptions should be written for that patient. The agreement makes it clear that the prescribing and use of opioids can be done only under specified conditions to which both parties (i.e., patient and practitioner) must adhere. This leaves little room for confusion or disagreement. Not intended to be a hardship, this agreement is an aid in the treatment of patients with recalcitrant severe pain.

INFLAMMATORY CONDITIONS

Unlike degenerative diseases such as OA, inflammatory conditions — such as SLE, RA, and vasculitis (e.g., polyarteritis nodosa, giant cell arteritis, or cryoglobulinemia) — are not only painful conditions, but also can be life-threatening. The musculoskeletal manifestations of these systemic diseases can be quite severe and can affect the nervous system directly through the deposition and activation of immune complexes.

RA is a chronic inflammatory connective tissue disease that can be potentially crippling and even life-threatening (Harris, 1990). It typically affects diarthrodial joints, but can also cause such extra-articular manifestations as scleritis, pericarditis, lymphadenopathy, arteritis, nodulosis, splenomegaly, neutropenia, anemia, and pleural effusions/pleuritis. The systemic nature of RA is reflected by the presence of an increased erythrocyte sedimentation rate, the presence of rheumatoid factor, antinuclear antibody, other autoantibodies, anemia (usually anemia of chronic disease, but iron deficiency anemia may also be present), or low plasma albumin in some, but not necessarily all, patients.

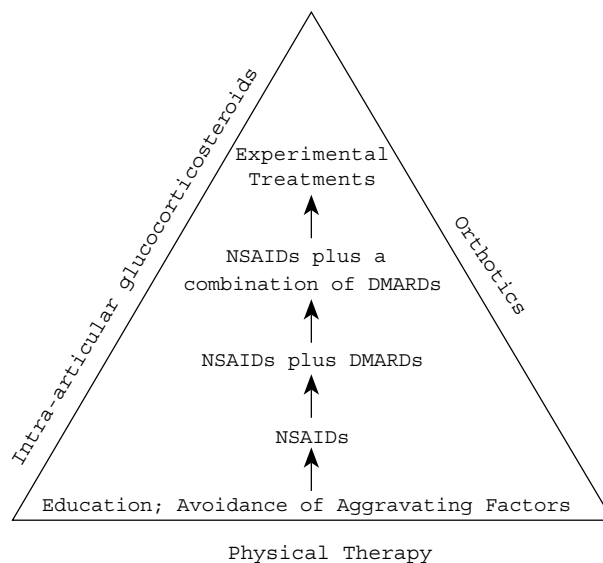
RA is found worldwide and is extremely common (approximately 1% of the U.S. population is believed to be affected) with the female to male ratio of 3:1. Peak incidence is between the ages of 40 and 60. Mild cases are usually treated symptomatically by patients using over-the-counter preparations, while more seriously afflicted individuals seek the services of their primary care doctor. The direct and indirect costs of RA are staggering (Clarke et al., 1997; Yelin & Wanke, 1999). Rheumatologists usually see more severe cases, especially when disease-modifying antirheumatic drugs (DMARDs) or remittive agents are needed in addition to NSAIDs and/or oral glucocorticosteroids. DMARDs are slow-acting agents whose function is to prevent RA from crippling, and they are also helpful in controlling systemic problems (Furst, 1990). Gold salts (injectable or oral), *d*-penicillamine, sulfasalazine, and hydroxychlorogorine were used over a decade ago with some success, but more recently immunosuppressive agents, such as methotrexate, azathioprine, and cyclosporin, have been used with greater success in halting the ravages of RA. However, even the immuno-


FIGURE 32.1 Treatment pyramid for RA.

suppressive agents were less than ideal due to either unacceptable side effects (e.g., bone marrow failure, hepatotoxicity, nephrotoxicity) or lack of efficacy. Within the past 5 years, leflunomide (Arava®), etanercept (Enbrel®), infliximab (Remicade®), and anakinra (Kineret®) have been introduced. In contrast to the first agent, which is a pharmaceutical, the last three are biological preparations. Each has been shown to be effective in treating many patients with RA already on methotrexate (Maini, Breedveld, & Kalden, 1998; Smolen et al., 1999; Weinblatt, Kremer, & Bankhurst, 1999). Leflunomide inhibits pyrimidine synthesis while etanercept blocks the action of tumor necrosis factor alpha (TNF-alpha), a substance necessary for the autoimmune inflammatory synovitis in RA. Infliximab, a monoclonal antibody, also neutralizes the activity of TNF-alpha, thus reducing disease activity (Lipsky, VanderHeijde, & St. Clair, 2000). Anakinra, on the other hand, inhibits interleukin-1 (IL-1), another cytokine that is produced in excess in patients with RA and contributes to its pathogenesis (Jiang et al., 2000).

For patients with particularly severe RA that is unresponsive to various combinations of one NSAID and a single DMARD, combinations of DMARDs have been used with success (McCarty et al., 1995a). The treatment pyramid for RA is shown in Figure 32.1.

Lately, many rheumatologists have chosen to deal with RA much more aggressively, initiating treatment with NSAIDs plus DMARDs earlier rather than later (Wiske & Healey, 1990). Suffice it to say, the rationale regarding RA therapy has undergone some changes recently (Mikuls & O'Dell, 2000). Many rheumatologists have abandoned the pyramid in patients with severe RA because delays in aggressive therapy can lead to irreversible joint damage and possibly severe systemic pathology. Each patient is unique, and given the variety of medica-

tions and techniques now at our disposal, it is more likely than ever that a safe, individualized treatment can be designed to fit each patient.

A word of caution: DMARDs with NSAIDs tend to have potentially more serious side effects than NSAIDs used alone. Alopecia, lowering of blood count (red blood count and/or white blood count and/or platelet count), hepatotoxicity, gastrointestinal upset, and oral ulceration are common to all DMARDs. Gold salts can cause renal problems and rashes, as can *d*-penicillamine, which can also cause such bizarre problems as polymyositis, a myasthenia gravis-type syndrome, and obliterative bronchiolitis. For this reasons, *d*-penicillamine is rarely used these days. Cyclosporin use can cause renal failure. It also is rarely used in the treatment of RA.

Leflonamide can cause hepatotoxicity and other side effects such as rash, diarrhea, and reversible alopecia. Etanercept must not be given to patients at risk for serious infection as it is immunosuppressive and may exacerbate infectious processes. One disadvantage in using etanercept is that it needs to be injected subcutaneously (25 mg.) twice a week. Another is cost — wholesale price for 6 month's treatment would be $6,000 to $7,000. For severe refractory RA, intravenous infliximab has been given in multiple administrations. The cost of three doses for a 70-kg patient would easily be several thousand dollars. This cost must be weighed against the potential benefit and, of course, potential life-threatening side effects.

The other biologic agent, anakinra (Kineret), must also be given subcutaneously (every 2 weeks) and can have the same drawbacks as etanercept and infliximab (Jiang et al., 2000). However, their efficacy has been demonstrated and these preparations have been a godsend for many RA sufferers.

Like OA, RA can involve weight-bearing joints in addition to its capacity to involve the small joints of the hands, wrists, feet, ankles, and elbows in a symmetrical manner. Often when knees are involved, large effusions result in aspiration and injection that can be dramatically effective (McCarty et al., 1995a). Analysis of synovial fluid generally shows an elevated white cell count (usually 10,000 to 50,000/µl) with a predominance of polymorphonuclear leukocytes. Complement levels in RA synovial fluid are generally low and rheumatoid factors are often found; however, this testing tends to be of only limited benefit as it usually does not affect the course of treatment. A more dramatic, convenient, and inexpensive test is the observation that RA synovial fluid is watery compared with the more viscous fluid found in joint fluid from patients wit OA and normal controls. This is because the hyaluronic acid and other macromolecular synovial fluid components have been degraded by the inflammatory mediators, such as superoxides, enzymes, lymphokines present in the affected joint.

If an inflamed RA knee develops a large effusion that becomes chronic, a popliteal or Baker's cyst may develop. Most of the time, the communication between the joint space and the cyst is one-way and this valve effect can cause high pressures in the popliteal space. Because fluid is incompressible, a rupture of the cyst can occur. The release of a large volume of fluid that contains inflammatory mediators posteriorly between the medial head of the gastrocnemius muscle and the tendinous insertion of the biceps femoris muscle can cause the affected calf to become swollen, red, and intensely painful. The patient thus involved can present to the physician with a problem that resembles acute thrombophlebitis. The Homen's sign is frequently positive, thus causing some confusion. A positive arthrogram (with or without a negative venogram, depending on the circumstances) can establish the presence or absence of a Baker's cyst. Treatment with intra-articular steroids, rest, elevation, and attention to the underlying rheumatological conditions should be effective in the vast majority of cases. Surgical synovectomy may occasionally be necessary. A word of caution: treating a patient with a Baker's cyst using an intravenous anticoagulant, like heparin (the preferred treatment for acute thrombophlebitis), is not only ineffective, but may be counterproductive, causing painful ecchymoses in the calf tissues that have become hyperemic from the inflammation.

Although many reports of improved and "unorthodox" treatments for RA are sprinkled throughout the lay press and touted by some health care professionals, it is important to remember that testimonials and endorsements are not a substitute for sound scientific research. However, one must keep an open mind regarding new RA therapies. Three recent studies offer examples of the utility of treatments not ordinarily thought of as antirheumatic that have been shown to be effective in treating RA: fish oil (Kremer et al., 1995) and an antibiotic, minocycline (Kloppenburg et al., 1994; Tilley et al., 1995). The clinician must weigh what he or she feels is the potential benefit versus the possible risks/toxicities of each therapeutic intervention and prescribe accordingly. RA may be unpredictable and often periodic reassessments of the patients' conditions need to be made with attendant adjustments in therapeutic regimen changes in therapy.

Other painful problems that can occur in RA are the development of fibromyalgia, severe metatarsalgia (often helped by wearing 3/8-inch metatarsal bars on the soles of the shoes), carpal tunnel syndrome (median nerve compression neuropathy), chest pain due to either pleuritis or pericarditis, and Sjogren's syndrome (a chronic autoimmune/inflammatory disorder that results in keratoconjunctivitis/sicca and xerostomia). The dry eyes associated with the last condition are painful and annoying, and other mucous membranes can also become affected. The lack of vaginal secretions can make sexual intercourse painful. If food is not chewed well and eaten with frequent sips

of water, it may become lodged in the throat. The paucity of saliva (with its attendant antibacterial activity) can lead to painful dental caries and frequently loss of teeth. Other complications of RA are legion but their enumeration and description fall outside the scope of this chapter.

SLE is a potentially very dangerous autoimmune disease that can call attention to itself by pain in various structures. When inflammation affects the pleura (pleuritis), severe chest pain occurs. Joint involvement can cause arthritis. Unlike RA, the arthritis associated with SLE tends not to cause erosion and destruction of bone and cartilage. Other painful manifestations of SLE include myositis, pericarditis, pancreatitis, thrombophlebitis, and mesenteric vasculitis. The pain the patient with SLE experiences may herald a life-threatening situation or be due to concomitant fibromyalgia (Romano, 1992). The clinician must be alert to this disease process affecting virtually any organ or organ system.

SLE tends to occur primarily in young women with a prevalence of about 1 in 2000 individuals (although prevalence and prognosis may vary; Ward, Pyun, & Studenski, 1995). Some medications can cause SLE. The most common offenders are hydralazine, procaineamide, phentoin, and phenothiazines. (Yung & Richardson, 1994). Diagnosis can be made by applying standard criteria (Tan, Cohen, & Fries, 1982). The presence of antinuclear antibody (ANA) is a hallmark of SLE (Tan, 1989) but ANA is nonspecific. Antibodies to double-stranded DNA, low levels of serum complement, and Smith antigen are more specific indicators of SLE and SLE-like processes (Davis, Cumming, & Verrier-Jones, 1977; Schur, 1975). Treatment is aimed at quickly suppressing the overactive immune system and often includes the use of oral corticosteroids such as prednisone or prednisolone. Many patients with SLE require antimalarial drugs such as hydroxy chloroquine; immunosuppressive agents such as cyclophosphamide, azathioprine, and cyclosporin A; or folic acid antagonists such as methotrexate. These agents need to be prescribed with great care due to many potentially serious side effects (Bacon, Treuhaft, & Goodman, 1981; Murtis & Horsman, 1979; Spalton, Verdon Roe, & Hughes, 1993). The use of such dangerous agents is justified because untreated SLE can lead to severe morbidity affecting virtually any organ system (Gladman, 1995) and can be potentially life-threatening.

Hormonal therapy, specifically with male hormones such as dehydroepiandrosterone (DHEA) and danazol, has been shown to favorably affect outcomes in SLE (van Vollenhoven, Engleman, & McGuire, 1995; West et al., 1988). The goal of treatment is not only the alleviation of symptoms such as pain and shortness of breath, but also the protection of organs at risk for serious damage. Often the treatment of drug-induced SLE consists of removing the offending medication and providing symptomatic relief.

However, as with most illnesses and injuries, the patient who is well informed can better collaborate with the health care professional to attain optimal results. An example of an informative booklet written for patients with SLE is *The Lupus Book* (Wallace, 1995). The Arthritis Foundation (Atlanta, GA) publishes pamphlets, each of which provides patients with information regarding many rheumatologic problems including SLE. Because the clinical manifestations of SLE are indeed protean and the potential for serious morbidity so great, the patient with SLE should be armed with adequate information to fully participate in his or her care.

MISCELLANEOUS CONDITIONS

Perhaps in no other area is the skill of the rheumatologist (vis-à-vis internist) put to more of a test than in the realm of such miscellaneous conditions as endocrine, metabolic, infectious, or neoplastic diseases that present with musculoskeletal signs and symptoms. The patient with a disease that fits into one of the above categories has more than a muscle, joint, bone, or soft tissue problem, but this may not be obvious early in the course of the disease, less so if the condition behaves in an atypical manner. One must remember, however, that FS can coexist with any of these disorders (Hudson, Goldenberg, Pope et al., 1992). In fact, FS has even been described in patients infected with human immunodeficiency virus (Simms, Zerbini, Ferrante et al., 1992).

The musculoskeletal problems attendant to certain endocrine diseases may be the first clue that an endocrinopathy is present. The rheumatological signs and symptoms are often eminently treatable and even curable if the underlying endocrine abnormality is rectified (Bland et al., 1979). If the patient presents with myofascial pain (especially fibromyalgia), carpal tunnel syndrome, shoulder capsulitis (periarthritis), crystal deposition disease (e.g., pseudogout due to calcium pyrophosphate deposition disease), proximal myopathy, or osteopenia (osteoporosis and/or osteomalacia), the presence of an underlying endocrine disorder should be strongly considered. Endocrine problems including, but not limited to, parathyroid disease (both hypo- and hyperparathyroidism), adrenal disorders, and diabetes mellitus can be causative or contributing to the development of the above rheumatologic problems.

The patient suffering from hyperparathyroidism often presents with back pain and even vertebral fractures that mimic osteoporosis senilis (Dauphine, Riggs, & Schlotz, 1975). Generalized muscular aching and stiffness, joint laxity and accompanying arthralgia from hypermobility, erosive OA (Resnick, 1974), spontaneous tender avulsion/rupture, and neuromyopathy (Patten et al., 1974) can also raise the suspicion of the presence of hyperparathyroidism, especially if serum calcium determinations are

elevated. Some 35% of patients with hyperparathyroidism have chondracalcinosis (Pritchard & Jessop, 1977). Acute arthritis in the setting of an acute myocardial infarction or postoperatively may be due to gout or pseudogout. A synovial fluid analysis that includes a crystal examination helps establish this diagnosis.

At the opposite end of the spectrum, the patient with hypoparathyroidism may present with signs and symptoms (typically back pain) of ankylosing spondylitis (Chaykin, Frame, & Sigler, 1969), carpopedal spasm with tingling due to the low serum calcium, as well as muscle cramps.

Musculoskeletal complaints seem to be associated with adrenal overactivity and adrenal underactivity, the latter condition (Addison's disease) frequently manifesting itself as severe muscle cramping. Cortisol excess (Cushing's syndrome) can be idiopathic or due to treatment with glucocorticosteroids, and severe osteoporosis may ensue with compression fractures of the spine and ribs, proximal muscle wasting, and possible aseptic necrosis of bone (especially the femoral head). When exogenous corticosteroids are withdrawn, pseudorheumatism (diffuse muscle, joint, and bony aching) may occur. It is imperative to be aware of this, as such a problem can have the same symptoms as a flare of certain types of arthritis for which the medication may have been prescribed in the first place. When and if such symptoms occur, their interpretation in light of the patient's clinical course is crucial for optimal management because pseudorheumatism usually abates gradually with a slowing down of the steroid tapering schedule and the administration of mild non-narcotic analgesics. However, a flare of RA, for example, could demand a much more thorough reassessment and revision of the treatment plan.

Thyroid disease often affects the musculoskeletal system and its manifestations are protean. Hypothyroidism often presents with a myopathy, with profound muscle weakness and elevated serum muscle enzymes. It can be confused with inflammatory disorders of muscles, such as polymyositis or dermatomyositis. The peripheral joints of hypothyroid patients with myxedema may be swollen in a symmetrical fashion much like the joints in rheumatoid arthritis (Dorwart & Schumacher, 1975).

In contrast to the joint fluid from patients with RA, the synovial fluid aspirated from the joints of hypothyroid patients is definitely not inflammatory. It is thick and highly viscous, with white cell counts of 1,000 cells/mm^3 or less. Thyroid replacement often results in dramatic resolution of the above rheumatic problems.

If a patient has an overactive thyroid, rheumatic problems often manifest. Diffusely swollen and painful hands and feet associated with periositis (thyroid acropachy) can be seen in Graves' disease as can thyrotoxic myopathy, bone pain caused by osteopenia, shoulder periarthritis, and shoulder-hand syndrome complicating adhesive capsulitis (Wohlgethan, 1987). Musculoskeletal pain may also occur

with Hashimoto's thyroiditis. This disorder has been seen with increased frequency in association with RA and possibly other connective tissue disease (Gordon et al., 1981; Smiley, Husain, & Indenbaum, 1980). Ironically, one of the treatments of hyperthyroidism, the administration of propylthiouracil, has been reported to cause such rheumatic diseases as SLE (Amrheim, Kenney, & Ross, 1970) and vasculitis (Houston et al., 1979).

Diabetes mellitus, probably the most common endocrine disease, also has numerous rheumatologic manifestations (Gray & Gottlieb, 1976). Painful neuropathy may first bring the patient with diabetes to the attention of the pain specialist. Other problems, such as Charcot joints are often not completely painless and confused with osteomyelitis (Sinha, Munichoodappa, & Kozak, 1972). Other conditions to which patients with diabetes are susceptible, shoulder periarthritis (Bridgman, 1972), carpal tunnel syndrome and palmar flexor tendinitis (Jung et al., 1971), and a scleroderma-like digital sclerosis (Seibold, 1982), can plague the patient with diabetes. The rheumatologist often encounters patients with both adult and juvenile onset diabetes who have painless contractures of the proximal and distal interphalangeal joints. Recognition of these conditions is important because such microvascular complications as nephropathy and retinopathy may parallel the development and progression of these contractures (Fitzcharles et al., 1984).

Excess pituitary secretion of growth hormone, which causes acromegaly, can result in a characteristic arthropathy that mirrors the enhanced action of this hormone on bone, cartilage, and periarticular soft tissue. With regard to the diarthrodral joints, early cartilage hypertrophy causes the joint space to be abnormally wide, as seen on radiograph. This cartilage tends to break down more easily than normal cartilage, and such patients develop OA at a relatively early age. Carpal tunnel syndrome is also common. Spinal pain and polyarthritis have been reported to respond dramatically when the underlying pituitary disorder is treated successfully (Lachs & Jacobs, 1986). The importance of the identification and treatment of the underlying endocrine problem is crucial to alleviating the pain and suffering of patients with endocrine disease in whom musculoskeletal manifestations may be severe.

It should be noted that FS often coexists with endocrine problems (Crofford, 1996; Griep, Buersmat, & deKloet, 1993) necessitating even more vigilance and circumspection on the part of the clinician. Clearly, the most common metabolic disease that causes musculoskeletal pain in the general population is osteopenia. The scope of this problem is enormous and the differential diagnosis lengthy (Table 32.2). Acute bone fracture can result from osteopenia, and thousands of patients suffer from hip fractures annually, making it a major public health problem with high morbidity and mortality. Metabolic bone disease can also cause muscular pain and weakness, symptoms of which are often

TABLE 32.2
Differential Diagnosis of Generalized Osteopenia in Adults

Osteoporosis	Parallel loss of mineral and matrix
	Predisposing factors including aging, menopause, female sex, white or Asian race, immobilization, low physical activity, inadequate dietary calcium, smoking, alcohol, corticosteroid therapy, family history
Osteomalacia	Inadequate mineralization of bones, matrix
	Differential diagnosis includes:
	Vitamin D deficiency: Inadequate intake, low sunlight exposure, drug-induced catabolism of vitamin D, intestinal malabsorption
	Phosphate-wasting syndrome; Acquired renal tubular defects, with isolated phosphate loss, combined tubular defects (Fanconi's syndrome, renal tubular acidosis, antacid abuse
Osteitis fibrosa	PTH-induced increase in mineral and matrix reabsorption
	Differential diagnosis includes:
	Primary hyperparathyroidism
	Secondary hyperparathyroidism: Vitamin D deficiency states, primary decrease in intestinal calcium absorption with age, reduced renal mass (chronic renal insufficiency)
Glucocorticoid-induced osteopenia	Differential diagnosis includes:
	Iatrogenic
	Adrenal corticosteroid overproduction: Indiopathi (Cushing's syndrome)
Other disorders	Hyperparathyroidism
	Diffuse osteolytic malignancies (e.g., multiple myeloma)
	Congenital disorders: Osteogenesis imperfecta tarda, vitamin D–resistant rickets

confused with other musculoskeletal conditions. Osteopenia can also occur in patients who have other rheumatic diseases, especially those necessitating long-term glucocorticosteroid treatment (Hahn & Hahn, 1976).

The scope of the problem is so vast that a chapter devoted to it could not even begin to outline the problem and discuss therapy. However, some major factors need to be considered. The patient with osteopenia usually has osteoporosis (loss of bone mineral and matrix in parallel), osteomalacia (accumulation of unmineralized matrix after loss of bone mineral), hyperparathyroidism with osteitis fibrosa (replacement of bone by fibrous tissue), or cortisteroid-induced osteopenia. The last problem often is unavoidable due to the patients' need for such medication, but the ability of steroids to interfere with calcium absorption from the intestine may be partially overcome by the

administration of calcium and vitamin D supplementation (Hahn et al., 1979). The use of these medications is recommended for patients with osteoporosis senilis, as is estrogen, fluoride, calcitonin, biphosphonates, or a combination of these agents based on the individual patient's needs. Gastrointestinal distress may accompany the use of diphosphanates (aldetronate, Fosama®; risedtronate, Actonel®). This side effect has been minimized by the introduction of preparations that can be taken once weekly. The best method of treating osteoporosis is prevention, if feasible. Patients at risk, typically sedentary, small-framed women approaching menopause who smoke and drink alcohol and who have low calcium and vitamin D intake, should use preventative measures such as regular exercise, adequate intake of calcium and vitamin D (Matkovic et al., 1979; NIH Consensus Conference, 1984), and consultation with a physician who may feel that other measures, such as estrogen therapy, are necessary.

The most common causes of osteomalacia in adults are decreased absorption of vitamin D due to intestinal or biliary tract disease, accelerated catabolism of vitamin D due to drug-induced increases in hepatic oxidase activity, and acquired renal tubular defects with phosphate wasting. Correcting the cause of the metabolic problem is necessary for reversal of the osteomalacia.

While not as common as osteopenia, Paget's disease of bone is a frequent cause of bony pain and is estimated to affect 1 to 3% of people over the age of 45 in the United States. It is usually polyostotic, and men tend to predominate. While the cause of Paget's disease (osteitis deformans) is unknown, late manifestation of viral infection has been suggested. It is characterized by excessive bone resorption followed by excessive bone formation, culminating in a bizarre mosaic pattern of lamellar bone associated with increased local vascularity and increased fibrous tissue in adjacent marrow (Smiger et al., 1977). The disease is a focal disorder, as normal bone exists even in patients severely affected. The sites most commonly involved are the pelvis, skull, femur, tibia, and spine. In addition to pain, gross deformity, compression of neural structures, fracture of involved bone, and alteration of joint structure/function often result. Increased serum alkaline phosphatase and urinary hydroxproline reflect the increased bone turnover in this disease. An infrequent (<1%) but dreaded complication of Paget's disease is osteosarcoma. Other associated neoplasms include nonneoplastic granulomas and giant cell tumors.

Paget's disease can be asymptomatic with little clinical disability and, therefore, no therapy may be necessary (Altman & Singer, 1980). However, specific therapy is available for patients who are suffering. While NSAIDs help control pain, they do not affect the biochemical abnormalities. Disodium etidronate, a diphophonate compound (Krane, 1982), decreases bone resorption, but this oral agent should be given for no longer than 6 months at

a time. Bone pain usually responds to this medication, but a temporary paradoxical increase in bone pain may occur in some patients. Subcutaneous injections of synthetic salmon calcitonin are also used to provide pain relief and help prevent deformity. Clinical improvement usually occurs within a month or two. Some patients may become refractory to this medication if they produce neutralizing antibodies to this salmon protein.

Joint pain can be caused by a variety of pathophysiological mechanisms. While disorders such as RA, OA, and SLE are chronic and incurable causes of arthritis and arthralgia, infectious agents can cause an acute arthritis, which with early detection and proper management can be cured with little or no permanent sequelae.

While any infectious agent can cause septic arthritis, pyogenic bacterial arthritis causes the most rapidly destructive form of infectious arthritis. Bacterial arthritis is usually divided into two groups, that caused by *Neisseria gonorrhea* and that caused by other bacteria (e.g., staphylococci, enteric organisms). Most cases of bacterial arthritis are the result of hematogenous spread to the affected joint(s). Other causes include direct infection from a puncture wound or skin infection. Once inside the joint space, the infectious agent multiplies rapidly, and the inflammatory response can become very severe, causing so much joint swelling and intense pain that the patient can neither actively extend nor flex the affected joint. Usually, such patients are febrile with high peripheral white blood cell counts. If untreated, the infection can cause destruction of cartilage and bone, as a result of a direct toxic effect of the bacteria and enzymatic destruction from purulent inflammatory exudates (Goldenberg & Reed, 1985). *Staphylococcus aureus* and Gram-negative bacilli often destroy joints rapidly, whereas other organisms, such as *Streptococcus pneumoniae* and *N. gonorrhea*, cause damage much more slowly.

To make a correct diagnosis, an aspiration of the affected joint needs to be performed under aseptic conditions and the fluid sent for cell count, differential, and culture. A septic joint typically has a white cell count in excess of 50,000 cells/mm^3 with predominance (often 90%) of polymorphonuclear leukocytes. It may take several days for the offending organism to grow in culture, and therapy should not be delayed. The prompt initiation of intravenous antibiotics, the exact nature of which depends on the likelihood of having a particular organism under certain clinical conditions, may be critical. Periodic joint aspiration and reassessment need to be performed while the patient is hospitalized. Depending on the organism, intravenous antibiotics need to be administered from 2 to 6 weeks. Some patients can be managed with home intravenous therapy at the discretion of the physician.

Patients at risk for the development of septic arthritis include patients taking systemic or locally injected corticosteroids, immunocompromised patients, and patients

TABLE 32.3
Types of Tumors of Joint, Tendon Sheaths, and Bursae

Benign

Neoplasms and tumoral conditions
    Pigmented villonodular synovitis
    Synovial chondromatosis (osteochondromatosis)
    Other benign tumors: lipoma including lipoma arborescens,
      chondroma, hemangioma, fibroma
Tumor-like lesions
    Ganglion bursitis, synovial cyst, parameniscal cyst, nodules

Malignant

Primary
    Synovial sarcoma (malignant synovioma); biphasic and monophasic
    Clear cell sarcoma
    Epithelioid sarcoma
    Synovial chondrosarcoma
Secondary
    Metastatic carcinomatous arthritis
    Joint invasion by leukemia, lymphoma, myeloma
    Continuous spread of malignant bone tumors

with hemarthroses. Among otherwise young, healthy patients, disseminated gonococcal infection is the most common cause of septic arthritis in the urban population. Increasing in prevalence (Veasy et al., 1987), although still considered uncommon, is acute rheumatic fever, which is an inflammatory disease induced by an antecedent group A beta-hemolytic streptococcal pharyngitis. The most common features are carditis and polyarthritis. The Jones criteria enable the physician to establish the diagnosis (Stollerman et al., 1965) and act as a guide in the evaluation of patients with polyarthritis of unknown etiology.

Patients with neoplastic diseases often are seen by a rheumatologist for musculoskeletal symptoms. Primary neoplasms of bursae, joints, and tendon sheaths are uncommon (Jaffe, 1958). Most arise from the synovium and are benign. Tumor-like swelling in and around a joint most likely is the result of inflammatory and traumatic lesions and, hence, should not be considered true neoplasms. However, tumors can occur (see Table 32.3). More often, secondary neoplastic involvement of joints occurs as a complication of contiguous spread of primary bone sarcomas, invasion by hematologic malignancies such as leukemia, lymphoma, myeloma, or carcinomatous metastases (Schajowica, 1982).

Most subtle involvement of the musculoskeletal system with malignancy manifests itself as the group of disorders and is termed paraneoplastic syndromes. True paraneoplastic syndromes include myopathies, arthropathies, and other conditions such as hypertrophic pulmonary osteoarthropathy, amyloidosis, and secondary gout. Polyarthritis resembling RA may be the presenting sign of malignancy (Calabro, 1967). The cause is unknown, but the action of circulating immune complexes and alter-

ations in cellular immunity have been offered as explanations (Awerbuch & Brooks, 1981; Robins & Baldwin, 1978). In addition, a syndrome similar to SLE has been reported in association with underlying malignancies (Pierce et al., 1979; Wallack, 1977). Unfortunately, other rheumatic conditions, such as polymyalgia rheumatica, scleroderma, necrotizing vasculitis, cryoglobulimenia with Raynaud's phenomenon (seen most commonly with metastatic malignancy), and reflex sympathetic dystrophy have been associated with various malignancies. This confusing picture often requires much in the way of energy and expertise to understand and properly treat the specific condition(s).

ROLE OF THE RHEUMATOLOGIST IN THE MULTIDISCIPLINARY APPROACH TO THE TREATMENT OF THE PATIENT WITH PAIN: THE RHEUMATOLOGIST AS A "TEAM PLAYER"

To paraphrase the eminent poet John Donne, no physician is an island, especially when it comes to the treatment of the patient with pain. Often the physician needs to coordinate the efforts of several health care professionals (e.g., orthopedists, neurologists, anesthesiologists, counselors, psychologists, physical therapists) and educate his or her colleagues regarding the special requirements of such patients. Physical therapy, for example, is an extremely useful adjunct in the treatment of many patients who require specialty care. However, the approach of the physical therapist needs to be individualized to each and every patient he or she sees. Most physical therapists see patients with such varied disorders as strokes, arthritis, postsurgical states, sports injuries, and myofascial pain syndromes. The stroke victim has different pathology and hence different needs than the patient with RA or adhesive capsulitis of the shoulder. While general principles of physical therapy usually are the same for all patients, the practical application of these principles can vary greatly from patient to patient depending on the problem. The patient with arthritis of the knees, for example, who requires quadriceps muscle strengthening therapy to combat atrophy of the thigh muscles due to disuse requires different management if a concomitant myofascial pain syndrome (MPS) is also present. The same is true for work-hardening programs. If the deconditioned patient with a regional MPS enrolls in a standard program, he or she will be unable to tolerate the strengthening exercises as they will exacerbate the condition (Travell, 1990, personal communication). It is only when the rheumatologist or other pain specialist treats the MPS successfully, that work-hardening can proceed.

The physical therapist can play a pivotal role in treating MPS with spray-and-stretch techniques, massage, acupressure, local heat, or ultrasound. In fact, the therapist

often can alert the referring physician to the possibility that the patient may have a concomitant regional MPS if the patient in question has a paradoxical response to correctly applied physical therapy modalities. As mentioned above, if work-hardening causes increased pain, one should suspect a regional MPS. The same principle holds true for cervical traction, a very useful treatment for chronic cervical radiculopathies. If, in addition, the patient has a regional MPS in the vicinity of the occiput or cervical musculature or trapezius/rhomboid areas, the force of the correctly applied traction applied to taut muscles usually results in more pain rather than less. Such a scenario should alert the therapist to the possibility of a regional MPS and this information should be shared with the referring physician. If the MPS persists, rheumatologic or physiatric consultation should be obtained.

Often, patients with FS, RA, or SLE with bothersome neuritic symptoms need the expertise of a neurologist to help determine if peripheral neuropathy, nerve entrapment, or another neurological problem exists. Tests such as electromyograms (EMGs), nerve conduction studies, somatosensory evoked potentials (SEPs), and radiographic studies (e.g., CT scans, MRI scans) may need to be done to complement the neurological examination and more precisely define (or rule out) a particular problem. FS sufferers tend to have an exacerbation of their symptoms after EMGs, probably due to their abnormal perception of pain and aberrant central processing. In fact, the first clue that a patient may have FS is often the observation that the patient in question, who is being treated or evaluated by a neurologist for numbness, tingling, or lancinating pain, behaves quite differently from other patients with similar symptoms. The patient may report that the EMG was very painful and may, in fact, terminate his or her participation in the study before it is completed due to unbearable pain. The neurologist can be of great help to the patient referred for neuritic symptoms but for whom no definable neurological abnormality can be found. As mentioned earlier gabapentin may be helpful in the management of neuropathic pain. These patients may be suffering from FS or a polyneuropathy/mononeuritis multiplex and should be referred to a rheumatologist or physiatrist for further evaluation.

The orthopedist is frequently called upon to help the rheumatologist when medical management of rheumatologic conditions fails. As mentioned earlier, patients with end-stage osteoarthritic or rheumatoid arthritic changes in knee or hip joints often require total joint replacement. It is up to the rheumatologist to help select suitable candidates for such procedures. The ideal surgical candidate not only has failed conservative measures but is not overweight (the heavier the patient, the more likely the prosthesis may loosen or dislodge), is motivated and intelligent so as not to take undue risks after the procedure is performed (i.e., avoid activities that put increased mechanical

stress on the prosthetic joint), and is sufficiently advanced in years so, statistically speaking, the life span of the prosthesis should exceed that of the patient. Conversely, many practicing orthopedists evaluate patients with joint pain who, inspired by media-hype, self-refer themselves for total joint replacement. Some need the procedure, but many others do not. Their arthritis can be managed quite well with a program of anti-inflammatory drug therapy, weight reduction, physical therapy, and orthotic use such as a cane, if necessary. Conservative medical management of this type can often help patients avoid premature and possible unnecessary surgery while adequately controlling their pain.

The rheumatologist is most likely to call upon the services of his or her colleagues in anesthesiology when a patient requires a nerve block for such diverse conditions as occipital neuralgia (as the cause of some chronic headache conditions) and reflex sympathetic dystrophy (which can often complicate arthritic conditions). Many "failed back" patients benefit from lumbar nerve root blocks, which often give effective, albeit temporary, relief from severe pain. Other modalities (outlined elsewhere in this text) can be extremely effective, especially if timely referrals are made.

Frequently, the orthodontist and the rheumatologist need to work together in the treatment of FS patients with temporomandibular joint (TMJ) disorders, as these two entities frequently coexist in the same patient and one can exacerbate the symptoms of the other (TMJ and related disorders are discussed elsewhere in this text).

A valuable ally in treating patients in pain is the psychologist or counselor. Often, patients with chronic painful states such as RA, fibromyalgia, or OA are anxious or depressed or lack coping skills necessary to deal with their pain. Cognitive behavioral approaches to pain such as pain imaging, for example, may be very useful tools in helping patients take an active role in controlling their pain level not just becoming a victim of their disorder. Biofeedback training may help some patients, especially those afflicted with myofascial pain states. Families whose members have painful diseases often are under a great deal of stress and become dysfunctional. Family counseling and/or marital counseling can go a long way in aiding the patient and those around him or her in coping with chronic illness. The patient suffering from chronic pain must avoid the feelings of helplessness and despair that can occur, especially when the patient feels that he or she is a victim and has no control over his or her pain. Overcoming such obstacles is essential for optimal care of the patient with chronic painful states. Insight into how certain aspects of a patient's lifestyle can aggravate the underlying painful condition can also be attained through counseling, thus further benefiting patients and conceivably lessening their need for analgesics and other medications.

While multidisciplinary pain clinics have been a great boon in the treatment and further understanding of the pain patient, they are beyond the reach of many, and probably most, patients. However, that does not mean that such an approach to patients in pain cannot be attempted at the community level. Such an endeavor requires that the professionals caring for the patient strive to cooperate and communicate with each other in order to provide the most conducive atmosphere for encouragement and eventual improvement.

CONCLUSIONS

For the patient who comes to the rheumatologist with a complaint of pain, it is not sufficient for the physician to offer only symptomatic relief. As an internist, as well as a specialist in the rheumatic diseases, the rheumatologist needs to accurately pinpoint the cause of the pain and take appropriate measures to minimize associated morbidity. Investigations necessary for the accurate and prompt identification of the scope of the patient's illness may be costly in terms of time and money, but the advantages of an accurate, early diagnosis and prompt effective treatment far outweigh these other considerations. Patients trust their physicians to care for them when they are suffering. That trust must never be betrayed; patients deserve no less than the very best we have to offer.

Orthopaedic Pain

Gerald Q. Greenfield, Jr., MD, FACS, FICS

INTRODUCTION

Orthopaedics is typically concerned with the treatment of arthritis, fractures, sprains/strains, infection, cancer/metastasis, spinal care/surgery, nerve injury, and osteoporosis/vertebral compression fractures, all of which are likely to result in a manifestation of pain. Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage (Mersky & Trimble, 1979). Pain is not a primary sensation such as smell, taste, touch, or vision, but rather it is an emotional state like sorrow or love. The International Association for the Study of Pain defines neuropathic pain as "pain initiated or caused by a primary lesion or dysfunction of the nervous system" (Mersky & Trimble, 1994). Neuropathic pain is characterized by lesions or dysfunction of the systems that under normal conditions, transmit noxious information to the central nervous system. This definition has been called vague, and the inclusion of "dysfunction" allows it to be assigned to disorders such as chronic regional pain syndrome.

Orthopaedics in the United States is a surgical specialty. However, in many areas of the world orthopaedics is a nonsurgical specialty, which may even be described as orthopaedic medicine. Indeed, the initial approach to many orthopaedic pain problems is nonsurgical. Surgery should be reserved for those situations in which an alteration in anatomy offers the possibility of pain relief or functional improvement. Nevertheless, orthopaedics is concerned with the treatment of complaints of the bones, joints, spine, and peripheral nerves. Pain is the presenting symptom in almost all patients with orthopaedic problems.

The practice of orthopaedics encompasses the treatment of fractures, sprains, strains, arthritis, spinal care, nerve compression, infection, primary cancer and metastatic disease, and osteoporosis. The variety of pain complaints is limited only by the patients' ability to describe the sensation. The first steps are to define whether the pain is local or referred, due to compression or disruption of structures, and mechanical or neurological in origin. Next a differential diagnosis should be made and appropriate laboratory and radiological studies obtained. Interpretation of these studies in conjunction with the patient's history and physical examination will lead to a diagnosis, for which a treatment plan can be formulated.

Most orthopaedic pain is neuropathic (Table 33.1). Clinically, neuropathic pain responds to certain pharmacological, mechanical, or surgical treatments. Also included in the realm of orthopaedic pain is pain that is the result of inflammation, such as an abscess, infection, or an inflammatory process (arthritis, tendonitis, and bursitis). The presence of neuropathic pain does not exclude the possibility of the presence of other types of pain. It has even been suggested that there is a continuum of pain with varying degrees of neuropathic and inflammatory components (Barkonja, 2003). Most importantly, all pain must be regarded as real. The terms that patients use to describe pain may be difficult to understand. Therefore, a high level of competence is needed to translate the patient's subjective description into something objective and useful. This variety of orthopaedic pain etiologies requires both an open mind as well as acceptance of a multidisciplinary approach to the treatment of pain.

TABLE 33.1
Types of Orthopaedic Pain

Fractures	Sprains/strains
Inflammation from overuse	Inflammation from metabolic disease
Arthritis (rheumatoid arthritis, osteoarthritis)	Infection
Postsurgical	Neoplasm/metastasis
Compressive neuropathy (upper extremity, lower extremity)	Spine pathology
Phantom limb pain	Complex regional pain syndrome I and II
Myofascial pain syndrome and fibromyalgia syndrome	

SOURCES OF PAIN FIBER IRRITATION

Pain is *mediated* by impulses carried in specific nerve fibers, but *modulated* by a number of other processes. Pain perception is the result of a combination of the effects of impulses carried by nerves and the physical and psychological factors in the patient's environment. The nerves that carry the impulses (A-delta and C) remain constant in their response to applied stimuli. However, the same noxious stimulus delivered to the same patient can produce different results or be perceived differently depending on environmental, physical, and mental factors. Even in specialized pain research settings, it is sometimes difficult to identify specific neuropathic pain mechanisms. Peripheral sensitization occurs when there is a constant state of hyperexcitability in response to a peripheral nerve injury. Central sensitization occurs as a result of changes in nociceptors resulting in a state of hyperexcitability. If these states do not decay once the stimulus or its effects are removed, the alteration in afferent function may persist and become resistant to treatment. In peripheral sensitization, C-nociceptors and fibers show pathologic adrenergic sensitivity (Baron, 2000; Fields, Rowbotham, & Baron, 1998). These effects can be reversed by the application or injection of local anesthetics. The increased activity in peripheral C-fibers is transmitted centrally by large myelinated A-beta fibers. Through these fibers, stimuli, which would under normal circumstances be innocuous, are transmitted to dorsal horn nuclei and then centrally. Thus, the activity of A-beta fibers is necessary for impulses to reach the central nervous system and incite allodynia. All of these factors may come into play in the evaluation and treatment of orthopaedic pain and its sequelae.

TYPES OF ORTHOPAEDIC PAIN

Fracture treatment is the mainstay of orthopaedic surgery. All fractures cause pain in neurologically intact persons although the character and intensity of the pain may vary from person to person. The pain that results from a fracture may come from a variety of sources. The periostium is richly supplied with free nerve endings. Likewise surrounding tendons and ligaments are innervated with free nerve endings as well as pressure and stretch receptors. Because this pain is acute, it responds to routinely used analgesics given by mouth, by intramuscular injection, or intravenously. The transdermal use of analgesics is not recommended for acute pain management.

Ligament sprains or muscle or tendon strains are also among a number of acute pain problems that are treated by orthopaedic practitioners. Usually the result of low-energy trauma, these injuries may affect a variety of areas. The basis of treatment is signified by the pneumonic R-I-C-E, which stands for rest, ice, compression, and elevation. Analgesic use is typically nonsteroidal anti-inflammatory drugs (NSAIDs). In some severe cases narcotic analgesics may be necessary. Physiotherapy or other rehabilitation methods are also useful. The weekend athlete is usually treated nonsurgically for an acute stretch to ligament, tendon, or muscle. However, for those involved in more organized contests where the degree of injury is greater, surgery may be a consideration. These patients have ligament tears or ruptures (grade III sprain) or muscle/tendon tears.

Inflammation as a source of orthopaedic pain encompasses a wide variety of injuries and disease processes. These include both rheumatoid and osteoarthritis, bursitis, tendonitis, gout and other deposition-type diseases, overuse syndromes, and repetitive motion injuries. The widespread use of computers and occurrence of associated injury has provided a new diagnostic category, which has political and financial overtones for employers and insurance carriers. Although the exact pathophysiology differs, the common process is inflammation with the presence of mast and other cells and the release of lysosyme and other inflammatory agents. Although pain may be the presenting symptom, the underlying process is inflammation; treatment should thus be aimed at relief of that process. Methods of pain relief include ice or heat, bandages, braces or supports, modalities such as ultrasound or trigger point therapy, drugs to limit the body's absorption of certain materials, and simply resting the area. It is not usually necessary to use narcotics, injections, or surgery in the early phases. Because of the potential for disability as the result of deformity in the later stages, some inflammatory processes require surgical intervention or joint replacement.

Infection in the form of a generalized process or an abscess can be a source of pain. The pain may be the result of inflammation associated with the presence of bacteria and their by-products or the result of an expanding lesion such as an abscess. Once thought to be a problem of the past due to the introduction of antibiotics, infection is

again a major medical problem. Treatment is aimed at pain relief through the elimination of the infection. While antibiotics alone may be appropriate in some instances, in others, surgical evacuation of the abscess or removal of diseased tissue is necessary. Narcotic or other analgesic agents may be necessary until the infection is resolved.

Postsurgical pain, typically acute, can be treated in a variety of ways. These range from NSAIDs to narcotics, with more complex cases requiring regional anesthetic blocks, to a combination of multiple interventions. Patient-controlled analgesia using a variety of drugs via an intravenous route or transdermal analgesic patches are popular with both patients and nursing staff. Recent studies have shown that local anesthetics injected into the surgical area prior to incision significantly reduce the need for postoperative narcotics. When preoperative NSAIDs are added, there is a further reduction. Finally, the additional use of regional anesthetic techniques (nerve blocks or epidural anesthesia) reduces the blood pressure elevations seen in surgical procedures and decreases the pain and the amount of narcotic required to keep patients comfortable postoperatively. Through the skillful use of NSAIDs and regional anesthetics, the need for narcotics can actually be eliminated in all but a few cases. These and other combination analgesic therapies offer promise for the future.

The pain of cancer or metastatic disease to bone may be referred to the orthopaedic surgeon. In addition to their pain management these patients often have significant psychological problems. Treatment of the latter problem does not fall within the skills of most surgeons and is usually best referred to another professional. Pain treatment or management, however, may be left to the surgeon. A variety of oral agents are now available including tablets as well as pain cocktails. Orthopaedics is mainly concerned with the pain that accompanies expanding or destructive metastatic lesions. Restoration of mechanical stability through surgical stabilization of fractures (current or impending) allows functional recovery as long as there is adequate pain control. Central or peripheral nerve stimulation or lesioning offers another option for pain control. Advances in oncology often mean that patients are already on long-acting analgesics from their oncologist and orthopaedics need only control postoperative pain.

COMPRESSIVE NEUROPATHIES

Compressive neuropathies account for a number of pain syndromes involving the upper and lower extremities. Upper extremity neuropathies (Table 33.2) include thoracic outlet syndrome, radial, ulnar, and median nerve compression, and brachial plexus lesions. Nerve compression in the upper extremity can be a debilitating problem. Lower extremity compression can affect the lateral femoral cutaneous, ilioinguinal, genitofemoral, posterior femoral cutaneous, or several lesser nerves. Gait and ambu-

TABLE 33.2
Compressive Neuropathies (Upper Extremity)

Thoracic outlet	Cubital tunnel
Carpal tunnel	Radial nerve (pronator)
Ulna nerve (Guyon)	Long thoracic nerve
Suprascapular nerve	Axillary nerve
Musculocutaneous nerve	Pancoast tumor
Secretan's disease	

lation are affected by these disorders. They are also not as well understood as those affecting the upper extremity.

The median nerve can be compressed or entrapped at one of four locations in the upper extremity: under the ligament of Struthers (Werrtsch & Melvin, 1982), under the lacertus fibrosis (Laha, Lunsford, & Dujovny, 1978), at the pronator teres (Bell & Goldner, 1956), and at the proximal fibrous arcade of the flexor digitorum superficialis (FDS) (Hill, Niven, & Knussen, 1996). At times vascular leashes around or across the nerve may cause compression. The nerve can also be compressed at the wrist as it passes through the carpal tunnel beneath the transverse carpal ligament. Three named syndromes define compression of the median nerve: carpal tunnel syndrome, pronator teres syndrome, and anterior interosseous syndrome. Sir James Paget first described median nerve entrapment at the carpal tunnel in 1854 (Paget, 1854). It was not until the 1950s when carpal tunnel syndrome (CTS) was formally described (Phalen, Gardner, & Lalonde, 1950). The causes of CTS include inflammation, displaced fractures, gout, acromegaly, amyloidosis, myeloma, and anamolous muscles. Many cases have no identifiable cause. Hand numbness and weakness are the most common symptoms. Treatment includes the use of splints in a neutral or dorsiflexed position, anti inflammatory drugs, and steroid injection into the carpal tunnel. The success of nonsurgical treatment decreases with the presence of risk factors (age > 50 years, positive Phalen's test, symptoms > 10 months, constant paresthesias, and associated trigger finger) (Kaplan, Glickel, & Eaton, 1990). When the above techniques fail surgical intervention is the next option.

Pronator teres syndrome was first described by Seyffarth (1959). The symptoms of anterior forearm pain and paresthesias in the median nerve distribution can be confused with carpal tunnel syndrome. There is pain and tenderness at the point of compression. Nonsurgical treatment involves splinting in slight elbow and wrist flexion with forearm pronation, avoidance of repetitive elbow flexion and pronation/supination, and anti-inflammatory drugs. In most cases these options are successful. Surgery involves wide exposure of the median nerve in the forearm, identification of the median nerve, and release of all potentially compressive structures.

Anterior interosseous nerve syndrome (Kiloh & Nevin, 1952) may be due to amyotrophy, fracture, laceration, or compression. The only sign or symptom is weakness of the flexor pollicus longus (FPL) and flexor digitorum profundus (FDP) of the index finger. There are no sensory findings. Nonsurgical treatment includes avoidance of aggravating activities, NSAIDs, and splinting. If these fail, surgical intervention is a consideration; however, spontaneous recovery has been reported after as long as 18 months. Recovery is faster in surgically treated patients if conservative treatment was not successful after a three-month trial (Howard, 1986).

The ulnar nerve may be entrapped at two sites along its course. The cubital tunnel at the elbow is the most common site by a factor of 10. The other site is Guyon's canal at the wrist (Panas, 1878). After carpal tunnel, cubital tunnel syndrome is the most frequent compressive neuropathy in the upper extremity. Nonsurgical treatment includes splints, activity modification, and NSAIDs. Steroid injection is to be avoided due to the superficial location of the nerve. Surgical treatment in the form of decompression, medial epicondylectomy, or anterior transposition is generally successful in 85 to 90% of cases (Osterman & Davis, 1996). Entrapment of the ulnar nerve at Guyon's canal is often referred to as ulnar tunnel syndrome. It is usually due to repetitive trauma or fracture of the hamate or pisiform bones; other causes are mass lesions, fascial bands, or thrombosis. Conservative treatment depends on the cause and includes splints, activity modification, and NSAIDs. When these fail surgical decompression is considered.

Radial nerve compression syndromes can affect either the superficial or the deep portion. The superficial portion is purely sensory and is rarely affected. The deep or posterior branch provides motor innervation to the extensor muscles of the forearm and sensation to the dorsum of the hand distal to the wrist. Agnew (1963) first described posterior interosseous nerve syndrome. This is also referred to as radial tunnel syndrome. In some cases it may be confused with tennis elbow or lateral epicondylitis. The most common source of compression is an anatomic variant, usually at the arcade of Frohse. Other causes include the vascular leash of Henry, fibrous bands from the supinator, radiocapitellar joint, or extensor carpi radialis brevis (ECRB); mass lesions such as synovitis or bursitis are also implicated. Radial tunnel syndrome can produce pain without muscle weakness as first described by Michele and Kreuger (1956). There are three described signs that differentiate radial tunnel syndrome from tennis elbow: (1) tenderness to palpation distal to the radial head not at the lateral epicondyle, (2) increased pain with forearm supination due to posterior radial nerve compression by the arcade of Frohse, and (3) increased pain with extension of the middle finger against resistance when the wrist and elbow are in extension (middle finger test). Elec-

tromyography can be helpful in distinguishing radial tunnel syndrome from cervical radiculopathy. Conservative trials of splints for elbow flexion with wrist extension, activity modification, NSAIDs, and local injection should be attempted before surgical decompression.

The long thoracic nerve (of Bell) is a pure motor nerve and as such lesions do not present with pain. Injury to the nerve presents as scapular winging, which is accentuated by having the patient push against a wall with the arm flexed. There are three major causes for isolated long thoracic nerve injury: neuralgic amyotrophy, trauma, and stretch or traction on the nerve (Gregg, Labosky, & Harty, 1979). In the military, rucksack palsy is a frequent cause of long thoracic nerve palsy (Hirasawa & Sakakida, 1983; Holzgraefe, Kuwowski, & Eggert, 1994). Because most injuries are due to carrying or stretch and are incomplete, prognosis for spontaneous functional recovery is good. Physical therapy and orthotic devices may be helpful while waiting. Recovery should occur by 2 years postinjury. If there is no recovery, muscle transposition (pectoralis major/minor, rhomboids, teres major) or scapulothoracic fusion are possible treatment options.

Entrapment of the suprascapular nerve at the suprascapular notch or spinoglenoid notch presents as shoulder pain and weakness. This injury is more frequently noted due to the increasing use of backpacks in our society, especially in children. Direct blows to the area may also be a factor. There is deep pain and throbbing along the superior border of the scapula and shoulder joint, with radiation down the arm. Weakness of the supraspinatus and infraspinatus muscles is manifested by decreased shoulder abduction and external rotation strength. The pain is exacerbated by reaching across the body with the involved shoulder while rotating the head away from the affected side. It must be differentiated from inflammatory conditions of the shoulder, cervical radiculopathy, neuralgic amyotrophy, and axillary neuropathy. Electromyography (EMG) may be helpful in these cases. This will also allow exclusion of Parsonage–Turner syndrome, which is idiopathic brachial neuritis. Other causes include ganglion cyst at the spinoglenoid notch, rotator cuff tear, or superior glenoid labrum lesions, shoulder trauma, or repetitive motion injury. Plain radiographs help rule out occult bony pathology and apical lung tumors. Magnetic resonance imaging (MRI) allows evaluation of the shoulder joint and surrounding tissues. Non-operative therapy in the form of physical therapy is often successful. However, if there is a clearly defined pathologic lesion, surgery for release of the transverse scapular ligament or excision of a ganglion cyst is a reasonable option.

Axillary neuropathy presents as a patch of decreased sensation in the deltoid region or atrophy or weakness of the muscle. The most common cause is trauma, especially shoulder dislocation (Toolanen, Hildingsson, & Hedlund, 1993) or humeral fracture. Because partial injuries usually

recover fully, physical therapy is important in order to maintain range of motion during the recovery period. Brachial plexus injuries in association with axillary injuries have a less favorable prognosis (Berry & Bril, 1982). Any nerve grafting should be performed by 6 months after injury (Petrucci, Morelli, & Riamondi, 1982).

The musculocutaneous nerve is a mixed motor and sensory nerve. Injury to this nerve presents as weakness in elbow flexion and forearm numbness. Pain in the cubital fossa occurs with more distal injuries. The differential diagnosis includes biceps tendon rupture, cervical radiculopathy, median nerve compression, and lateral epicondylitis. Nerve injury is most often due to trauma to the shoulder or upper arm, especially proximal humeral fractures. Shoulder surgery in which the coracoid is transposed has been shown to injure the nerve (Chaung, Yeh, & Wei, 1992). In the event nonsurgical therapy is ineffective, surgical decompression at the elbow would be indicated (Bassett & Nunley, 1982). Nerve grafting before six months (Chaung et al., 1992; Nagano, Ochiai, & Okinaga, 1992) or free muscle transfer (Alasaka, Hara, & Takahashi, 1990) are options for those patients with electromyography/nerve conduction velocity (EMG/NCV) proven lesions that fail to improve. Isolated stretch lesions of the musculocutaneous have a good prognosis when treated conservatively, while grafting procedures have a variable outcome.

Tumors at the apex of the lung may grow and directly affect the brachial plexus. In Pancoast tumor syndrome this can cause arm pain and in some patients Horner's syndrome. There may also be destruction of the first and second ribs. The pain is neuritic in nature and may develop a deep ache or boring quality. Because the great majority of the patients have no antecedent trauma history, there is often a delay in diagnosis. The diagnosis should be high on the list of any patients who are smokers and present with atypical arm or neck pain. Treatment is directed at the tumor itself and pain management is palliative. Direct surgical treatment of brachial plexus lesions is usually disappointing from both a functional and pain relief perspective. Even direct irradiation of the tumor may cause residual neuropathic pain.

Secretan's disease or post-traumatic edema syndrome, while not due to nerve entrapment, is an enigmatic syndrome of pain and swelling over the dorsum of the hand. The pattern of pain may be mistaken for a radial sensory nerve injury. It is usually associated with minimal trauma. Most often it is seen after minor traumatic events such as bumping the hand against objects. It may not be reported for days and then only because of persistent pain. Wounds or abrasions are seldom noted. There is diffuse swelling over the dorsum of the hand with accompanying restriction of finger motion, especially flexion of the metacarpophalangeal (MCP) joints, due to peritendinous fibrosis. It must be differentiated from reflex sympathetic dystrophy, which presents with accompanying sudomotor or

TABLE 33.3
Compressive Neuropathies (Lower Extremity)

Posterior femoral cutaneous nerve (PFC)	Tarsal tunnel
Morton's neuroma	

vasomotor signs. Treatment is symptomatic including compression, elevation to control swelling, and cast or splint application for support and protection against further trauma. Physical therapy for restoration of range of motion must be gentle in order to avoid exacerbation of painful symptoms. The use of NSAIDs may be helpful. Injection of local anesthetic and steroid into the peritendinous fibrosis is an alternative in recalcitrant cases.

Lower extremity compressive neuropathies (Table 33.3) are sometimes more confusing as the neuroanatomy is generally less familiar to most clinicians. The anatomy of the lumbar plexus is less studied in anatomy class than that of the brachial plexus. These factors make their diagnosis much more challenging. Lower extremity symptoms are usually not reported as quickly as are those in the upper extremity. Meralgia parestetica presents as numbness, tingling, or pain in the anterior and lateral thigh region. The lateral femoral cutaneous nerve is compressed by the inguinal ligament, tight clothing, or belts or due to contusion over the iliac crest and resultant hematoma. In some cases the signs follow iliac crest graft harvest for bone grafting in anterior cervical spinal fusion cases. Because the nerve is purely sensory, no motor deficits are noted. Treatment is nonsurgical using analgesics, NSAIDs, or sometimes physical therapy modalities. Some cases resolve spontaneously.

Ilioinguinal and genitofemoral neuralgia are common causes of lower abdominal and pelvic pain complaints (Starling & Haarms, 1989). Injury to the nerves can occur anywhere along their course. Sources include compression, direct trauma, or damage during pelvic or inguinal procedures. Rarely neuralgia may occur spontaneously. Pain, paresthesias, or numbness occur over the lower abdomen and inner thigh and may radiate to the labia majora or scrotum. Because stretching the nerve by lumbar extension exacerbates symptoms, patients often bend forward at the waist. The diagnosis is best made by clinical examination with the pattern of pain rather than muscle testing. Intra-abdominal tumor or other process needs to be ruled out as well as lumbar plexus lesions or inguinal hernia or infection. Aside from treatment of the primary lesion, management is usually by specific or selective nerve block. Care in examination will prevent mistaking one syndrome for the other.

Piriformis syndrome is an entrapment neuropathy characterized by pain, paresthesias, and sometimes weak-

ness in the distribution of the sciatic nerve. The piriformis muscle compresses the nerve as it passes through the sciatic notch. Patients may develop an altered gait that may precipitate the development of sacroiliac, back, and hip pain. The clinical picture is sometimes so confusing that symptoms are attributed to lumbar disc herniation. In rare cases, patients have even undergone laminectomy and disc excision. Physical findings include sciatic notch tenderness, a positive straight leg raise on the affected side, and pain radiating down the leg into the calf or ankle. If present for a prolonged time or left untreated, weakness of the gluteal muscles and lower extremity may result. In addition to lumbar disc herniation, hip pathology must be excluded. This is best accomplished by careful physical examination, appropriate radiographs, and MRI scans of the spine or hip. Treatment begins with analgesics and NSAIDs along with physical therapy. Local application of modalities such as heat or cold may be of benefit. Steroid combined with local anesthetic is successful in the great majority of cases such that the need for surgical release of the entrapment is rare. Other lower extremity entrapments include the posterior femoral cutaneous nerve, the obturator nerve, the femoral nerve, and saphenous neuropathy. All present as pain in a specific distribution and accompanying motor weakness. Direct trauma from contusion or surgical procedures in the area is the most frequent etiology.

Nerves in the ankle and foot are also injured by compression. The tarsal tunnel is classically located posterior to the medial malleolus. The posterior tibial nerve passes through this osteo-ligamentous tunnel along with the tendons of the posterior tibial and flexor hallicus longus muscles, and the posterior tibial artery. Symptoms of nerve compression include pain and paresthesias on the sole of the foot, weakness of the foot intrinsic muscles, and nighttime pain similar to carpal tunnel syndrome. Tenderness over the tarsal tunnel may also be present. While most cases respond to nonsurgical therapy including NSAIDs, splint or cast application, activity modification, and injection, release of the ligament enclosing the tunnel may be necessary in some cases. The deep peroneal nerve may be compressed as it passes beneath the superficial fascia of the anterior ankle. This has been called anterior tarsal tunnel syndrome. Pain and paresthesias in the nerve distribution are the result. Active plantar flexion of the foot or hyper-dorsiflexion, as in squatting, may exacerbate symptoms. Treatment is again nonsurgical except in recalcitrant cases.

Morton's neuroma occurs when the common digital nerve is compressed between the toes, usually the third and fourth. Presenting symptoms are pain or paresthesias in the toes, pain with prolonged standing or walking, and pain when wearing tight shoes or boots. Physical examination reveals pain with local compression in the interspace or from compression or squeezing the metatarsals

together. Women may complain of pain exacerbated from wearing high heels. Nonsurgical therapy includes metatarsal pads or bars, NSAIDs, or injection of steroid into the area. When this fails, section of the common digital nerve may be necessary.

LOW BACK PAIN

Low back pain is the bane of humankind's upright posture. It is present in all societies from the most technologically advanced to the most primitive. As developed societies have become more technologically and less labor based, fitness of the society has decreased and with this has come an increase in the incidence of low back pain. In most cases the origin of low back pain is not known. The spine is a complex structure consisting of bones and joints, ligaments, muscles, discs, peripheral nerves and nerve roots, and the spinal cord. An appreciation of the anatomy, biomechanics, biochemistry, and pathophysiology of the spine is needed to understand low back pain. Structures that contain unmyelinated nerves or substance P or related peptide are capable of causing pain. There are free nerve endings in the outer one third of the disc annulus, the facet joint and joint capsule, the periosteum, and the paraspinous muscles and ligaments. These various nerve endings are sensitive to stretch, direct trauma, pressure, vibration, and chemical irritation as from inflammation or anaerobic metabolism and can be pain generators. While the nociceptive response is normally a gradual one dependent on the amount of stimulus applied to the tissue, this may not be the case in chronic pain situations. Nerve endings that have been previously sensitized may have a more rapid and sustained response to repeat application of a noxious stimulus. The spinal cord modulates nociceptive stimuli through a number of processes (Melzack & Wall, 1965). Theories include the gate-control (Melzack & Wall, 1965) and the convergence–perception (Hirsch, Ingelmar, & Miller, 1963). There is also evidence that descending seratonogenic pathways and endorphins allow individuals to modify or even turn off their pain responses (Haldeman, 1992). Thus, the pathophysiology of low back pain is extremely complex with multiple points at which it may be modified or modulated, including the dorsal root, the spinal cord, and centrally in the brain and brainstem. Treatments for low back pain are as varied as are the causes. Objective reviews have failed to show efficacy of any single treatment modality over another (Nachemson, 2000). Even in cases of frank disc herniation, surgery may provide only short-term improvement, with no long-term benefit over nonsurgical care. Recent treatment of "discogenic" pain has had at best only marginal success.

Spondylolisthesis is derived from the Greek *spondy-* meaning spine, and *-olisthesis* meaning slip. The anatomic finding in patients with spondylolisthesis is an alteration in the alignment of the spine, usually in the lumbar region.

The condition occurs four to six times more frequently in women than men, and usually after age 50 (Cauchoix, Benoist, & Chassaing, 1976; Newman, 1976). The L4–L5 level is most frequently affected. Displacement of one vertebra on another is slowed and eventually stops due to the onset of degenerative changes in the disc and facet joints (Matsunaga, Sakou, & Morizondo, 1990). The forward slippage of one vertebra on the other causes a decrease in the cross-sectional area of the spinal canal and may result in spinal stenosis and compression of the lumbar nerve roots. Rarely does cauda equine syndrome or myelopathy develop. Patients with spondylolisthesis complain of a deep, dull backache exacerbated by motion of the lumbar spine. Changing from a sitting to a standing position will often produce symptoms. More than one dermatome may be affected, and bowel and bladder function is spared until very late in the process. Likewise, motor function is affected only late in the course. In cases of bowel, bladder, and motor dysfunction, emergent surgical consultation is needed. Careful physical examination will help to identify the level and to rule out a disc herniation. Plain radiographs will usually identify the affected level. Myelography, computerized tomographic scan, or MRI may be necessary to identify nerve root compression. Treatment is multifaceted, including medication, physical therapy, and possibly application of braces. The use of caudal or lumbar epidural blocks with local anesthetic and steroid is also an effective alternative. Surgical intervention is needed for those with severe nerve compression or those who fail nonsurgical treatment. Prior to surgical intervention lytic defects in the pars interarticularis from spondylolysis must be considered. These may be a source of pain and may contribute to segmental instability.

Spinal stenosis was first described in the Netherlands (Verbiest, 1954). It is generally a disease of the aging spine, whether as the result of years or of years of use. It is the result of a combination of factors including disc collapse, "wrinkling" of the ligamentum flavum, facet joint hypertrophy, and the resultant nerve root compression. The hallmark is neurogenic claudication with calf pain and cramping. It must be differentiated from vascular claudication through the use of history, examination, radiographic and laboratory studies, and response to noninvasive treatment trials. Spinal stenosis may respond to epidural injection, but in advanced cases decompressive spinal surgery is usually necessary.

The aging population combined with diets low in calcium has led to a dramatic increase in the incidence of osteoporosis, especially among women (Riggs, 1995). A consequence of this increase is a corresponding increase in vertebral compression fractures. This painful condition affects about 8 million women annually in the United States, according to the National Osteoporosis Foundation. Men are also affected accounting for 20% of all cases of osteoporosis (Licata, 2003). There are roughly 700,000 vertebral compression fractures annually of which more than 80% are due to osteoporosis. While pain is the major presenting symptom, associated conditions include spinal deformity, chest and abdominal compression, decreased lung capacity, sleep disorders, loss of independence, and depression (Gold, 2003; Lyles, Gold, and Shipp, 1993; Silverman 1992). Most vertebral compression fractures heal spontaneously and without residual pain. However, recently a more aggressive approach has been adopted in the treatment of these patients. Injection of bone cement or other bone-space filler is often recommended to treat both the pain and in many cases the deformity associated with the fracture (Gaughen, Jensen, & Schweickert, 2002; Ryu, 2002). While this form of treatment is not applicable to all such fractures it does offer an option where none previously existed.

Coccydynia affects women more frequently than men. Characterized by pain localized to the tailbone region, it is due to direct trauma from a fall or as the result of a difficult vaginal delivery. The pain is due to sprain of the sacrococcygeal ligament, fracture of the coccyx, or a combination of both. Patients present with point pain and tenderness over the coccyx that is exacerbated by movement or pressure as with sitting. Primary pathology of the anus or rectum such as primary or metastatic tumors must be differentiated. Peri-rectal abscess is a frequent mimic as are sacral insufficiency fractures. Treatment is usually symptomatic with use of a pillow or donut for sitting and analgesics or NSAIDs for pain. If radiographic evaluation demonstrates coccyx displacement, especially in acute situations, digital rectal examination and reduction of the displaced fragment can provide sudden and dramatic relief of symptoms. Surgery should be avoided to prevent producing incompetence of the pelvic floor by disruption of supporting muscles and ligaments.

OTHER PAIN SYNDROMES

Ambrose Pare first described phantom limb or post amputation pain in military amputees in the 16th century. While most often described for loss of an extremity, phantom pains of a digit, eye, nose, teeth, breast, bladder, anus, and genital organs have been reported (Davis, 1993; Jensen & Rasmussen, 1989; Loeser, 1990; Marbach, 1993). Nonpainful phantom sensations are divided into three types: kinetic, kinesthetic, and exteroceptive. Kinetic sensations involve the perception of movement and may be perceived as spontaneous or volitional. Kinesthetic perceptions involve the size, shape, and position of the body part. This perception may be either normal or distorted. Exteroceptive perceptions are usually more intense on the involved area and include touch, pressure, temperature, or vibration. Visceral organs may have phantoms related to function of the organ such as the urge to urinate or defecate. Phantom pains are differentiated from annoying sensa-

tions and are often described as more intense versions of normal sensations. Stump pain is persistent wound pain that is usually due to a pathologic process such as delayed healing, infection, tumor recurrence, neuromas, or a poorly fitting prosthesis. These pains may even occur as paroxysms or spasms. Patients, however, are able to differentiate annoying or nonpainful sensations from what they classify as pain. More than 80% of amputees experience significant phantom pain (Stein & Warfield, 1982). The intensity is variable (Jensen, Krebs, & Nielsen, 1985) as is the duration (Sherman & Sherman, 1983). The intensity varies from 3 to 7.5 and the duration from seconds (38%) to hours (37%) to continuous (12%). The phantoms can change in character and location over time. The limb may even be perceived as telescoping or shortening (Sherman, Katz, & Marbach, 1997). Some studies imply a pain memory where phantoms replicate preamputation pain (Hill, Niven, & Knussen, 1996). Treatment of phantom pain is as varied as are the descriptions. Included are medications, nerve stimulation, nerve ablation procedures, physical therapy, psychological and behavioral therapy, and complementary or alternative therapies. In several reviews of therapeutic interventions, none was uniformly successful (Davis, 1993; Jensen & Rasmussen, 1989; Loeser, 1990; Sherman, Sherman, & Gall, 1980). Limb amputees report that prosthetic wear may act to either exacerbate or diminish phantom pains. Current research includes brain imaging and mapping, modified surgical techniques, and altered postoperative regimens.

Complex regional pain syndrome I or II (CRPS I or II) is the name now applied to the disorder formerly called reflex sympathetic dystrophy or causalgia. Because traumatic neuropathic pain and neuralgias probably represent more than one specific disease entity, the term *syndrome* is applied to these disorders. According to the new definitions CRPS I is equated with reflex sympathetic dystrophy in which minor lesions of the limb precede the onset of symptoms. CRPS II or causalgia develops after injury to a major peripheral nerve. In CRPS I there is a preceding minor traumatic event (e.g., sprain, fracture, surgery, or other injury) resulting in symptoms whose severity is out of proportion to the severity of the trauma and with a tendency to spread in the affected limb. There is no nerve injury identifiable on EMG testing. Symptoms in CRPS I occur regardless of the type of inciting injury (Evans, 1946) or the site of the injury (Pak, Martin, & Magness, 1970); neither determines symptom location. Mitchell (1865) first described CRPS II as causalgia in soldiers wounded in the Civil War. He noted burning pain; smooth, cold, and sweaty mottled skin; and hypersensitivity of the skin to light touch. In nearly all cases the limb was involved. Partial nerve laceration was the inciting factor. By definition the difference in CRPS I and II is the presence of a partial nerve injury to a major nerve. Patients with CRPS usually experience more that one type of pain

(burning, throbbing, shooting) that is out of proportion to the injury. Temperature differences of as much as 3.5°C occur, comparing side to side. Sweating, edema, and swelling of the affected limb are also noted. Pathogenesis may be inflammatory based on recent investigations (Christiansen, Jensen, & Noer, 1982; Oyen, Arntz, & Claessens, 1993). Although patients are noted to be anxious or depressed, these psychological symptoms are the result not the cause of CRPS (Lynch, 1992). There are no diagnostic tests that are specific for the diagnosis of CRPS; clinical criteria alone must be used. The basic treatment of CRPS relies on pain and symptom relief and rehabilitation of involved limbs. Pharmacologic agents include antidepressants, opioids, local anesthetics, GABA agonists, and oral steroids. Nerve stimulation in the form of transcutaneous electrical stimulation, peripheral or spinal cord stimulation (Hassenbusch, Stanton-Hicks, & Schoppa, 1996), or even deep brain stimulation have been reported to be helpful in CRPS treatment. Physical therapy and rehabilitation are maximally important in functional recovery. Only through regaining the use and strength in the involved limb can there be any confidence in avoiding a relapse.

Fibromyalgia and myofascial pain represent a varied presentation of the same symptoms. Fibromyalgia or fibromyalgia syndrome (FMS) is characterized by widespread muscular aching, pain, and stiffness with tenderness to palpation at multiple sites called tender points (Goldenberg, 1987). *Primary fibromyalgia* is the term used when there is no significant underlying or concomitant condition identified that contributes to the pain (Bengtsson, Henriksson, & Jorfeldt, 1986). However, when there is another condition that may contribute to the pain, such as rheumatoid arthritis or osteoarthritis, the term *concomitant fibromyalgia* is applied. The clinical characteristics of the two are identical (Wolfe, Smyth, & Yunus, 1990). Myofascial pain syndrome (MPS), on the other hand, is defined as regional rather than widespread soft tissue pain. There is evidence that the MPS and FMS overlap clinically (Inanici, Yunus, & Aldag, 1999) and that the former leads to the latter in 40% of cases (Inanici, Yunus, Castillo, & Aldag, 1998). Described as muscular rheumatism in the 17th century, the first controlled study of the clinical characteristics of fibromyalgia was not published until 1981(Yunus, Masi, & Calabro, 1981). In this study the presence of a group of symptoms, including pain, fatigue, sleep disturbance, soft tissue swelling, and tender points, was noted to be more common in patients with fibromyalgia than a group of matched normal controls. This was the first attempt to recognize fibromyalgia as a syndrome. It occurs mostly in White women in the 40- to 60-year-old age group. Symptoms are often present for 6 to 7 years prior to diagnosis (Yunus, 2000). The most common symptoms are generalized pain, stiffness, fatigue, and sleep distur-

bance. The onset of symptoms usually follows an infection, trauma, or mental stress (Greenfield, Fitzharles, & Esdaile, 1992). Thus far, there are no laboratory studies that are specific for the diagnosis of fibromyalgia, which may be readily diagnosed by its characteristic symptoms and multiple tender points (Wolfe et al., 1990).

Central sensitization is defined as an exaggerated response of the central nervous system to peripheral stimulus that is normally painful (Coderre, Katz, Vaccarino, & Melzack, 1993). Pain is perceived as prolonged or persistent. These same mechanisms may be present in FMS patients (Yunus, 2000). A number of other factors including genetics, psychology, endocrine, and social are involved in fibromyalgia and its treatment. Principles involved in the management of FMS involve a multidisciplinary approach using pharmacologic and nonpharmacologic methods. These principles include positive attitude in the physician, well-established diagnosis, management of comorbid conditions, improved sleep pattern, gradual increase in physical activity, appropriate medications, and psychological therapy. Even with this approach the prognosis in FMS is one of chronic pain and disability (Kennedy & Felson, 1996; Wolfe, Anderson, & Harkness, 1997). Prognosis can be improved by several factors including early diagnosis, younger age (Felson & Goldenberg, 1986), higher education level (Hench, Cohen, & Mitler, 1989), and longer periods of time spent exercising (Granges, Zilko, & Littlejohn, 1994).

TREATMENT TECHNIQUES

First and foremost, there is no silver bullet for the treatment of orthopaedic or neuropathic pain. Any treatment technique must be a component of a comprehensive program that incorporates pharmacology, physical therapy, psychological, anesthesia, and surgical options. While not all will be necessary in all cases, the availability of multiple disciplines assures the greatest possibility for improvement in function, if not pain relief. In addition to treatment, all patients must be involved in an education program about their disorder and pain treatment in general.

Nonsurgical treatment is the appropriate initial effort for many types of orthopaedic pain (Table 33.4). Topical agents from analgesic balms to local anesthetics to transdermal narcotics are also useful. Frequently application of cold (ice) or heat (heating pad) to a painful area will

Topical and physiotherapy
Oral agents and medications
Injections and acupuncture
Regional anesthetic/nerve blocks

---

provide some temporary relief and can be a valuable adjunct to any treatment program. This provides a safe and easily available method of pain control that has few if any side effects. Other liniments and salves, including homemade remedies, have been shown to be efficacious in pain management.

Often the first-line treatment selected for any painful situation is an oral medication, either over the counter or prescription. Patients themselves will attempt to treat pain with a variety of medications including acetaminophen, aspirin, or NSAIDs. Other oral agents include opioid analgesics, tricyclic antidepressants, sedative hypnotics, anticonvulsants, tramadol, and gabapentin. Dosages and frequency vary from patient to patient and practitioner to practitioner. There are, however, recommended dosage ranges. In the hands of a skilled practitioner these medications either alone or in combination are a powerful adjunct in the management of orthopaedic pain. Although they may not eliminate the pain completely they allow for enough reduction to restore function and a return to a functional lifestyle.

When topical and oral medications fail to give significant pain relief physical therapy and other manual medicine techniques offer another option. Whether through a formal physical therapy program, chiropractic or osteopathic manipulation, acupressure applied at acupuncture points, yoga or other therapeutic exercise, or massage therapy, the "laying on of hands" itself has proven value in healing. Often in the modern technical medical world practitioners may come to rely on and utilize tests and investigations more than patient inquiry and contact. The establishment of a therapeutic relationship with manual medicine practitioners often results in a more frequent and lengthy meeting than with physicians. This also has therapeutic value. During these more extended contact periods, there is time to ask more questions, explore other options, and sometimes receive more guidance in the recovery process.

When the initial non-invasive options fail to provide symptom relief, more aggressive and invasive methods may be necessary. Injections of materials such as NSAIDs, narcotics, local anesthetics; radiofrequency blocks; and regional anesthetic blocks are treatment options. Local injections in the area of a wound or trigger point are frequently used to either treat the pain or to break the pain–spasm cycle. Injection of local anesthetic agents prior to surgical incision reduces intraoperative anesthetic requirements and also reduces the level of postoperative pain and thus analgesic requirements. The use of NSAIDs has in some cases eliminated the need for any analgesics at all in some minor surgery cases. Injection of local anesthetic either alone or in combination with steroid is a mainstay in the treatment of trigger points. This same technique is sometimes useful in the treatment of muscle spasm or torticollis in adult and pediatric patients. Facet syndrome

and other low back pain problems may be treated by injection of local anesthetic or other agents or the application of a radiofrequency generator in the area of the nerves to the facet joint. Because the nerve is not divided, it may regenerate and require repeat application for continued pain relief. Injection of phenol or other neurolytic agents is useful in the treatment of Morton's neuroma, intercostal nerve pain, or other persistent pain syndromes. Acupuncture has been and is currently used in a variety of pain treatment programs. In the hands of a licensed practitioner it is a powerful addition to the range of treatment options.

Regional nerve block or anesthesia is useful in the diagnosis, treatment, and prevention of orthopaedic pain. Based on the location of the pain, anatomy, and patient needs, regional anesthetic blocks can be used to prevent pain as in surgery, block the perception of pain to allow diagnosis, or treat a pain problem to allow return to normal function. The proper selection or agents, location of the block, and timing for length of the block allow the technique to be tailored to particular patients and clinical situations. As an extension of regional techniques nerve or even spinal cord stimulators can be used to modify or eliminate the patient's pain. These offer the possibilities of the generator being turned on or off based on patient needs and of adjusting the degree of nerve stimulation order to achieve the desired effect. Percutaneuos placement or the use of temporary devices adds to the flexibility of the technique. Similar to stimulators in terms of indication is the use of pain pumps or reservoirs that dispense a measured amount of analgesic to a local area or to the spinal cord or cerebral spinal fluid. When narcotics are used, the dose required is lower than parenteral so there is less tolerance. There is also minimal if any central effect so there is neither interference with judgment nor the development of euphoria.

Surgical options are the treatment of choice in many orthopaedic situations or when initial attempts with non-surgical methods fail to provide pain relief (Table 33.5). Because of the nature of this chapter, surgical techniques are not be described in detail. These techniques can be classified as falling into several categories: (1) decompression/neurolysis, (2) transposition, (3) sectioning/ablative procedures, and (4) nerve grafting. The majority of compressive neuropathies can be treated by relief of the pressure on the nerve through decompression if there is an external source. The use of neurolysis may be necessary when there is residual deformity of the nerve due to scarring of the sheath. Both external and internal neurolysis may be needed to restore anatomy and function to the nerve. Transposition of a nerve may be necessary to relieve excess tension on the nerve as a result of alteration in the course due to injury, abnormal motion or stress, or developmental changes such as growth or muscular development. The procedure, however, carries with it a risk of postsurgical scarring and later compressive problems. Nerve sectioning or ablative procedures are rare and gen-

---

erally irreversible. Thus, great care must be exercised in the evaluation and nonsurgical treatment of these pain conditions. This technique is frequently applied to the treatment of Morton's neuroma, but may also be applied to painful spinal cord or metastatic syndromes.

Kyphoplasty and vertebroplasty are two relatively new procedures aimed at the treatment of painful vertebral compression fractures. Currently, both techniques involve the injection of bone cement into the vertebral body to provide additional strength. While kyphoplasty has as a part of the procedure the restoration of normal anatomy in deformed bodies, its goal is restoration of strength lost as a result of osteoporosis and fracture. Vertebroplasty has as a goal only the restoration of strength. The use of bone cement may in the future be supplanted by "bone filler." There are currently several under investigation. The increasing age of the population indicates that procedures such as these will be more frequent in the future. As a technique for pain relief, they are minimally invasive and can be performed on an outpatient basis using general or even conscious sedation anesthesia. Pain relief is also nearly immediate. If other levels are affected at a later date, the procedure can be repeated at those levels.

SUMMARY

The goal of this chapter has been to present an overview of factors and disorders to consider in the evaluation of patients with pain from an orthopaedic source. Just as the specialty of orthopaedic surgery is broad, the areas to consider as sources of pain are equally broad. Patient evaluation is aided by a thorough history and physical examination, knowledge of musculoskeletal and neurological anatomy and physiology, and use of appropriate laboratory, radiology, and other studies. Only through the application of these principles can a rational approach be developed and a firm diagnosis reached. Once the diagnosis is verified, a treatment plan can be proposed and instituted. The perception of pain is both physical and psychological so a purely physical approach to treatment is not likely to be completely successful.

Treatment of Myofascial Pain Syndromes

Robert D. Gerwin, MD, and Jan Dommerholt, PT, MPS

INTRODUCTION

The treatment of persons with myofascial pain syndrome (MPS) follows the general principles that apply to all medical disorders. The nature of the pain problem first must be understood through developing an appropriate differential diagnosis and evaluating the contributions of coexisting disorders, until a single working diagnosis emerges. Following the initial assessment and formulation of diagnostic hypotheses, new data are collected. A regular review at each encounter and modification of the hypotheses facilitate a more efficient and effective management of patients with MPS and dictate the actual program components (Higgs & Jones, 1995; Jones, 1994). After addressing the issue of diagnosis, the practitioner must determine the structural or biomechanical functioning of the patient and the contribution that any dysfunction may have to the individual's pain. Medical and psychological disorders that may alter the presentation of MPS or that may predispose to its becoming chronic are assessed. Treatment of persons with MPS addresses each of these issues specifically (Figure 34.1). There must be relief of pain by the direct inactivation of the myofascial trigger point (MTrP) itself. The mechanical and structural factors that affect or overload the muscle and aggravate the pain must be resolved or alleviated. The medical and psychological problems that affect muscle function, including those that alter and impair intracellular metabolism, must be identified and corrected where possible. Inactivation of the MTrP may occur with direct intervention at the MTrP itself, through correction of the mechanical factors that produced it or through improvement in the underlying medical disorders that predispose to the development or maintenance of the MTrP.

DIAGNOSIS

The diagnosis of MPS should be suspected when there is a non-neuropathic pain complaint almost anywhere in the body, including headache. At first glance, such a statement may seem to be so nonspecific as to be meaningless, but it emphasizes the need to be aware of the role of soft tissue or muscle in all types of pain. Indeed, MPS has been reported as the most common diagnosis responsible for chronic pain and disability (Fricton, 1990; Masi, 1993; Rosomoff et al., 1989; Skootsky, Jaeger, & Oye, 1989). MPS is often thought of as a regional pain syndrome in contrast to fibromyalgia as a widespread syndrome; however, as many as 45% of patients with chronic MPS have generalized pain in three or four quadrants (Gerwin, 1995b). Thus, regional pain syndromes should certainly raise a suspicion of MPS (Cummings, 2003; Gerwin, 2001), but patients with widespread musculoskeletal pain can also have MPS. Patients with widespread MTrPs should be diagnosed with MPS and not with fibromyalgia, even though the classification criteria for fibromyalgia suggest making the diagnosis of fibromyalgia "irrespective of other diagnoses" (Wolfe et al., 1990, p. 169). In clinical practice the diagnosis of fibromyalgia should not be made without considering all differential diagnoses (Dommerholt, 2001; Dommerholt & Issa, 2003; Gerwin, 1999). A survey of members of the American Pain Society showed general agreement with the concept that MPS exists as an entity distinct from fibromyalgia (Harden et al., 2000).

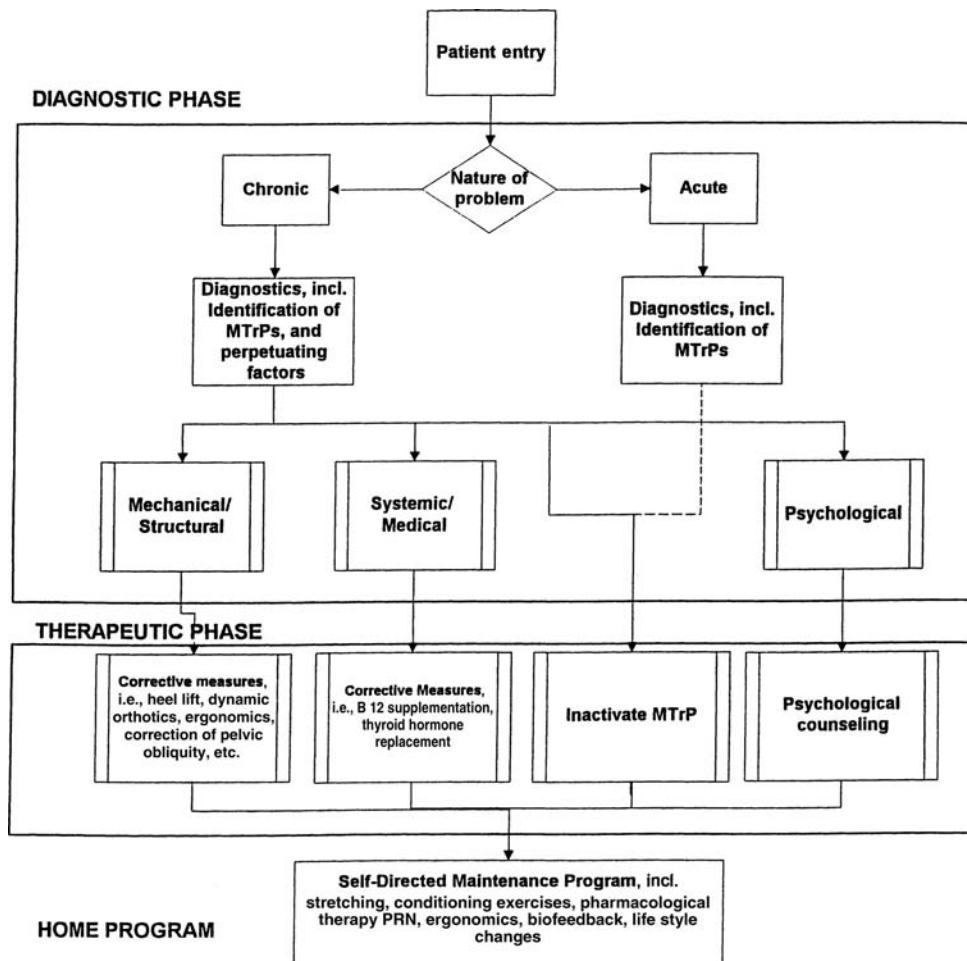
Muscle pain tends to be dull, poorly localized, and deep, in contrast to the precise location of cutaneous pain. The diagnosis of MPS is confirmed when the MTrP is identified by palpation. Systematic palpation differentiates


FIGURE 34.1 Treatment program example.

between myofascial taut bands and general muscle spasms (Janda, 1991). An active MTrP is defined as a focus of hyperirritability in a muscle or its fascia that causes the patient pain (Simons & Travell, 1984). The key features of the trigger point have been established by Simons, Travell, and Simons (1999) and are listed in Table 34.1. The interrater reliability of the clinical examination has been established by Gerwin et al. (1997) for the five major

TABLE 34.1
Myofascial Trigger Point Characteristics

1. Focal exquisite tenderness in a taut band of muscle
2. Referral of pain to a distant site upon activation of the trigger point
3. Contraction of the taut band (local twitch response) upon mechanical activation of the trigger point
4. Reproduction of the pain by mechanical activation of trigger point
5. Restriction of range of motion
6. Weakness without muscle atrophy
7. Autonomic phenomenon such as piloerection or changes in local circulation (regional blood flow and limb temperature) in response to trigger point activation

features of the trigger point. Individual features of the trigger point are differentially represented in different muscles. For example, the local twitch response is easier to obtain and therefore more commonly found in the extensor digitorum communis than in the infraspinatus muscle. One should not expect to find each feature of the trigger point in every muscle by physical examination. Reliability of the clinical examination for MTrPs has been confirmed in a study by Sciotti et al. (2001). This study is significant in that is demonstrates that identification of the precise localization of trigger points within a muscle has a high correlation among four examiners. The minimum criteria that must be satisfied in order to distinguish an MTrP from any other tender area in muscle are a taut band and a tender point in that taut band. The presence of a local twitch response, referred pain, or reproduction of the person's symptomatic pain increases the certainty and specificity of the diagnosis.

Making a diagnosis of MPS may itself be therapeutic and may constitute the first step in treatment, as many patients may not have been given a correct diagnosis previously. Patients are often depressed, confused, or frus-

trated, as they may not have been given an appropriate explanation of their pain in previous evaluations. They often appear relieved when the practitioner can literally put the finger on the source of the pain, which usually results in instant rapport between patient and clinician.

The introduction of pressure algometers has improved the assessment of sensitivity significantly (Fischer, 1986c; Keele, 1954); however, only recently have pressure algometers been applied to the assessment of MTrPs (Fischer, 1984, 1986a, 1986b). Several studies have confirmed the reliability of pressure measurement for the assessment of pain sensitivity (Jensen et al., 1986; Merskey & Spear, 1964), for pressure sensitivity of MTrPs, and for the detection of their location (Delaney & McKee, 1993; Jaeger & Reeves, 1986; Ohrbach & Gale, 1989; Reeves, Jaeger, & Graff-Radford, 1986). Tenderness and the presence of a taut band in muscle may be quantified by pain pressure algometry and tissue compliance measurements (Fischer, 1986a, 1986c, 1993). Fischer (1997) discusses the role of algometry and tissue compliance testing in the diagnosis of MPSs. He incorporates the two main criteria for the diagnosis of MTrPs, local point tenderness (as quantified by algometry) and recognition of patient's symptoms, into his concept of segmental sensitization, radiculopathy, and paraspinal spasm.

Hubbard and Berkoff (1993) identified a characteristic electrical discharge emanating from the trigger point and unique to it. Simons, Hong, and Simons (1995) have further studied this activity, whereas Chu (1995) has reported finding it in the trigger points of persons with lumbosacral radiculopathy. The phenomenon of spontaneous electromyographic activity typical of end plate noise occurring in myofascial trigger points has been further confirmed in a study of young subjects with chronic shoulder and arm pain (Couppé et al., 2001). Studies by Simons, Hong, and Simons (2003) have shown that end plate noise without spikes was found at trigger point sites to a significantly greater degree than at end plate zones outside of trigger points, and not at all in taut band sites outside of an end plate zone. They concluded that end plate noise is characteristic of, but not restricted to, the region of a myofascial trigger point. Phentolamine infusion reduced the average integrated signal of the spontaneous electrical activity by about one third in the experimental animal model. This result shows that there is a modulating effect of the sympathetic nervous system on the motor activity of the trigger point (Chen et al., 1998). Thus, an objective electromyographic (EMG) signature of the trigger point is now available for diagnostic and research purposes.

PRINCIPLES OF TREATMENT

The ultimate goal of treatment of persons with MPS is restoration of function through inactivation of the trigger point, restoration of normal tissue mobility, and elimina-

tion of pain (Dommerholt, 2001; Miller, 1994). The patient and the clinician need to identify appropriate goals and develop the means to implement them through therapy. Inactivation of the trigger point is a means to achieve relief of pain, to improve biomechanical function, and thus to improve the ability of the patient to better perform whatever desired tasks have been selected as goals. Relief of pain or increased range of motion, both of which can be the result of trigger point inactivation, are not in themselves the final goals of treatment. For some individuals, an initial goal may be simply to sleep through the night. For another patient, it may be eating out of bed at a table, or fastening a bra behind the back. For yet another, it may be regaining sexual ability or returning to work or to a recreational activity. Reasonable goals that can be achieved and measured as being reached or not are more important to focus on than simply the inactivation of a tender point or an increase in the range of a particular movement (Gerwin, 2000).

Inactivation of the MTrP can be achieved manually, by correcting structural mechanical stressors, by direct injection of a local anesthetic into the muscle, or by dry needle intramuscular stimulation of the MTrP. Treatment of the patient with MPS can be very effective when used in the context of a comprehensive diagnostic and treatment spectrum (Yue, 1995). After establishing an accurate medical diagnosis with identification of systemic, mechanical, and psychological perpetuating factors, the patient with chronic MPS is best treated through an interdisciplinary team approach (Turk & Okifuji, 1999). The term *interdisciplinary* is preferred to multidisciplinary because it reflects the coordinated working relationship between members of the treatment team (Melvin, 1980; Turk & Rudy, 1994). Essential members of the interdisciplinary team include the patient, physicians, psychologists, clinical social workers, occupational therapists, physical therapists, ergonomists, massage therapists, and others actively involved in patient care (Ghia, 1992; Khalil et al., 1993). Not every patient with MPS necessarily requires such an extensive collaboration. For example, patients with acute MPS may only require treatment by physicians and physical therapists. The treatment plan can be divided into a pain control phase and a training or conditioning phase (Saal & Saal, 1991). During the pain control phase, the most essential components are manual therapy, trigger point injection, dry needling, and elimination of mechanical perpetuating factors. Throughout the treatment process, much attention should be paid to educating the patient concerning the etiology, perpetuating factors, and self-management. Patients must learn to modify their behaviors and avoid overloading the muscles without resorting to total inactivity (Simons & Simons, 1994). Following the pain control phase, patients should be introduced to therapeutic exercises, movement reeducation, and overall conditioning. Too often, patients with

chronic myofascial pain dysfunction are introduced too soon to isotonic training and conditioning, causing further aggravation of active trigger points and an increase of pain and dysfunction. Likewise, work hardening programs should never be conducted during this phase of treatment. This can lead to further discouragement and depression, as well as an increase in pain. On the other hand, the pain control phase must be time limited, and patients must understand that progressing to the conditioning phase is imperative. If they do not move beyond the pain control phase, patients can be restricted in their functional abilities and be at greater risk of reinjury (Saal & Saal, 1991). In daily practice, the various aspects of the rehabilitation process are addressed simultaneously and not treated as separate entities.

MANUAL THERAPY

Manual therapy is one of the basic treatment options for MPS. In conjunction with manual therapy approaches, Simons et al. (1999) advocate the stretch-and-spray technique, which combines use of a vapocoolant spray with passive stretching of the muscle. Application of vapocoolant spray stimulates thermal and tactile A-beta skin receptors, thereby inhibiting C-fiber and A-delta fiber afferent nociceptive pathways and muscle spasms, MTrPs, and pain when stretching. Prior to applying the stretch-and-spray method, the patient is positioned comfortably. The muscle involved is sprayed with a few sweeps of a vapocoolant spray, after which the muscle is stretched passively. With the muscle in the stretched position, the spray is applied again over the skin overlying the entire muscle, starting at the trigger zone and proceeding in the direction of, and including, the referred pain zone. Following the stretch and spray, the area is heated with a moist heat pack for 5 to 10 min. The patient is encouraged to move the body part several times through the full range of motion. The stretch-and-spray technique can be used in physical therapy as a separate modality or following MTrP injections.

Lewit (1991) suggests using the stretch technique for short or taut muscles and fascia while promoting postisometric relaxation for treatment of trigger points. Postisometric relaxation is also known as muscle energy technique (Mitchell, 1993) or hold–relax technique (Knott & Voss, 1968) and can easily be combined with stretch-and-spray techniques either in the clinic or as part of the patient's home program. The muscle is gently lengthened, taking up the slack until a barrier is reached. The patient is then asked to contract the muscle isometrically against resistance for about 10 s at approximately 10% of maximal effort. Because it is difficult for patients to gauge a level of effort, the clinician presents a force against which the patient pushes. The patient is instructed, "Meet my force, but do not exceed it." Thus, the clinician is in complete control of the effort exerted by the patient, and an appropriately slight contraction of muscle is achieved. Then the patient relaxes the muscle. Once total relaxation is achieved, the slack is taken up again and the process is repeated three to five times (Lewit, 1991; Lewit & Simons, 1984; Simons & Simons, 1994). Respiratory facilitation of muscle relaxation utilizes the contraction of nonrespiratory muscles that occurs with inspiration and the relaxation of the same muscles during expiration. During the relaxation phase, the patient is asked to exhale and look down to facilitate muscular relaxation (Lewit, 1988). A variation on Lewit's approach combines isometric contractions, reciprocal inhibition, and stretch (Fischer, 1995).

Soft tissue mobilization is an essential component of the treatment. Soft tissue biomechanics including stress–strain patterns; the normal inflammatory, repair, and remodeling stages following soft tissue injury (Carlstedt & Nordin, 1989; Nolan & Nordhoff, 1996; Soderberg, 1992); the reactivity of the tissues; and tolerance level and comfort of the patient are considered (Ellis & Johnson, 1996). The intratissue (muscle tone) and intertissue mobility (muscle play) of the structures involved and of the adjacent muscles, fascia, and joints must be evaluated and treated as well. Myofascial adhesions may develop with secondary or "satellite" trigger points in nearby muscles. MTrPs appearing in muscles that are part of a functional unit must be treated together. Muscles that work together as agonists, or that work in opposition to each other as antagonists, constitute a functional muscle unit. The same muscles can be related to each other both as agonists and antagonists, depending on the action being performed. For example, the muscles that move or stabilize the shoulder form a functional unit. The trapezius and levator scapula muscles display this relationship well. These two muscles work together as agonists in elevation of the shoulder, but are antagonists in rotation of the scapula, the trapezius rotating the glenoid fossa upward and the levator scapula rotating it downward. When one of these two muscles contracts to rotate the scapula, the other must relax. If these or some other shoulder muscles become dysfunctional because of the presence of MTrPs that weaken or shorten them and restrict their range of motion, excessive loading on other muscles in the shoulder functional unit may occur. Trigger points in the levator scapula limit upward rotation of the lateral border of the scapula, thereby placing a greater load on the trapezius, which is unable to accomplish the movement with usual effort, or perhaps is not able to accomplish the movement at all, causing a compensatory lifting of the entire shoulder to raise the arm.

The functional relationships of muscles may differ at each end of the muscle because the agonists and antagonists for each muscle may be different at the proximal and distal ends of the muscle. MTrPs may spread from one region to another because of these relationships.

Bilateral axial muscles such as the trapezius, sterno-cleidomastoid, quadratus lumborum, and iliopsoas act as both agonists and antagonists to each other, facilitating the spread of MTrPs across the midline. Muscles that bridge regions, such as the latissimus dorsi, and those that influence posture, such as the effect of the iliopsoas or quadratus lumborum muscles on scoliosis, also facilitate the spread of MTrPs. Thus, MPS can involve a single region of the body or it can spread to involve all four quadrants of the body. Effective treatment should address all the affected areas. Otherwise, remaining dysfunctional muscle units may lead to the recurrence of active or spontaneously painful MTrPs.

Myofascial release techniques and gentle, sustained pressure may soften or elongate shortened or hardened muscles. The principle of the least possible force is applied, instead of applying high stress to the muscle. Effective myofascial release techniques include strumming, perpendicular and oscillating mobilizations, tissue rolling, and connective tissue massage, among others (Cantu & Grodin, 2001; Ellis & Johnson, 1996). Deep muscle massage consisting of effleurage (stroking massage technique) and pétrissage (kneading massage technique) is also recommended (Lehn, 1990; Vis, Raats, & Van der Voort, 1987). After the introductory superficial approach over the entire muscle and adjacent muscles, massage therapy can be applied directly to the taut band and trigger points. Massage and exercise were found to be effective in reducing the number and intensity of trigger points, but the addition of therapeutic ultrasound did not improve the outcome (Gam et al., 1998).

Soft tissue mobilizations may result in improved local circulation, normalization of muscle tone and muscle play, and reduction of reflex activity and pain (Vis et al., 1987; Wells, 1994). By combining gentle approaches with more aggressive techniques, the Swiss physician and psychologist Dejung (1988a) has developed a seven-step treatment approach to myofascial dysfunction. Dejung's approach combines sustained compression, stretch-and-spray techniques, myofascial release, restoration of muscle play, active and passive movements, and dry needling (Dejung, 1987a, 1988b; Grosjean & Dejung, 1990). As part of Dejung's protocol, the patient actively moves the involved muscle, while the physician or therapist maintains constant pressure over the trigger point (Dejung, 1987b, 1994).

Simons et al. (1999) also describe direct manual compression of the trigger point to inactivate trigger points. Although it previously has been described as ischemic compression, it is now termed trigger point pressure release or trigger point compression. The patient can apply direct compression for self-treatment using a Thera Cane® (Thera Cane Co., Denver, CO) or a similar device. Acupressure may be another form of direct compression of trigger points (Kodratoff & Gaebler, 1993). Following the

Simons et al. (1999) protocol or using acupressure guidelines, compression of trigger points is moderately painful.

Trigger points may also be directly related to underlying articular dysfunction (Ellis & Johnson, 1996). In the treatment of myofascial pain, the practitioner must evaluate and, when indicated, treat both soft tissue and joint dysfunction. Muscular and joint dysfunction are closely related and should be considered as a single functional unit (Janda, 1994). Restrictions in joint capsules inhibit muscle function for those muscles overlying the particular joint. Conversely, muscle dysfunction results in joint capsule restrictions (Dvorák & Dvorák, 1990; Warmerdam, 1992). Zygopophyseal joints may have referred pain patterns similar to MTrPs (Bogduk & Simons, 1993; Dwyer, Aprill, & Bogduk, 1990; McCall, Park, & O'Brien, 1979). In addition, Butler (2000) suggests that impaired mechanics and physiology of the nervous system may be another contributing factor in the overall etiology of various pain problems, including myofascial pain. Somatic dysfunction affecting muscle and joint may result in restricted range of motion and weakness that can be rather quickly reversed by manual therapy.

INVASIVE INACTIVATION OF THE MYOFASCIAL TRIGGER POINT (TRIGGER POINT NEEDLING)

Needling of an MTrP, whether injecting an anesthetic or not, is done for very specific purposes (Table 34.2). It rarely is done to eliminate a trigger point permanently, something that occasionally happens when a localized myofascial pain syndrome is acute (weeks, but not months, old). Facilitation of physical therapy is the most common appropriate use of this technique.

Inactivation of the MTrP by injection appears to be the result of the mechanical action of the needle in the trigger point itself, because it can be successfully accomplished by dry needling without the use of local anesthetics or other materials (Chu, 1995; Gunn, Milbrandt, Little, & Mason, 1980; Hong, 1994b). When using injection needles, the use of a local anesthetic is more comfortable for many patients and results in a longer lasting reduction in trigger point pain (Hong, 1994b; Travell, 1976). However, no credible study exists comparing the two techniques, anesthetic injection versus "dry needling" or needling without anesthetic, in a manner consistent with

---

TABLE 34.2

Indications for Myofascial Trigger Point Needling

1. Therapeutic: Relief of an acute myofascial pain syndrome
2. Diagnostic: To identify a MTrP as the cause of a particular pain
3. Adjunctive: Inactivation of MTrPs to facilitate physical therapy

current standards of medical evidence. The use of solid acupuncture needles versus injection needles has not been examined at this time. Gloves are recommended consistent with the practice of universal precautions. After identifying and manually stabilizing the tender area in the taut band with the fingers, the needle is quickly passed through the skin and then into the trigger zone. A local twitch response or a report of referred pain indicates that the trigger zone has been entered. A small amount, usually 0.1 or 0.2 ml, of local anesthetic may be injected into the trigger zone. The needle is withdrawn to just below the skin, the angle of the needle is changed, and the needle is again passed through the muscle to another trigger zone. A conical volume of muscle can thus be examined for active trigger points without withdrawing the needle through the skin. The trigger zone is explored in this manner until no further local twitch responses are obtained. At this point, the taut band is usually gone, and the spontaneous pain of the trigger point has subsided. Patients who have previously undergone treatment can tell when trigger points remain, and when they have been sufficiently inactivated. A knowledgeable patient urges the clinician to continue in an area until a key trigger point is inactivated, at which time there is a noticeable decrease in pain. The process is repeated until the symptomatic MTrPs are treated throughout the functional muscle unit (Hendler, Fink, & Long, 1983; Hong, 1993, 1994a).

Trigger point injections can be performed without anesthetic, so-called dry needling, or with a local anesthetic (Hong, 1994b). Historically, procaine has been used for this purpose, although lidocaine is used primarily today. Procaine is no longer generally available except in powdered form and has to be reconstituted for use, which for all practical purposes means that it has been replaced by the more readily available lidocaine. Procaine had the advantage of a short half-life, which was pertinent if there was a nerve block. Cummings and White (2001) published a systematic review of needling therapies in myofascial trigger point pain. They concluded that direct needling of myofascial trigger points appears to be an effective treatment, but that there is insufficient evidence that needling therapies have efficacy beyond placebo. Moreover, they found no evidence to suggest that the injection of one material was more effective than another. They found no advantage to adding steroids, ketorolac, or vitamin B_{12} to local anesthetic (Cummings and White, 2001). Steroids have the disadvantage that they are locally myotoxic and that repeated administration can produce all the unwanted side effects associated with steroids. For persons allergic to local anesthetics, saline or dry needling can be used.

Dry needling is the act of inserting a needle into the trigger point without injecting any substance. It can be performed by anyone who is licensed to give injections (physicians, nurses, physician's assistants) and by physical therapists in an increasing number of states in the United States, and in other countries such as Spain and Switzerland, and by acupuncturists. Dry needling elicits a twitch response in the muscle, a response that seems to be related to pain relief. To be most effective, the needle should enter the trigger point itself. A detailed account of dry needling has been published by Dommerholt (2004).

Botulinum toxin has been tried successfully in MTrP inactivation, although it can cause a flu-like myalgia lasting days to a week and occasionally weakness beyond the area of injection (Cheshire, Abashian, & Mann, 1994; Childers et al., 1998; Childers, Wilson, & Simison, 1999; Yue, 1995). It is essentially a long-lasting trigger point injection, capable of about a 3-month inactivation of the trigger point compared with the days to 1 week effect of conventional trigger point injections with local or no anesthetic. Porta (2000) reported in a comparative and randomized, but not double-blinded, study that botulinum toxin type A was as effective in relieving MTrP pain as was steroid injection. There was no placebo control in this study. Lang (2000) proposed injecting botulinum toxin type A into the mid-belly of affected muscles in order to place the toxin where neuromuscular junctions or motor end plates are concentrated. In her uncontrolled, open-label pilot study, 17 to 21% of subjects had an excellent outcome, and an additional 39 to 52% had a good outcome (the range representing different subpopulations of patients).

There is no limit to the number of MTrP that can be needled. Common sense and patient comfort dictate restraint. Nevertheless, when treating a regional MPS, a sufficient number of muscles in the region must be treated to resolve the problem and allow effective post-needling stretching. All the muscles in a functional muscle unit must be released and returned to full length, if possible, either by needling or by trigger point compression and stretching. Inadequate treatment that leaves critical trigger points within a functional muscle unit usually results in the recurrence of trigger points throughout the muscles of the functional unit. From 5 to 10 different MTrP sites can readily be treated per session, and some physicians skilled in MPS management treat considerably more in one session. Repeat injections or dry needling into the same area are best done after an interval of 1 week to allow the muscle to recover. Muscles of the affected functional unit must always be stretched, to their full length if possible, after MTrP needling. Moist heat is applied to the muscle to improve the local circulation and to reduce postinjection soreness. Otherwise, MTrPs recur because of residual significant muscle dysfunction. Local anesthetic patches can be applied to reduce the superficial or cutaneous soreness from needling. Complications of MTrP injections are listed in Table 34.3.

Trigger point injections or dry needling is a highly effective way to reduce the local pain and contraction of the taut band. This does not, however, constitute the whole treatment of MPS. The causes that led to the condition

TABLE 34.3
Complications of Trigger Point Injections

1. Local hemorrhage into muscle
2. Local edema
3. Painful contraction of a taut band from inadequate MTrP inactivation (missing the MTrP)
4. Infection
5. Perforation of a viscous body, most commonly the lung
6. Nerve injury from direct trauma by the needle
7. Transient nerve block
8. Syncope
9. Allergic reaction from the anesthetic

must be corrected, when possible. Mechanical, medical, and psychological perpetuating factors must also be eliminated or alleviated to reduce the chance of recurrence. Inadequate attention to these aspects of treatment leads to failure to relieve the pain (Table 34.4).

Acupuncture is used to treat many different types of pain, including myofascial pain (Baldry, 1993). Acupuncture can be performed by the traditional method of using predetermined acupuncture points along set meridians or by the more recently developed method of placing the needle close to the point of pain (Liao, Lee, & Ng, 1994). Japanese acupuncture (shallow needling) reduced the pain of chronic myofascial neck pain in one study (Birch & Jamison, 1998). Acupuncture, in a randomized, double-blind, sham-controlled study, was found to be superior to sham acupuncture when treating trigger points in chronic neck pain, and was also better than dry needling in improving range of motion (Irnich et al., 2002).

Baldry (1993, 2001) has developed a technique of sub-dermal needling over the trigger point. Edwards and Knowles (2003) reported that patients who received superficial dry needling combined with active stretching improved on the Short Form McGill Pain Questionnaire and improved in their pressure pain thresholds more than controls. Gunn, Milbrandt, Little, and Mason (1980) and Gunn, Sola, Loeser, and Chapman (1990) used a method of dry needling called intramuscular stimulation (IMS). IMS involves the insertion of the needle into the taut band without necessarily considering the actual trigger point. It may be

TABLE 34.4
Causes of Trigger Point Injection Failure

1. Missing the trigger point
2. Injecting the secondary or satellite trigger point and not the primary trigger point
3. Inadequate stretching of the muscle following the injection in the clinic
4. Inadequate stretching of the muscle by the patient at home
5. Failure to correct perpetuating factors

combined with electrical stimulation delivered through the needle (percutaneous electroneural stimulation).

MECHANICAL PERPETUATING FACTORS

Biomechanical perpetuating factors have long been known to cause persistent musculoskeletal pain (Simons et al., 1999; Travell & Simons, 1992). Major mechanical factors to be considered in the management of MPS include anatomic variations, poor posture, and work-related stress (Simons & Simons, 1994).

CORRECTION OF ANATOMIC VARIATIONS

According to Simons et al. (1999), the most common anatomic variations are leg length discrepancy and small hemipelvis, the short upper arm syndrome, and the long second metatarsal syndrome.

The leg length inequality syndrome produces a pelvic tilt that results in a chronic shortening and activation of a chain of muscles in an effort to straighten the head and level the eyes. Any asymmetrical position of the pelvis or spine requires a regulatory adjustment of the neck muscles to maintain equilibrium and an appropriate head position (Janda, 1994). The quadratus lumborum and paraspinal muscles contract to correct the deviation of the spine caused by the pelvic tilt. This correction in turn causes a tilt of the shoulder in the direction opposite to that of the pelvic tilt when a simple C-shaped scoliosis occurs. The shoulder and neck muscles then chronically contract and shorten to correct the subsequent neck tilt. Excessive loading perpetuates MTrPs and may result in low back, head, neck, and shoulder pain (Gerwin, 1995a). Trigger points in these chronically shortened and constantly contracted muscles are not readily inactivated until the muscles are unloaded. The combination of trunk muscles that undergo shortening as they constantly pull the spine toward one side or the other is more complex in an S-shaped scoliosis, but the problem is the same. A similar loading of trunk, shoulder, and neck muscles occurs when one hemipelvis has a diminished height relative to the other or in the presence of pelvic obliquity. According to Grieve (1994), the quadratus lumborum may be less likely to develop trigger points during the teenage years, and typically, unilateral low back pain is located on the side of the shorter leg because of early attenuation of the annulus fibrosis on that side. In adults, it occurs on the side of the longer leg, due to later arthritic and spondylitic changes and shortening of the quadratus lumborum. A true leg length discrepancy is corrected by placing a heel lift on the shorter leg. The asymmetry caused by a small hemipelvis is corrected by placing an ischial or "butt" lift under the ischial tuberosity.

A distinction must be made between a true and an apparent leg length discrepancy. An apparent leg length

discrepancy or functional shortening may be caused by a pseudo-scoliosis where the legs are actually of equal or nearly equal length, by hip adductor contractures, by hip capsule tightness, or by posterior innominate rotation, because the acetabulum is anterior to the iliosacral rotation axis (LeVeau, 1994; Mitchell, 1993; Reid, 1992). The cause must be identified and then corrected where possible. If the problem is an ilial rotation, the rotation should be corrected. If it is combined with a sacroiliac joint dysfunction, that should be corrected as well. Quadratus lumborum or iliopsoas muscles shortened by trigger points, a cause of pseudo-scoliosis, must be inactivated by stretching or by other means, such as MTrP injections. Placing a heel lift under an apparent shorter leg may increase the leg length discrepancy. Functional shortening, pseudo-scoliosis, and pelvic obliquity can be corrected via osteopathic mobilizations and muscle energy techniques (Fowler, 1994; Greenman, 1991).

When clinical determination by physical examination is uncertain, a radiographic study of the pelvis and lumbar spine using a plumb line can be helpful (Travell & Simons, 1992). A functional scoliosis can be corrected or reduced by a heel lift, even if it has been present for years. A fixed skeletal cause of scoliosis does not correct with a heel or butt lift. Functional scoliosis must be distinguished from those asymmetries that cannot be corrected before attempting to use a heel or butt lift. Relief of pain in the neck, shoulder, low back, and legs can result from the complete or partial correction of leg length inequality and scoliosis.

Saggini et al. (1996) describe the incomplete resolution of pain in persons with peroneus longus MTrPs and leg length inequality corrected only by a heel lift. The peroneus longus has an increased shear force in the medial-lateral plane when loading, which increases eccentric muscle involvement, leading to muscle injury. Correcting abnormal loading associated with leg length discrepancy with a dynamic insole eliminated both the pain and the trigger points.

Short upper arms result in forward shoulder roll, pectoral muscle shortening, and abnormal loading of neck and trunk muscles as the individual attempts to find a comfortable position when seated. Another cause of biomechanical stress on muscles that can lead to the persistence of MTrPs is a long second metatarsal bone. In this situation, the normal, stable tripod support of the foot created by the first and second metatarsal bones anteriorly and the heel posteriorly may not be present. Instead, in some individuals with this foot configuration, weight is carried on a knife-edge from the second metatarsal head to the heel, overloading the peroneus longus that attaches to the first metatarsal bone. Diagnostic callus formation occurs in these individuals in the areas of abnormal loading, under the second metatarsal head, and on the medial aspect of the foot at the great toe and first metatarsal head.

Correction is accomplished with support under the head of the first metatarsal, restoring the normal tripod support of the foot (Travell & Simons, 1992).

POSTURE CORRECTION

In addition to postural deviations due to anatomic variations, muscle imbalances and altered movement patterns play an extremely important role in the etiology and management of poor posture. The clinician should become familiar with Vladimir Janda's extensive research in posture and muscle dysfunction. Janda distinguished "tonic or postural" muscles from "phasic or dynamic" muscles. Postural and phasic muscles are physiologically different in their oxidative ability and their ability to contract over a specified time period. Tonic muscles are slow-twitch (Type I) muscles. Phasic muscles are fast-twitch (Type II) muscles. MTrPs can develop in both tonic and phasic muscles. Tonic muscles include the hamstrings muscles, rectus femoris, iliopsoas, quadratus lumborum, erector spinae muscles, pectorals, sternocleidomastoids, descending trapezius muscles, and levator scapulae. Phasic muscles include the rectus abdominus, serratus anterior, rhomboids, ascending and transverse trapezius, deep neck flexors, suprahyoid, and mylohyoid (Cantu & Grodin, 2001; Carriere, 1996; Janda, 1983, 1993, 1994). Tonic muscles have a tendency to tighten in response to abnormal stress or dysfunction, whereas phasic muscles have a tendency to become weak. These typical response patterns result in the "upper and lower crossed syndromes" (Janda, 1993, 1994). The upper crossed syndrome or forward head posture is the most common postural deviation in patients with MPS (Fricton et al., 1985; Janda, 1994; Mannheimer, 1994).

In the forward head posture, total body alignment is severely affected. There is posterior cervical rotation with hypomobility of the upper cervical and subcranial motion segments and hypermobility of the mid and lower cervical spine. Muscle imbalances occur between the anterior and posterior cervical muscles and between the anterior and posterior shoulder muscles. The shoulder girdle protracts, and there is an increase in thoracic kyphosis, a loss of lumbar lordosis, and an increase in posterior pelvic rotation. Muscular imbalances may lead to abnormal afferent input and MTrPs (Cantu & Grodin, 2001). There is a statistically significant relation between the degree of forward head posture, posterior cervical rotation, and pain (Haughie, Fiebert, & Roach, 1995). Poor body alignment, forward head posture, and muscle imbalances predispose and perpetuate chronic pain problems including MPS.

Correcting poor body posture and alignment is an important component of treating patients with MPS, even when posture seemingly may not be directly related to the region of musculoskeletal pain. Core (trunk) stabilization as part of a closed kinetic chain rehabilitation allows opti-

mal control of the lumbopelvic complex and improves the recovery of persons with a kinetic chain dysfunction manifest as a postural stress syndrome (Clark, Fater, & Reuteman, 2000). Good posture minimizes stress and improves efficiency in the use of muscles (Sahrmann, 1988). The physical therapist needs to determine on an individual basis whether manual therapy procedures should precede postural corrections or vice versa. In some instances, joint and myofascial restrictions must be removed prior to any postural corrections. Without the mobilizations, shortened muscles may restrict movement so much that treatment to correct postural abnormalities may not succeed. In other cases, patients may be able to alter their posture prior to or even without any manual therapy (Dommerholt & Norris, 1996).

Correction and prevention of abnormal postures require a comprehensive program that includes exercises to restore normal dynamic pelvic and vertebral stabilization and mobility, motor control, muscle balances, strength, endurance, and breathing patterns. Certain activities of daily living may predispose a patient to chronic musculoskeletal overload, increasing the risk of myofascial dysfunction. A dynamically stable trunk in neutral position is essential, as is normal pelvic mobility (Carriere, 1996). Paradoxical breathing should be corrected with functional abdominal breathing. Paradoxical breathing is a common cause of overload of the auxiliary breathing muscles, most notably the scalene muscles (Carriere, 1996; Travell & Simons, 1992). To improve posture, the individual components must be integrated into total motor patterns (Walpin, 1994). Both the Alexander technique (Barlow, 1973; Jones, 1992; Knebelman et al., 1994) and the Feldenkrais method (Feldenkrais, 1977; Rywerant, 1983) aim to restore function to body awareness and movement retraining and can be used in combination with physical therapy (Dommerholt, 2000). It should be noted that postural control and activation of a sequence of muscles when moving or stabilizing a body part can be impaired by MTrPs, which must be inactivated to correct body mechanics. Lucas, Polus, and Rich (2004) have shown that the normal sequential muscle activation pattern in such movements as scapular rotation becomes abnormal when latent MTrPs are present. Treatment of the latent MTrPs to inactivate them restores normal muscle activation sequencing.

Although posture is usually described in terms of relative alignment of body parts, it is important to realize that a person's posture reflects more than just biomechanical principles. Buytendijk (1964) states that "posture is an individual's innermost means of expression." People express their emotions, feelings, and overall well-being through their posture. Therefore, posture must be viewed as a physiological, biomechanical, and psychological phenomenon. Addressing biomechanical issues without consideration of a more phenomenological approach to posture reduces the treatment approach to strict mechanistic intervention.

WORK-RELATED STRESS

Certain jobs and work-related activities are associated with an increased risk of developing cumulative trauma disorders or work-related musculoskeletal disorders (Kuorinka & Forcier, 1995). In certain instances, MPS may be associated with work exposures (Grosshandler & Burney, 1979). In the ergonomics literature, the term *tension neck syndrome* is preferred over MPS (Viikari-Juntura, 1983). Ergonomics is a broad profession and incorporates knowledge from anatomy, physiology, and psychology. More specifically, ergonomics includes anthropometry and biomechanics, work and environmental physiology, and skill and occupational psychology (Singleton, 1972). Thompson (1991) defines *ergonomics* as "the application of the human physical and behavioral sciences together with the engineering sciences in the study of humans working with machines and tools." Ergonomics is based on the so-called human–machine system. In designing the ideal human–machine system, ergonomics recognizes four strategies, namely, stress reduction, machine and task design, match between the job demands and human abilities, and education and training (Ayoub, 1994; Khalil et al., 1993). Pheasant (1991) summarizes the field as "the science of matching the job to the worker and the product to the user."

Awareness of generic risk factors in work-related musculoskeletal disorders is important. They include awkward postures, musculoskeletal loading, task invariability, cognitive demands, and organizational and psychosocial work characteristics (Kuorinka & Forcier, 1995). Prolonged static postures, awkward postures, excessive force, and repetitiveness are the most likely specific risk factors for MPS (Armstrong, 1986a). Several studies have confirmed that occupational groups with repetitive arm movements and constrained work postures have high rates of MPS (Amano et al., 1988; Bjelle, Hagberg, & Michaelsson, 1979; Hünting, Läubli, & Grandjean, 1981). Awkward postures include wrist flexion and extension, ulnar and radial abduction, forearm supination and pronation, extended reaches beyond the shoulder-reach envelope, and pinch grips that are either too wide or too narrow (Armstrong, 1986b; Feuerstein & Hickey, 1992). For example, the intramuscular pressure in the supraspinatus muscle exceeds 30 mmHg at 30° flexion or abduction, resulting in impairment of blood circulation, mechanical overload of the muscle and adjacent muscles, and increased risk for myofascial pain (Järvholm et al., 1988). Particular occupational groups at increased risk include data entry operators, typists (Hünting et al., 1981), musicians (Norris & Dommerholt, 1996), teachers and nurses (Onishi et al.,

1976), and industrial and assembly line workers (Amano et al., 1988; Silverstein, 1985).

Considering work-related aspects of myofascial pain enhances treatment outcomes. Modifying the workplace or the patient's work habits is critical. If a patient continues to be exposed to certain workplace stress factors without modification of the conditions, the potential cause of myofascial dysfunction may not be addressed adequately. Physical therapists and occupational therapists can contribute significantly to integrating basic ergonomic principles into therapeutic practice, although specific training in ergonomics is indicated (Berg Rice, 1995). More complicated ergonomic problems require the assistance of ergonomists (Ayoub, 1994; Khalil et al., 1994).

SYSTEMIC MEDICAL FACTORS

The problem of unresolved or persistent MTrPs can be the result of systemic medical factors that affect muscle metabolism primarily or affect muscle function secondarily. These factors can be categorized broadly as nutritional, hormonal, metabolic, infectious, autoimmune, etc. An important principle that Janet Travell often emphasized in her lectures is that insufficiency states impair the ability of stressed or overloaded muscle to respond adequately to therapy. Levine and Hartzell (1987) have applied this concept to vitamin C insufficiency. They propose that the optimum concentration of an enzyme cofactor (vitamin or mineral) is that which allows each enzymatic reaction to proceed maximally (not rate limited) when required. For example, many vitamin or mineral enzyme cofactors, such as ascorbic acid (vitamin C) or iron, participate in a number of different enzymatic reactions that are not all equally active at any one time. However, if a limited concentration of an enzyme cofactor becomes rate limiting, then the products of the associated reaction may be insufficient, like the underproduction of high-energy organic phosphates for certain iron-dependent enzymes or the underproduction of serotonin or norepinephrine for certain vitamin-C-dependent enzymes. It is postulated that the needs of the body under physical stress are different from those when unstressed and what may be an adequate concentration of enzyme cofactor under normal conditions may be insufficient at times of physical stress. Hence, the concept of nutritional insufficiency states is distinguished from that of disease-producing deficiency states such as scurvy, the disease associated with vitamin C deficiency. Vitamin C taken in the amount of 10 mg/day prevents scurvy, but 250 mg/day is considered the optimum daily intake for good health.

Four nutritional or hormonal factors have repeatedly been found to be low or in the lower quartile of the normal range in persons studied in our clinic who have persistent myofascial pain, namely, insufficiencies of iron, folic acid, vitamin B_{12}, and thyroid hormone. Of women with a chronic sense of coldness and chronic myofascial pain, 65% have a low normal or below normal serum level of ferritin, largely from an iron intake insufficient to replace menstrual iron loss. Other causes of low serum ferritin include blood loss associated with chronic intake of mixed cyclooxygenase-1 and -2 nonsteroidal anti-inflammatory drugs), and gastrointestinal blood loss associated with parasitic disease. Ferritin represents the tissue-bound nonessential iron stores in the body that supply the essential iron for oxygen transport and iron-dependent enzymes. Serum levels of 15 to 20 ng/ml mean that muscle and other storage sites for iron (liver and bone marrow) are depleted of ferritin. Anemia is common at levels of 10 ng/ml or less. The disease of iron deficiency is anemia. Symptoms of iron insufficiency are fatigue, muscle cramps, and coldness. The association between iron insufficiency and chronic myofascial pain suggests that iron-requiring enzymatic reactions such as reduced nicotinamide adenine dinucleotide dehydrogenases and the cytochrome oxidase reaction may be limited in such persons. This may in turn produce an energy crisis in muscle when it is overloaded and thereby produce metabolic stress. MTrPs may not easily resolve in such circumstances. Iron supplementation in persons with chronic MPSs and serum ferritin levels below 30 ng/ml prevents or corrects these symptoms.

Vitamin D deficiency has been shown to be very common in persons with persistent, nonspecific musculoskeletal pain. Measurement of 25-OH vitamin D was very low in 89% of such subjects in one study (Plotnikoff & Quigley, 2003). Persons who are housebound and those whose clothing covers most of their bodies, reducing exposure to sunlight, are at greatest risk.

Vitamin B_{12} and folic acid metabolism are closely related. They function not only in erythropoiesis but also in central and peripheral nerve formation. Studies have shown that in a subset of patients, serum levels of vitamin B_{12} as high as 350 pg/ml may be associated with a metabolic deficiency manifested by elevated serum or urine methylmalonic acid or homocysteine and may be clinically symptomatic (Pruthi & Tefferi, 1994). Preliminary studies show that 16% of patients with chronic MPS either were deficient in vitamin B_{12} or had insufficient levels of vitamin B_{12}, and that 10% had low serum folate levels (Gerwin, 1995b). Replacement of vitamin B_{12} is life-long, either orally, transmucosally, or intramuscularly.

Hypothyroidism is suspected clinically in chronic MPS when there is a complaint of coldness, dry skin or dry hair, constipation, and fatigue. Hypothyroidism occurred in 10% of subjects with chronic MPS in one study (Gerwin, 1995b). The MTrPs tend to be widespread in hypothyroid persons. The thyroid-stimulating hormone level may only be in the upper range of normal but, as shown by thyroid-releasing hormone (TRH) stimulation tests, still be abnormal for a given individual. Thyroid

hormone supplementation to restore the thyroid state may resolve many myofascial complaints and allow resolution of the problem by the usual means of physical therapy and trigger point inactivation. Thyroxine (levothyroxine) is generally used to treat hypothyroidism. However, not all tissues are equally able to convert thyroxine to triiodothyronine, the active form of thyroid hormone. The addition of triiodothyronine to thyroxine has been shown to result in an improved sense of well-being, an improvement in cognitive function and mood, and an increase in serum levels of sex-hormone-binding globulins, a sensitive marker of thyroid hormone function (Bunevicius et al., 1999; Toft, 1999).

Other less commonly associated medical problems that are found in patients with chronic MPS and that act as perpetuating factors include recurrent candida yeast infections, particularly in women who have been given courses of antibiotic therapy for recurrent urinary tract infections. Persons with myofascial pain dysfunction syndromes affecting the temporomandibular joint often complain of sore throat or earache and may be given antibiotics, thereby predisposing them to candida overgrowth. Women who present with widespread MTrPs resistant to usual treatment should be investigated for candida infection. If the history is very suggestive, treatment is indicated even if the organism cannot be implicated by hanging drop examination or culture. Men and postmenopausal women who have elevated uric acid levels may also have persistent MTrPs.

Parasitic infections can also be associated with widespread MTrPs, often complicated by fatigue and an often nonspecific sense of discomfort, and occasionally gastrointestinal distress. Amoebiasis is the most common parasite encountered in MPS in the United States, but giardia, trematode, and nematode infection have also been found. Treatment of these infections results in an overall improvement, and often in a diminution of the extent of trigger point involvement of muscle. Lyme disease can cause myalgia, arthralgia, and chronic fatigue. The myalgia may be associated with trigger points. Post-Lyme syndrome in the untreated individual is characterized by high titers of IgG antibody and no elevation of IgM antibodies. The clinical picture is one of diffuse arthralgia, myalgia, and fatigue. The chronic cases show no evidence of borrelial infection by culture or detection of DNA in blood or spinal fluid. Unfortunately, these patients do not improve with antibiotic therapy given for 3 months (Weinstein & Britchkov, 2002).

Persons with osteoarthritis, rheumatoid arthritis, Sjögren's syndrome, carpal tunnel syndrome, or peripheral neuropathy caused by diabetes mellitus are more prone to develop MTrP. The post-laminectomy syndrome is frequently caused by MTrP. Treatment is always directed toward the underlying condition, as well as the trigger point, where possible.

Viscerosomatic pain syndromes include the development of typical myofascial pain, generally in the body wall, but sometimes in a limb. Visceral organs have segmental pain referral patterns derived from their primary sensory innervation (Gerwin, 2002; Hetrick et al., 2003). Hence, interstitial cystitis and irritable bowel syndrome most often display pain referral patterns to the muscles of the pelvic region that can respond to manual or needling therapy of trigger points (Doggweiler-Wiygul & Wiygul, 2002; Weiss, 2001). Ureteral stone commonly refers pain to the flank or abdominal wall muscles (Giamberardino et al., 2003). Treatment of the trigger points referred to the abdominal wall or flank muscles can eliminate local pain and pain that is referred from muscle that mimics the initial visceral pain, such as the pain of renal colic (Iguchi, Katoh, Koike, Hayashi, & Nakamura, 2002). The myofascial representation of a visceral pain syndrome can long outlast the acute visceral pain. A common viscerosomatic pain syndrome is abdominal and pelvic floor pain caused by endometriosis. The pain may be eliminated by treating lower abdominal MTrPs.

Sleep disturbance can be a major factor in the perpetuation of musculoskeletal pain. Pain is magnified in the presence of insomnia, whether the insomnia is caused by pain or by other factors. There is the rare case in which chronic musculoskeletal pain is eliminated by the restoration of normal sleep when caffeine was reduced or eliminated from the diet. More often, however, sleep must be addressed directly, noting that sleep disturbance is increased in persons with chronic pain. Attention is paid to pain control at night, to sleep apnea, and to mood disorders such as depression or anxiety. Management is both pharmacological and nonpharmacological. Pharmacological treatment utilizes drugs that promote normal sleep architecture, induce and maintain sleep through the night, and do not cause daytime sedation. Nonpharmacological treatment emphasizes sleep hygiene, such as using the bed only for sleep and sex, and not for reading, television viewing, and eating (Menefee et al., 2000).

Psychological stress may aggravate MPS and activate MTrP (Lewis et al., 1994; McNulty et al., 1994). Trigger point EMG activity has been shown to increase dramatically in response to mental and emotional stress, whereas adjacent nontrigger point muscle EMG activity remained normal. Thus, the effect of stress on the trigger point can be highly selective, instead of generalized throughout the muscle. MPS may be the major symptomatic expression of psychological distress. In addition, pain-related fear and avoidance can lead to the development of a chronic musculoskeletal pain problem (Vlaeyen & Linton, 2000). Treatment directed toward reducing stress has been shown to diminish MPS symptoms (Banks et al., 1998). The clinician must be sensitive to this possibility and refer the patient for psychological counseling when appropriate.

SUMMARY

In summary, treatment of MPS begins with the identification of the MTrP as a source of the pain or as a contributing factor, and a delineation of the extent of the problem. The problem may be confined to a few muscles or may be more widespread, regional, or generalized. Direct inactivation of the MTrP is accompanied by correction of mechanical and systemic medical factors that contribute to the development of the syndrome. Exercise to restore physical conditioning reduces the chances of recurrence. Persons with chronic MPS who have not responded as expected to appropriate therapy must be evaluated for further mechanical, medical, or psychological problems that have been associated with persistent MPS. Attention to the postural and physical stresses of work and awareness of the effect that psychological stress has on muscle pain identify those areas that need to be addressed. These problems must be corrected or alleviated to effectively treat the MPS. Effective treatment can be provided through the application of a variety of manual techniques, by invasive inactivation of the trigger point, and by carefully identifying and correcting the factors that interfered with recovery.

Fibromyalgia

Richard E. Harris, PhD, and Daniel J. Clauw, MD

INTRODUCTION

Virtually nothing regarding "functional" somatic syndromes is agreed upon in the medical community. There is disagreement about the appropriate semantic terms we should use to describe these conditions, whether these conditions have a primarily "physiologic" or psychologic origin, and in particular, whether these are truly disabling conditions. In this chapter, fibromyalgia, a "prototypical" functional somatic syndrome, is discussed.

Although the terms we now use to describe fibromyalgia are relatively new, the condition is not. For centuries in the medical literature, there have been descriptions of symptom complexes nearly identical to those we now label as fibromyalgia (McKenzie & Straus, 1995). Many terms previously used to describe this condition, such as myofibrositis or fibrositis, were attempts to link the symptom complex to an underlying pathophysiologic process. The more generic terms we now use to describe this illness reflects the recognition that we know what *does not* cause fibromyalgia, not what *does*. We are fairly certain that there is no *-itis* (i.e., inflammation) of the muscles in fibromyalgia and that it is not simply in the minds of those afflicted (Godfrey, 1996; Straus, 1993; Yunus, 1992).

DEFINITION

Clinical Features

To fulfill the criteria for fibromyalgia published by an American College of Rheumatology (ACR) committee in 1990, an individual must have both a *history* of chronic widespread pain involving all four quadrants of the body (and the axial skeleton), and the presence of 11 of 18 "tender points" on *physical examination* (Wolfe et al., 1990). These criteria were never intended to be strictly applied to individual patients as diagnostic criteria, and most agree that at least half of the individuals who have the clinical diagnosis of fibromyalgia will not fulfill this definition.

There are problems with the ACR criteria, and especially with the requirement that an individual needs a certain number of tender points to fulfill these criteria. Tender points are predefined anatomic points that are present in various areas of the body, and are considered to be "positive" when an individual complains of pain when 4 kg (approximately 9 pounds) of pressure is applied (approximately the amount of pressure required to blanch the examiner's nail). Although early studies suggested that patients with fibromyalgia experienced tenderness only in these discrete regions, we now know that individuals with fibromyalgia display increased sensitivity to pain throughout the body (Granges & Littlejohn, 1993). Tender points (e.g., the mid-trapezius region, epicondyles) appear to merely represent regions of the body where everyone is tender; thus individuals who are more diffusely tender will generally have a greater number of tender points. Also, tender points measure not only how tender an individual is, but also how "distressed" he or she is (Petzke et al., 2003). Finally, tenderness is influenced by many factors. Female gender, increasing age, poor aerobic fitness, and mood disorders all tend to increase cutaneous pressure sensitivity. Therefore, rigidly adhering to the ACR criteria in clinical practice will skew the diagnosis of fibromyalgia toward older females with poor aerobic fitness, and high levels of distress.

Although both pain and tenderness are defining features of fibromyalgia, the latter is rarely a presenting complaint. The pain of fibromyalgia frequently waxes and

wanes, may be quite migratory, and may be accompanied by dysesthesias or paresthesias following a nondermatomal distribution. In some instances, patients will present with "aching all over," whereas in other instances patients experience several areas of chronic regional pain. In this setting, regional musculoskeletal pain typically involves the axial skeleton, or areas of "tender points," and may originally be diagnosed as a local problem (e.g., low back pain, lateral epicondylitis). Regional pain involving nonmusculoskeletal regions is also common, including a higher than expected prevalence of both tension and migraine headaches, temporomandibular joint dysfunction (TMD or TMJ) syndrome, noncardiac chest pain, irritable bowel syndrome, a number of entities characterized by chronic pelvic pain, and plantar or heel pain.

In addition to pain and tenderness, most individuals with this illness also experience a high lifetime and current prevalence of nondefining symptoms (Clauw, 1995). For example, most patients with fibromyalgia experience fatigue, and at least half of individuals who meet ACR criteria for fibromyalgia will also meet criteria for chronic fatigue syndrome (CFS) (Buchwald & Garron, 1994). The fatigue is commonly worse after activities and may be accompanied by memory difficulties. Memory difficulties, especially with attention and short-term memory, may be the most debilitating aspect of their illness (Park et al., 2001). Other constitutional symptoms include fluctuations in weight, heat and cold intolerance, and the subjective sensation of weakness.

Patients with fibromyalgia and related illnesses also display a wide array of "allergic" symptoms, ranging from adverse reactions to drugs and environmental stimuli (as seen in multiple chemical sensitivity), to higher than expected incidences of rhinitis, nasal congestion, and lower respiratory symptoms. Although some of these individuals may truly be atopic, many of these symptoms are due to neural mechanisms (e.g., hypersensitivities, vasomotor rhinitis). Hearing, ocular, and vestibular abnormalities have also been noted, including a high incidence of sicca symptoms, a decreased painful sound threshold, exaggerated nystagmus and ocular dysmotility, and asymptomatic low-frequency sensorineural hearing loss.

Individuals with fibromyalgia likewise suffer from a number of symptoms of "functional" disorders of visceral organs, including a high incidence of recurrent noncardiac chest pain, heartburn, palpitations, and irritable bowel symptoms. However, prospective studies of randomly selected individuals with fibromyalgia have detected a high frequency of *objective* evidence of dysfunction of several visceral organs, including echocardiographic evidence of mitral valve prolapse, esophageal dysmotility, and diminished static inspiratory and expiratory pressures on pulmonary function testing. Neurally mediated hypotension, postural orthostatic tachycardia, and syncope also occur more frequently in these individuals. Similar syndromes characterized by visceral pain and/or smooth muscle dysmotility are also seen in the pelvis, including dysmenorrhea, urinary frequency and urinary urgency, interstitial cystitis, endometriosis, and vulvar vestibulitis or vulvodynia.

ETIOLOGY

There is evidence of familial aggregation for fibromyalgia. First-degree relatives of patients with fibromyalgia display a higher than expected frequency of fibromyalgia, as well as related conditions (Buskila & Neumann, 1997; Hudson et al., 1993). Like many illnesses, the expression of fibromyalgia may occur when a person who is genetically predisposed comes in contact with certain environmental exposures that can trigger the development of symptoms. There are many environmental exposures that are generally accepted triggers of fibromyalgia, all of which can be considered "stressors." Examples of stressors include physical trauma (especially to the axial skeleton), infections (e.g., parvovirus, Hepatitis C), emotional distress (acute or chronic), endocrine disorders (e.g., hypothyroidism), and immune stimulation, as may occur in a variety of autoimmune disorders (Buskila & Neumann, 1997; Hudson et al., 1993). Although studies of *groups* of individuals suggest that there are many "stressors" that can trigger the development of this illness, because of the plethora of potential exposures to which an individual may be exposed, it is sometimes difficult to assess the putative role of a single exposure in an individual.

PATHOGENESIS

Most investigators in this field feel that the primary abnormality that leads to expression of symptoms in fibromyalgia and related conditions is aberrant central nervous system function (Clauw & Chrousos, 1997; Yunus, 1992). Furthermore, there is a general belief that the central components of the "stress response" may be playing a major role in symptom expression. The principal components of the human stress response are the corticotropin-releasing hormone and locus ceruleus-norepinephrine/autonomic (sympathetic/LC-NE) nervous systems. These systems are capable of being activated by a variety of stressors, and disturbances in this system can have effects on sensory processing, autonomic, and neuroendocrine function.

Sensory Processing

The hallmark of fibromyalgia and other central pain syndromes is abnormal sensory processing. Under experimental conditions, individuals display both *hyperalgesia* — an augmentation of pain processing in which a painful stimulus is magnified and perceived with higher intensity than it would be by a normal volunteer — and *allodynia* — perceiving pain even from a nonpainful stimulus such

as light touch (Arroyo & Cohen, 1993; Desmeules et al., 2003; Gracely et al., 2002; Mountz et al., 1995). These data are suggestive of a state of heightened pain perception in fibromyalgia (Desmeules et al., 2003; Staud & Smitherman, 2002), which could conceptually result from widespread changes within the target organs (i.e., skin, muscles, etc.), or from alterations in nociceptive processing within the central nervous system, or some combination of both processes.

Some early theories of fibromyalgia pathophysiology posited that peripheral abnormalities (particularly alterations in skeletal muscle) were underlying the pathophysiology of fibromyalgia pain (Olsen & Park, 1998). However, more recent studies have generally failed to confirm the presence of such alterations (Olsen & Park, 1998; Simms, 1998; Simms et al., 1994; Sprott et al., 1998), although it is recognized that changes in the periphery could play a role in instigating or maintaining fibromyalgia (Ernberg et al., 2000; Staud & Smitherman, 2002). On the other hand, several lines of inquiry support the role of altered central pain processing (i.e., "central sensitization") as underlying the pain of fibromyalgia. Several investigators have moved beyond determinations of tender point counts and dolorimeter values in fibromyalgia to more extensively examine the basis for widespread pain and tenderness in this condition. Such studies have demonstrated that patients with fibromyalgia cannot *detect* electrical, pressure, or thermal stimuli at lower levels than normals, but the point at which these stimuli cause pain or unpleasantness is lower (Arroyo & Cohen, 1993; Lautenbacher et al., 1994). Although nearly all of the research on sensory processing in fibromyalgia has focused on the processing of pain, there are some data suggesting a more generalized disturbance in sensory processing. For example, many patients experience sensitivity to loud noises, bright lights, odors, drugs, and chemicals. These data point to a more centralized disturbance in fibromyalgia.

Additional evidence for central nervous system changes in fibromyalgia comes in the form of studies of central neurotransmitters. In particular, four independent studies have demonstrated that levels of substance P (SP) are elevated two- to threefold in the cerebrospinal fluid (CSF) of patients with fibromyalgia versus controls (Bradley et al., 1996; Russell et al., 1994; Vaeroy et al., 1988; Welin et al., 1995), and it appears to act as a neuromodulator, sensitizing (via the neurokinin 1 receptor) neurons to the effects of other excitatory neurotransmitters and thus potentially playing an important role in chronic pain states (Dougherty et al., 1995). However, the meaning of these elevated CSF SP levels is not entirely clear. The SP could theoretically be derived from overactive peripheral nociceptive fibers or from central neurons. An elevated CSF SP is not specific for fibromyalgia because this finding has also been noted in patients with osteoarthritis of the hip and chronic low back pain. It is likely that these

findings are related to the presence of pain, because persons with CFS do not display this finding. Russell et al. (1994) have demonstrated that these SP levels in fibromyalgia are stable, or rise, over time, and do not change in response to acute painful stimuli. Also, the same magnitude of elevation of CSF SP is found in patients with fibromyalgia with and without psychiatric co-morbidities.

Finally, functional neuroimaging has been shown to be abnormal in fibromyalgia, another piece of evidence supporting a disorder of central pain processing. Single photon emission computed tomography was the first functional imaging technique used in fibromyalgia, and identified decreased blood flow in several brain regions known to be involved in pain processing (Mountz et al., 1998). More recently, Gracely et al. (2002) used functional nuclear magnetic resonance imaging (fMRI) modality to investigate differences in cortical activation between 16 patients with fibromyalgia and 16 controls while they underwent pressure-pain testing (thumb-nail pressure). Each subject with fibromyalgia had an fMRI performed while subjected to "moderately painful" pressure as defined by the Gracely Scale (Gracely & Kwilosz, 1988). The control subjects were scanned under two conditions: (1) the "stimulus pressure control" condition and (2) the "subjective pain control" condition. The former referred to testing the controls with the same level of mechanical pressure as the patients with fibromyalgia, while the latter involved scanning the controls when they, like the patients with fibromyalgia, reported moderate pain. It was found that the levels of cortical activation between the patients with fibromyalgia and the controls under the "subjective pain control" condition were similar. However, fMRI scans of control subjects under the "stimulus pressure control" condition showed no significant activation. These results are strongly supportive of alterations in the threshold and gain of the nociceptive system in patients with fibromyalgia and are consistent with a model of central sensitization (Gibson et al., 1994; Lorenz, 1998; Lorenz et al., 1996). These findings of augmented pain processing by fMRI have been confirmed by this same group, as well as a different group of investigators using heat instead of pressure stimuli (Cook et al., 2004).

Autonomic and Neuroendocrine Function

Although stress response function is acknowledged to be abnormal in fibromyalgia, the precise nature of the abnormality has been variable among studies (Clauw & Chrousos, 1997; Griep et al., 1993; Pillemer et al., 1997). The most consistent finding in fibromyalgia is hyporesponsiveness of both hypothalamic-pituitary adrenal (HPA) and autonomic function to standardized stressors (Adler et al., 1999; Griep et al., 1993). The baseline HPA activity in fibromyalgia has been shown to be increased or decreased, depending on the clinical setting (i.e., ambulatory deter-

minations or patients in highly controlled environments) and subject selection (patients with and without comorbid chronic fatigue syndrome or depression) (Catley et al., 2000; Crofford & Demitrack, 1996). The precise nature of the defect in HPA function has also yielded somewhat inconsistent findings, but can best be summarized as showing decreased basal cortisol levels, decreased adrenal sensitivity to adrenocorticotropic hormone (ACTH), and exaggerated ACTH response to exogenous or endogenous (e.g., insulin-induced hypoglycemia) corticotropin-releasing hormone (Adler et al., 1999; Crofford & Demitrack, 1996; Riedel et al., 1998). There is also no consensus regarding baseline autonomic function in fibromyalgia, with early reports suggesting hypoactivity, whereas recent better-controlled studies suggest hyperactivity, manifest as abnormal heart rate variability, and sustained hypercatecholaminemia (Martinez-Lavin et al., 1997, 1998; Petzke & Clauw, 2000).

Psychiatric, Psychological, and Behavioral Factors

There has been a long-standing debate over the role of psychiatric, psychological, and behavioral factors in fibromyalgia. Some contend that *all* of these symptoms are "supra-tentorial" in origin or that fibromyalgia represents a state of distress or vulnerability, whereas others counter that the rate of psychiatric comorbidities in these conditions is similar to any chronic disease. Increased levels of psychological distress resulting in psychiatric syndromes are a common accompaniment of many painful chronic illnesses (Katon et al., 2001). Approximately 20 to 30% of patients with fibromyalgia have significant current depression (i.e., meeting DSM IV criteria) and more than 60% of patients with fibromyalgia will have issues with depression over their lifetimes (Epstein et al., 1999). However, some of these differences in the current and lifetime history of mood disorders may be due to health care–seeking behaviors because lower lifetime incidences of affective disorders are typically noted in individuals with fibromyalgia who are identified in the general population.

Other psychosocial factors play a significant role in some individuals with fibromyalgia, as with nearly any chronic medical illness. These include behavioral pathways, such as sick role behavior and maladaptive coping mechanisms, cognitive pathways such as victimization and loss of control, and social pathways, such as interference with role functioning and deterioration of social or other support networks. As pain progresses from the acute phase into chronicity, problems emerge for the individual such as job loss, financial constraints, distancing of friends, etc. If patients' responses to these problems are maladaptive such as avoidance of work, friends, financial responsibilities, and physical activity, the patient may become distressed and overwhelmed by the pain and its negative impact on life. Increased stress, learned helpless-

ness, depression, increased anxiety, anger, distrust, entitlement, and somatization can all emerge and worsen symptoms. All of these factors are important in dictating how individuals report symptoms, how and when they seek health care, and their response to therapy. This may also explain why cognitive-behavioral therapy has generally been effective in the treatment of individuals with fibromyalgia, as well as nearly any other chronic medical condition (NIH, 1996).

Regardless of the precise percentage of individuals with psychiatric comorbidities, at least 60% of individuals with fibromyalgia have no identifiable concurrent psychiatric condition. Furthermore, psychological factors are capable of not only worsening fibromyalgia; in some individuals it appears as though such factors can lead to "resilience" and mitigate against the underlying neurobiological pain amplification processes. The best example of this phenomenon comes from a study that identified three distinct subgroups of individuals with fibromyalgia (Giesecke et al., 2003). In approximately half of the patients with fibromyalgia, there was no evidence of depression or anxiety, nor of cognitive factors associated with a poor prognosis in pain, such as catastrophizing or external locus of control. A second group, which comprised approximately 30% of this sample, had prominent psychological factors that were likely contributing to symptoms. But a third group, which comprised just under 20% of the total subjects in this study, experienced extreme tenderness and had extremely low levels of depressive symptomatology, as well as an absence of catastrophizing, and very strong rating of control over their pain.

ASSESSMENT/DIAGNOSIS

Diffuse pain is a defining symptom of fibromyalgia and also occurs in a number of other settings. The diagnostic evaluation of an individual with diffuse pain varies depending on the duration of symptoms, and the findings in the history and physical examination. Diffuse pain that has been present for years is likely to be due to fibromyalgia, especially if there are accompanying symptoms such as fatigue, memory difficulties, and sleep disturbance, and the individual is tender on examination. In this setting, a minimal workup is necessary.

In contrast, an individual who has diffuse pain for weeks or months needs a more extensive evaluation. In performing the history, particular attention should be focused on the onset and character of the pain, accompanying symptoms, and "exposures" that could be causing the symptoms (especially to both prescription and over-the-counter drugs and supplements). The examination should focus on identifying signs of inflammation (e.g., synovitis) or other findings (e.g., objective weakness) that are not seen in fibromyalgia.

At a minimum, individuals who present with chronic, widespread pain should have a complete blood count, liver and kidney function tests, thyroid stimulating hormone (TSH), and sedimentation rate (or C-reactive protein) performed during the course of their illness. Because fibromyalgia occurs less frequently in males, some have suggested more aggressive diagnostic testing when a male presents with symptoms consistent with fibromyalgia (especially for conditions that are more common in males such as sleep apnea and hepatitis C infection.)

The physical examination is generally unremarkable in fibromyalgia, other than finding tenderness. The tenderness may be virtually anywhere and is not just confined to tender points. The former concept of "control points," previously described as areas of the body that should not be tender, has been abandoned.

Laboratory testing should be used judiciously. Even if the individual has acute or subacute onset of symptoms, ordering serologic assays such as antinuclear antibody (ANA) and rheumatoid factor should generally be avoided unless there is strong evidence for an autoimmune disorder. There are several reasons for this, including the fact that these tests have a low predictive value in the setting of nonspecific symptoms and that the rate of ANA positivity may be higher in persons with illnesses within this spectrum (Bates et al., 1995; Pincus, 1993).

The overlap between fibromyalgia and autoimmune disorders deserves special mention. Many individuals early in the course of autoimmune disorders may present with symptoms reminiscent of fibromyalgia. Symptoms that can be seen in both fibromyalgia and autoimmune disorders include not only arthralgias, myalgias, and fatigue, but also morning stiffness and a history of subjective swelling of the hands and feet. In addition, a Raynaud's-like syndrome (characterized by the *entire hand* turning pale or red instead of just the digits), malar flushing (in contrast to a fixed malar rash), and livedo reticularis are all common in fibromyalgia and can mislead the practitioner to suspect an autoimmune disorder.

Persons with established autoimmune disorders may also suffer from symptoms of fibromyalgia. Studies have suggested that approximately 25% of persons with systemic inflammatory disorders such as systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis will also meet ACR criteria for fibromyalgia. Because both inflammatory and non-inflammatory mechanisms may be causing symptoms in this setting, fibromyalgia should be suspected when an individual with an autoimmune disorder has symptoms despite normal inflammatory indices, or when symptoms are unresponsive to anti-inflammatory regimens. These same symptoms that mimic fibromyalgia may occur when individuals are being tapered from high-dose corticosteroids (this phenomenon previously had been termed "pseudo-rheumatism").

TABLE 35.1
Frequency of Comorbidity in Fibromyalgia

Syndrome	Point Prevalence in Patients with Fibromyalgia	Prevalence in General Population
Chronic low back pain	67%	12–33%
Irritable bowel syndrome	59%	15–20%
Mood disorder	29%	10–15%
Temporomandibular joint disorder	24%	3.7–12%
Chronic tension-type headaches	23%	2–3%
Chronic fatigue syndrome	18%	1%
Multiple chemical sensitivities	18%	Unknown

Both physiologic and psychobehavioral factors are involved in this spectrum of illness. Perhaps when individuals first develop symptoms, physiologic factors may be primarily responsible. However, with the chronicity of illness, some individuals may develop psychological and behavioral cofactors that exacerbate or perpetuate the illness. These factors, in combination with the physiologic factors, are likely to be the biggest determinants of disability in this spectrum of illness. These latter factors are seen much more commonly in individuals who attend tertiary care clinics, and conversely, individuals who are found with these syndromes in the general population, or in primary care, are less likely to have such factors and are likely to respond much better to purely physiologic (e.g., pharmacologic) interventions.

Table 35.1 presents the frequency of comorbidity in fibromyalgia.

TREATMENT

GENERAL CONSIDERATIONS

Patients with fibromyalgia are diagnosed most often in the primary care setting, and almost half of the office visits are to internal medicine and family practice providers (Centers for Disease Control, 2005; Woodwell, 2000). Rheumatologists are the leading specialty group managing patients with fibromyalgia, which make up 16% of their office visits on average. Indeed, fibromyalgia is second only to osteoarthritis as the most common diagnosis in rheumatology offices. Patients with fibromyalgia have been shown to be extremely heavy utilizers of health care, because of both excess diagnostic testing and the costs of treatment (Wolfe et al., 1997a). A wide variety of approaches — both pharmacological and nonpharmacological — have been applied with varying degrees of success in the treatment of fibromyalgia. The management of patients with fibromyalgia involves a complex interplay between pharmacological management of pain and associated symptoms, and the use of nonpharmacological

modalities, especially to address functional loss and disability. As the elimination of all fibromyalgia symptoms (i.e., a cure) is not currently possible, the philosophy of management is symptom palliation and functional restoration. The presentation of fibromyalgia symptomatology is highly variable and each patient must have an individualized evaluation before deciding on an initial treatment plan (Bennett, 2002). Regular follow-up and modification of the initial management strategy is usually required, depending upon the response pattern.

It is important to try to understand the complex interplay between symptoms and functional behavior in patients with fibromyalgia. A typical pattern is that as a result of pain and other symptoms of fibromyalgia, individuals begin to function less well in their various roles. They may have difficulties with spouses, children, and work inside or outside the home, which exacerbate symptoms and lead to maladaptive illness behaviors. These include isolation, cessation of pleasurable activities, reductions in activity and exercise, etc. In the worst cases, patients become involved with disability and compensation systems that almost ensure that they will not improve (Hawley & Wolfe, 1991). Many consequences of these symptoms (cessation of exercise, disruption of sleep, distress because of diminished functional status, etc.) are directly capable of worsening pain, fatigue, and other symptoms.

In the above scenario, only the initial symptoms are likely to be responsive to pharmacological therapy. The dysfunction and resultant behaviors will not necessarily improve if the symptoms improve. Thus, a dual approach that addresses symptoms with pharmacological therapy when appropriate, and uses nonpharmacologic therapies to improve function, modify behaviors, etc., may be optimal.

General Approach

Once an individual with this diagnosis is identified, the practitioner first has to consider whether to "label" the individual. For the majority this label will help them understand their symptoms and the most appropriate treatment, but there may be some individuals for whom this is harmful (Hadler, 1997).

The practitioner should schedule a prolonged visit, or series of visits, when this diagnosis is considered. Although there are no data to support this, it is likely that this "upfront" time is extremely useful for both patients and providers, as it helps the physician understand precisely what is bothering the patient and assists the patient in understanding the goals and rationale of treatment. The physician should explore the symptoms that are most bothersome, the impact these symptoms are having on various aspects of the patient's life, the patient's perception about what is causing these symptoms, and the stressors that may be exacerbating the problem.

Some patients who present with symptoms of fibromyalgia want only to be told that this is a benign, nonprogressive condition. These patients generally have milder symptoms that have been present for some time, and they possess adequate strategies for improving symptoms and maintaining function.

But for all patients with fibromyalgia, education about the nature of this disorder is critical. Physicians should describe this condition in terms with which they feel most comfortable, and then refer the patient to reputable sources of information such as the Arthritis Foundation, several national patient support organizations (e.g., American Fibromyalgia Syndrome of America, National Fibromyalgia Research Association, and Fibromyalgia Alliance of America), or up-to-date Web sites (e.g., www.med.umich.edu/painresearch).

Pharmacologic Therapies

As noted above, pharmacologic therapies are very useful for managing the *symptoms* of fibromyalgia. One useful approach is first to introduce pharmacological therapies to improve pain, fatigue, sleep, mood, etc., and then once these symptoms have improved, to aggressively use non-pharmacological therapies (e.g., exercise, cognitive behavioral therapy) to improve function.

Antidepressants

The majority of clinical trials in fibromyalgia have involved antidepressants of one class or another. Trials studying the oldest class of agents, tricyclic antidepressants, are most abundant, although several recent studies have focused on selective serotonin reuptake inhibitors (SSRIs) and "atypical antidepressants" — a class that includes dual reuptake inhibitors and monoamine oxidase inhibitors. Despite the multiplicity of antidepressant classes, practically all of the agents that are currently in clinical use either directly or indirectly increase neurotransmission mediated by the monoamine neurotransmitters, particularly serotonin (5-HT) and/or norepinephrine (NE; also called noradrenaline) (Rao, 2002b). These activities are thought to underlie the antidepressant activity of these compounds, although the exact mechanism by which this occurs is unknown. These pharmacological activities also appear to be an important mechanism by which antidepressant compounds effect centrally mediated analgesia (Rao, 2002b).

Tricyclic Antidepressants
Unfortunately, the anticholinergic and antihistaminergic activities of tricyclic antidepressants (TCAs) contribute to the relatively poor side-effect profile of these agents. This point may be particularly relevant to the fibromyalgia patient population, due to the relatively high prevalence of comorbid chemical intolerance and multiple chemical sen-

sitivity. Despite these tolerability issues, the use of TCAs (particularly amitriptyline) to treat the symptoms of pain, poor sleep, and fatigue associated with fibromyalgia is supported by several randomized, controlled trials (Bennett, 2001; Kranzler et al., 2002). Surprisingly, the story is less clear regarding the mood-elevating effects of these agents in the context of fibromyalgia or other pain states, perhaps as a result of the fact that most trials have evaluated sub-antidepressant doses of TCAs (Bennett, 2001; Kranzler et al., 2002). In most forms of major depressive disorder, however, the efficacy and remission rates of TCAs are equal or superior to those of other classes of agents, an effect that is hypothesized to result from their effects on both the serotonergic and noradrenergic systems (Dwight et al., 1998). TCAs also have an established track record in treating various chronic pain syndromes, including functional somatic syndromes. Double blind, randomized controlled trials also support the use of TCAs in related syndromes such as irritable bowel syndrome (IBS) (Ringel & Drossman, 2002), temperomandibular joint disorder (TMD) (Plesh et al., 2000), and idiopathic chronic low back pain (CLBP) (Salerno et al., 2002).

Selective Serotonin Reuptake Inhibitors

SSRIs have revolutionized the field of psychiatry, providing safe and effective treatment of common psychiatric conditions including major depressive disorder, anxiety, and social phobia. Much of their success is attributable to the fact that SSRIs display improved tolerability compared with TCAs, a result of their much higher degree of pharmacological specificity. As implied by their name, SSRIs primarily inhibit the reuptake of 5-HT, and they typically lack the extra-monoaminergic activities that characterize TCAs. The SSRIs fluoxetine, citalopram, sertraline, and paroxetine have each been evaluated in randomized, placebo-controlled trials in fibromyalgia (Arnold et al., 2002; Capaci & Hepguler, 2002). The results of these trials have been somewhat inconsistent, leaving some debate regarding the relative efficacy of the SSRIs, especially in comparison with TCAs. Two studies have demonstrated positive efficacy for fluoxetine when compared with either placebo or amitriptyline in treating sleep, pain, fatigue, and depression (Arnold et al., 2002; Goldenberg et al., 1996). However, a third study failed to demonstrate any significant improvement in pain, although mild improvements were noted in sleep and depression (Wolfe et al., 1994). Two placebo-controlled trials of citalopram have been performed. The first was convincingly negative, with citalopram failing to demonstrate any improvements in pain, fatigue, sleep, or mood (Norregaard et al., 1995). The second study demonstrated that citalopram significantly improved mood, although other outcome measures did not improve significantly (Anderberg et al., 2000). One study comparing sertraline with amitriptyline demonstrated that the two compounds were equivalent in producing signifi-

cant improvements in pain, sleep, and fatigue. Finally, a study comparing paroxetine to amitriptyline concluded that while both improve the symptoms of pain, sleep, and depression, amitriptyline had a larger, more robust effect (Capaci & Hepguler, 2002). Further, amitriptyline was beneficial for fatigue, while paroxetine did not improve this symptom. Taken together, SSRIs appear to be effective for treating certain fibromyalgia symptoms, particularly mood. However, overall their effect sizes on pain, sleep, and fatigue appear to be less robust in comparison with amitriptyline and, perhaps, other TCAs. It is possible that SSRIs that are less-selective serotonin inhibitors, and that have noradrenergic effects especially at higher doses (e.g., sertraline, fluoxetine) may be the best drugs in this class to use to treat the cardinal symptoms of fibromyalgia.

Dual Reuptake Inhibitors

Dual reuptake inhibitors (DRIs) are pharmacologically similar to some TCAs in their ability to inhibit the reuptake of both 5-HT and NE, a feature that may improve their analgesic efficacy (Rao, 2002b). Importantly, DRIs differ from TCAs in being generally devoid of significant activity at other receptor systems, and this selectivity results in diminished side effects and enhanced tolerability (Rao, 2002b). Venlafaxine is the only DRI currently available within the United States, and its current labeled indications are depression and anxiety. Data support its use in the management of neuropathic pain (Mattia et al., 2002) and retrospective trial data demonstrate that this compound is effective in the prophylaxis of migraine and tension headaches as well (Adelman et al., 2000). An open-label study suggested venlafaxine is useful in treating multiple symptoms of fibromyalgia (Dwight et al., 1998). However, these results were not replicated by a more recent randomized, placebo-controlled trial (Zijlstra et al., 2002). One significant difference between these two trials was drug dosage: the study by Dwight et al. pushed each patient to the maximally tolerated dose or 375 mg/day (mean 167 mg/day), while the study by Zijlstra et al. had a single drug arm with a dose of 75 mg/day. Like some SSRIs, data suggest that venlafaxine is primarily a 5-HT reuptake inhibitor at lower doses (i.e., <150 mg), with NE effects apparent only at higher doses (Harvey et al., 2000; Roseboom & Kalin, 2000).

Milnacipran is a DRI that is currently available in parts of Europe and in Japan for the treatment of depression. Milnacipran is unique among clinically available DRIs in its preferential blockade of NE reuptake over that of 5-HT; in addition, this compound is a low-affinity N-methyl-D-aspartate (NMDA) antagonist (Rao, 2002a). Milnacipran is now in clinical development for fibromyalgia in the United States, and the results of a Phase II clinical trial were recently announced (Gendreau, 2002). In a double-blind, placebo-controlled, randomized study, treatment with milnacipran resulted in statistically significantly improvements in the pain, sleep, fatigue, and mood of patients with fibromyalgia.

Duloxetine, another dual reuptake inhibitor, has been recently shown to improve multiple symptoms in fibromyalgia (Arnold et al., 2004). In a randomized, double-blind placebo-controlled trial, duloxetine showed significant improvement over placebo for fibromyalgia pain; however, this effect was seen only in the female subjects. The presence of baseline depression did not influence results because participants with and without current major depressive disorder responded well to duloxetine. Duloxetine is a more potent blocker of 5-HT and NE reuptake transporters than venlafaxine.

Antiepileptic Drugs

The majority of the antiepileptic drugs (AEDs) increase the seizure threshold through sodium and/or calcium channel blockade or by increasing inhibitory neurotransmission; this mechanism of action appears to underlie their analgesic activity as well (Kranzler et al., 2002). Indeed, these compounds are widely used in the treatment of various chronic pain conditions, including postherpetic neuralgia and painful diabetic neuropathy (Wiffen et al., 2000). Pregabalin — an AED at present in clinical development — demonstrated efficacy in a Phase II trial against pain, sleep disturbances, and fatigue in patients with fibromyalgia (Crofford et al., 2002). The precise mechanism of action of pregabalin is unknown, although its analgesic activities may result from the agent's ability to block certain calcium channels (Crofford et al., 2002). Neurontin, a compound with similar pharmacology to pregabalin, is specifically indicated for the treatment of postherpetic neuralgia, and studies support its use in the symptomatic treatment of a variety of pain states as well as headache prophylaxis (Redillas & Solomon, 2000; Wiffen et al., 2000).

Nonsteroidal Anti-Inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs; including COX-2-selective agents) and acetaminophen are used by a large number of patients with fibromyalgia (Wolfe et al., 1997b). However, numerous studies have failed to confirm their effectiveness as analgesics in fibromyalgia, although there is limited evidence that patients may experience enhanced analgesia when treated with combinations of NSAIDs and other agents (Lautenschlager, 2000). This phenomenon may be a result of the fact that concurrent "peripheral" pain (i.e., due to damage or inflammation of tissues, e.g., osteoarthritis, rheumatoid arthritis) conditions may be present, or that these comorbid peripheral pain generators might lead to worsening of "central" pain or both.

Nonpharmacological Treatment Strategies

Many feel that "multimodal" treatment programs that combine symptom-based pharmacologic therapy with extensive use of nonpharmacologic therapies are the most effective in this illness. The two best-studied nonpharmacological therapies are cognitive behavioral therapy (CBT) and exercise. Both of these therapies have been shown to be efficacious in the treatment of fibromyalgia, as well as a plethora of other medical conditions (Clauw & Chrousos, 1997; Janal, 1996; Keefe et al., 1986; Mannerkorpi et al., 2000; Minor et al., 1989; NIH, 1996; Park et al., 2001; White & Nielson, 1995; Williams et al., 2000).

Extensive excellent reviews of these topics are referenced for specific guidelines (Mannerkorpi & Iversen, 2003; Williams, 2003). Both of these treatments can lead to sustained (i.e., greater than 1 year) improvements and are very effective when an individual complies with therapy. The challenge for new studies examining these treatments is to improve long-term adherence and compliance, and to move toward using modalities (e.g., the Internet, telemedicine) that will allow a larger number of patients access to these therapies. Also new studies need to address the optimal manner to combine pharmacologic and nonpharmacologic therapies.

There are some general recommendations that can be made based on anecdotal experience. When practitioners first encounter a patient with fibromyalgia or a related condition, they should attempt to determine "where" the individual is in this spectrum of illness. At one end of the continuum is an individual with mild or moderate symptoms and no identifiable functional limitation, concurrent distress, etc. This individual may be completely content with an explanation regarding the benign nature of his/her complaints (i.e., this is not a progressive or destructive process) and encouragement to exercise more, sleep better, etc. On the other hand, this individual may instead wish to take a medication to reduce the symptoms, and then the best initial choice would be a low dose of tricyclic compound because of the global effects on pain, sleep, and other symptoms associated with this class of drugs. If the individual fails to respond to a TCA, then any number of other medications described would be reasonable alternatives, using classes of drugs that make the most sense given the cardinal symptoms the patient displays. This less symptomatic and less impaired group may also benefit from a self-directed aerobic exercise program, or "diluted" CBT, as is offered by the Arthritis Foundation self-help courses.

The other end of the continuum is an individual with significant comorbid psychiatric illnesses, significant functional disability, very high levels of distress, etc. Management of these individuals frequently requires a multidisciplinary approach. Again, it may be useful first to attempt to reduce symptoms with pharmacological therapy, but these individuals may require many psychoactive drugs to manage symptoms, depression, anxiety, etc. When exercise and/or CBT is added, it may need to be more intensive, requiring individualized therapists.

COGNITIVE BEHAVIORAL THERAPY

CBT refers to a structured education program that focuses on teaching individuals skills that they can use to improve their illness. CBT has been shown to be effective in improving patient outcomes in nearly every chronic medical illness, including fibromyalgia, and needs to be tailored to the specific condition being treated (Godfrey, 1996). The skills most commonly associated with CBT for pain include relaxation training, activity pacing, pleasant activity scheduling, visual imagery techniques, distraction strategies, focal point and visual distraction, cognitive restructuring, problem solving, and goal setting. A goal of CBT is to allow patients to gain more control of their illness, and to give them the tools to accomplish this.

AEROBIC EXERCISE

Aerobic exercise has likewise been demonstrated to be effective at improving outcomes for a wide range of conditions including fibromyalgia (Minor et al., 1989). The reason for the benefit is likely multifactorial: aerobic exercise has an analgesic as well as antidepressant effect and can enhance the sense of well-being and control.

In designing an aerobic exercise program, it appears that careful planning is required to enhance tolerability and to ensure long-term compliance. Especially in illnesses such as fibromyalgia, patients may experience a worsening of symptoms immediately after exercise and thus fear that any form of exercise will exacerbate their condition. To reduce the pain associated with exercise, low-impact exercises such as aquatic exercise, walking, swimming, or stationary cycling are recommended. Just as with medication, a "start low, go slow" approach appears to be most effective, with a gradual progression in exercise intensity and a focus on adherence to a lifelong program of paramount importance.

COMPLEMENTARY THERAPIES

There are several different types of complementary therapies that are used by physicians and patients to treat fibromyalgia. Some of these are physical modalities such as trigger point injections, myofascial release therapy (or other "hands on" techniques), acupuncture, and chiropractic manipulation, each of which has some data supporting efficacy (for review, see Berman et al., 1999; Harris & Clauw, 2002).

An early randomized clinical trial testing electroacupuncture in fibromyalgia found significant improvement over sham therapy; however, blinding was not assessed (Deluze et al., 1992). Because electroacupuncture can be felt by the patient, blinding may have been compromised in this trial. Two more recent acupuncture trials that were better blinded both failed to show superiority of acupuncture over control conditions (Harris et al., 2003; D. Buchwald, personal communication). However, in both trials, the control interventions produced a significant reduction in pain (approximately one third of participants having a 2 cm or 30% reduction in a pain on a 10 cm visual analogue scale), suggesting that the control treatments were not inert.

Others alternative therapies fall under the general category of "cure *du jour*": nutritional supplements, diets, devices, etc., that are frequently advertised over the Internet, usually accompanied by testimonials to their efficacy. Because there are very few controlled trials to guide the practitioner in how to grapple with these treatment modalities, a general approach is suggested. The practitioner should first evaluate the safety of the proposed treatment and point out to the patient any potential harmful effects. The physician should then consider whether this treatment is reinforcing a maladaptive belief that in the long run will be harmful to the patient (e.g., a treatment program of prolonged bed rest or of isolation). If the treatment is neither harmful nor maladaptive, then the practitioner may suggest that patients conduct the equivalent of a clinical trial on themselves (as is done in "*n* of 1" trials). In this setting, the patient begins a single treatment (keeping all other variables constant) and determines if the treatment is beneficial. If the patient judges the treatment to be helpful, then the treatment should be discontinued to determine if the symptoms worsen. If the treatment withstands this test of efficacy, a placebo effect cannot be excluded, but in clinical practice, especially in an enigmatic condition such as fibromyalgia, it is difficult to argue with success.

CONCLUSION

Fibromyalgia is a complex disease of unknown etiology with multiple symptoms that overlap with other illnesses. In addition the population of patients is heterogeneous, and a single effective treatment for all symptoms does not exist at this time. We suggest a multipronged approach to treatment that takes into consideration where the patient is in the continuum of pain and psychological comorbidity. An effective treatment may include both pharmacologic and nonpharmacologic therapies.

Complex Regional Pain Syndrome, Types I and II

Nelson H. Hendler, MD, MS

INTRODUCTION

Complex regional pain syndrome, type I (CRPS I) (formerly known as reflex sympathetic dystrophy, RSD) and complex regional pain syndrome, type II (CRPS II) (formerly known as causalgia) are symptom complexes that evoke a great deal of confusion. Very often, physicians do not recognize that these are separate and distinct entities, and commonly assume that they are disorders of the same etiology, as well as responsive to the same treatment. Clinically, this has not proven accurate. CRPS I is a group of symptoms and clinical signs that usually follows a minor injury to a limb. In contradistinction, CRPS II is usually associated with peripheral nerve injury, classically from a bullet wound or some other partial nerve damage. Throughout this chapter, for the sake of consistency, earlier references that used the terms of RSD are referenced or quoted as CRPS I, despite the original nomenclature. This same approach is used for references using the term causalgia, which are changed, for the sake of continuity, to CRPS II. In a very fine review article, Payne (1986) clearly defined the distinction between CRPS I and CRPS II, although at the time he called them RSD and causalgia, respectively. This has been further expanded by the International Association for the Study of Pain in a supplement edited by Merskey (1986; Table 36.1). A further expansion of this comparison is offered by Baron, Blumberg, and Janig (1996; Table 36.2).

CLINICAL SIGNS AND SYMPTOMS

Clinically, one can make the distinction between the two disorders on the basis of signs and symptoms. This is a more important set of criteria than results of laboratory tests or response to treatment because test results for this disorder are highly variable and the accuracy of diagnosis of this disorder is low. If a disorder is misdiagnosed, then how can a physician rely on the response to treatment as a way of establishing a diagnosis? However, sometimes physicians establish a diagnosis based on a response to treatment. This circular logic predicts that all disorders respond equally well to a given treatment, and those that do not are the fault of the patient. This ego-protective trap is a convenient one into which an unsuspecting physician might easily fall. However, there is valuable information that can be derived from a patient's response to treatment, from both a retrospective and a prospective research position. Obviously, the variables in clinical research are legion and include the variable responses patients have to a single pathological etiology, the similar manifestations patients have to diseases of multiple etiologies, the variability of accurate diagnosis, the variability of the skill of the physician performing a procedure, and the variable response to a single, well-performed procedure. Five variables have already been mentioned, giving rise to a 5-factorial variable, or 120 possible combinations of factors. Therefore, in analyzing the results of clinical research in humans, one has to be very circumspect. As Sir William Osler (Osler

TABLE 36.1
Comparison between CRPS Type I and Type II

Complex Regional Pain Syndrome, Type II (Causalgia)

Definition	Burning pain, allodynia, and hyperpathia, usually in the hand or foot, after a partial injury to a nerve or one of its major branches
Site	In the region of the limb innervated by the damaged nerve, not around the entire limb
Main features	Onset usually immediately after partial nerve injury or may be delayed for months; CRPS II of the radial nerve very rare; the nerves most commonly involved are the median, the sciatic, and tibial, and the ulnar; spontaneous pain; pain described as constant, burning, exacerbated by light touch, stress, temperature change or movement of involved limb, visual and auditory stimuli (e.g., a sudden sound or bright light, emotional disturbances)
Associated symptoms	Atrophy of skin appendages, secondary atrophic changes in bones, joints, and muscles
	Cool, reddish, clammy skin with excessive sweating; sensory and motor loss in structure innervated by damaged portion of nerve
Signs	Cool, reddish, clammy, sweaty skin with atrophy of skin appendages and deep structures in painful area
Laboratory findings	Galvanic skin; responses and plethysmography revealing signs of sympathetic nervous system hyperactivity, roentgenograms possibly showing atrophy of bone
Usual course	If untreated, the majority of patients having symptoms that persist indefinitely; spontaneous remission occurring
Relief	In early stages of CRPS II (first few months), sympathetic blockade plus vigorous physical therapy usually providing transient relief; repeated blocks usually leading to long-term relief; when a series of sympathetic blocks not providing long-term relief, sympathectomy indicated; long-term persistence of symptoms reducing the likelihood of successful therapy
Social and physical disabilities	Disuse atrophy of involved limb; complete disruption of normal daily activities by severe pain; risk of suicide, drug abuse if untreated
Pathology	Partial injury to major peripheral nerve; actual cause of pain unknown; peripheral central and sympathetic mechanisms involved in an unexplained way
Essential features	Burning pain and cutaneous hypersensitivity with signs of sympathetic hyperactivity in portion of limb innervated by partially injured nerve

Complex Regional Pain Syndrome, Type I (Reflex Sympathetic Dystrophy)

Definition	Continuous pain in a portion of an extremity after trauma that may include fracture but does not involve a major nerve, associated with sympathetic hyperactivity
Site	Usually the distal extremity adjacent to a traumatized area; all around the limb
System	Peripheral nervous system; possibly the central nervous system
Main features	The pain follows trauma (usually mild), not associated with significant nerve injury; the pain described as burning, continuous, exacerbated by movement, cutaneous stimulation, or stress; onset usually weeks after injury
Associated symptoms	Initially vasodilatation with increasing temperature, hyperhidrosis, edema, and reduced sympathetic activity also occurring; atrophy of skin, vasoconstriction, and appendages; cool, red, clammy skin variably present; disuse atrophy of deep structures possibly progressing to Sudeck's atrophy of bone; aggravated by use of body part, relieved by immobilization; sometimes follows a herniated intervertebral disc, spinal anesthesia, poliomyelitis, severe iliofemoral thrombosis, or cardiac infarction; may appear as the shoulder–hand syndrome; later vasospastic symptoms becoming prominent with persistent coldness of the affected extremity, pallor or cyanosis, Raynaud's phenomenon, atrophy of the skin and nails, and loss of hair, atrophy of soft tissues and stiffness of joints; without therapy these symptoms possibly persisting; not necessary for one patient to exhibit all symptoms together; an additional limb or limbs possibly affected as well
Signs	Variable; may be florid sympathetic hyperactivity
Laboratory findings	In advanced cases, radiographs possibly showing atrophy of bone, and bone scan changes over time
Usual course	Persists indefinitely if untreated; small incidence of spontaneous remission
Relief	Sympathetic block and physical therapy; sympathectomy if long-term results not achieved with repeated blocks; may respond in early phases to high doses of corticosteroids (e.g., prednisone, 50 mg daily)
Complications	Disuse atrophy of involved limb; risk of suicide and drug abuse if untreated; sometimes spreads to contralateral limb
Social and physical disabilities	Depression, inability to perform daily activities

TABLE 36.1 (Continued)
Comparison between CRPS Type I and Type II

	CRPS I	CRPS II
Pathology	Unknown	Partial nerve lesion
Essential features	Burning pain in distal extremity usually after minor injury without nerve damage	Nerve damage
Differential diagnosis	Unrecognized local pathology (fracture, strain, sprain)	Post-traumatic vasospasm, nerve entrapment syndromes radiculopathies, or thrombosis

TABLE 36.2
Criteria for Differential Diagnosis of CRPS Types I and II

	CRPS I	CRPS II
Etiology	Any kind of lesion	Partial nerve lesion
Localization	Distal part of extremity, or entire limb; independent from site of lesion	Any peripheral site of body; mostly confined to territory of affected nerve
Spreading of symptoms	Obligatory	Rare
Spontaneous pain	Common, mostly deep and superficial orthostatic component	Obligatory, predominately superficial, no orthostatic component
Mechanical allodynia	Most of patients with spreading tendency	Obligatory in nerve territory
Autonomic symptoms	Distally generalized with spreading tendency	Related to nerve lesion
Motor symptoms	Distally generalized	Related to nerve lesion
Sensory symptoms	Distally generalized	Related to nerve lesion

Note: From "Classification of Chronic Pain," edited by H. Merskey and the Subcommittee on Taxonomy, 1986, *Pain*, *3*(Suppl), pp. 28–29. Reprinted with permission.

& Churchman, 1907) said about syphilis, "it is almost impossible to describe its clinical symptoms without mentioning almost every symptom of every disease known." The same may be said for CRPS I and CRPS II.

COMPLEX REGIONAL PAIN SYNDROME TYPE I (REFLEX SYMPATHETIC DYSTROPHY)

Following the distinction drawn by Payne (1986), one considers CRPS I as the result of minor trauma; inflammation following surgery, infection, or lacerations resulting in some degree of swelling in the affected limb; infarctions; degenerative joint disease; frostbite; and burns. One should add to this list the possibility of any compression, such as casting or swelling due to injury that may cause prolonged pressure on peripheral nerves. As an example of this, we have seen at least two or three cases per year of CRPS I brought about from arthroscopy. The probable etiology is not injury to the nerve from the use of the arthroscope, but instead from using the tourniquet for a long period of time to create a bloodless operating field. Hendler (2002) has emphasized the need for more refined differential diagnosis between nerve entrapments and CRPS I. This distinction is critical, since proper diagnosis is essential for proper treatment, and is based on the distribution of the pain, which follows nerve pathways for nerve entrapments, and is circumferential for CRPS I (Hendler, 2002).

According to Schwartzman and McKellan (1987), there seem to be three phases to CRPS I. Importantly, these stages are not temporal in their definition, but rather describe a progression of pathology. Additionally, physicians should recognize that CRPS I is a symptom complex that is a cluster of symptoms and signs, and that patients do not present with all signs and symptoms during the course of their disease. In fact, very often they may have only one or two of the signs and symptoms of the disorder.

As described by Payne (1986) and by Schwartzman and McKellan (1987), the acute stage of CRPS I is characterized by spontaneous pain, usually aching or burning, that follows the distribution of blood vessels or peripheral nerves. The acute stage may manifest as "hyperpathia" (this is described as a painful syndrome of overreaction to a stimulus or after-sensation following a stimulus) and may include hypesthesia or hyperesthesia (described as a decreased or an increased sensation to pain stimulation, respectively), or dysesthesia (described as an unpleasant abnormal sensation). Associated with these tactile sensations are usually warm, dry, red skin or cold, blue, sweaty skin, with some swelling and, surprisingly, increased hair

and nail growth. A number of authors have interjected the notion of allodynia, or a painful response to a normally nonpainful stimulus (Chaplan et al., 1994; Kim & Chung, 1995; Lee et al., 1994). Additionally, the patient has dependent redness and reduced motion in the damaged extremity. This summarizes the acute stage of this disorder, which may last several weeks and may begin immediately or several days after the onset of the injury. However, it is possible for CRPS I to remain in this stage, and never progress to stage II or stage III. This is a highly individualized response.

The second stage of CRPS I (which may begin about 3 to 6 months after the injury, or may occur within weeks or may never occur) is called the dystrophic stage by Payne (1986). During this stage, the patient experiences a burning type of pain, which radiates either above or below the site of the injury, and increased hypersensitivity or hyperalgesia (an exquisite sensitivity to touch or temperature — in counterdistinction to allodynia, a painful response to a normally nonpainful stimulus, a most important distinction that is discussed later in the chapter). The patient has changes in the nails on occasion, as well as decreased hair growth. This seems to be a variable finding and certainly is not a *sine qua non* of the diagnosis of CRPS I. Joints may become stiff, with decreased range of motion and possible thickening, associated with some degree of muscle wasting. Edema may be present, as well as bullous skin lesions that are not related to an autoimmune disease (Baron et al., 1996). Osteoporosis may be noted, with proper testing (Payne, 1986). Movement disorders may begin at this stage, with either dystonias or contractures noted (Schwartzman and Kerrigan, 1990; Webster et al., 1991). Symptoms may vary and fluctuate from individual to individual.

The third stage described by Payne is the atrophic stage, which usually occurs 6 months or longer after the injury. According to Payne, the patient experiences pain, decreased skin temperature, trophic changes in the skin associated with a smooth glossy skin, stiff fixed joints associated with contractures, increased or decreased sweating in the affected extremity, and demineralization of the bone associated with wasted muscles and reduced strength (Payne, 1986). Again, the progression to this stage is highly variable and may progress, in a rapidly fulminating case, in less than 2 to 3 months. As always in medicine, there are only guidelines, but no hard and fast rules. (A summary of many of the clinical symptoms is shown in Table 36.3.)

COMPLEX REGIONAL PAIN SYNDROME, TYPE II (CAUSALGIA)

CRPS II is usually associated with peripheral nerve injury and severe pain. According to Payne (1986), pain occurring in CRPS II follows an injury to a nerve trunk, usually a major proximal nerve branch, and is described as a persistent burning pain, but it does not necessarily have to be burning in quality. It is unrelated to associated damage from surrounding tissue and seems to be worsened by emotional or environmental stimuli. Most importantly, the pain seems to persist more than 5 to 6 weeks, which seems to be the length of time needed for surrounding tissue to recover from injury. Typically, the injury is due to damage by a bullet, a knife, sharpened rocks or parts propelled by a machine, or other such objects. When the injury is associated with a high-velocity missile, one must consider not only actual damage to the tissue itself, but also hydrostatic effects caused by shock waves. When one takes into account the fact that the body is made up largely of water, it is easy to see how a high-velocity missile can cause damage not only to the actual tissue that has been penetrated, but also to surrounding tissue as a result of hydrostatically transmitted shock waves. If the reader desires additional information concerning the hydrostatic effects of high-velocity missiles, he or she is referred to a most amazing book entitled *Split Seconds* (Dalton, 1984). Photographs in the book clearly illustrate the hydraulic effect in soft tissue caused by a bullet.

Typically, patients with CRPS II report an onset of pain within several hours to a week after the injury and describe the pain using words such as stinging, aching, burning, or tingling. Patients may experience paroxysms of deep pain (Payne, 1986) superimposed on the regular pain. Long (1982) clearly makes the distinction between CRPS II and CRPS I. CRPS II is secondary to partial injury to major mixed nerves, caused by low- or high-velocity missiles, and manifests as trophic changes in the distribution of the nerve associated with extreme hypersensitivity. The pain is diffuse and burning, and true CRPS II may respond to sympathectomy. However, Payne reports a surgical meta-analysis in which the response to sympathectomy was 12 to 97%. Long suggests performing three or more sympathetic blocks, sometimes every day for up to a week or longer, with the expectation that longer relief should follow each subsequent block. With positive responses to sympathetic blocks, Long would suggest a sympathectomy for CRPS II. On the other hand, CRPS I usually follows a minor injury and does not involve a major nerve root. Frequently, the site of injury for CRPS I is the knee, ankles, or wrist; and the pain seems to get worse with cold but not with emotional upset, unlike CRPS II. Demineralization of the bone occurs more often with CRPS I, with fibrosis of tendons and sheaths and spasm of the muscle. Dysesthesia suggests that there will be less success with sympathectomy.

TABLE 36.3
Clinical Symptoms Associated with CRPS II and CRPS I

Clinical Symptoms	Mechanism	Diagnostic Studies	Treatment
CRPS II			
Burning pain[a,b]	Unmyelinated C-fibers[c]	Rarely have cold hyperalgesia (2/7) or heat hyperalgesia (0/9);[b] do have mechanical hypersensitivity;[b] use a drop of acetone and Von Frey hairs to test	Phenoxybenzamine DREZ[a] sympathectomy 12% to 97% effective, clonazepam,[e] gabapentin[f]
Paroxysms of pain[a]	Nerve stretch and axon disruption[a]	Clinical reports	None
Partial motor paralysis (70%)[d]	Peripheral nerve injury proximal nerve trunk[a,b]	EMG/nerve conduction velocity studies	No relief with sympathetic blocks;[b] no success proximal nerve trunk[a,b] with beta-blockers[d]
Worse with stress[a]	Lots of theory, no proof	Clinical reports	Clonidine
Vasomotor changes, but rare trophic change[d]	Unknown	Clinical observation	Sympathetic blocks
CRPS I			
Hyperalgesia and Allodynia			
Mechanical-hypersensitivity to light touch	Ectopic alpha-adrenergic chemosensitivity;[g] sensitization of WDR neurons in the spinal cord;[i] central nervous system mediated;[k] intact low-threshold mechanoreceptor with A-delta afferents[c]	All patients have mechanical hypersensitivity; use Von Frey hairs to test[b]	Sympathectomy possibly relieving it;[c] sympathectomy not relieving it;[j] low-dose naltrexone possibly working[l] nifedipine?[m] gabapentin?[f]
Thermal-hypersensitivity	No mechanism delineated	Patients having cold either heat or cold,[b,c,k] hyperalgesia (3/4), and/or heat hyperalgesia (4/5); use a drop of acetone to test[b]	6/6 receiving relief with sympathetic blocks or sympathectomy,[b] nifedipine?
Dystrophy Phase			
Osteoporosis[n]	No mechanism delineated	X-ray did not correlate well with clinical symptoms, but bone scan did[r] (abnormal flow images, 83% abnormal static images)[r] (also true for clinical features c. and e.);[a] if clinically had CRPS I, 22/23 had positive delay image bone scan[s]	Maybe calcitonin[n,o,p]
Diffuse or patchy, bony,[n,o,p] demineralization[r]	No mechanism delineated	X-ray and bone scan[s]	Calcitonin[n,o,p,r]
Molted skin[a,b,r]	No mechanism delineated	Themography[t,u]	Prednisone 60 to 80 mg, tapering[r]
Hair loss[b,n]	No mechanism delineated	Clinical observation[r]	Steroids[n,r]
Vasomotor instability[r]	No mechanism delineated	History or longitudinal observation[r]	Sympathetic blocks,[n] steroids[r]
Nail brittleness[a,n]	No mechanism delineated	Clinical observation	Sympathetic blocks,[n] steroids[r]
Muscle spasm[n,v,w]	No mechanism delineated	EMG biofeedback used as test[u]	Trigger point injections[a] baclofen[l]
Contractures[a,n]	May be attributed to disuse, may be central dystonia[x]	Longitudinal observation[n]	Physical therapy,[n] sympathectomy
Contralateral involvement[n,w]	Cross-communication between sympathetic chain in 80% of cadavers[w]	Effective contralateral block[w]	Contralateral sympathectomy[w]
Edema[a,n]	No mechanism delineated[y]	History and clinical observation	Nifedipine,[m] spironolactone, acetazolamide, epidural, spinal cord stimulation[aa]

TABLE 36.3 (Continued)
Clinical Symptoms Associated with CRPS II and CRPS I

Clinical Symptoms	Mechanism	Diagnostic Studies	Treatment
Lower skin temperature[u]	No vasospasm, but may be an afferent and efferent reflex arc[bb]	Thermography[t,u]	Phentolamine;[a,b,t,u] Bier block with reserpine,[bb] guanethidine i.v.,[n] sympathetic blocks[b,n]
Joint stiffness[a,s] and tenderness[r]	No mechanism delineated	Proximal interphalangeal joint 12.9 mm greater (average)[n] affected hand; negative rheumatoid and connective tissue blood studies[r]	Maybe calcitonin[p]
Pathological fractures	May be related to osteoporosis or patchy demineralization	72 hours after a break 95% of bone scans are positive[cc]	Maybe calcitonin,[n,o] maybe Fosamax
Pins and needles[u] and dysesthesias[a]	No mechanism delineated	History	Sympathectomy[u]
Skin lesions[q,y,z,dd]	Disruption of basement membrane and destruction of collagenous anchoring fibrils,[y] circulating immune complexes[q]	Observation and electron microscopy[y]	Prednisone not working,[y] maybe tetracycline[y]
Dystonias,[z] myoclonus[z]	Spinal cord mediated?	Observation	Epidural bupivicaine, epidural baclofen, epidural clonidine, sympathetic blocks[ee]

SYMPATHETICALLY MAINTAINED PAIN

The term sympathetically maintained pain (SMP) has come into use in an effort to further define diagnostic accuracy, which would then allow better selection of treatment methods and have some predictive value in terms of outcome. Raja and Hendler (1990) report clinical features of sympathetically maintained pain to be (1) spontaneous pain, (2) hyperalgesia to both mechanical and cooling stimuli, (3) soft tissue swelling, (4) vasomotor disturbances, (5) trophic skin changes, (6) diminished motor function, and (7) pain relief after sympathetic blockade. By using these criteria, one can have SMP that could have features of either CRPS I or CRPS II because either of these conditions could have features of SMP.

Hendler (1982) originally described the use of oral phentolamine to treat CRPS I using the rationale that this drug was a postsynaptic alpha-1-blocker. Raja and his co-workers (1991) later described the use of intravenous phentolamine as a diagnostic test to confirm whether the pain a patient had was sympathetic in origin, that is, "sympathetically maintained." There is evidence that the mechanism of SMP is present not only in CRPS I, but also in some cases of CRPS II. However, various authors have reported the benefit of sympathetic blocks and sympathetcomies in both disorders (Bosco Vieira Durate et al., 2003a; 2003b; Ghostine et al., 1984; Hannington-Kiff, 1979; Long, 1982). Perhaps the best conceptual framework to use is one that takes into account both neurophysiology (i.e., the presence or absence of major peripheral nerve injury documented by electromyography, EMG; nerve conduction velocities studies, NCV; and the somatosensory-evoked potential, SSEP) and response to pharmacological intervention (i.e., response to I.V. phentolamine testing or sympathetic blocks). A physician might consider six separate types of disorders, as shown in Table 36.4.

USING THE CLINICAL HISTORY AND SENSORY EXAMINATION FOR DIFFERENTIAL DIAGNOSIS

A number of authors have advanced the notion that there are other types of sensory mechanism, other than hyper-

TABLE 36.4
Diagnostic Considerations

Response to I.V.	Positive Response to Phentolamine I.V.	No Response to Phentolamine I.V.	Partial Response to Phentolamine I.V.
EMG/nerve conduction velocity/somatosensory-evoked potential: all negative	CRPS I SMP	Microvascular damage with swelling and mechanical hyperalgesia; sympathetically independent pain (SIP)	Mixed injury
EMG/nerve conduction velocity/somatosensory-evoked potential: at least one positive	CRPS II	Neuroma or nerve entrapment at site of injury; SIP	Mixed injury
Positive response to alcohol drop test	CRPS I, SMP	Too low a dose phentolamine	Too low a dose phentolamine
Positive response nerve to a local nerve block (radial, ulnar, median, peroneal, saphenous, tibial) with 100% relief of all symptoms	Nerve entrapment syndrome with sympathetic component	Nerve entrapment syndrome without any sympathetic component	Nerve entrapment syndrome with sympathetic component
Positive response to sympathetic block, or a warm limb and 100% relief of all symptoms	CRPS I, SMP	Too low a dose of phentolamine; too slow an infusion	Too low a dose of phentolamine; too slow an infusion
Partial relief of pain with local nerve block	Mixed injury	Poor nerve block	Mixed injury

algesia evident in CRPS I and II (Chaplan et al., 1994; Kim and Chung, 1995; Lee et al., 1994; Lee & Yaksh, 1996). Unfortunately, the vast majority of the research reports are in animal models, using animals fairly low on the philogenetic scale. There is always a danger in extrapolating from animal models to clinical work in humans because there are species-specific differences, and some of the sensory values assigned to a rat reveal more about the creativity of the researcher than they do about the sensory experience of the rat. However, bearing these caveats in mind, clinicians should be aware of the research observations that may have significant value for their patients. A sensation called allodynia has been described, which is a painful response to a normally nonpainful stimulus. It is important to make a distinction between this sensation and hyperalgesia, which is a more intense response to a normally painful stimulus. This distinction bears reemphasis, for this is the most commonly confused terminology in the hands of inexperienced clinicians. Clinically, hyperalgesia is seen in the early phases of nerve entrapments and radiculopathies. In counterdistinction, allodynia is seen in CRPS I and II.

Also, it is important to distinguish among cold hyperalgesia, heat hyperalgesia, and mechanical hyperalgesia. Both cold and heat hyperalgesia are rarely seen in CRPS II (Meyer et al., 1985; Raja et al., 1986). Moreover, it is important to make a distinction between cold allodynia and mechanical allodynia. Cold (thermal) allodynia is most often seen in CRPS I and II, whereas mechanical allodynia is seen commonly in CRPS I and II, nerve entrapment syndromes, and radiculopathies (Hendler & Raja, 1994). This clinical distinction has led to the use of the Hendler alcohol drop and swipe test to make a distinction between CRPS I and II, with cold allodynia (which has a painful response to alcohol dropped on an affected limb); and CRPS I and II, nerve entrapment syndromes, and radiculopathies, with mechanical allodynia, demonstrated by lightly stroking the affected limb with the used alcohol swab (Hendler, 1995). Concisely stated, mechanical allodynia is of less use diagnostically because it may be present in CRPS I and II, nerve entrapment syndromes, and radiculopathies, whereas thermal allodynia is a more useful clinical feature, usually being limited mostly to CRPS I and occasionally to CRPS II (Meyer et al., 1985; Raja et al., 1986). Hendler has also reported a third type of allodynia, chemical allodynia, which is seen with the use of the alcohol swab test. The patient may not respond to the cold produced by evaporation of alcohol, but then 2 to 3 minutes later, the patient reports a burning sensation, as the alcohol presumably diffuses through the skin and reaches the unmyelinated C-fibers associated with producing allodynia in CRPS I.

Additionally, a cool limb is not diagnostic of CRPS I and II, despite many reports in the literature to that effect (Hannington-Kiff, 1979; Prough et al., 1985, Wasner et al., 2002). First and foremost, for a clinician to hold an affected limb in one hand and a normal limb in another, and pronounce that the temperatures are either equal or different is a demonstration of arrogance more than clin-

ical skills. The ability to detect temperature differences varies due to the ambient temperature of the clinical setting and the "physiological zero" of the organism sensing the temperature change, which lowers the "threshold of detection for thermal sensation of the opposite quality" (Geldard, 1962, p. 137). In an extensive report by Uematsu et al. (1981) reviewing 803 cases at Johns Hopkins Hospital, the authors found that (as expected) patients with CRPS I and II had cold limbs most of the time, with ranges of 0.5°C to more than 3.0°C coldness being reported for more than 79% of the cases diagnosed with CRPS I. However, in 89% of the cases in which there were abnormal EMG or NCV studies, the affected limb was also cold, although not to the same severity as the patients with CRPS I. These figures included cases of CRPS II, as well as patients with radiculopathies and nerve entrapment syndromes. Wasner and co-workers (2002) used the response of skin temperature to whole-body cooling and warming in a "thermal suit," measured by infrared thermometry, to compare and contrast 25 patients with CRPS I with 20 healthy controls and 15 patients with "painful limbs of other origins." They found that under normal resting conditions, there were "minor skin temperature asymmetries," with 32% sensitivity, which increased to 76% under artificial changes. However, specificity was 100% at rest and 93% under thermal regulation. Therefore, thermography could be made a more useful diagnostic tool by artificially heating or cooling the torso.

The anatomic distribution of the pain is another important feature to consider. Sympathetic fibers travel with the sensory nerves, so an injured sensory nerve may have a component of sympathetic damage reported, such as coldness or hyperalgesia. However, the actual location of the pain is a critical factor. If the pain is in the distribution of a peripheral nerve, even if all the sensations for CRPS I are present, then the clinical syndrome is really a nerve entrapment, with the sympathetic sensory components of it coming from the sympathetic fibers traveling with the sensory nerve. CRPS I has a circumferential pain distribution (i.e., it is all around the limb, in the pattern of the blood flow, not in a discrete nerve distribution or in a radicular distribution). Failure to recognize this distinction has led to the misdiagnosis of a number of nerve entrapment syndromes, which are mistakenly called CPRS I (Hendler & Kozikowski, 1993; Hendler, Bergson, & Morrison, 1996). Hendler (2002) reported that 71% of the patients sent to Mensana Clinic with the diagnosis of CRPS I had just nerve entrapments, proven by EMG/NCV studies, and total temporary relief to peripheral nerve blocks. Additionally, 10 of 38 (26%) had a combination of CRPS I and nerve entrapments. This means that 37 of all 38 patients in the study actually had unrecognized, and therefore undiagnosed, nerve entrapment syndromes. Only 1 patient of 38 had pure CRPS I.

TREATMENTS

Appropriate treatments for CRPS I and II have been described in the Consensus Report, sponsored by the International Association for the Study of Pain (IASP) (Stanton-Hicks et al., 1998). In this report, the participants emphasized the need for functional restoration and psychological counseling, as well as medical intervention. Not only is there disuse as the result of a painful limb, creating multiple disabilities and atrophy, but there is also evidence that once the disorder of CRPS I spreads, there may be a centrally mediated muscle disorder, resembling dystonia (Schwartzman & Kerrigan, 1990). Therefore, the problem of a painful limb in CRPS I and II is compounded by a real motor disorder.

The psychological problems associated with both CRPS I and II have been well described for patients with chronic pain in general. Hendler (1982, 1984) has long reported that patients with both chronic pain and depression really have become depressed as the result of their chronic pain. The earlier psychiatric "wisdom" of feeling that depression manifests as chronic pain has not been supported by more careful observations (Hendler & Talo, 1989). This is a serious problem to overlook. Fishbain et al. (1991) reported that in patients with chronic pain, white males complete suicide at a rate two times higher than general population, white females three times higher, and white males involved in workers' compensation three times higher. Therefore, the use of group therapy seems to be the most efficient and productive way of providing support for patients with all types of chronic pain problems, and certainly is applicable to patients with CRPS I and II (Hendler et al., 1981). Family counseling and patient education is also of great use, when available.

The pharmacological management of CRPS I and II is complicated (Hendler, 2000). The treatments shown in Table 36.3 are meant to deal with the specific symptoms associated with CRPS I and II. However, there is a role for a more generalized pharmacological approach, especially dealing with the issue of depression and pain relief. Antidepressants, in and of themselves, provide relief of many of the symptoms by (1) reducing depression, (2) reducing anxiety, and (3) promoting natural sleep and actually have some limited pain-relieving properties (Max et al., 1991; Watson et al., 1981; 1991). For symptomatic relief in CRPS I and II, narcotics are problematic. A number of authors have reported reduced efficacy, or variable effects, of narcotics in the palliative treatment of pain in patients with CRPS I and II (Arner & Meyerson, 1988; Lee, Chaplan, & Yaksh, 1995; Portenoy, Foley, & Inturrisi, 1990). The variability and usual lack of efficacy of narcotics for CRPS I and II may be explained by recent elegant research, which shows only a kappa-2 opioid agonist blocks the pain of hyperalgesia and allodynia, seen with peripheral neuritis and neuropathy, by inhibiting the

activity of the *N*-methyl-D-aspartate (NMDA) receptor in the spine (Eliav, Herzberg, & Caudle, 1999). Although this research is in animals, with all the attendant problems of translating to human use, this avenue seems to hold a great deal of promise because the formulation of a kappa-2 opioid agonist is a feasible endeavor for major drug companies. However, as of the date of writing this material, there is no practical kappa-2 agonist available for human use; thus, the use of narcotics in CRPS I and II for allodynia and hyperalgesia is of limited usefulness. Opioids may help pain caused by other symptoms of CRPS I and II, such as muscle spasm and pathological fractures. There are even case reports of patients with the associated tremors being treated with carbidopa/levodopa 25/100 mg (Navani et al., 2003). A review of other pharmacological approaches for the management of pain can be found in several chapters by the author (Hendler, 1997, 2000).

Sympathetic blocks have always been the mainstay of diagnosis and treatment. The important feature of these blocks is to be certain of the efficacy of the block before interpreting the result. The clinical criterion that best correlates with an efficacious block is the report of total limb warming. This tells the clinician that the sympathetic block did what it was supposed to do (i.e., blocked the sympathetic input to a limb, thereby producing warming of the limb). At this point, the next question to ask the patient is, "What do you feel?" If the patient has a warm limb and 100% total absolute relief of all pain, then one may consider that the block was (1) effective and (2) appropriate for pain relief. From this, a clinician may conclude that the pain is sympathetic in origin. If, however, the block did not warm the limb, then the clinician must conclude that the block was not effective; and no information of any value can be determined from this type of block, except that another block, at a later date, is needed. If the block produces a warm limb, but only partial relief of the symptoms, then the question is, "Where do you still have pain?" If the remaining pain is reported in a nerve distribution, then the patient has both CRPS I and a nerve entrapment syndrome, which coexist, or a nerve entrapment syndrome with a sympathetic component. If the limb is warm, and the patient has no relief, then the chances are the patient has a pure nerve entrapment syndrome (see Table 36.4).

After a clinician determines a block is effective, then the patient should have a series of 6 to 10 blocks. After this series of blocks, several results are possible: (1) the CRPS I or II may go away; (2) the CRPS I or II may temporarily go away for weeks or months, only to return; or (3) the CRPS I or II may temporarily go away for hours or days following the blocks, only to return. If scenario 1 occurs, the diagnostic blocks have also provided the cure. If scenario 2 or 3 occurs, then the patient is a candidate for sympathectomy. This author favors the surgical sympathectomy because direct visualization of the sympa-

thetic chain and pathology reports on the tissue are more reassuring than blind ablation techniques. Moreover, the author has seen disastrous results in patients, in which phenol was used for a neuroablative procedure. Despite the obvious benefit of direct visualization for sympathectomy, there are still some physicians, mostly anesthesiologists, who continue to use blind chemoablative techniques, with neurolytic agents, such as phenol, or radiofrequency lesions (Stanton-Hicks et al., 1998).

In extreme cases, the use of epidural stimulation has been reported efficacious, although there are only a small number of cases in the literature (Barolat, Schwartzman, & Woo, 1989; Peuschl et al., 1991; Robaina, Dominguez, & Diaz, 1989). The epidural infusion of SNX-111 has been suggested as a possible treatment for CRPS I or II, as has the infusion of baclofen. SNX-111 is a conotoxin that works on specific calcium channels to block the message of pain, whereas baclofen is a gabaminergic muscle relaxer. Epidural opioid infusion has been reported (Broseta, Roldan, & Gonzales-Darder, 1982), but the absence of a kappa-2 agonist may have reduced the potential results (Eliav et al., 1999). Clonidine actually seems more effective than morphine in humans, for deafferentation pain, after spinal cord injury (Hassenbusch, Stanton-Hicks, & Covington, 1995). Other researchers have explained this difference, based on the independence of the opioid and noradrenergic pathways of the spinal cord (Glynn, Dawson, & Sanders, 1988). Opioid receptors exist in only a small group of neurons in the dorsal horn and have various subsets, of which only the kappa-2 subset seems to be effective in reducing the allodynia of CRPS I (Eliav et al., 1999). On the other hand, clonidine has multiple sites of action, such as inhibiting pain transmission in the dorsal horn of the spinal cord and inhibiting norepinephrine release, due to its alpha-2 partial agonist effect, which inhibits the release of norepinephrine.

THEORY

With the clinical descriptions from Table 36.4 in mind, one can make an effort to define the various anatomic, neuroanatomic, and physiological bases for these two disorders. Ghostine and colleagues (1984) have suggested multiple etiologies for CRPS II. Various considerations include ephapse, in which there seems to be an erosion of the insulation between nerve fibers, allowing for short-circuiting between somatic afferent fibers and sympathetic efferent fibers; and experimentally produced neuromas, with resultant ephapses occurring both acutely and chronically between myelinated fibers. Because of the delay in developing the ephapses, which does not correspond to the clinical observations of a relatively rapid onset of CRPS I and II, however, the theory of ephapses as the etiology of CRPS II has fallen from favor. To replace this theory, the concept of nerve sprouts or free nerve endings that are

sparsely myelinated seems feasible. Axonal sprouting has been noted to occur early after an injury, with a high frequency and without total axonal disruption. The possibility that causalgia is produced by these sparsely myelinated fibers is supported by evidence that the blood–nerve barrier, which is similar to the blood–brain barrier, has been destroyed in the injured nerve.

Perhaps the most comprehensive review of the neurophysiological basis of CRPS I and II has been advanced by Roberts (1986). In his extensive review article, Roberts deals with the neural mechanisms associated with pain of CRPS II and I. He calls these disorders SMP. His hypothesis concerning SMP is based on two assumptions: "(1) that a high rate of firing in spinal wide dynamic range (WDR) or multireceptive neurons results in painful sensation and (2) that a nociceptor response is associated with trauma which can produce long-term sensitization of the WDR neurons." Furthermore, his theory postulates that SMP is mediated by low-threshold, myelinated mechanoreceptors and that these impulses, which carry messages to the brain, are the result of sympathetic fibers carrying messages from the spine and brain to act on the receptors or to act on the fibers carrying messages to the brain. The most important part of this hypothesis is the fact that Roberts does not postulate the need for nerve injury or for dystrophic tissue. Before one can more fully appreciate Roberts's theories, however, one has to explore the basic anatomy of the sympathetic chains.

Bennett (1991) at the National Institutes of Health has advanced a brilliant theory that integrates clinical observations with basic neurophysiology. Bennett synthesizes three theories that show that damaged nerves, when they regenerate, have sprouts that are sensitive to norepinephrine; they will discharge on exposure to norepinephrine; there is enough norepinephrine produced by sympathetic fibers to trigger firing of damaged nerves; damaged nerves actually produce norepinephrine receptors at the damaged end; and nociceptors (pain receptors) in intact nerves fire more in response to norepinephrine. "All of these mechanisms may be operating in the case of patient nerve damage due to physical trauma," he says, and "these events are likely to sensitize surviving afferent terminals, perhaps to the point of inducing an ongoing discharge." Bennett further differentiates between the types of injury: constriction or entrapment versus partial destruction of a major peripheral nerve. The former injury (constriction) does not seem to respond to sympathetic blocks 1 to 2 weeks after the injury, and this is attributed to the loss of noradrenergic vasomotor innervation, which takes several weeks to develop. The latter injury (partial nerve destruction) becomes painful within hours of the injury, remains painful for months, and responds to sympathetic blocks even months after the injury.

Other researchers have expanded on a purely neuron-mediated mechanism and have suggested that autoimmune factors may be involved. The Schwartzman group at Thomas Jefferson University School of Medicine in Philadelphia found inflammatory skin lesions in the late stages of CRPS I, and attribute these lesions to a deposition of immune complexes in the skin. They believe the skin lesion supports the concept that cytokines and lymphokines such as interleukin-2 (IL-2) are produced as the result of the activation of complement; this in turn is excited by the progression of events beginning with local injury causing nerve growth factor release, thus activating sympathetic neurons and causing recruitment of neutrophils and monocytes, which in turn activate complement (Webster et al., 1991). Interestingly, IL-2 has been found to selectively stimulate sympathetic neurons, whereas nerve growth factor (NGF) is produced in high concentrations after injury, which stimulates inflammation and in turn activates complement. Knobler (1996) has expanded on this and advances the notion of aberrant immunologic mechanism as a cause for CRPS I. He traces trauma as the cause for the release of NGF, which then stimulates inflammation and activates the complement components of the immune response, "promoting the expansion of antibody-producing B cells of the immune system." He reports that substance P and the lymphokine IL-2 are released in response to NGF, with both of these factors acting on the sympathetic nerve to activate it. As research progresses, the various factors described earlier need to be explored with rigorous controls for (1) the type of lesion (crush vs. cut), (2) the stage of the disease correlating with anatomic and neurohumoral changes over time, and (3) the attempt to correlate the clinical symptoms with response to various treatments.

In a discovery that led to her Nobel prize, Rita Levi-Montalcini describes the effect of NGF on sympathetic nerve (Levi-Montalcini et al., 1996). In response to an injury or lack of innervation, the end organ, i.e., the sensory receptor, releases NGF, which chemotaxically stimulates a nerve to grow toward the newly denervated receptor. This chemotaxic agent was found to be NGF. Clearly, sympathetic ganglions grow profusely in response to the addition of NGF to their growth medium. This is not limited to just sympathetic nerves. Skin and sensory nerves also have sprouted after injury (Inball et al., 1987).

A study by Ro et al. (1999) shows that this process can be reversed in rats by the administration of anti-NGF antibodies. Previous work shows that anti-NGF antibodies prevented collateral sprouting of dorsal root ganglion in rats (Mearow & Kril, 1995). Ro and others (1999) studied the specific sensory response to anti-NGF, which showed that in a dosage- and time-dependent fashion, heat and cold hyperalgesia, as well as collateral sprouting, can be reduced.

Finally, one of the most seminal concepts to emerge from animals studies is the idea of plasticity of the central nervous system (i.e., its ability to change in response to

stimuli). Nowhere is this more important than for the understanding of CRPS I and II. In response to a chronically painful stimulus, the cells of the dorsal horn of the spinal cord actually alter their cytoarchitecture (the structure of the chemistry of the cell). Hyperalgesia and allodynia are largely created by the enhancement of NMDA receptor activity in the spinal cord and treated by blocking the NMDA receptor (Ren & Dubner, 1993). The central role of NMDA receptor activity in the creation of allodynia must be emphasized. Unfortunately, there is not a practical way to modify the NMDA receptor in humans, so the treatment of hyperalgesia and allodynia remains elusive. Therefore, mechanisms other than NMDA inhibition need to be explored.

To briefly summarize the material presented earlier, three sensations are associated with CRPS I and II: (1) pain, which is a sensation usually experienced when tissue damage occurs; (2) hyperalgesia, which is an increased response to a normally painful stimulus; and (3) allodynia, which is a painful response to a normally nonpainful stimulus. This stimulus can be hot, cold, mechanical, or even chemical. The message of pain is initiated at two receptor sites: (1) a nosioceptor, which is usually a free nerve ending, or unmyelinated C-fiber, which detects tissue damage such as temperature or chemical changes and (2) a mechanoreceptor, such as a Pachinian corpusle, which is sensitive to pressure. When tissue is damaged, it produces a primary hyperalgesia, which is a sensitivity to pain, at the site of the pain, and a secondary hyperalgesia surrounding the zone of primary hyperalgesia, in the absence of tissue damage. A sensitized nosioceptor has a lower threshold to pain and produces hyperalgesia, whereas a sensitized mechanoreceptor transmits a message of pain to a normally nonpainful stimulus (i.e., allodynia).

Both hyperalgesia, and allodynia are the result of spinal dorsal horn body sensitization. The afferent fibers carry the sensory message to the brain, and the efferent fibers modify the sensory input from the brain back to the periphery. They have their origins in the brainstem, medulla, and periaquaductal gray and are called descending afferent pathways. These pathways modify sensation. At the spinal cord level, increased sensory input from the peripheral nosioceptor actually changes cell functioning in the spinal cord by altering chemical mediators and receptor activity. The persistent sensory stimuli activate NMDA at certain cells of the dorsal horn of the spinal cord, called WDR neurons or nociceptive specific (NS). Phosphorylation of the NMDA receptor is the result of constant sensory input, which then activates the NMDA receptor, and this creates central sensitization of the receptor ion channel. Mg^{2+} is removed, so Ca^{2+} enters the channel, which causes cell sensitization. This spinal cord change produces allodynia in the peripheral nerves. Therefore, tissue damage produces damage to the nocioceptor in the periphery, causing sensitization or hyperalgesia; and

the result of this chronic increase in activity at the spinal cord level produces central sensitization. Likewise, damage to the nerve causes growth hormone to produce nerve sprouts; these are very sensitive, which cause continued input the spinal cord, producing central sensitization. This increased sensory input, which produces central sensitization, actually changes the cells in the dorsal horn of the spinal cord, which results in allodynia. The damaged nerve produces sprouts, as the result of NGF stimulation. These sprouts have alpha-2 adreno-receptors on them, which are sensitive to norepinephrine circulating in the bloodstream.

GROSS ANATOMY

The most startling finding, and one that flies in the face of commonly held beliefs, is a report by Kleinman (1954) in which sympathetic chains were found to have communication between them, in up to 80% of cases. This was an important finding because this anatomic consideration is rarely, if ever, discussed in surgical textbooks or clinical papers. This finding also explains why some cases of CRPS I do not respond to sympathetic denervation, and why, paradoxical as it may seem, some cases do respond to contralateral blocks (i.e., if a patient has pain in the left leg, blocking the right lumbar sympathetic chain may produce relief).

Additional anatomy has been described by Allen and Morety (1982). When one traces the pathway of the sympathetic nerves, cell bodies are located in the lateral columns of the cervical, thoracic, and lumbar spinal cord. Cell bodies then give off axons, which form the preganglionic fibers of the sympathetic nervous system. From C7 to L2, these fibers are associated with the anterior spinal nerve roots and leave the spinal cord in this pathway. They then separate from the nerve root and become the white rami communicantes, which then continue on to the paravertebral ganglia, forming a chain running from the skull to the coccyx. From the ganglia themselves postganglionic fibers run back to nerve roots, or become separate nerves supplying various organs.

It is important to note that some ganglion cells are found in the anterior roots, as well as the white and gray rami. By the same token, some pre- and post-ganglionic fibers do not pass through sympathetic trunks, which again indicates that there is residual sympathetic innervation due to either normal variants or aberrant fibers that bypass the sympathetic trunk. This anatomic finding explains the failure of some ganglionectomies and suggests that one might need to do anterior nerve root sections and preganglionic rami sectioning (Smithwick procedure) in patients in whom ganglionectomy has failed.

Cervical outflow, coming from the upper portion of the cervical chain, sends fibers to the pupils and the eyelids. These fibers radiate from the upper stellate ganglion, which also supplies various fibers in the head and

face. The upper thoracic sympathetic chain receives preganglionic input from upper thoracic roots and supplies the upper extremity through postganglionic fibers that pass through the brachial plexus. The lower extremities receive input from the T11 to L3 nerve roots, forming ganglia, and from the lower two lumbar and upper sacral nerve roots, with gray rami (postganglionic) to the lumbosacral plexus.

MICROANATOMY

As described earlier in the gross anatomy portion, there are various sites along the sympathetic chain where damage can occur to a nerve. Additionally, there are several sites where chemical intervention is possible, notably at the synapses that occur along the sympathetic pathways. Additionally, the various fibers that carry sympathetic messages are important. It has been widely held that C-fibers, which are small unmyelinated fibers carrying sensory messages, are responsible for the transmission of pain. Some theories consider that SMP is mediated by activity in A fibers, however, because C-fiber blockade fails to eliminate pain in patients with SMP (Roberts, 1986). Therefore, one must start at the very beginning of the onset of pain (i.e., the receptor itself) to fully understand SMP and CRPS I and II. Originally, it was thought that nociceptor afferents (nerves that carry the message of pain from the periphery to the cord and the brain) were responsible for the continuous pain of SMP, CRPS I, and CRPS II (Bonica, 1970; Devor & Janig, 1981; Roberts, 1986). In Roberts's (1986) article, however, he adheres to a theory first advanced by Loh and Nathan (1978) that indicates low-threshold mechanoreceptors are responsible for SMP. Roberts takes this position because nociceptor afferents, which are typically considered unmyelinated C-fibers, do not have appropriate responses to sympathetic activity; therefore, both practically and conceptually they cannot be included as the receptors that mediate SMP. Roberts (1986) reports that mechanoreceptors do respond appropriately to both touch and sympathetic activity, however. For CRPS II, others have proposed a neuroma formation as the cause of pain. Roberts believes that the sympathetic action of a neuroma is not capable of explaining why treatments that occur distal to the injury (in the form of either a nerve block or guanethidine infusion) are able to ameliorate CRPS II. Even so, Roberts (1986) uses the summation theory, or convergence theory, to say that both the peripheral receptors (in this case, mechanoreceptors) that arise in the neuroma and those that arise in the skin itself are transmitting painful messages to the cord and that distal blocks eliminate only the mechanoreceptors from the skin, which is not enough to trigger responses in the WDR neurons in the spinal cord. Additionally, the concept of a neuroma causing prolongation of CRPS

II–type pain does not fit the clinical observation that SMP may occur even in cases in which the nerve is not injured.

Ochoa et al. (1985) advances the theory that mechanical A-delta nociceptor endings become sensitized to multiple sensory inputs. This gives rise to the thermal hyperalgesia that is seen in CRPS I. On the other hand, Ochoa believes that there are abnormalities in distal nociceptor fibers that seem to have a low threshold. These low-threshold mechanoreceptors reside within large myelinated fibers and are nonsympathetic dependent because they transfer their information to nociceptor pathways proximal to the site of injury. These fibers may account for the mechanical hyperalgesia, manifesting as sensitivity to light touch. The previously mentioned receptors, which are the source of the hyperalgesia seen in CRPS I, are different from the burning pain receptors seen in CRPS II. Ochoa and colleagues (1985) believe that the burning pain of CRPS II is mediated by unmyelinated C-fibers, whereas Payne (1986) believes that this pain is due to nerve stretch and axon disruptions. Another consideration is the fact that such pain may be mediated by nerve fascicles where all three types of C-fibers exit (Ochoa et al., 1985). Therefore, in summary, the current thinking seems to suggest that sparsely myelinated C-fibers carry the message of burning pain found in CRPS II, whereas sparsely myelinated afferent fibers or the A-delta nociceptors may be responsible for pain in CRPS I.

SYNAPSES

Both synaptic considerations and axonal considerations have been raised as possible factors controlling both CRPS I and CRPS II. Ephapses, or artificial synapses, have been demonstrated in normal peripheral nerves. The concept of synaptic factors in CRPS I and II pain was first advanced by Granitt, Leksell, and Skoglund (1944) when they found that stimulating the motor root of a damaged mixed motor sensory nerve also produced recordable electrical events in the sensory root. According to the review by Payne (1986), the formation of ephapses after nerve injury may allow a short-circuiting or shunting of current from sympathetic fibers coming from the cord to the peripheral nerve into somatic fibers arising at the site of injury, carrying the message of pain back to the cord. Unfortunately, these cross-connections between fibers coming from the cord to the periphery, and conversely coming from the periphery to the cord, have been demonstrated in animal models, but not in humans (Payne 1986). Another consideration is the possibility of an ectopic impulse resulting from alterations in calcium, sodium, and potassium channels (Payne, 1986). In effect, the damaged nerve becomes "epileptic," and the spontaneous discharges from the sensory nerve may give rise to the episodic pain noted in some individuals. This could be due to lowered threshold or heightened mechanical sensitivity.

Neurosynaptic mediation of CRPS II and I holds great promise for the future. When reviewing the synapses that are present within the sympathetic chain, it is apparent that these provide a potential site of mediation for sensory input. To understand synaptic mediation, one must review the anatomy of a synapse per se. By borrowing heavily from Roberts (1986), one can define the functional neuroanatomy and delineate the location of various synapses. First, the trauma occurs, with receptors in the skin detecting various components of the trauma. Initially, the C-fiber nociceptors carry the message to the dorsal root ganglion and then back to the spinal cord neuron, where they synapse. After synapsing with the neuron in the spinal cord, these multiple neurons transmit information to the WDR neurons, which then send messages, via their axons, to the central nervous system or higher levels of the spinal cord. With use of Roberts' model, additional light touch activates the mechanoreceptors, which travel in the A-fibers instead of the C-fibers. Because the WDR neurons are already sensitized by the C-fiber nociceptors, they respond to what is usually subthreshold stimuli to the A-fiber mechanoreceptors. These mechanoreceptors travel in the A-fiber, reaching a neuron within the spinal cord, which again impinges on the WDR neuron; this, in turn, again sends messages up the spinal cord to the brain.

Sympathetic fibers exist within the lateral portions of the thoracic cord, sending efferent messages to the sensory receptor. These efferent messages (i.e., messages traveling from the cord to the periphery, mainly to the sensory receptors) may occur in the absence of cutaneous stimulation. According to Roberts' theory, however, the sympathetic efferent activity requires no cutaneous stimulation and is the cause of the SMP. In response to this efferent activity, the WDR neurons fire, again sending messages to the spinal cord and brain. The key to Roberts' theory is that the WDR neurons in the spinal cord remain sensitized, and they give a vigorous response to mechanical stimulation of A-fiber mechanoreceptors even after healing has occurred. In this schema, multiple synapses occur within the spinal cord, at the WDR neuron, and in the sympathetic ganglion. Therefore, synaptic regulation can occur at the spinal cord level or at the sympathetic ganglion level. When reviewing the actual synapse, one must conceptualize a presynaptic area wherein various chemicals are formulated, becoming neurosynaptic transmitters. The two synaptic transmitters that are of most interest to the study of CRPS I and II are the indolamines, of which serotonin is an example, and the catecholamines, of which norepinephrine, epinephrine, dopa, and dopamine are examples. In the presynaptic area of the nerve, precursor substances are manufactured into neurosynaptic transmitters, which confer a degree of specificity on nerve transmission. L-Tryptophan becomes 5-hydroxytryptophan, which becomes 5-hydroxytryptamine (serotonin); dopa

becomes dopamine, which can be converted to norepinephrine and epinephrine.

The specific type of the neurosynaptic transmitter determines whether it will occupy a specific postsynaptic receptor site. Biogenic amines, such as the indolamines and catecholamines, are constantly being formulated and broken down by monoamine oxidase (MAO). Thus, chemically, the presynaptic area may be described as an area of high flux, with formulation and degradation of the same chemical occurring in the relatively steady state. As electrical impulses travel down the axon, pore diameter changes, altering the permeability of the membrane and causing the release of neurosynaptic transmitters. These synaptic transmitters flow across a minute gap between nerves and occupy postsynaptic receptor sites. The gap, of course, is called the synapse. The postsynaptic receptor sites determine the strength and duration of the electrical impulse that the synapse propagates. This is done by the degree of specificity that the neurosynaptic transmitters have for a particular receptor site. It also depends on the affinity that a specific neurosynaptic transmitter has for a particular receptor site and whether it is easily displaced or forms a tight bond. Almost all neurosynaptic transmitters have their activity ended by presynaptic reuptake; that is, the chemical that occupies the postsynaptic receptor site is taken back into the presynaptic area. Acetylcholine is an exception, being degraded on the postsynaptic receptor site by acetylcholinesterase. Additionally, some small amount of degradation of biogenic amines occurs in the synapse itself by catechol-*O*-methyltransferase (COMT). It is thought that less than 5% of the chemical degradation of synaptic transmitters occurs in the synapse by COMT, and 95% of the degradation occurs presynaptically by MAO. Of course, there is constant rebuilding of the neurosynaptic transmitter presynaptically, creating the steady state mentioned earlier.

Obviously, there are multiple ways to modify the synapse. One can inhibit MAO, thereby enhancing the buildup of a monoamine neurosynaptic transmitter, such as the indolamines or the catecholamines. In fact, a class of drugs called MAO inhibitors does exactly that. By the same token, certain drugs can function as MAO exciters, which facilitate the degradation of biogenic amine neurosynaptic transmitters, such as the indolamines (serotonin) and the catecholamines (epinephrine, norepinephrine, dopamine, and dopa). Because the majority of the neurosynaptic transmitters have their activity ended by presynaptic reuptake, one can enhance the synaptic transmission by blocking presynaptic reuptake. This is how tricyclic antidepressants work. Conversely, one can diminish synaptic transmission by facilitation of presynaptic reuptake. Finally, one can work at the receptor end by using drugs that mimic the action of the presynaptic transmitters and occupy receptor sites, thereby triggering them as if the actual chemical had been released. By the same token, other drugs can be used that occupy the receptor sites but have no pharmacological

activity other than to inhibit the presynaptic transmitter from occupying the receptor site. For example, curare effects a total blockade of the acetylcholine receptor. In this sense, these drugs become inhibitors of neurosynaptic transmission. Receptor sites are found not only postsynaptically but also presynaptically, very often for the same presynaptic neurosynaptic transmitter. As the number and sensitivity of these receptors change, so does the response to the neurosynaptic transmitter itself.

DIAGNOSIS OF COMPLEX REGIONAL PAIN SYNDROME, TYPE II

With the foregoing theoretical information, the clinical components of CRPS I and II should be more readily differentiated by appropriate diagnostic studies. According to both Raja et al. (1986) and Payne (1986), CRPS II manifests as a burning pain, which is not a consistent finding of CRPS I. Additionally, patients with CRPS II may experience paroxysms of pain, especially after stress, whether it be emotional or environmental. In an elegant study, Raja et al. (1986) found that patients with CRPS II rarely have cold hyperalgesia (two of nine), and they do not have heat hyperalgesia (none of nine). Additionally, these patients obtain no relief from sympathetic blocks. Raja et al. (1986) differentiated various types of hyperalgesia using sensory testing with either Von Frey hairs for touch, a drop of acetone for cold, or laser thermal stimulation for heat. Ochoa et al. (1985) believe that CRPS II is not always sympathetically mediated, but instead is mediated by unmyelinated C-fibers. Stretch injuries to the nerve or axon disruption of a major nerve branch is one explanation favored by Payne (1986). Usually, the patient with CRPS II has a history of a nerve injury to a peripheral nerve or surgery that has damaged the proximal portion of the nerve trunk (Payne, 1986; Raja et al., 1986). CRPS II may be related to damage of nerve fascicles where all three types of C-fibers exist (Ochoa et al., 1985).

TREATMENT OF COMPLEX REGIONAL PAIN SYNDROME, TYPE II

Various authors have reported that sympathetic blocks are or are not effective, with efficacy for sympathectomy reported to be between 12 and 97% (Payne, 1986). However, Raja et al. (1986, 1991) reported no relief with sympathetic blocks. Payne has suggested that a dorsal root entry zone (DREZ) procedure may prove effective. Ghostine et al. (1984) have suggested the use of phenoxybenzamine. They reported 40 consecutive cases of CRPS II, all of which involved nerve injuries from bullet or shrapnel wounds. The hydraulic effect of high-speed bullet injuries is well demonstrated by photographs taken of a bullet striking an object. The Ghostine group noted partial motor paralysis in the distribution of the damaged nerve in 70% of the cases. Over time, these deficits resolved in many of the cases, however. They also noted vasomotor changes, usually severe vasodilatation and sweating and less often vasoconstriction (Ghostine et al., 1984). Rarely were trophic changes noted. The majority of the cases involved the sciatic nerve, median nerve, brachial plexus, cauda equina, and occipital nerve, in descending order. The treatment that Ghostine et al. (1984) used was phenoxybenzamine, which is a postsynaptic alpha-1-blocker and a presynaptic alpha-2-blocker. As mentioned earlier under the etiology of CRPS II, nerve sprouts, which are one of the theoretical origins of this disorder, seem to be highly excitable on the administration of norepinephrine; the excitability can be reversed with alpha-blocking agents such as phentolamine, but are unaffected by beta-blocking agents. The dosage of the drug used by Ghostine et al. initially was 10 mg three times a day, although this varied from patient to patient. Eventually maximum dosages of 40 to 120 mg/day were reached, with treatment lasting 6 to 8 weeks. Common side effects were orthostatic hypotension in about 45% of the patients and reduced ejaculatory ability in about 8% of the patients. In some instances, treatment lasted as long as 16 weeks. It is important to note that the patients were all treated within 2 to 70 days after the onset of their injury.

For this treatment to be effective, it is most important that rapid diagnosis and institution of treatment occur. Another possibility for the pharmacological treatment of CRPS II would be the use of clonazepam, which has been reported by Bouckoms and Litman (1985) to be effective for "burning" pains.

Surgical sympathectomy has been recommended as a treatment for CRPS II, after repetitive sympathetic blocks. Additionally, guanethidine, which is a ganglionic blocking agent, has proved effective in treating some forms of CRPS II. Guanethidine must be used with caution, however, because it causes the release of norepinephrine prior to occupying the receptor sites and the time course of the cessation of activity is variable. The fact that one may occlude an affected limb below the site of the CRPS II and still achieve effective blocks with guanethidine suggests that its activity is not at the ganglion but instead on the peripheral sensory nerves, which produces its effect on CRPS II (Hannington-Kiff, 1979). Surgical intervention, in the form of surgical sympathectomy, has been used to treat CRPS II with variable cure rates, ranging from 12 to 97%. The variability may be ascribed to lack of precision and diagnosis, with an overlap of CRPS I with CRPS II, or CRPS I mistakenly diagnosed as CRPS II; varying skills in performing blocks; collateral reinnervation of postganglionic sympathetic fibers; and delay in performing a sympathectomy (Payne, 1986). For CRPS II that is not responding to sympathectomy, the possibility of a contralateral sympathectomy has been raised (Kleinman, 1954).

DIAGNOSIS OF COMPLEX REGIONAL PAIN SYNDROME, TYPE I

The clinical diagnosis of CRPS I is more complicated than that of CRPS II. Some authors believe that there is a very definite set of criteria to establish the diagnosis, whereas other authors think that only several symptoms from a whole list of symptom complexes need be present to establish the diagnosis of CRPS I. Kozin et al. (1981) have established the criteria for CRPS I as a patient presenting with pain and tenderness in an extremity associated with vasomotor instability (particular temperature or color changes) and generalized swelling in the same extremity. The second group of patients they consider are those with pain and tenderness associated with a vasomotor instability or swelling in an extremity; they call this group "probable CRPS I." This system lacks precision, however, because it does not take into account the particular type of pain that patients with CRPS I experience.

Raja et al. (1986) define patients as having CRPS I if they have pain associated with signs of sympathetic hyperactivity (e.g., lower skin temperature, skin discoloration, increased sweating, and some trophic changes) and symptomatic relief after sympathetic blocks; they found that those with CRPS I also had thermal hyperalgesia either to cold or to heat. In contrast, their patients with CRPS II did not experience thermal hyperalgesia to heat, and only two of seven experienced hyperalgesia to cold. Both patients with CRPS II and with CRPS I experienced hyperalgesia to mechanical stimulation (Raja et al., 1986). On the other hand, Ochoa et al. (1985) found mechanical hyperalgesia, which they called allodynia, in their patients with CRPS I. Additionally, hypersensitivity to temperature was also found in patients with CRPS I, whether it be to heat or to cold (Meyer et al., 1985; Ochoa et al., 1985; Raja et al., 1986).

One proposed mechanism for mechanical hypersensitivity is ectopic alpha-adrenergic chemosensitivity (Devor, 1983). Another consideration is a secondary abnormality in distal nociceptor fibers that escaped injury, or intact low-threshold mechanoreceptors with large myelinated fibers that are not sympathetic dependent because of transfer of information to nociceptor pathways proximal to the site of injury (Ochoa et al., 1985). Additionally, Ochoa et al. advanced the concept of alpha-receptor sensitization, whereas others believe that the hypersensitivity of the mechanoreceptors could possibly be a central nervous system event (Meyer et al., 1985).

TREATMENT OF COMPLEX REGIONAL PAIN SYNDROME, TYPE I

Treatments for the mechanical hypersensitivity or hyperalgesia of CRPS I have been advanced by several authors, without clear-cut definition. One group of authors believes that sympathectomy may relieve mechanical hyperalgesia (Meyer et al., 1985), whereas another group of authors reports that sympathectomy does not. Another group has advanced the notion that nifedipine, a calcium channel-blocking agent, may prove effective (Prough et al., 1985). Finally, a group from South Africa suggested that low-dose naloxone, and possibly longer acting naltrexone, may prove effective for reducing mechanical hyperalgesia, because of the existence of a hypergesic kappa system of opiate receptors (Gillman & Lichtigfeld, 1985). Again, the area of mechanical hyperalgesia is quite muddy, because all the patients with either CRPS II or CRPS I had mechanical hypersensitivity (Raja et al., 1986).

Thermal hypersensitivity to either heat or cold (hyperalgesia) has been reported by several groups (Meyer et al., 1985; Ochoa et al., 1985; Raja et al., 1986). The mechanism behind the thermal hypersensitivity is not well elucidated, but one can clinically differentiate mechanical from thermal hypersensitivity by the use of a drop of acetone. Patients with CRPS I in the series studied by Raja et al. (1986) had hyperalgesia to cold (three of four, as tested by acetone drop) or to heat (four of five, as tested using a laser thermal stimulator). Some patients had hypersensitivity and hyperalgesia to both heat and cold; however, these patients did not have CRPS II, but instead CRPS I. Of the group of patients with hyperalgesia to temperature change, six of six got relief with sympathetic blocks or sympathectomy (Raja et al., 1986). Other authors have reported that nifedipine is effective for treating hyperalgesia (Prough et al., 1985). Specifically, in 13 patients with pain having a burning character, dysesthesia, and cold intolerance, nifedipine beginning at 10 mg three times a day, and increasing to 30 mg three times a day, proved effective in 7 of 13 patients. Nifedipine is a calcium channel-blocking agent, and as such may work by dilating blood vessels and antagonizing the effects of norepinephrine on arterial and venous muscle (Payne, 1986). Also, nifedipine may interfere with ectopic impulse formation that occurs in regenerating nerves by blocking calcium channel protein.

The dystrophic component of CRPS I is more difficult to delineate. Some authors have reported a diffuse or patchy bony demineralization (Kozin et al., 1981), whereas others have reported frank osteoporosis late in the disorder (Schott, 1986). A number of authors have reported molted skin, again late in the disorder (Kozin et al., 1981; Payne, 1986; Raja et al., 1986). Some authors have reported hair loss, yet again late in the disorder (Raja et al., 1986; Schott, 1986). Vague terms such as vasomotor instability have also been reported, as well as trophic skin changes (Kozin et al., 1981). The etiology for these components is not well defined, but the consensus seems to be reduced blood flow to the various involved organs.

A more precise diagnostic assessment was advanced by Holder and MacKinnon (1984). They evaluated patients with CRPS I, which they defined as diffuse hand

pain, diminished hand function, joint stiffness, and skin and soft tissue trophic changes with or without vasomotor instability. They also used three other control groups, including patients with diffuse pain, focal pain, or vascular disease. Holder and MacKinnon (1984) found that 22 of the 23 patients who met their criteria for diagnosing CRPS I had positive delayed image bone scans, 12 of the 23 patients had positive blood pool images, and 10 of the 23 patients had positive radionucleotide angiograms. Approximately half the patients with CRPS I had positive early phase bone scans, whereas almost all patients with CRPS I had positive delayed image bone scans.

This study compared favorably with work done by Kozin et al. (1981), who found that radiography is not a useful tool for diagnosing CRPS I. Kozin et al. (1981) did find that 83% of the patients with CRPS I had positive static (delayed) bone scans, however, whereas 69% of the patients had positive flow studies. Therefore, it is apparent that between 50 and 60% of patients with CRPS I will have positive early phase bone scans, but between 83 and 96% of patients will have positive delayed image bone scans (Holder & Mackinnon, 1984; Kozin et al., 1981). Treatment for this component of CRPS I is difficult to assess. Kozin et al. (1981) reported that 90% of patients with positive bone scans had good to excellent steroid response, beginning with steroids at the level of 60 to 80 mg/day and tapering the dosages.

Schott (1986) has reported a variety of therapeutic modalities, including steroids, nonsteroidal anti-inflammatory drugs, alpha- and beta-blocking agents, griseofulvin, calcitonin, transcutaneous electrical nerve stimulation, physical therapy, sympathetic blocks, and intravenous guanethidine. None of these treatments has been studied in a systematized fashion, however.

Nail brittleness has been reported by Schott (1986) and Payne (1986) late in the disorder. The etiology of this is not clear and there is no clear-cut treatment. Muscle spasm has been reported by a number of authors (Kleinman, 1954; Long, 1982; Schott, 1986), again without a clear-cut mechanism describing the etiology (Payne, 1986). Interestingly, EMG nerve conduction velocity studies seem to be relatively negative in CRPS I (Uematsu et al., 1981). The treatments that seemed most effective for muscle spasm were trigger point injections (Payne, 1986) and the use of baclofen. Baclofen is a gamma aminobutyric acid (GABA)-minergic drug that centrally reduces muscle spasm. The inhibition of substance P may be implicated as part of its mechanism for reducing spasm and the pain associated with spasm (Gillman & Lichtigfeld, 1985). Soma and quinine have also been tried, with only limited success (Hendler, unpublished observations). Contractures, usually in the hand, have also been reported (Payne, 1986; Schott, 1986). The etiology of this is unclear but is probably related to disuse. Again, there is an absence of positive EMG-NCV studies (Uematsu et al., 1981), and

the only treatment seems to be preventative, by the use of passive range-of-motion exercises and physical therapy.

Contralateral involvement has been reported by several authors (Kleinman, 1954; Schott, 1986). The etiology for this may be quite direct. In approximately 80% of examined cadavers there is cross-communication between the sympathetic fibers and the sympathetic chains (Kleinman, 1954). Countralateral blocks and denervation have been recommended (Kleinman, 1954). Edema of the affected limb (Payne, 1986; Schott, 1986), as well as swelling of a specific joint (Kozin et al., 1981), has been reported. Again, the etiology is unclear. The diagnosis is established by measuring the proximal interphalangeal joint, which averages 12.9 mm larger in the affected hand than in the control hand (Kozin et al., 1981). No treatment has been advanced for this, although nifedipine is suggested to be effective (Prough et al., 1985). At the Mensana Clinic in Stevenson, MD, we have observed some benefit from the use of spironolactone or carbonic anhydrase inhibitors, but not on a consistent basis.

Lower skin temperature has been reported by a variety of authors (Hendler et al., 1982; Payne, 1986; Raja et al., 1986), but it does not seem to be due to vasospasm (Janoff et al., 1985). Reflex contraction due to altered activity within the afferent and efferent nerves is proposed as the etiology (Janoff et al., 1985). Thermography is an excellent diagnostic tool to document the reduced skin temperature (Hendler et al., 1982; Uematsu et al., 1981). In fact, very often patients with CRPS I are diagnosed as having psychosomatic disorders, and thermography can be a most convincing diagnostic tool to confirm the otherwise subjective complaint (Hendler et al., 1982). However, nerve entrapments and radiculopathies can also lower limb temperature (Uematsu et al., 1981).

Treatment for lower skin temperature associated with pain is best effected using regional sympathetic blocks employing reserpine. It is important to note that these reserpine blocks, or Bier blocks, are not effective for vasospasm, but specifically seem to function best for treating CRPS I. Therefore, vasospasm does not seem to be the etiologic mechanism for the coldness noted in the limb in CRPS I (Janoff et al., 1985). Stiffness (Holder & MacKinnon, 1984; Payne, 1986) and tenderness (Kozin et al., 1981) of the joints have been reported; again, the etiology is not clear (Payne, 1986). Very often, the involvement of the joint leads to misdiagnosis and confusion with other diseases that can affect the joint, notably infective arthritis, rheumatoid arthritis, Reiter's syndrome, systemic lupus erythematosus, and arthritides (Kozin et al., 1981). In one series, 71% of the patients with joint tenderness and stiffness had poor responses to stellate ganglion blocks. Steroids, notably prednisone (60 to 80 mg) for 2 to 4 days, then 40 to 60 mg for 2 to 4 days, and then 30 to 40 mg for 2 to 4 days, in four equally divided doses, were the initial therapy. Subsequently, the dose was rap-

idly tapered using a single morning dose of 40 mg, then 30 mg, 20 mg, 10 mg, and 5 mg over 2 or 3 days at each dose. By using this regimen, 82% of the patients with joint stiffness and tenderness obtained good or excellent relief.

An unusual complication of CRPS I is the appearance of pathological fractures subsequent to minor trauma. In patients complaining of persistent pain in the limb that seems to be bony in origin, instead of part of the CRPS I, it would be imperative to obtain bone scanning to confirm the presence or absence of an undetected break. In our experience, one patient with long-standing CRPS I received a minor trauma (i.e., bumping her ankle while walking in a train) that resulted in a chronic intense worsening of pain in the heel. Radiographs of this area were within normal limits, but the pain persisted for several days after the event, and a bone scan was obtained. Only on bone scan did the break in the calcaneus appear, which had been totally missed by routine radiograph. Of any breaks present, 95% will have a positive bone scan after 72 h (Matin, 1979). Interestingly, after the fracture is healed, 90% of the bone scans returned to normal 2 years from the date of the injury. Therefore, in patients with CRPS I who have minor injuries and complain of bony pain, it would be prudent to obtain a bone scan and not rely on radiographs.

Payne (1986) has enumerated many attempted treatments for CRPS I. Unfortunately, there seems to be a lack of systematic investigation for these treatments, and most are based on clinical reports instead of systematized trials. Reported pharmacological interventions that may work for CRPS II are the use of propranolol, a beta-blocking agent; prazosin, an alpha-1-adrenergic-blocking agent; phenoxybenzamine, both an alpha-1- and an alpha-2-blocker; and guanethidine, a drug that produces a chemical "sympathectomy." Physical therapy has been advanced for the treatment of CRPS I, specifically to minimize muscle contractures and joint stiffness. It is never a definitive treatment, however, and should not be considered such. Electrical stimulation of the central nervous system, using either electrodes centrally implanted into the periaqueductal or periventricular gray or epidural stimulators, may prove effective, as might transcutaneous electrical nerve stimulation. Tricyclic antidepressants, nonsteroidal anti-inflammatory drugs, narcotics, and anticonvulsants have all been reported as treating some components of CRPS, type I, with varying degrees of success.

Surgical intervention is a treatment that is reserved until all other modalities of treatment have been attempted. In all cases, the criterion for surgical intervention would be repetitive successes with repeat sympathetic blocks. The most commonly employed surgical interventions are resection of the lower third of the stellate ganglion and resection of the upper two thoracic ganglia; however, some surgeons resect the second through fifth thoracic ganglia in an attempt to treat upper-extremity difficulties. There are four surgical approaches to upper extremity sympathectomies (Allen & Morety, 1982):

1. Above the clavicle (anterior cervical approach)
2. Posterior resection of the transverse processes of ribs 2 and 3, and proximal section of ribs 2 and 3
3. Anterior transpleural entry through the pectoralis muscle to the third intercostal space, pressing the lung, to reach the operative area
4. The axillary approach, which is through a transaxillary incision over the second intercostal space

Also, a lumbar approach can be made through the external and internal obliques, and then the transversalis muscle, below the twelfth rib, behind the kidney; others have suggested a thoracolumbar presacral neurectomy. Side effects of surgical approaches are postsympathectomy neuralgia, beginning 7 to 10 days after surgery, and postsympathectomy dysesthesia that may last 2 to 14 weeks and is described as continuous, severe, and worse at night. Anticonvulsants, such as diphenylhydantoin or carbamazepine, may be used to treat this (Allen & Morety, 1982). Medication, such as valproic acid and gabapentin may be useful (Mellick & Mellick, 1995). Dorsal root entry zone procedures, which produce lesions in the dorsal root interrupting the nociceptive pathways in the tract of Lissauer and in laminae I-V of the dorsal horn of the spinal cord, may prove to be an effective modality for treating CRPS II for stretch injuries (Payne, 1986). A treatment guideline is shown in Table 36.5.

CONCLUSIONS

In summary, it is quite apparent that a great deal of confusion has arisen concerning the diagnosis of CRPS I and CRPS II. This is evidenced by the lack of uniformity in clinical criteria for establishing the diagnosis. Because of this lack of uniformity, assessment of various articles detailing treatment of CRPS I and/or CRPS II is difficult. What some clinicians take as symptoms of CRPS I are not always present in their entirety. Unfortunately, if one adheres rigorously to these criteria, proper diagnosis, and more importantly proper treatment, may be withheld. The various clinical symptoms that have been reported as associated with CRPS I and CRPS II are shown in Table 36.3. A patient should be considered to have CRPS I if he or she has both types of allodynia (mechanical and thermal), altered skin temperature, and pain in a circumferential distribution. At a minimum, diagnostic studies that would facilitate the diagnosis of CRPS I would be sympathetic blocks, phentolamine testing, and a bone scan. Clinical diagnostic studies that would prove important would be testing with the Hendler alcohol drop and swipe test, for

TABLE 36.5
Recommended Treatment Flow Sheet

Treatment	Dosage	Time Course	If Ineffective, Next Step
1. Prednisone	80 mg to start and taper by 10 mg q.d.	8 days	Go to 2
2. Physical therapy	3 times a week	2 weeks	Go to 3
3. Transcutaneous electrical stimulation	Wear constantly	1 week	Go to 4
4. Sympathetic blocks	3 times a week	2 weeks	If lasting relief, stop; if 100% pain relief but temporary, go to 5
5. Sympathectomy	—	1-week recovery	If lasting relief, stop; if no relief, go to 6
6. Contralateral blocks	3 times a week	2 weeks	If lasting relief, stop; if 100% pain relief but temporary, go to 7; if no relief, go to 8
7. Contralateral sympathectomy	—	1-week recovery	If relief, stop; if no relief, go to 8
8. Epidural spinal cord stimulator	—	1-week recovery	If relief, stop; if no relief, go to 9
9. Epidural pump	Start with clonidine (Rauck et al., 1993)	1-week recovery	If relief, stop; if no relief, try other meds in combination or alone, go to 10
10. Psychotherapy (supportive)	Use antidepressants	6 months to 2 years	Maintenance

thermal and mechanical allodynia. EMG and NCV studies, SSEP, and neurometer studies should be conducted to detect whether there is an associated nerve entrapment. All patients suspected of having CRPS I should have at least three sympathetic blocks. After that, one should use various diagnostic and treatment techniques, including pharmacological intervention, depending on the patient's type of complaints. If there is residual pain in a peripheral nerve distribution while the limb is warm from the sympathetic block, concomitant nerve blocks should be performed.

To make the diagnosis of CRPS II, one certainly should establish that the symptoms of burning pain are constantly present, in association with a partial peripheral nerve injury. EMG and NCV studies, SSEP, and neurometer studies should be conducted to detect whether there is an associated nerve injury. Certainly, patients should receive a peripheral nerve block, sympathetic blocks, and a trial with phenoxybenzamine, valproic acid, and gabapentin.

Regardless of whether a patient has CRPS I or CRPS II, one must be aware of the need to distinguish between the two diagnoses because the treatments vary. More importantly, if the patient has even a single symptom of CRPS I, a diagnostic assessment involving the previously recommended modalities would be warranted, and further diagnostic studies should be pursued if the diagnosis of CRPS I is not confirmed. Kozin et al. (1981) clearly defines a number of overlapping conditions that may originally be misdiagnosed as CRPS I. Of the patients who were found not to have CRPS I, 25 to 71% had peripheral neuropathy or trapped peripheral nerves, and half the patients misdiagnosed as having CRPS I had inflammatory arthritis (Hendler 2002; Kozin et al., 1981). Therefore, laboratory studies, including erythrocyte sedi-

mentation rate, antinuclear antibody, rheumatoid factor, Lyme disease, HIV, and the like, should be conducted in patients thought to have CRPS I but in whom the diagnosis is not complete. In any event, CRPS II and I require clinical acumen to establish the diagnosis, and persistence to effect appropriate treatment. Aggressively pursuing all the diagnostic studies available, as well as relying on clinical judgment, provides better care for these patients.

HIV and AIDS Pain

Maurice Policar, MD, and Vasanthi Arumugam, MD

INTRODUCTION

The acquired immune deficiency syndrome (AIDS) pandemic has by no means begun to abate. There are more than 38 million cases worldwide. In the United States, there are an estimated 1 million individuals infected with human immunodeficiency virus (HIV) and about 40,000 new infections occur each year. Some evidence suggests that current behavior may result in an increase in these numbers.

The AIDS era can be divided into two major stages: before and after highly active antiretroviral therapy (HAART). The availability of effective medications in 1996, along with the use of triple drug therapy as a treatment strategy (HAART), has had a major impact on those infected, resulting in dramatic decreases in the rates of death, hospitalization, and opportunistic infections. Persons being treated for HIV are now healthier and, in most cases, live otherwise normal lives.

Much is written about treating AIDS-related pain with the same approach used in treating cancer-related pain. This was a reasonable approach in the past when a large proportion of patients with AIDS in care were debilitated and considered to be terminal. Many people with AIDS are still being diagnosed at a late stage of disease, and some harbor virus that has become resistant to all current antiretroviral agents. However, the aspect of pain management in HIV must also be focused on the healthy individuals with active daily lives in whom adequate pain management could dramatically improve quality of life. In a national study of more than 2000 patients infected with HIV from 52 sites, patients surveyed as late as 1998 continued to list various pains as associated with worse perceived health and worse perceived quality of life (Lorenz et al., 2001).

Physician underestimation of pain in HIV-infected individuals has been well described. Providers are often concerned about drug dependence, especially in patients with current or prior substance use. Several reports have demonstrated the underutilization of analgesics in patients with HIV (Breitbart et al., 1996; Larue, Fontaine, & Colleau, 1997). This seems to be more pronounced with opioid analgesia. Poorly controlled pain has been reported as one of the reasons chronically ill patients have asked for physician-assisted suicide (Abrams, 1997).

In discussing the topic of pain in those with HIV infection, it is important to differentiate between pain that is a result of HIV infection or its complications, and pain that is a complication of therapy. In addition, pain syndromes that are unrelated to HIV or its treatment can occur in those infected with HIV.

It is also important for the practitioner to recognize pain syndromes in patients with undiagnosed HIV infection. Painful neuropathy in a patient not known to have a condition that may be associated with pain (i.e., diabetes) is one example. In such situations, it is incumbent on the practitioner to recommend HIV testing to the patient. In the United States today, it is estimated that one of three HIV-infected patients is unaware of his or her diagnosis, and many are first diagnosed when they are afflicted with their first opportunistic infection. Earlier diagnosis of HIV can have a dramatic impact on outcome.

HEADACHE

Headache is one the most common neurologic complaints in patients with HIV infection and may occur at any time from seroconversion to advanced disease (Graham & Wip-

pold, 2001). The causes of headache in persons with HIV infection vary widely. The published incidence of primary headaches versus those caused by an infection or malignancy varied according to the population surveyed.

The evaluation of headache in a patient with HIV infection may include imaging of the head and a lumbar puncture, in addition to history and physical examination. The order and pace of testing should be directed by the acuity and severity of the headache, the accompanying features, and the level of immunosuppression, i.e., the CD4+ lymphocyte count (CD4). Evaluations of HIV-positive patients with headaches suggested little value in computerized tomography (CT) scanning for patients with a CD4 > 200, unless they had focal neurologic signs, altered mental status, or seizures (Gifford & Hecht, 2001; Graham et al., 2000). Complaints of "worst headache of life" should always prompt evaluation for subarachnoid hemorrhage. When accompanied by fever or focal neurologic changes, headache in an HIV-infected individual should prompt a rapid evaluation for infection. Outpatients should probably be referred to a hospital setting where imaging, lab evaluation, and medical treatment are more readily available.

CHRONIC HEADACHE

Chronic headache in patients with HIV is a common complaint. In general, headache is most likely due to a benign, non-infectious cause when it occurs early in the course of HIV infection, before the onset of significant immunologic impairment (Masci, 2001). Causes include muscle tension, vascular headache, depression, or occasionally, chronic sinusitis. Headache may be caused by antiretroviral medications (most commonly zidovidine) and chronic opioid use.

A reasonable approach to the treatment of chronic headache is to begin with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs). Tricyclic antidepressants (TCAs) are used with variable results, but their use is limited at times by their side effects. Gabapentin may be initiated at low doses (i.e., 100 mg tid) and increased gradually to allow for tolerance to side effects. Doses up to 1200 mg tid have been used. Carbamazepine is also sometimes useful, and beta-blockers and calcium channel blockers may be helpful in the prevention of vascular headaches. Opioids may be used for chronic headaches, but chronic use may lead to tolerance and decrease in efficacy.

MENINGITIS

In addition to headache, fever, meningismus, and photophobia, with or without altered mental status, are not unusual in patients with meningitis. In some cases, cranial nerve palsies or seizures may also occur. A lumbar puncture is the study of choice to diagnose meningitis and its

etiology. A retinal evaluation to rule out papilledema should always be done prior to a lumbar puncture, in order to avoid herniation in those with increased intracranial pressure. Some advocate an imaging study of the brain in all patients with HIV infection to prevent this complication.

The most common cause of meningitis in AIDS is the fungus *Cryptococcus neoformans*. Most infections occur in patients with CD4 counts below 200. While headache and fever are common, meningismus may be absent. Cerebrospinal fluid (CSF) cell counts and chemistries can vary and may occasionally be normal. A cryptococcal antigen should be positive in the CSF and is usually found in the serum as well. An India ink preparation of the CSF may be positive in more than 50% of cases, showing encapsulated yeast forms, at times with budding.

Other causes of meningitis in the HIV-infected patient include the usual causes of bacterial meningitis such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*. Among patients infected with HIV, risk for infection is significantly higher with *S. pneumoniae* and marginally increased with *Listeria monocytogenes* (risk is also higher in cirrhosis and pregnancy).

Aseptic or nonbacterial meningitis is usually caused by a self-limited enteroviral infection, but may also be related to HIV itself. With reactivation and skin lesions, Herpes simplex virus (HSV) or Varicella zoster virus (VZV) infection may be related to aseptic meningitis. The presence of genital or skin lesions should suggest these diagnoses. Tuberculous meningitis should be suspected in patients from endemic areas. The course tends to be more chronic than that of bacterial or viral meningitis. The CSF typically reveals a lymphocytic pleocytosis and low glucose, and may have extremely elevated protein levels. Spinal fluid staining and culture for acid-fast bacilli are usually negative; CSF polymerase chain reaction (PCR) for *Mycobacterium tuberculosis* may be helpful, but is frequently nondiagnostic. CT scan may show meningeal enhancement, and about half of patients have findings suggestive of tuberculosis on chest x-ray. Treatment is usually empiric, based on the clinical findings. Occasionally, lymphoma may spread from a primary site to the central nervous system (CNS), causing lymphomatous meningitis. CSF cytology, and/or Epstein–Barr virus (EBV) PCR may be diagnostic.

BRAIN LESIONS

Patients who present with headache and focal neurologic abnormalities or seizures should be evaluated for space occupying lesions (SOL) of the brain. At times, patients with an SOL can present with only headache or mental status changes. The most common diagnosis in this group is toxoplasmosis, a reactivation disease in persons with past exposure to *Toxoplasma gondii*. Less commonly diagnosed are primary lymphoma of the brain and tuber-

culoma of the brain. In patients with CNS toxoplasmosis, the characteristic finding on CT scan or magnetic resonance imaging (MRI) is multiple ring-enhancing lesions, with a predilection for involvement of the basal ganglia. With appropriate treatment, rapid clinical and/or radiographic improvement is the rule. Rapid improvement with treatment is considered diagnostic, obviating the need for a biopsy. Primary lymphoma of the brain is most commonly seen as a well-defined focal lesion that enhances with contrast. On single positron emission computed tomography imaging, lymphoma shows a greater thallium uptake than infection (Lorberboym et al., 1998). When a lumbar puncture can be safely done, detection of EBV DNA by PCR is diagnostic of lymphoma. EBV infection has been associated with certain lymphomas, especially in the immunocompromised host. Tuberculosis is an uncommon cause of brain lesions in the United States. Tuberculomas or cerebral abscesses may be solitary or multiple, nodular or ring enhancing, and they have a clear predominance in the supratentorial compartment. They are more likely to occur in intravenous drug users and individuals from tuberculosis endemic areas. This form of CNS tuberculosis is less common than meningitis and usually occurs when the CD4 drops below 200. Radiographs of the chest show evidence of tuberculous infection in about half the patients (Lesprit et al., 1997). A host of other organisms can cause abscesses of the brain in patients with HIV, and these may be diagnosed by an aspiration or biopsy of the lesions.

OTHER CONDITIONS

Sinusitis is more common in HIV-infected individuals than in those without HIV. The presentation can be subtle, and headache may be the only symptom. In addition to the usual bacterial and viral pathogens, fungi have been found to be a fairly common cause of sinusitis in HIV, at times becoming invasive into surrounding bone and soft tissue (Hunt et al., 2000). Radiographic evaluation of the sinuses is important to help establish the diagnosis, eliminate other diagnoses, and evaluate for tissue invasion, a rare condition requiring surgical intervention.

Syphilis can cause various manifestations in the HIV-infected patient. Syphilitic meningitis can be seen at any stage of infection with syphilis. Meningovascular syphilis or gummas of the brain are manifestations of tertiary syphilis. Serum testing for syphilis is usually diagnostic, but nontreponemal screening tests may be falsely negative. A treponemal test for syphilis, the VDRL (Venereal Disease Research Laboratory) is usually positive in syphilitic meningitis.

With advanced HIV, headache may be one of several manifestations of infection with "JC virus," the cause of progressive multifocal leukoencephalopathy. JC virus PCR in the CSF is diagnostic. CT scanning reveals white matter lesions.

In patients who have headaches as a result of lumbar puncture, so-called postdural puncture headaches, an autologous epidural blood patch may be helpful in alleviating the symptoms (Tom et al., 1992).

OROPHARYNGEAL PAIN

Patients with HIV/AIDS have frequent oropharyngeal and esophageal conditions that cause pain as one of their manifestations. Significant discomfort can interfere with adequate nutrition and may contribute to weight loss.

ORAL CANDIDA INFECTIONS

Oral candidiasis may be an early manifestation of HIV infection and may have variable presentations: pseudomembranous, erythematous, and angular cheilitis. The most common presentation, pseudomembranous candidiasis or thrush, appears as white or cream-colored patches that are easily scraped off mucosal surfaces. The erythematous form is more subtle and easily overlooked. Patients may complain of pain, burning, or soreness, along with dysguesia. Angular cheilitis results in cracks or fissures at the angles of the mouth. Pain on opening the mouth is a common manifestation. Each of these forms of oral candidiasis can be treated with topical antifungal therapy in the form of solutions or troches (Darouich, 1998). Systemic antifungal agents are also effective. A condition known as hairy leukoplakia can resemble thrush, but is painless, cannot be removed by scraping, and does not respond to antifungal therapy.

GINGIVITIS AND PERIODONTITIS

Gingivitis is common in patients infected with HIV, who most often present with oral pain, inflammation, and receding of gum lines, and at times, progression to bone loss (periodontitis). Spontaneous bleeding can occur. A topical antimicrobial rinse such as chlorhexidine is used as treatment. A form of gingivitis specifically related to HIV has been termed "linear gingival erythema." It presents as a brightly inflamed band of marginal gingiva. The treatment consists of debridement plus antibiotic administration (Obernesser, 2004).

ORAL ULCERS

Oral ulcers are a common finding in HIV-infected patients, and may result from viral infections (HSV, CMV), bacteria (oral fusospirochetosis), fungi (histoplasmosis), or neoplasm or they may be idiopathic (aphthous ulcers). HSV is one of the more common causes of oral ulcerations in patients with HIV. Ulcers due to HSV are usually painful and may be recurrent. In advanced disease, they may be chronic, resolving only after antiviral therapy. Diagnosis is usually by viral culture. Acyclovir 400 mg tid, valacy-

clovir 500 mg bid, or famciclovir 500 mg bid can be used until the lesions resolve, usually a few days.

Aphthous ulcers are more common in individuals with HIV/AIDS than in those without HIV. These ulcers may be single or multiple, may persist for weeks or longer, and can be extremely painful (Greenspan & Greenspan, 1999). Diagnosis is clinical, and treatment consists of topical steroids such as triamcinolone mixed with orabase and applied topically to the lesions two to three times per day. In patients with multiple ulcers, or those located in the posterior oropharynx, rinsing with dexamethasone elixir (0.5 mg/5 ml), 5 ml tid, may be helpful. Patients should be instructed to expectorate the solution after rinsing. Thalidomide has also been found to be helpful in the treatment of aphthous ulcers in HIV (Jacobson et al., 1997). Topical treatment with 2% viscous lidocaine can help ameliorate pain. At times, narcotic analgesics are required to control pain.

Patients with ulcers that do not respond to empiric treatment with antivirals and topical steroids should probably have a biopsy done to exclude other causes such as *Cytomegalovirus* (CMV), or fungal infection, or malignancy.

Neoplasms

Kaposi's sarcoma (KS) and non-Hodgkin's lymphoma (NHL) may present as oral lesions in the patient with HIV infection. The lesions of KS are seen predominantly in men who have sex with men. They usually involve the hard palate, appearing as blue, purple, or red lesions that may be nodular. The oral lesions of KS may be painful because of ulceration and secondary infection (Greenspan & Greenspan, 1999). The diagnosis is made by biopsy, and the treatment may be intralesional or systemic chemotherapy, or radiation therapy. Pain can usually be controlled with oral narcotics. NHL can occur anywhere in the mouth and can present as diffuse swellings, nodules, or ulcers (Greenspan & Greenspan, 1999). Biopsy is required for diagnosis, and treatment is with systemic chemotherapy. Narcotic analgesics in various forms may be required for control of pain.

Esophageal Conditions

Chest pain, dysphasia, and odynophagia are all manifestations of esophageal disease in HIV. Esophageal candidiasis is the most common cause of these symptoms. Although common, oral candida may be absent in these patients. Esophageal candidiasis is an AIDS-defining opportunistic infection and is indicative of late-stage disease (CD4 < 200). Patients usually present with dysphasia and/or odynophagia, usually localizing their pain to the substernal area. These symptoms should prompt empiric treatment with a systemic antifungal agent. If there is no response to therapy in 3 to 4 days, endoscopy with biopsy should be done (Darouich, 1998). Other than candidal infections, the most common findings are esophageal ulcers, which may be due to HSV, CMV, or idiopathic aphthous disease. The diagnosis is made by biopsy. Idiopathic ulcers usually respond to systemic steroids. Resolution of pain occurs with treatment of the causative agent. With esophageal ulcers, analgesics may be necessary as pain may respond slowly to specific therapy.

CHEST PAIN

The manifestation of chest pain in the HIV-infected individual is fairly common. When the pain is pleuritic in nature, one should consider bacterial pneumonia, but pleural tuberculosis may be a cause in patients who have been exposed to tuberculosis. In patients with AIDS, spontaneous pneumothorax may occur, usually in relation to *Pneumocystis carinii* pneumonia (PCP). Chest radiographs may indicate infection or pneumothorax. Infection should be treated with the appropriate antimicrobials, and pleuritic pain usually responds well to NSAIDs. Patients with pneumothorax will likely require narcotic analgesics, especially if a chest tube is inserted.

The use of HAART has been associated with insulin resistance and abnormalities of lipid metabolism. Although definitive evidence of an increased risk of coronary disease in HIV/AIDS is still lacking, there are some studies supporting this notion (Hsue et al., 2004; Vittecoq et al., 2003). Coronary disease should be considered in patients with HIV who present with chest pain.

Esophageal manifestations can also present with chest pain (see above).

BACK PAIN

A longitudinal study was done to evaluate the painful symptoms associated with HIV infection and its treatment. Back pain was listed among the most common painful illnesses reported (Singer et al., 1993). In patients who are infected with HIV, back pain is likely caused by the same musculoskeletal conditions that plague uninfected persons.

In persons who are active injecting drug users, osteomyelitis of the spine with or without a spinal epidural abscess can occur. Back pain, most commonly cervical, is the most frequent manifestation, followed by fever. Radiculopathy, myelopathy, and sensory loss may accompany local pain and tenderness. Plain film radiography, CT scan, MRI, and bone scan are useful for diagnosis (Broner, Garland, & Zigler, 1996). Biopsy is indicated for lesions of the bone, and aspiration for abscesses. In patients with neurologic signs of cord compression, high dose steroids and urgent surgical debridement are indi-

cated. Depending on the extent of involvement, pain may be controlled with mild analgesics or may require opioids. Postoperative pain is best relived with narcotics administered via patient-controlled analgesia (PCA) pumps.

Back pain can be a symptom of renal conditions as well. A side effect of indinavir therapy is the development of nephrolithiasis. At times, no stones are found, but crystalluria may cause the classic syndrome of renal colic (Kopp et al., 1997).

ABDOMINAL PAIN

The list of causes of abdominal pain in the HIV-infected individual is extensive. A host of etiologies are similar to those seen in patients without HIV infection. The focus of this section is to list and define entities either that are unique to the patient with AIDS or that occur with a higher frequency in those with HIV infection. We also discuss manifestations that result from complications of antiretroviral therapy.

In the emergency department (ED), abdominal pain in the HIV-infected patient can be especially challenging. Even in the general population, the cause of abdominal pain is not diagnosed in the ED 25 to 46% of the time (Yoshida & Caruso, 2002). In the patient with HIV infection and abdominal pain, one must consider additional diagnoses related to HIV or its management. The CD4 count may help narrow the differential diagnosis. Patients with a CD4 count above 200 are very unlikely to have a condition related to an opportunistic infection. When CD4 counts are <100, diagnoses such as disseminated *Mycobacterium avium* complex (MAC) infection must be considered, while CMV infection of the gastrointestinal tract occurs almost exclusively in patients with a CD4 count <50.

The incidence of opportunistic conditions related to the gastrointestinal tract seems to be decreasing. Monkemuller et al. (2000) reviewed results of gastrointestinal endoscopies in patients with HIV infection, from April 1995 to March 1998. They document a clearly decreasing incidence of opportunistic diseases (69 to 13%), associated with an increase in the use of HAART (0 to 57%).

Yoshida and Caruso (2002) reported on a series of patients with abdominal pain, seen in an inner-city emergency department. Of 108 patients reviewed, two thirds used drugs and/or alcohol and approximately half were taking antiretroviral medication. The most common diagnoses were the same as those in patients without HIV infection: abdominal pain of unknown etiology, gastroenteritis/diarrhea, and ulcer disease/gastritis/dyspepsia. In comparing two groups at different stages of infection (CD4 < 200 vs. CD4 ≥ 200), they found no statistically significant differences in etiologies, except for the presence of disseminated MAC infection in the advanced group. Opportunistic conditions made up only 10% of diagnoses in the advanced group. Only 8% required surgical procedures. A portion of the apparent reduction in AIDS opportunistic conditions is attributable to HAART. Of note, four patients had nephrolithiasis due to indinavir therapy. The admission rate for HIV-infected patients was 37%, twice that of patients without HIV infection. Other studies have quoted higher rates of opportunistic conditions and surgery, but the populations consisted of inpatients not ED patients.

Presence or absence of fever may be misleading. Although low-grade fever may not be uncommon with advanced HIV infection, one review found that 40% of patients with AIDS with appendicitis had no fever (Whitney et al., 1992). The peripheral white blood count (WBC) in patients with AIDS tends to be low and may rise to normal in the face of infection. For that reason, a normal WBC should not dissuade the practitioner from considering infections or serious conditions, especially if the patient's baseline WBC is known to be low.

Slaven et al. (2003) organize the causes of abdominal pain into five categories, which include HIV-related, iatrogenic (medication- or procedure-related), immune surveillance–related (malignancies), non-HIV-related, and nonspecific (resolution without specific diagnosis). In the following discussion, we focus on only the first three categories, including malignancies as HIV-related conditions because lymphoma and KS have strong associations with HIV infection.

ENTEROCOLITIS

Enterocolitis is one of the most common gastrointestinal manifestations of HIV and is often associated with pain. This condition may be acute or chronic and may be associated with fever and weight loss. Etiologies include a variety of organisms including bacteria, viruses, mycobacteria, parasites, and fungi. Stool studies are most useful, although frequently negative. Endoscopic biopsies may be necessary for the diagnosis of some viral and parasitic infections. *Clostridium difficile*–associated disease can be diagnosed by a toxin assay of the stool. Antimicrobial treatment is usually indicated although antimotility agents may be helpful with some organisms such as cryptosporidium. Specific antimicrobial treatment, with or without antimotility drugs, usually helps relieve the diarrhea along with the pain.

PANCREATITIS

In patients with AIDS, pancreatitis is 35 to 800 times more common than in those without HIV infection. In addition to alcohol use and gallstones, other pathologies related to pancreatitis in HIV infection include medications such as didanosine, Kaletra, and pentamidine, as well as opportu-

nistic infections including CMV, toxoplasmosis, mycobacteria, and cryptosporidium (Dassopoulos & Ehrenpreis, 1999). Infiltration of the pancreas by lymphoma or KS is rare. The presentation is similar to that seen in immunocompetent hosts, but tends to be more severe. Diagnosis relies primarily on symptoms, an elevated amylase and lipase, and ultrasound or CT evidence of pancreatic inflammation. Stool studies or blood cultures may be helpful for some infections, but CMV requires tissue diagnosis. Associated pain will usually respond to pareneterally administered narcotic analgesics, preferably by PCA pump. When pancreatitis is a result of drug toxicity, the offending agent must be discontinued. Patients with a history of pancreatitis should not receive didanosine, Kaletra, or pentamidine. When an infection is the cause, specific antimicrobial therapy should be administered.

APPENDICITIS

The incidence of appendicitis with HIV infection is likely similar to rates in non-infected individuals. The usual causes (i.e., appendoliths) are frequent in HIV, but opportunistic infections may also play a role. AIDS-related pathology was identified in 30% of cases of acute appendicitis in one series (Whitney et al., 1992). The more commonly identified infections associated with appendicitis in HIV are *Mycobacterium tuberculosis* (tuberculosis), MAC, and CMV (Slaven et al., 2003). KS has also been seen in cases of appendicitis in AIDS. The various etiologies could not be predicted from the clinical presentation. As opposed to the findings in immunocompetent hosts, elevated WBC is unusual, and 40% of patients with AIDS with appendicitis have no fever (Whitney et al., 1992). Although perforation rates have been documented to exceed 40%, delays in surgery have also been documented and were likely related to the increased perforation rate (Slaven et al., 2003). Diagnosis is made by clinical and CT findings, and treatment is appendectomy. When an opportunistic infection is identified, specific antimicrobial therapy should be administered.

CHOLECYSTITIS

Cholecystitis in persons with HIV infection may occur with or without stones. Acalculous cholecystitis is approximately twice as common as cholelithiasis (French et al., 1995). Acalculous cholecystitis has been most commonly associated with infection with *Cryptosporidium paarvum*, *Microsporidium,* and CMV although a host of other pathogens have been described (Slaven et al., 2003; Fantry & Chen-Chih, 2002). These opportunistic infections are usually a complication of severe immunosuppression (Walden, 1999). Presentation may be acute or chronic, with right upper quadrant pain in 90%, and fever, nausea, and vomiting in about half. As in appendicitis in patients with AIDS, leukocytosis is unusual. Transaminase and bilirubin levels are usually unremarkable. Ultrasound evaluation commonly shows a thickened gallbladder wall and/or a distended gallbladder, with or without stones. Cholecystectomy is the treatment of choice. Specific antimicrobial therapy should be used when an infection is diagnosed.

CHOLANGITIS

In HIV, cholangitis is usually associated with opportunistic infection, malignancy, or immunologic destruction of the biliary epithelium. Manifestations include sclerosing cholangitis and/or papillary stenosis. *Cryptosporidium* and CMV are the most commonly identified associated infections. The clinical presentation is similar to that of cholecystitis. The alkaline phosphatase is usually markedly elevated, with minimally elevated transaminases and bilirubin, and a CD4 count <100. Ultrasound or CT will usually show dilated biliary ducts. Evaluation with endoscopic retrograde cholangiopancreatography (ERCP) is indicated, during which biopsy and bile cultures may be obtained. Stents can be placed to relieve obstruction from strictures, and sphincterotomy may help treat pain in some cases (Slaven et al., 2003). Celiac plexus neurolysis should be considered in patients with refractory pain (Collazos et al., 1996). Antimicrobial therapy is indicated when an infection is identified.

INTESTINAL PERFORATION

Intestinal perforation in patients with HIV infection is uncommon, but most commonly caused by ulceration resulting from CMV infection. Manifestations can be misleading, with minimal tenderness, no fever, and a normal WBC. Other causes include lymphoma, KS, histoplasmosis, peptic ulcer disease, and appendicitis. Treatment is surgery, together with antimicrobials or chemotherapy depending on the etiology.

OTHER CONDITIONS

Pain can be due to enlarged intra-abdominal lymph nodes due to MAC, KS, or tuberculosis. In patients with MAC, the infection is disseminated, and patients may also have fever, diarrhea, hepatosplenomegaly, anemia, and increased alkaline phosphatase and gamma-glutamyl transpeptide (GGT). Intestinal obstruction is an unusual manifestation of KS or lymphoma. Intussesception is rare and may be due to lymphoma, KS, or mycobacterial infection. The presence of skin or oropharyngeal lesions of KS may be a clue to visceral disease. Lymphoma in AIDS is usually NHL and may lack peripheral adenopathy as a presenting manifestation. Lactate dehydrogenase (LDH) is frequently elevated. Toxic megacolon has been described in association with CMV, *Clostridium difficile,*

or bacterial infection. Surgical resection of affected area is probably the best approach, but endoscopic decompression has been reported to be effective in a few cases. Mortality remains high. Tuberculosis in persons from endemic areas can reactivate in HIV infection. Enteritis is an unusual manifestation and usually affects the ileo-cecal region and causes right lower quadrant pain. Tuberculous peritonitis can manifest with fever, pain, and ascites. The diagnosis of tuberculosis requires pathologic findings on tissue biopsy and is confirmed by culture. In advanced patients, intra-abdominal abscesses may form from tuberculosis or MAC. Abdominal aortic aneurysms have been described as part of a vasculopathy syndrome related to HIV infection. It is caused by a vasculitis in arterioles of the gastrointestinal tract, resulting in ulceration. Some individuals have been reported to have multiple aneurysms. Surgical repair is likely the best approach, but stenting has been used (Chetty, Batitang, & Nair, 2000).

ANTIRETROVIAL MEDICATION-RELATED MANIFESTATIONS

Lactic Acidosis

Although asymptomatic lactic acidosis is often seen with the use of nucleoside reverse transcriptase inhibitors, the syndrome of severe, potentially fatal, lactic acidosis in AIDS is fortunately very rare. Abdominal pain is usually part of the presentation along with marked weakness and fatigue. At times, this entity will progress to profound lactic acidosis, hepatic steatosis, hepatic failure, and frequently death. The only definitive treatment to date is withholding antiretroviral therapy. Zidovidine and stavudine are the most commonly identified culprits (Smith, 2002).

Pancreatitis

See above.

Nephrolithiasis

Nephrolithiasis has been associated with indinavir use, especially with inadequate hydration (Kopp et al., 1997). A case of cholelithiais due to indinavir has also been reported (Verdon et al., 2002).

RHEUMATOLOGIC/MUSCULOSKELETAL PAIN

ARTHRITIS AND ARTHROPATHIES

HIV infection has been associated with various nonspecific arthralgias, reactive arthritis, and psoriatic arthritis. Reiter's syndrome typically affects young men and may be associated with urethritis and conjunctivitis. Some patients may have keratosis blennorrhagia, stomatitis, or balanitis. The arthritis tends to be severe, most often involving knees and shoulders, and treatment with

NSAIDs and or steroids is usually unsuccessful. Psoriasis and seborrheic dermatitis seem to occur more commonly in patients with HIV infection. Psoriasis-associated arthritis may be severe and deforming. NSAIDs, sulfasalazine, or gold therapy may be effective in the treatment of psoriatic arthritis. A form of seronegative arthritis not associated with Reiter's syndrome or psoriasis has been described in patients with advanced HIV infection. The few cases reported were described as having severe and debilitating arthritis of the lower extremities (Masci, 2001). NSAIDs and intra-articular steroid injections are the treatment of choice (Tehranzadeh, Ter-Oganesyan, & Steinbach, 2004). In the past, treatment of Reiter's syndrome or psoriatic arthritis with methotrexate had resulted in clinical deterioration. It is not clear what effect the use of HAART would have on these conditions.

AVASCULAR NECROSIS

The incidence of avascular necrosis (AVN) in HIV-infected patients has increased over the past few years. The increase in the use of HAART might have contributed to the increase in AVN, although the mechanism remains unclear. The most common symptom is hip pain, but the process may affect other locations such as the knee, shoulder, ankle, and wrist. Weight-bearing and activity-associated pain is seen in most cases, but rest pain can occur in two thirds of patients, especially those with advanced disease. The process is usually progressive, resulting in joint destruction within a few years. Conventional radiographs, CT, MRI, and nuclear studies can all be used to diagnose AVN. With a sensitivity around 90%, MRI can reveal the stage of the disease and the extent of the necrosis (Tehranzadeh et al., 2004). The definitive treatment is hip replacement, but the mainstay management is pain control. NSAIDs may be effective in early disease, although opioids are frequently required to control pain.

POLYMYOSITIS

Polymyositis is the most frequent muscle disorder seen in association with HIV. It typically occurs early in the course of HIV infection. The manifestations include proximal muscle weakness, muscle wasting, and elevated creatine kinase (CK) levels. Electromyography (EMG), MRI, and muscle biopsy are the principal diagnostic techniques (Masci, 2001; Tehranzadeh et al., 2004).

ZIDOVIDINE MYOPATHY

Drugs used in the treatment of HIV, particularly zidovidine, have also been associated with the development of myalgias and myositis. Clinically indistinguishable from polymyositis, it is characterized by myalgia, fatigue, proximal muscle weakness, and elevated CK levels. The mechanism is thought to be mitochondrial toxicity. Discontinuation of

the medication leads to resolution of the syndrome within several months (Tehranzadeh et al., 2004).

SKIN

Various skin conditions can result in pain in patients with HIV infection. KS is a neoplastic condition, occurring predominantly in men who have sex with men. When it involves the skin, typical lesions are nodular and violaceous in color. Pain is not a usual manifestation unless the lesion ulcerates or, more commonly, it causes lymphatic obstruction. Lesions may occur in the lower extremities causing edema and pain. Radiation and/or systemic chemotherapy are used to treat KS, and pain is usually treated with opioid analgesics. If lesions respond to therapy, pain may resolve; however, persistent pain due to neuropathy as a result of chemotherapy, radiation, or HIV is common. Non-narcotics are more suitable to treat this type of pain (see section on neuropathic pain).

In debilitated patients, most frequently those with advanced AIDS, decubitus ulcers may be seen due to nutritional deficiencies and poor healing. Pain relief can be addressed with small doses of narcotics, if tolerated. Incontinence of stool and urine can result in frequent soiling of the affected area and may prevent healing (Grothe & Gottlieb, 1999). Topical treatments and dressings along with relief of pressure and improved nutrition may help to heal decubitii and relieve pain. In patients with nonhealing or expanding ulcers, viral cultures should be done to exclude herpes simplex infection, and treatment for infection of the soft tissue or underlying bone should be considered.

HSV infection can cause recurrent genital or rectal lesions. In the immunocompromised individual, these can occur more frequently and at times remain as chronic ulcerations. These are usually painful, and symptoms of pain or tingling can herald the onset of an outbreak. Specific treatment of the infection with an antiviral agent is usually all that is necessary to treat the pain. Acyclovir 400 mg tid, valacyclovir 500 mg bid, or famciclovir 500 mg bid can be used until the lesions resolve. Occasionally resistant HSV requires treatment with intravenous foscarnet. The incidence of resistance to oral agents may be rising (Reyes et al., 2003).

Herpes zoster (HZ) can be painful and may lead to postherpetic neuralgia (PHN) (see below).

PERIPHERAL NEUROPATHY

INTRODUCTION

HIV-associated neuropathies have become the most frequent neurological disorders associated with HIV infection. They may be due to a variety of factors, including antiretroviral medication toxicity, immunological dysregulation produced by HIV infection, opportunistic infection, or a combination of all of these factors. Neuropathy can also result from other causes, such as heavy alcohol consumption, vitamin deficiency, diabetes, or chemotherapy.

PREVALENCE

Symptomatic neuropathies occur in approximately 15 to 50% of patients with HIV (Martin et al., 2003). The prevalence of pain increases in the advanced stages of illness. The risk of peripheral neuropathy increases with higher plasma HIV viral load, lower CD4 cell counts, and increasing age (Lopez et al., 2004; Simpson et al., 2002).

NEUROPATHIES ASSOCIATED WITH HIV INFECTION

Several types of peripheral neuropathies have been diagnosed in patients with HIV and AIDS (Luciano, Perdo, & McArthur, 2003; Pardo, McArthur, & Griffin, 2001). The following discussion is separated into sections on clinical features, diagnosis, and management. Most can have pain as a component of the condition; however, even those that do not present with pain will be mentioned here for the sake of completeness. They include:

1. Distal symmetrical polyneuropathy (DSP)
2. Antiretroviral toxic neuropathies (ATN)
3. Herpes zoster (HZ) and postherpetic neuralgia (PHN)
4. Mononeuropathy mutiplex (MM)
5. Diffuse infiltrative lymphocytosis syndrome (DILS)
6. Lumbosacral polyradiculopathy (cauda equina syndrome)
7. Mononeuropathies
8. Inflammatory demyelinating polyneuropathies
9. Autonomic neuropathy

Clinical Features and Classification

Distal Symmetrical Polyneuropathy

This condition is one of the most common neuropathies in HIV infection and usually presents in the middle and late stages of HIV infection (Keswani et al., 2002; Luciano et al., 2003). It commonly begins as tingling and numbness in the toes bilaterally, then gradually spreads proximally from the lower extremities, rarely involving the upper extremities. Early painful dysesthesias of the lower extremities are common, but patients may also complain of numbness. Ankle jerks are decreased or absent. Knee jerks are occasionally decreased and may be absent in severe cases. Vibratory, pain, and temperature sensation are usually decreased, but muscle weakness is not a prominent symptom of DSP and generally occurs only in advanced disease.

Antiretroviral Toxic Neuropathies

This type of neuropathy may occur at any stage of HIV infection. ATN can be indistinguishable from DSP, except for the temporal association of symptoms with the initiation of antiretroviral medication. ATN is more likely than DSP to be painful, have an abrupt onset, and progress rapidly (Dieterich, 2003). Nucleoside reverse transcriptase inhibitors (NRTIs) are the class of drugs most frequently associated with peripheral neuropathy, particularly the so called "d" drugs: ddI (didanosine), ddC (zalcitabine), and d4T (stavudine) (Luciano et al., 2003; Keswani et al., 2002). Some evidence suggests mitochondrial toxicity as a mechanism for NRTI-associated neuropathy (Luciano et al., 2003).

Herpes Zoster (Shingles) and Postherpetic Neuralgia

HZ or "shingles" is a localized cutaneous eruption that results from reactivation of VZV infection. HZ can occur in anyone who has had varicella, but is more common with increasing age and in immunocompromised patients. Pain of variable severity occurs in virtually all patients with acute herpes zoster. An erythematous macular rash usually occurs in a dermatomal distribution, but may be delayed by up to 5 days after the onset of pain. The rash progresses to clusters of clear vesicles, evolving to pustules and ulcers, and finally to crusted lesions. Healing occurs in 2 to 4 weeks and frequently results in scarring. Pain that persists for more than 30 days after the onset of the rash is termed PHN. Pain and hyperesthesias can persist for months and occasionally years (Gnann and Whitley, 2002).

Mononeuropathy Mutiplex

A condition called mononeuropathy multiplex can occur either early or late in the course of HIV infection. In early stages of HIV infection, MM is immune mediated, whereas in advanced AIDS it can be caused by infection with CMV, hepatitis B, or hepatitis C, particularly when associated with cryoglobulinemia (Stricker et al., 1992; Verma, 2001). Patients can present with numbness, tingling, abnormal sensation, burning pain, dysesthesia, or paralysis. Symptoms are restricted to the territory of the affected nerve, although multiple nerves may be affected. Presentation may be that of an asymmetric sensorimotor polyneuropathy affecting multiple nerves, often in a stepwise progression.

Diffuse Infiltrative Lymphocytosis Syndrome

An unusual cause of peripheral neuropathy, DILS is characterized by a persistent peripheral blood polyclonal CD8+ lymphocyte (CD8) expansion. Peripheral lymphocytosis is present, with lymphocytic infiltration of parotid glands, lungs, lymph nodes, lacrimal glands, kidneys, muscles, and nerves. The most common manifestation is salivary gland enlargement, mainly bilateral parotid gland enlargement (Kazi et al., 1996). Other manifestations include peripheral sensory neuropathy, as well as diffuse lymphadenopathy, xerostomia, hepatosplenomegaly, interstitial pneumonitis, and profound muscle weakness (Berger & Simpson, 1998; Kazi et al, 1996; Nopachai, Garwacki, & Moll, 2004).

Lumbosacral Polyradiculopathy

Lumbosacral polyradiculopathy is usually associated with CMV infection, but may rarely be associated with HSV infection, tuberculosis, syphilis, or cryptococcal infection (Hernandez-Albujar et al., 2000; Kolson & Gonzalez-Scarano, 2001). A rapidly progressing cauda equina syndrome can occur in patients with AIDS, but has not been reported in patients with asymptomatic HIV infection. The clinical picture is one of severe back and leg pain associated with lower extremity weakness. Numbness and tingling can begin in the feet or in the saddle region. Symptoms can be asymmetric, especially early in the course of this condition. Progression occurs rapidly, resulting in a flaccid paraplegia with bowel and bladder incontinence. Most untreated patients die within a few weeks.

Mononeuropathies

Mononeuropathies associated with HIV infection include cranial neuropathies and others such as median neuropathies at the wrist, ulnar neuropathies at the elbow, peroneal neuropathies at the fibular neck, and phrenic neuropathy at the diaphragm (Piliero, Estanislao, & Simpson, 2004). Symptoms and signs depend on the location of the nerve involved and include numbness, decreased sensation, tingling, burning pain, weakness, and paralysis. Other symptoms include impairment of taste and hyperacusis.

Inflammatory Demyelinating Polyradiculoneuropathy

Two major forms of demyelinating polyradiculopathy have been reported in HIV-infected patients: acute inflammatory demyelinating polyneuropathy (AIDP) and chronic inflammatory demyelinating polyneuropathy (CIDP). AIDP, also known as Guillain–Barre syndrome (GBS), has been reported in HIV-infected patients, usually occurring at the time of seroconversion or in asymptomatic individuals with CD4 cell counts > 500.

The AIDP (GBS) clinical course evolves fairly rapidly, over days to weeks. Although AIDP and CIDP share many clinical features, CIDP usually occurs in the advanced stages of illness and evolves over weeks to months. In both disorders, the motor deficit predominates but mild sensory symptoms may be present (Verma, 2001). Patients typically have absent or reduced reflexes as well as patchy numbness and weakness. Cranial palsies, respiratory muscle involvement, and autonomic dysfunction can occur in GBS but are uncommon in CIDP.

Autonomic Neuropathy

Autonomic dysfunction appears to be common in HIV-infected individuals, with as many as 76 to 84% having at least one abnormality on a battery of autonomic tests. The manifestations of autonomic dysfunction in patients

infected with HIV appear to be similar to those in non-HIV-infected patients. The severity of autonomic dysfunction generally correlates with the progression of HIV disease. Common symptoms include nausea, vomiting, orthostatic hypotension, heat intolerance, diarrhea, constipation, urinary incontinence, bladder dysfunction, impotence, anhidrosis, or hyperhydrosis (Rogstad et al., 1999).

Diagnosis

The diagnosis of the peripheral neuropathy syndrome in patients infected with HIV is based on the clinical picture supported by electrophysiological studies. Blood tests are frequently obtained to exclude other causes of neuropathy such as vitamin B_{12} or folate deficiencies, thyroid disease, or syphilis. Lumbar puncture is indicated only if neuropathy is associated with encephalopathy or with a presentation suggestive of lymphoma or CMV infection.

Distal Symmetrical Polyneuropathy and Antiretroviral Toxic Neuropathies

1. Laboratory evaluation in DSP/ATN is relatively unrevealing, but it should exclude other causes of this type of neuropathy. Testing should include
   - Vitamin B_{12} and folate levels
   - Thyroid-stimulating hormone assay
   - Fasting blood sugar
   - Liver function tests
   - Blood urea nitrogen and creatinine
   - Serum protein electrophoresis and immuno-electrophoresis
   - Screening test for syphilis (RPR or VDRL)
2. Spinal fluid is mostly acellular and protein levels may be slightly increased.
3. EMG and nerve conduction velocity studies show predominantly axonal sensory-motor polyneuropathy.
4. Nerve biopsy shows axonal degeneration of long axons in distal regions. The density of both small and large myelinated fibers is reduced, and in particular, the density of unmyelinated fibers is reduced.

Herpes Zoster (Shingles) and Postherpetic Neuralgia

Diagnosis is usually based on the distinctive clinical appearance of the rash. However, the appearance may be atypical, especially in the immunocompromised host. A direct immunofluorescent assay is a sensitive and rapid confirmatory test. Viral culture is possible, but VZV is difficult to recover (Gnann & Whitley, 2002).

Mononeuritis Mutiplex

Lab tests are ordered to identify and screen for other causes of MM. These include complete blood count with differential, lyme antibody titer, hepatitis screen, cryoglobulins,

and erythrocyte sedimentation rate (ESR). Diagnosis is made mostly by EMG and nerve conduction studies (electrophysiological studies). Electrophysiological studies show an asymmetric, sensorimotor, axonal polyneurpathy. Patients infected with HIV with mononeuropathy multiplex and CD4 counts less than 200 cells should be evaluated for CMV infection. CNS infection can be diagnosed by identification of CMV by viral culture or PCR of the spinal fluid. CMV can also be diagnosed in other commonly infected organs such as the eye, by characteristic retinal findings on slit lamp exam, and in the gastrointestinal tract by tissue biopsy (Keswani et al., 2002).

Diffuse Infiltrative Lymphocytosis Syndrome

Laboratory testing reveals CD8 lymphocytosis, with peripheral CD8 counts greater than $1,000/\mu l$ and CD8 lymphocytes representing more than 60% of peripheral lymphocytes. CD4 counts are variable, ranging from 44 to 847 cells/μl in one review. Antinuclear antibodies and anti-Ro and anti-La antibodies are absent. HLA DR5, DR6, or DR7 is positive in more than 50% of patients with DILS and DR2 present in more than 36% of patients. Nerve biopsy shows focal loss of myelin fiber and intense cellular infiltrate.

Lumbosacral Polyradiculopathy

Suspicion of this diagnosis should prompt immediate treatment. Lumbar puncture reveals a high white blood cell count consisting largely of polymorphonuclear leukocytes, an elevated protein content, and a glucose level that may be normal or significantly reduced. CMV can be cultured from the CSF in approximately 50% of the cases, but testing for CMV DNA PCR in the CSF can provide a more rapid diagnosis. EMG and nerve conduction studies reveal primary evidence of axonal loss in lumbosacral roots with later denervation potentials in leg muscle, sometimes with asymmetric involvement.

Mononeuropathies

Diagnosis is based on the clinical presentation and confirmed by EMG, nerve conduction studies, and nerve biopsy.

Inflammatory Demyelinating Polyradiculoneuropathy

Lumbar puncture should be performed in the evaluation of possible GBS or CIDP. CSF shows elevated protein and lymphocytic pleocytosis of 10 to 50 cells/mm^3, with a normal glucose. EMG may be helpful in the diagnosis of GBS and CIDP. Nerve conduction studies demonstrate slow conduction, delayed latencies and conduction blocks, and reduced sensory and motor amplitudes.

Autonomic Neuropathy

In patients infected with HIV with symptoms of dysautonomia, autonomic function can be assessed by measurement of pulse rate variability on standing, resting, and

deep breathing, Valsalva manuever, isometric exercise, cold face test, and mental stress. Blood pressure is measured during standing, lying down face up, resting, and on Valsalva maneuver.

Treatment

Distal Symmetrical Polyneuropathy

Treatment options for HIV-related and drug-induced distal symmetrical polyneuropathy are limited. Management of polyneuropathy is largely symptomatic and usually aimed at ameliorating dysesthesias. NSAIDs, tramadol, narcotics, and transdermal lidocaine are all used empirically. A pilot study of high-dose capsaicin patch has shown benefit in both DSP and ATN Simpson et al., 2004). Although TCAs are used for the treatment of painful diabetic neuropathies, they were ineffective in treating HIV-associated painful neuropathies in one study (Kieburtz et al., 1998). Despite this finding, TCA**s** are still used by many practitioners, alone or in combination with other agents. Anticonvulsants including gabapentin, carbamazepine, phenytoin, topiramate, and lamotrigine are widely used based on their efficacy with other types of neuropathic pain (Bennett & Simpson, 2004; La Spina et al., 2001).

The use of gabapentin for the treatment of painful HIV-related neuropathy was found to reduce pain in a small group of patients (La Spina et al., 2001). Efficacy with gabapentin has also been demonstrated for the treatment of painful diabetic neuropathy and postherpetic neuralgia. Beneficial effects began with doses greater than 1800 mg/day (Misha-Misroslav, 2002). In our practice, gabapentin is frequently used for the treatment of painful HIV-related neuropathies. The usual starting dose is 100 mg tid, but doses can be increased to 1200 mg tid. There should be a delay of several days between dose adjustments to allow for maximum effect at a given dosage. Slow escalation of doses can also allow for tolerance to side effects such as somnolence and dizziness. In patients requiring higher dosages, the addition of a second agent (antidepressant, anticonvulsant) may help to achieve a more rapid desired effect. In refractory cases, patients may respond to opioid analgesics.

Antiretroviral Toxic Neuropathies

Treatment should include the discontinuation of drugs that cause peripheral neuropathy. About two thirds of patients will eventually respond to NRTI discontinuation, but there may be a "coasting phenomenon," where the neuropathy worsens for 1 to 6 weeks. This is followed by gradual improvement, with recovery in 3 to 19 weeks (Nardin & Freeman, 2004). Remaining symptoms may be due to irreversible toxicity or concomitant DSP. In a small randomized, double-blind, placebo-controlled study, lamotrigine use was associated with a substantial decrease in pain compared with placebo in the treatment of HIV neu-

ropathy. A larger and more recent study demonstrated that the beneficial effect of lamotrigine was seen in patients with ATN rather than DSP. The starting dose was 25 mg given either daily or every other day. Dose escalation occurred over 7 weeks, to reach a maximum of 400 to 600 mg per day in two divided doses. Higher doses were used in patients who were taking drugs known to induce the metabolism of lamotrigine (Simpson et al., 2000, 2003). Recent studies have also shown that nerve growth factor is associated with major improvement of pain compared with placebo. However, there was no improvement in the secondary measures of nerve growth regeneration, and the drug is not commercially available. Amitriptyline, mexiletine, topical capsaicin, acupuncture, 5% lidocaine, and gabapentin may also be useful for treating ATN.

Herpes Zoster (Shingles) and Postherpetic Neuralgia

HZ may be treated with acyclovir, valacyclovir, or famciclovir. In the immunocompetent host, treatment with antivirals may accelerate the rate of healing and reduce the severity of acute pain. Variable benefit has been reported with respect to a reduction in the frequency and duration of postherpetic neuralgia. The addition of corticosteroids may shorten the course of the acute illness, but has no effect on the incidence or duration of postherpetic neuralgia. For acute pain associated with HZ, short-acting narcotic analgesics should be prescribed. For persistent pain, long-acting opioids are preferred, by either oral or transdermal routes. Sympathetic nerve blockade can provide rapid, temporary relief of severe pain (Kotani et al., 2000).

Treatment of PHN may be complex. The value of aspirin is limited, and ibuprofen is ineffective. Topical formulations of aspirin, ibuprofen, lidocaine, and prilocaine have all been reported to be useful. Capsaicin cream may offer modest benefits, but one third of patients may suffer intolerable burning during application (Kost & Strauss, 1996). In various studies, opioids, tricyclic antidepressants, and gabapentin have been shown to reduce the severity and duration of PHN, either as a single agent or in combination (Gnann & Whitley, 2002). A reasonable approach is to use escalating doses of gabapentin, with the addition of TCAs and possibly opioids if necessary. In patients with intractable pain, intrathecal methylprednisolone once weekly for 4 weeks has shown promising results (Kotani et al., 2000).

Mononeuritis Mutiplex

Treatment of mononeuritis mutiplex depends on the underlying cause. For early-stage patients with CD4 counts > 200 cells/µl, only supportive care is recommended as patients may improve spontaneously. If cryoglobulins are found, plasma exchange is the treatment of choice. If CMV is documented in the CSF, in other organs, or by finding typical CMV inclusions on nerve biopsy, treatment with an antiviral agent should be initiated. Gan-

ciclovir is the treatment of choice, but those who are intolerant of this drug can be treated with foscarnet or cidofovir. If a nerve biopsy demonstrates vasculitis, treatment options include intravenous immunoglobulin, plasma exchange, and prednisone (Nardin & Freeman, 2004).

Diffuse Infiltrative Lymphocytosis Syndrome

DILS is treated primarily with antiretroviral drugs, mainly protease inhibitor–containing regimens, with or without corticosteroids. Although DILS often improves with treatment, spontaneous improvement has also been reported.

Lumbosacral Polyradiculopathy

CMV-induced cauda equina syndrome is a medical emergency, and treatment should be started based on clinical suspicion. Ganciclovir intravenously is the treatment of choice. Foscarnet is recommended as an alternative therapy for patients with suspected ganciclovir resistance or ganciclovir-induced leucopenia (Corral et al., 1997).

Mononeuropathies

No clear treatment has been defined. For facial nerve palsy, which may occur during seroconversion, acyclovir with or without prednisone may be considered as this is the treatment for non-HIV-associated Bell's palsy. For other mononeuroathies, a nerve biopsy may provide an etiology, and specific treatment can be administered — immunosuppression for vasculitis or antimicrobials for infection (Nardin & Freeman, 2004).

Inflammatory Demyelinating Polyradiculopathy

The treatment of choice for AIDP (GBS) is plasmapheresis or high-dose intravenous immunoglobulin (IVIG), while that for CIDP is oral corticosteroids. Acute exacerbations of CIDP may require plasmapheresis or IVIG. For patients with advanced disease (CD4 < 100) and evidence of CMV end-organ disease, consideration should be given to treatment with ganciclovir, foscarnet, or cidofovir. In AIDP (GBS), patients may develop significant respiratory muscle weakness, requiring ventilatory support.

Autonomic Neuropathy

Treatment for autonomic neuropathy is supportive. The use of elastic stockings and sleeping with the head elevated may reduce the symptoms of postural hypotension, but some patients may require treatment with Fludrocortisone. Reduced gastric motility can be treated with reglan, small frequent meals, and sleeping with the head elevated. Bladder dysfunction is treated with intermittent catheterization or medication such as bethanechol.

SUMMARY

In dealing with the symptom of pain in the patient infected with HIV, one should be aware of the possible etiologies of the pain, with special attention to the possibility of infection or malignancy. In many cases, diagnosing and treating the underlying condition will be crucial to amelioration of pain. The degree of immunosuppression should direct the pace and extent of medical evaluation. Much of the existing literature regarding treatment of pain in the HIV-infected patient predates the availability of effective treatment for HIV and may not be relevant to patients currently receiving effective antiretroviral medication.

It is likely that inadequate treatment of pain by physicians continues to exist among providers of HIV care. It is important that evaluation and treatment of pain be systematic, with assessment of the impact on daily activities. The aspect of pain management in HIV must also be focused on healthy individuals with active daily lives in whom adequate pain management could dramatically improve quality of life.

Injuries from Motor Vehicle Accidents

Christopher R. Brown, DDS, MPS

INTRODUCTION

In the last 30 years, there have been more than 10 million "moderate to severe" injuries and over 1.5 million deaths in the United States from motor vehicle accidents (MVAs). The National Safety Council reported in 1996 that 11.2 million traffic collisions occurred. Of those, 9.6 million were a combination of property damage only and/or non-disabling injury collisions. The economic cost to the United States was estimated to be $176.1 billion, a staggering amount of money.

In terms of the dollar costs involved, Evans in *Traffic Safety and the Driver* indicates property damage to top the list at 37%, with medical costs in fifth place at 6% of the total (1991). Data from the National Highway Traffic Safety Administration (1987) referencing the total cost are presented in Table 38.1 (Evans, 1991).

As presented by the Association for the Advancement of Automobile Medicine in 2003, work-related motor vehicle crash injuries cost employers $41.5 billion in 2000 and required them to pay $18.4 billion in wage–risk premiums. Employer health care spending on MVAs was $7.7 billion in 2003 with another $8.6 billion spent on sick leave and life and disability insurance for crash victims. New York and New Jersey employers carry the highest per cost per employee in the United States at $630 and $540, respectively (Miller, 2003).

Understanding what happens to humans in MVAs takes more than statistics, graphs, and charts. It requires a combination of learning tools, investigative procedures, and a thorough understanding of human anatomy and physiology. There is often an educational gap between clinicians who treat MVA victims and engineers who observe the vehicles involved. As automobiles become

relatively "more safe" in terms of death rates, resulting soft tissue injuries probably will increase. People who used to die in car wrecks are now living thanks to improved car safety, an efficient emergency medical (EMS) system, and specialized trauma training, the result of which presents diagnostic, therapeutic, and economic challenges. The more clinicians know about the biomechanics and occupant kinematics (human motion), the more efficient and accurate the care that can be delivered and the more informed the rendering of opinions regarding causation.

From an engineering perspective, certain factors about the automobile such as its weight, speed, and vector (direction of motion) can play a part in the resulting occupant trauma. Other factors that may affect occupants need to be understood as well to fully appreciate and estimate the resulting forces that may contribute to human injury potential.

BIOMECHANICS

Biomechanics is a very inexact science when it comes to human beings and their injuries. Although mathematical predictions are accurate and easily obtainable, human reactions under different stresses are not. How can one explain when a person's parachute fails to open, and he or she beats the odds and survives a multithousand foot fall while another person will trip coming down some stairs, fall several feet, and die? Examples of human response to energy input quickly lead one to the conclusion that the predictability of individual response is based strictly on the individual's response to energy input at a given body location as a function of time; nothing more, nothing less. It is important, however, to understand generalities so that a practicing clinician can approach human injury with logical sense.

TABLE 38.1
National Highway Traffic Administration $
Estimate (1987) of U.S. Traffic Crashes

	Dollars Lost/Spent	Percent of Total Expenses
Property	27.0	37.0
Insurance	21.0	28.0
Productivity	16.0	22.0
Legal and court	4.0	6.0
Medical	4.0	6.0
Emergency (transportation, diagnosis, and support)	0.7	0.9
Miscellaneous	0.45	0.6

There are four basis response modes for a body subjected to external forces:

1. Elasticity: Elasticity is defined as deformation induced during forced application, which is completely recovered when the load is recovered. An example of this is the perfect spring. This type of reaction is rarely found in the human body.

2. Plasticity: Plasticity results from deformation of the initial geometry when the load is released. In other words, the loading and unloading paths are different. The absorbed energy is the product of force × motion in the direction of motion. Plastic deformation in essence equals the permanently stored (absorbed) energy. A good example of plastic deformation is the human earlobe's response to weighted earrings or inserts. When pressure is applied over time, the soft tissue of the ear will bend and be permanently changed.

3. Viscoelasticity: Viscoelasticity is body deformation under a load such that it recovers its geometry upon load release, but it does so by following a different loading path. The initial geometry is recovered but the body absorbs some of the applied energy. In a mechanical sense, shock absorbers and tires are good examples. Human soft tissue responds in a viscoelastic manner unless force is applied to the point of actual tissue rupture.

4. Brittleness: A brittle body ruptures with negligent plastic flow. Up to the point of rupture, however, response is purely elastic. The best example of this is glass.

Although each part of the human body under various conditions can exhibit some of these properties, in the true sense of the word, the human soft tissues respond in a viscoelastic manner.

REAR-END MOTOR VEHICLE ACCIDENTS

In reality, actual numbers regarding rear-end motor vehicle accidents (REMVAs) are impossible to track (fatal vs. nonfatal). While statistics on fatalities are easy to track, the statistics on injuries are not. This especially holds true when it comes to REMVAs. Take, for instance, the port of statistical entry for comparing the two. With a fatality, police are involved, certificates are signed. A definite path, which societies have determined as necessary is followed.

With injuries, however, this is not the case. Take into consideration the possible portals of entry into the medical system of the United States. A victim of an MVA may very well start out at the emergency room with a description of minor injuries, which may not need immediate attention. At that point, there may or may not be any type of follow through. The victim may be referred back to a family physician if he or she has one, or the victim may be left to find his or her own way. The choices people have for treatment of pain are varied. For instance, for the treatment of headaches following a REMVA, the person may choose to visit a physician, a chiropractor, a dentist, a massage therapist, an acupuncturist, an optometrist, an ophthalmologist, and so on.

Statistics, as a result, are not accurate and there is no predetermined course of action as in fatalities. In fact, even the accepted terminology varies, depending upon the source, as to how to even describe injuries as a result of REMVAs. They may be described as STI (soft tissue injuries), MIST (minimal impact soft tissue) injuries, or CAD (cervical acceleration/deceleration) injuries. All these descriptions are used to describe a pattern or type of injury as a result of "whiplash." Even with the difficulty of tracking these types of injuries, it has been estimated that 1 million to 2 million CAD injuries occur per year from REMVAs (Evans, 1992). The 2 million per year estimates occur at rates roughly 5,480/day, 1,827/8 hours, 228/hour, 114/half hour, and 4/minute. Not only are REMVA injuries substantial in number, they also can produce long-term residual effects. In fact, the rate of recovery in whiplash injuries is often reported as poor. Literature suggests 20 to 40% of whiplash injuries have debilitating symptoms that persist for years (Carette, 1994).

Most clinicians assume all REMVA vehicular motion and occupant kinematics are predictable and identical. This is far from accurate. There is no such thing as a typical REMVA. Most REMVAs are in actuality offset collisions producing nearly simultaneous torsion, tension, compression, and shear forces to the human body when viewed diagrammatically as a whole, especially when viewing individual anatomical units.

LOW SPEED VERSUS HIGH SPEED

For practical purposes, the working definition of a low-speed impact is a collision in which the change in velocity of the vehicles (usually the one that contains an occupant claiming an injury) is less than 10 mph. It must be emphasized that this definition of low speed is subjective. Clearly, no general consensus among experts exists. This definition is used to delineate automobile speeds not predict occupant injury. In other words a "low speed" collision does not imply the lack of injuries just as "high speed" does not imply more severe injuries. In fact nearly one third of all injuries occur at below 20 miles per hour impact (Watts, Atkinson, & Hennessy, 1996). Essentially, the speed of the impact may not correlate with the severity of injury.

Although it is commonly accepted to describe impact severity and injury potential as functions of change in velocity, caution should be used when considering impacts of grossly dissimilar durations. Comparison of impacts based solely on their respective changes in velocity inherently assumes the impacts occurred over a similar duration, typically 90 to 140 ms for low-speed impacts. For the majority of accidents, this is a reasonable assumption. However, in some collisions, such as underride or sideswipe collisions, the impact duration may be in excess of 300 ms. Given an equal change in velocity, a vehicle that undergoes a longer-duration impact will be exposed to lower peak forces. For this reason, underride and override collisions, although sometimes involving very high dollar amounts of property damage, can be less severe in the resulting occupant injury than a "no damage" collision. There is no correlation between the amount of vehicle damage and occupant injury.

To provide an example, one must first understand the measurement of forces involved. The rate of acceleration, independent of mass, of an object falling to the Earth's surface represents a value due to gravity, referred to as g. The value of g (near the Earth's surface) is a constant measured as 32.2 ft/s^2 (or 9.81 m/s^2). Under normal conditions, this is the acceleration we are accustomed to experiencing in our daily lives, so it is often referred to as 1G. To exemplify the effects of impact duration, consider skidding a vehicle to a stop. In theory, decelerating a vehicle from 30 mph to a stop by applying the brakes involves an impact between the tires and the roadway with a change in velocity of 30 mph, but with impact duration of approximately 2.0 s. The skidding vehicle is decelerated at approximately 0.7 g. Although braking a vehicle to a stop involves a 30-mph change in velocity, this is a quite different event from a 30-mph front-to-barrier impact. The barrier impact occurs over a much shorter duration and typically involves decelerations of 30 to 50 g.

A factor to consider in low-speed rear-end motor vehicle accidents (LSREMVAs) is impact forces, which are concentrated over very small areas. As an everyday event, this may occur while backing into a small-diameter pole in a parking lot or contacting a corner or small area of a bumper. Vehicle structures typically deform in proportion to the amount of force applied. In impacts with narrow objects or to the corners of vehicles, the contact forces are distributed over a very small area producing large local stresses (force per unit area). These large local stresses can damage bumper and vehicle components at changes in velocity below the strength of that area. Testing by the Insurance Institute for Highway Safety indicates that the amount of damage and costs of repair will vary dramatically from car to car and will even vary greatly for the same vehicle depending on the type and angle of low speed collision (Kauffman et al., 1993). These factors have to be taken into consideration to determine forces transferred to the occupants.

In reality, however, the definition changes situationally according to needs; professions that deal with MVAs and human injury may erroneously assume that "one size fits all." In other words, there is a mechanism of injury that either happens or does not happen: people get hurt or they don't. From the perspective of the dental profession it had been assumed that for temporomandibular joints (TMJs) to become injured in an REMVA, the mandible had to go through a full range of motion and in essence hyperextend. Video recordings of LSREMVAs clearly indicate that in low-speed collisions this is often not the mechanism of injury. A few authors, therefore, erroneously assume that because this particular mechanism of injury is not present, the TMJs or other joints cannot be injured. That, of course, is false logic. All parts of the body, no matter where the location, receive injuries from many sources. The mechanisms of soft tissue injury are similar and subject to physiological response. Clinicians need to be aware of these mechanisms to clearly understand, diagnose, and treat the injuries they see. Understanding leads to a more definitive diagnosis and more effective treatment.

Statistics themselves are not applicable when trying to predict individual occurrences. Statistics may be used as an academic yardstick but cannot be used to predict how an individual or small group of occupants will respond in any given situation. Predicting or judging any injury based on a population smaller than what is statistically significant in the measured population is erroneous. There are countless examples of people who "beat the odds" in tremendously potentially destructive situations and escape unscathed. On the other hand, there are also many examples of people in seemingly less traumatic circumstances who are severely injured, even die. To this end, every patient should be evaluated independently. Patients destined to recover will do so in the first 3 to 4 months after initial injury (Barnsley et al., 1994). The consequences are both long term and far reaching, resulting in extended sick leave and increases in disability (Per-

Olof et al., 1998). Beyond that time period, the probability of permanency increases.

While statistics vary greatly, it is safely assumed that up to 50% of all REMVAs will result in some type of neck injury. The risk of occupant disability is approximately 3 to 6%, a staggering amount when one considers the number of motor vehicle accidents per year (Ono et al., 1993). As previously mentioned, future studies might indicate these numbers will increase as the deaths decrease. There is no truth to the assumption that injured people get better after some type of settlement or what is known as "green back poultice."

COLLISION DYNAMICS

There are three different types of collisions in every REMVA:

1. Automobile to automobile
2. Occupant to automobile interior
3. Occupant body part to body part

AUTOMOBILE TO AUTOMOBILE

The easiest type of collision to understand is automobile to automobile. The motion is commonly divided into four different phases:

1. Contact
2. Vehicle at the peak of acceleration
3. Vehicle starting to slow down
4. Vehicle slowing to a stop

All such factors as bumper height, weight of the vehicle, angle of impact, and environment may change the function of time and velocity resulting in an overlap of each phase.

OCCUPANT TO AUTOMOBILE

The second collision, occupant to automobile interior, can also be generalized into four separate phases:

1. 0 to 100 ms. The initial phase occurs at zero to 100 ms. When the vehicle moves forward out under the test subject, initial forward and vertical motion of the hips and low back occurs. Simultaneously, the upper part of the seat begins to flex rearward under the load of the torso, which remains stationary during this time period.
2. 100 to 200 ms. After the first 100 ms, the seatback reaches maximum rearward movement. The subject moves upward and forward resulting in neck compression, cervical spine straightening, and movement upward and rearward. The head is in a chin-up type of position and begins to rotate rearward. By 160 ms, the vertical motion of the torso begins to pull the neck forward as the head continues rearward.
3. 200 to 300 ms. At 200 ms, maximum vertical motion has taken place. At 250 ms, the head starts a forward motion. The seatback returns to its original position while the torso extends back down the seatback.
4. 300 to 400 ms. At 300 ms, the descent of the torso is now complete and is moving at the same velocity as the vehicle. At 400 ms, active deceleration of the neck occurs, all impact-related motions are virtually completed, and the human body is moving at the vehicle's velocity.

The total time for human movement in REMVAs is 0.1 to 0.2 s. Whether the impact results from low or high velocity, the time of energy exchanged is virtually the same. This is due to the biomechanical properties of the elements involved and may vary only by a few fractions of a second.

OCCUPANT BODY PART TO BODY PART

Human injury comes not from the first collision, but from the second and third collisions. Obviously, contact from the human being to parts of the automobile can produce great amounts of soft tissue injury. These can come from movement of the body into the seat, the headrest, a seatbelt, steering wheel, dashboard, automobile pillars, windshield, etc. All are potential injury mechanisms for human beings. However, the third collision (body part to body part) has a great effect, especially in low-impact situations. As the automobile goes through the motions, keeping in mind Newton's laws of motion, the occupants remain stationary relative to the automobile but seem to move toward the impact. The occupant lags behind the car, the torso lags behind the hips, the neck lags behind the torso, the head lags behind the neck, the vertebrae lag behind one another, the mandible lags behind the cranium, etc. As a result, the motion of the human during this time period is a nonphysiological motion resulting in points of injury, which will almost always be at the connective tissue junctions between hard and soft tissues (as commonly seen in the TMJs and cervical vertebrae). The result is injuries to muscles, ligaments, and tendons. In "offset" collisions, which are the most common, a great amount of rotational forces will be placed on the body. The occupants will experience compression and shear forces, which can result in great injury to the soft tissue. The differences in load variations to the human body during cycles of motion result in multiple stress

and strain points. One must remember that each REMVA is unique and is not likely to involve pure forward and backward motion. Biomechanical forces applied in REMVAs are always multidimensional. As a result, there is no *v* (change in velocity as a vector over time) or closing speed under which a person cannot get hurt. For that matter, nor is there a *v*, or closing speed, over which all people will sustain injury. The injuries are a result of individual response at a moment in time. These principles and conditions apply to soft tissue injuries and all body parts. The rate of acceleration of any given body part is of utmost importance (Newton's second law). The forces increase dramatically with an increase in acceleration. Soft tissue properties differ when applied with time variables.

Crushing of soft tissues can occur in blunt impact when body surface deforms and soft tissues become compressed between impact site and other hard tissues. Examples of these follow:

1. Tissues at the nuchal line and headrest (skull and headrest)
2. Tissues between spinal column and seatback
3. Tissues between vertebrae during ramping and submarining
4. Tissues between the condyles and skull (TMJ injuries)
5. Attachments of muscles (i.e., trapezius) during ramping and contact with friction of the seat, headrest, and body supports built into seats

Because a moving body has inertia, when it collides a force is immediately produced on the impacted surface that starts to slow the body as a whole. The result is a net force that produces differential deceleration between body segments. The resulting biomechanical stresses (shear, compression, torque, etc.) acting simultaneously, and in opposite directions, often yield soft tissue damage. Data studied with high-speed video indicate that facet shearing forces appear to be the most sensitive to increased acceleration. The spinal differentials are magnified by the phenomena of two distinct cervical motions. As the head and cervical spine extend into the head restraint, the greatest intersegmental rotation and posterior shear displacements occur along with peak neuroforaminal pressures. How the head contacts the head restraint is of vital importance when viewing the cervical deformations, which cause soft tissue "pinching" between vertebrae (Tencer, Huber, & Mirza, 2003).

DIRECT VS. INDIRECT TRAUMA

What is the difference between direct and indirect trauma? Can you separate the two when it comes to MVAs? Can you tell the difference clinically and with diagnostic testing? Actually, under the examination by magnetic resonance imaging (MRI) or clinician's diagnostic exam, tissue reaction and dysfunction are the same.

Examples of direct trauma

1. Penetrating — puncture
2. Penetrating — laceration
3. Crush mechanisms (Yes and No)

Examples of indirect trauma

1. Coup–contra-coup brain injury
2. Concussion (e.g., football helmet blow, boxer sustaining blow to the mandible)
3. Fracturing a bone
4. Spraining a knee, elbow, wrist by abnormal/repetitive movement (e.g., tennis elbow)
5. Repetitive strain syndromes of all types (e.g., carpal tunnel)
6. TMJ injuries

As previously mentioned injuries commonly occur at the interfaces between unlike tissues as a result of the following contributing factors:

1. Differential of speed of body parts (lagging behind)
2. Differential of tissue makeup yielding variance of wave transfer
3. Differential of hydraulic pressure
4. Hard tissue rebounding
5. Crush mechanism of hard tissues approximating each other
6. Cellular damage

Each connective tissue junction has potential for suffering stress/strain. These types of mechanisms rarely, if ever, occur by themselves. Biomechanical forces in the real world occur in multiple directions and conflicting degrees simultaneously. The delineation between direct and indirect trauma is not one of physiological origin but rather medicolegal only. Human tissues are limited in their ability to respond and are governed by the same laws of physics as the rest of the universe. To say that, for instance, the soft tissues of the TMJs or their supporting structures cannot be injured unless the mandible is directly struck indicates a lack of understanding, education, truthfulness, or all three. In fact, most injuries to the human body except at the exact point of impact are indirect in nature.

COMMON SOFT TISSUE ACCELERATION/DECELERATION (STAD) MIST INJURIES OF THE HEAD AND NECK RESULTING FROM LSREMVAs

1. Cervical strain/sprain
2. Cervical facet joint inflammation
3. Cervical strain
4. Cervical nerve root damage/compression
5. Occipital neuralgia
6. Myospasm/myalgia
7. Myofascial trigger points
8. Temporal tendonitis
9. Stylomandibular ligament insertion tendinosis (Ernest's syndrome)
10. Injuries to the TMJs
    - Lateral capsulitis
    - Posterior capsulitis
    - Hemarthrosis
    - Disc displacement
        Reducing
        Nonreducing
    - Adhesions in the superior and inferior joint spaces

TESTING METHODS FOR PREDICTING HUMAN INJURY

Testing methods used to determine the kinds and types of injuries received in MVAs fall into five categories:

1. Humans (live)
2. Animals
3. Cadavers
4. Computer modeling
5. Anthropomorphic test dummies

The only totally accurate way to predict human response in REMVAs is to actually use living, breathing humans. Obviously, some restrictions apply for these types of situations.

First of all, humans get injured. A review of studies using live, human testing reveals that humans are brought to the bare minimum level of injuries and then no more. Test situations have very specific parameters, and small variables can result in a great change in human response to input forces. Variables such as occupant seating, anticipation of impact, the weight of apparatus strapped to the patient, helmet versus no helmet greatly modify the parameters of human response, making each individual crash in truth anecdotal. Therefore, the threshold of human injury is not totally statistically accurate and varies greatly based on an almost inexhaustible amount of uncontrolled variables in a real-world situation.

It also should be noted that crash tests are not designed to hurt human beings. They are designed to note human motion and/or response to energy input. All other testing sources, while providing great statistical information, provide no actual correlation to human injury. If one carefully reads published reports through the Society of Automobile Engineers (SAE), it will be obvious with a few biased exceptions that human motion studies do not predict injuries or lack thereof, but carefully note that they are individually dependent.

All other types of testing including cadavers are not accurate for the human response in low-impact REMVAs. In high-speed crashes as the v increases, the correlation between live human response and other factors increases. This is because all other testing measures purely mechanical response but no material response. Pain and dysfunction often result from the material response of viscoelastic human tissue. In other words, the quicker the impact, the higher the forces received, the more mechanical a human will respond and, therefore, mechanical/cadaver/computer modeling becomes more relevant. In low-impact REMVAs, a few good studies with humans exist but virtually none with surrogates that correlate with human motion. As a result, while all crash test studies among living, nonliving, and nonhuman subjects yield good statistics for study and provide cost-effective ways to measure mechanical output, at best they provide unconfirmed approximate vague guidelines for human injury. In a comparison between Hybrid III crash test dummy biofidelity and cadaver variability, Kent and Benson concluded: "Any dummy measurement is relatively unimportant in an injury risk model that includes several experimental and cadaver characteristics as predictors." They also further conclude, "The functional relationship between any Hybrid III injury measure and actual injury risk is highly sensitive to experimental factors such as test speed, restraint condition, and seating position" (Kent & Benson, 2003, pp. 68–69).

Crash and test studies fall short in providing subjective and objective information relating to pain, central nervous system (CNS) information, biological information, physiologic information, kinetic dysfunction following impacts, and latent reaction.

All information gathered from crash test studies is statistical in nature and can never be applied to an individual in a given clinical situation.

PRINCIPLES AFFECTING SOFT TISSUE INJURIES (HOW PEOPLE GET HURT): THRESHOLDS FOR SOFT TISSUE INJURIES- — INDIVIDUAL TOLERANCES AND RISK OF INJURY

In the real world, there are no set thresholds for injuries to soft or hard tissues. Biomechanical trauma is unpredictable and anecdotal with tissue strengths and tolerance

varying under different conditions. Body parts accelerate and move at rates different from the car and from one another. To this end, there are several principles affecting soft tissue injuries.

INSTANTANEOUS CENTER OF ROTATION

The instantaneous center of rotation (ICR) of a joint is the mathematical determination of a theoretical point on which all motions rotate. The concept of ICR in a kinematic and biomechanical sense is an important one. It can be considered under healthy conditions to be the physiological center upon which human motions of a given joint will move. Various ICRs have been measured and determined for different body parts. However, in an REMVA, the ICR may change within microseconds, causing a great change in load distribution of the human body. In a landmark study by Kaneoka et al. (1999), the ICR of the spinal column was measured and found to change in as little as a sub-4-mph *v* resulting in a pathological motion.

The term ICR has been misapplied and misunderstood in some instances of human motion. This is especially true in the TMJs. First of all, the motions of TMJs are not purely rotational and do not move around the fixed axis of rotation. The axis rotation of TMJs will vary in anatomical planes. When subsequent motion of the head and neck apparatus or compressed tissue in the retro-discal area exists, the TMJs translate from the first moment. In this instance, virtually no pure rotation occurs. Under normal circumstances, the initial axis of rotation and resulting translation can very well be different from one TMJ to another within one person, resulting in axes of rotations that are not coupled symmetrically with one another.

The surface of the TMJs can be nongeometric for many reasons, including degenerative joint disease, remodeling, growth, angles of eminentiae, scar tissue, etc. The condition and surface of the articulating surfaces and supporting structures and the resulting musculature function determine the potential motions of the TMJs resulting in a very complex motion system.

For the ICR of the TMJs to be accurately determined, they would have to be rotating cylinders that remain stationary throughout the motion, which of course they do not. The mandible changes its position as it moves throughout the range of motion. The result is not just a change of the head of the mandible, but the mandible itself. As it translates, rotates, and moves in a three-dimensional position, the ICR changes as well. Studies also indicate that the trajectory of the condylar heads along the surfaces can be affected by velocity (distance/time) and is a multiplane vector that can be affected by muscle soreness, speed of forced opening, rotational forces, compressive forces, and shear forces. The ICR of the TMJ will change dramatically in a very slight, fractional opening. When the ICRs of the TMJs are not perfectly matched, the articulating surfaces of the joints can be either distracted or compressed, depending on which moment in time is measured. Rapid acceleration, such as that experienced in an REMVA, can affect the standardization of motion of the TMJs, creating nonhabitual moment arms resulting in excessive forces not physiologically compatible with the human anatomy involved. These changing patterns from moment to moment will result in gross motor dysfunction, which will produce differing articular motions. The result is that the ICR of the TMJs is a mathematical theory only and not an accurate representation of reality. TMJs and their supporting structures can become excessively damaged from indirect trauma such as that received from whiplash. The following is a list of potential TMJ injury mechanisms.

Wave Motion

Stress waves travel at the speed of sound (square root of the ratio of the Young's modulus to the material density). For the description of the elastic properties of linear objects such as wires, rods, and columns, which are either stretched or compressed, a convenient parameter is the ratio of the stress to the strain, a parameter called the Young's modulus of the material. Young's modulus can be used to predict the elongation or compression of an object as long as the stress is less than the yield strength of the material. These stress waves travel through the body, and are portions to local stresses and forces, resulting in both localized compressions and tensions. Wave speeds for car material are approximately 9,843 to 16,404 ft/s (10 times the speed of sound). Time of energy transfer is 0.1 to 0.2 s, which means the energy travels the length of the car (15 ft) in 1.5 ms. Elastic waves travel 67 times the car length (approximately 33 reverberations) in the energy transfer time of 0.1 to 0.2 s.

Although viscoelastic for the most part at low forces, human soft tissue responds in an elastic manner. At high forces and as a function of time in which the force is applied, soft tissue may respond in a plastic manner resulting in permanent injury. Plastic waves travel much more slowly (slightly faster than the collapsing of impact surfaces) in automobiles and in human tissue as well. In MVAs, both waves are present due to crushed and uncrushed vehicle components. As a result, not surprisingly, injuries often occur at locations remote from the impact site. The velocity (Newton's second law) of deformation is the predominant factor in determining the magnitude of wave created.

High Velocity

Stress waves from impact site travel at the speed of sound in the surrounding tissues. Injuries occur at interfaces of unlike tissues (e.g., meninges, TMJs, muscle to bone

attachments, facial lining), as well as tissue/air interfaces (e.g., intestinal wall/gas, sinus cavities/lining). A differentiation of tissue movement is contributed by the following mechanisms of injury: compression and expansion of the stressed tissues, production of pressure differential across a boundary, and "Spalling" energy release as an energy wave attempts to go from a dense to less dense medium (the wave is tensile; most human soft tissues can withstand more compression than tension).

Low Velocity (Most Commonly Experienced in MVAs)

Stress waves travel at less than 15 m/s. Transverse waves of lower velocity and long duration (shear waves) are produced by displacements of body surfaces. The results are differentials created at sites of attachments and sites of body part collisions. These forces will vary more when considering not only a difference in tissue viscosity but structural/architectural differences as well on both micro- and macrolevels.

Hydraulic Pressures

Tremendous amounts of pressure exerted within closed fluid systems cause tearing at micro- and macrolevels. Fluid systems (i.e., shock absorbers) exhibit various mechanical characteristics under different rates of loading. Different types react in a dissimilar manner. The "containers" burst and/or strain when loaded quickly. A study by Tencer et al. (2003) indicates that specimens show greatly increased pressure around the nerve roots during cadaver acceleration tests after the chest has accelerated but before peak head acceleration. In other words, tissue reaction is time sensitive. The forces generated will be released through the path of least resistance. In humans, this path is often the point of connection between soft and hard tissues.

$$\text{Energy Input and Force} \times \text{Compression: } F_{max} \times C_{max}$$

This formula relates to how much energy is placed on a subject (or body part) during impact and how much is "lost" during the transfer. Tissues and organs can disrupt and dissipate energy transference. The larger the $F_{max} \times C_{max}$, the more energy loss will be experienced in the soft tissues, and therefore, the greater the potential for destruction.

This relates to Newton's first law (an object at rest tends to stay at rest and an object in motion tends to stay in motion with the same speed and in the same direction unless acted upon by an unbalanced force). How much energy it takes to move tissues will determine injury potential. Tissues that slide over each other and do not resist will not absorb as much energy as those that cannot move as fast as others. The lag time between body part

motion due to differences in location, density, and reaction to forces plays a part in this phenomenon.

Occupant Position at the Time of Impact

Occupant position at the time of impact, one of the most important variables, is commonly overlooked and assumed in REMVAs. Occupant position will greatly reduce the v required to surpass the soft tissue injury threshold. The Biomechanical Assessment Profile (BAP), a position assessment questionnaire developed by the author, allows the clinician and the occupant to help estimate the occupant position at the time of impact. The slightest occupant position variation will greatly affect injury potential resulting in large increases of impact forces (SAE #930211; SAE #700361).

A normal position, such as that assumed by a crash test dummy, is not a normal position for most occupants (SAE #912914). Being out of position is actually more normal for occupants than being in position, if normal is defined by the posture of crash test dummies at the time of impact. Positioning varies by occupants' driving habits, anatomy, seat comfort, and anticipation of a collision.

There are three common actions of bullet vehicle drivers prior to impact; braking, swerving, and spinning/yawing. These motions will have an effect on the impact angle of vehicles, closing speed, and vehicle contact and could potentially negate built-in safety systems as well as directly affect vehicle damage.

These factors also greatly affect the passenger position at the time of impact. Virtually all rear impact testing with dummy and cadaver subjects has been conducted with properly positioned occupants (erect, backs firmly placed against the seat back; Whitman et al., 2003). Being out of position can dramatically change the occupants' reactions to forces and resulting kinematics. Humans react quite differently from crash test dummies especially in low-speed accidents. Variations in occupant positioning may contribute little to injury potential in high-speed crashes but can greatly increase or decrease injury potential in low-speed collisions. Whitman et al. (2003) report that as lateral vehicle motion increased in an REMVA the potential for head contact with vehicle interior surfaces increased. An "offset" REMVA therefore can greatly alter the dynamics of the occupant's kinematics (Pamjabi et al., 1998).

Preexisting Conditions

"Preexisting" is a term that is often misunderstood and abused. Susceptibility to injury does not negate the fact that damage can occur. A preexisting condition can radically lower the amount of energy required to cause soft tissue damage. While there may be evidence of a condition radiographically, such as in localized bone breakdown of the

cervical spine or the condylar head of the TMJs, the person may have been asymptomatic and remained so throughout his or her life if not for the large amount of energy transferred in such a short period of time as in an MVA.

In fact, preexisting conditions can make a person more susceptible to injury when the person forced to move faster or more than is habitually required. Conditions that may contribute include, but are not limited to, arthritis, cervical disc disease, fibromyalgia, TMD of many varieties, myofascial disorders, emotional disorders, chronic subluxation, poor spinal alignment, and cranial lesions. The curvature of the spine may also be altered due to tissue conditions or even seating posture at the time of impact.

Muscle Splinting (Pre-Tensed)

The effects of pre-tensing of the muscles can have a varying effect on injury in LSREMVAs. The potential for injury can be increased or decreased, or even not be affected. They may sound contradictory, yet any or all of these can apply to each individual on any occasion or all at once and can apply to various body parts. Examples of pre-tensing of muscles include tightening of the neck, locking the knees, pushing on the brake, and bracing with arms on the steering wheel. Any number of human responses can affect injury potential. The principles of movement are all the same.

All of the above can also relate directly or indirectly to cellular damage. Cell injury can occur when mechanical trauma damages the cell membrane, impairing its ability to act as a barrier to extra cellular calcium. Too much intracellular free calcium can overwhelm the mechanisms that normally maintain a relatively constant calcium concentration. The cell's inability to dispel the calcium can lead to an increase in osmotic pressure causing swelling, cell membrane damage, metabolic depletion, and cell death. This can occur in skeletal muscles, smooth muscles (blood vessel muscle lining), and nerve tissues. Mechanical cellular damage (from stretching) also can alter nerve tissue conduction. This cellular damage can result in muscle spasm, alteration of localized blood flow, hyperirritability, dysfunction, breakdown, and pain. All the aforementioned principles can apply to soft tissue injury on all levels simultaneously. These phenomena can occur from nonphysiologic vertebral intersegmental rotations (Deng et al., 2000), facet capsule tearing (Cusick, Pinitar, & Yoganandan, 2001), facet pinching (Tencer et al., 2003), facet translations which exceed normal limits (SAE #670919), and increased hydraulic pressure around the cervical nerve roots.

Reaction Time

The time span of energy input is rapid; total time is 0.1 to 0.2 s. In contrast, human response time is slow. Even healthy individuals' muscular reactions do not begin until 0.08 to 0.14 s. Total personal response time has been estimated at 2.5 s, but will vary according to each individual and the circumstance at the time of impact.

INDIVIDUAL HUMAN FACTORS AFFECTING INJURY

A preexisting condition will most likely increase the risk of injury. Simply understanding that an acute problem can be superimposed over a chronic condition is significant. As this would tend to lead to a predisposition to injury, it should be taken into consideration when arriving at a differential diagnosis. It is crucial that the clinician has a thorough understanding of the patient's condition. A thorough health history is essential and may include contacting previous treating clinicians.

With regard to gender, women have approximately two times more minor soft tissue injuries than men, in addition to smaller neck diameters and longer necks. As a population, they tend to demonstrate higher frequency of spinal stenosis. According to the National Safety Council, women are involved in a greater number of collisions per million miles driven and tend to have a higher frequency of injury claims with more severe injuries, requiring more extensive and costly treatment. Recovery tends to be slower, with greater disability and poorer prognosis.

Age is another important consideration, as older drivers are likely to be more prone to injury, complicated by a decreased capacity for recovery. The size of the occupant is also important. The larger the occupant's mass, the less likely an injury will occur. Taller occupants have been shown to be at risk for higher neck injury (tall and thin vs. short and fat). Size may correlate with age (children vs. adults; adults vs. elderly people). Size of body parts can also influence injury potential.

AUTOMOBILE COMPONENTS THAT CONTRIBUTE TO HUMAN INJURY POTENTIAL

HEADRESTS

Next to the position of the occupants at the precise time of impact, headrests are the most commonly overlooked contributors to head/neck injuries in REMVAs. They are often the silent contributors to occupant cervical injury. Federal law (Federal Motor Vehicle Safety Standards) requires that "head restraints must be at least 27.5 in. above the seating reference point in the highest position and not deflect more than 4 in. under a 120-lb load." Or, they must not allow the relative angle of the head and torso of a 95th percentile dummy to exceed 45° when exposed to an acceleration of 8 g.

Vans and light trucks from 1991 have had to comply with standards. Studies show an 85-cm seatback height

necessary to account for 95% of male occupants and 100% of female occupants. However, the generalization of headrest design does not allow for individual height differences and resulting cervical strain. The distance an occupant's head has to travel before impacting the headrest in a rear-end collision can greatly increase the forces applied to the head and neck (SAE #670919). This distance can vary not only from structural design but also because of the occupant's build and seating preference. American consumers as a rule prefer adjustable headrests, but rarely have them adjusted to achieve maximum effectiveness. They are often set too low to protect the head/neck complex.

Transfer of energy (0.1 to 0.2 s) and the slowness of human cervical muscles to respond (0.08 to 0.14 s) result in almost no one being able to avoid direct contact with the headrest. Therefore, in almost every case involving a rear-end motor vehicle collision direct impact to the head, neck, and torso of the target vehicle occupants by the seatbacks/headrests occurs, which can result in soft tissue injury.

Factors that affect headrest protection of occupants are positioning; ramping of the body, flexion of the seatback, head riding above and below, distance the occupant's head travels to make initial contact (longer = more force), occupant positioning, occupant's awareness of impact (bracing), and length of neck, arms, torso. Headrest design and position may contribute greatly to potential cervical/head injury. As a result of occupant motion or pre-impact positioning, the headrest may even increase occupant injury. The contact of the head and cervical spine producing posterior shear translation of the vertebrae can greatly alter injury potential.

Seat Construction

Federal Standard FMVSS 207 advocates strength requirements of 20 times the weight of the seatback. Most seats weigh about 40 lb. The resulting strength would be 800 lb, which may not be enough in a significant impact. In fact, impacts may produce forces beyond the seat's designed ability to rebound, resulting in seatback collapse that greatly affects the amount and direction of force to the occupant (SAE #930211). Seat construction is not uniform from one car to the next. It varies in angle, stiffness, elasticity, materials, and coefficient of friction. The seat design helps determine relative impact of each body part. It can lead to large differential between head, spine, shoulders, pelvis, and supporting soft tissues. Seat design can directly influence angle of force vectors, compression of the spine in association with bending forces of the rotating pelvis, as well as help determine relative flexibility of the spine. The seat can greatly affect shear and rotational forces on the occupant and influence occupant rebound motion after the input of energy. The seatback's rebound velocity is up to 150% of the initial velocity. If

the torso rebounds before the head has reached its rearmost position, the relative velocity between the head and torso will produce unequal rebound speeds (SAE #960665). In LSREMVAs, the rebound of the occupants in the front seat may be due more to the elasticity of the seat back than to vehicle deceleration. Lack of seat uniformity makes LSREMVA cervical studies difficult to standardize. As previously stated, any given study cannot be used to generalize or apply to a given individual.

Ramping

The angle of the seat produces forces that may direct the occupant up the seatback. The target vehicle's rear may be deflected upward or downward depending on the relative center of gravity between the target and bullet vehicles, resulting in the occupant traveling up the seat in a rearward position (relative to the car but stationary to the Earth). The extent of ramping depends on the angle of seatback deflection. Occupant ramping increases as seatback angle increases. In addition, the slack of the lap portion of the seatbelt is also crucial. Rearward deflection of the seat causes slack in the seatbelt. Use of a belt or no belt may affect occupant motion.

There are four important factors of body motion leading to occupant injury related to seat construction: head displacement, translation, rotation; differential motion of head, neck, torso; occupant ramping up seatback; and occupant rebound.

No fully instrumented rear impact tests are required by law for seat design. In high impacts, seatbacks cushion the occupants from great accelerations. In low impacts, the same qualities account for greater occupant acceleration in the rebound phase. The seatback design and resulting ramping may increase injury potential to the struck automobile occupants during low-speed collisions. There is a design trade-off between comfort and function/occupant protection.

Air Bags

More than 103 million (50.3%) of the more than 206 million cars and light trucks on U.S. roads have driver air bags. More than 77 million (37.5%) of these also have passenger air bags. Another 1 million new vehicles with air bags are sold each month.

Through September 2000, driver air bags have inflated in more than 3.3 million vehicles in crashes. More than 560,000 passenger air bags inflated when a passenger was occupying the right front seat.

The National Highway Traffic Safety Administration (Evans, 1991) estimates that more than 5,899 people are alive today because of air bags. Of the 62 drivers killed by air bags (48 females, 14 males), 40 are believed to have been unbelted, 21 are believed to have been using

lap/shoulder belts (5 of these may have misused their belts; 2 of these were unconscious and slumped over their steering wheels so they were on top of their air bags; 2 used the shoulder belt only; 1 used the lap belt only). Belt use is unknown for the remaining driver. By 1995, 100% of passenger cars had driver systems. A total of 85% of trucks have driver systems, and 23% have passenger systems (SAE #922523).

The purpose of air bags is to save lives. Overall, air bags have decreased belted fatalities by 12 and 27% of deaths in frontal crashes. It is estimated that 70% of frontal crash fatalities could be prevented by properly wearing safety belts and air bags (SAE #960658). Air bags save lives and decrease severity of major injuries in exchange for increasing the number of minor injuries. There is an increase in abrasions, contusions, and lacerations. The body regions most frequently injured are the head and neck, upper extremities, trunk, and lower extremities. Of injuries received, 90% are Abbreviated Injury Scale I (AIS I; SAE #960658). Air bags actually increase the total number of injuries from vehicle collisions, especially in the Δv of 16 to 32 km/h (10 to 20 mph) (Evans, 1992). There are also certain groups for which air bag deployment may pose a greater risk. These include the unrestrained, elderly people, people of small stature, disabled individuals, children, those with improper seating position, and occupants with compromised health.

There are other significant factors that may influence injuries in MVAs upon inflation: severity of crash; interior compartment intrusion; age of restrained occupant; health status including medications, drug, and alcohol use; occupant height, weight, and proportions; occupant position at time of impact/inflation; safety belt wearing including proper positioning; other occupants in the vehicle affecting the restrained driver; loose objects in the vehicle; pre-crash factors including pre-crash cardiac arrest, drowning, fire, and suicide.

AIR BAG SYSTEMS

Air bag inflation is an explosion (200 mph) capable of killing a person, in which the force is stopped in time by a nylon bag. It comprises four elements: crash sensors and controls, inflator, the air bag itself, and diagnostic circuitry. The sensor comprises a ball in a tube or spring mass sensors, which are mounted in the front of the vehicle. It is designed to activate air bag deployment when a sudden deceleration of approximately 16 to 19 km/h (9 to 11 mph) occurs in the vehicle's forward motion. Deployment starts 15 to 20 ms after initial impact. The inflator is made of a pyrotechnic device that inflates a gas generant (sodium azide) in 18 to 23 ms; 21 to 27 ms after impact. The burning sodium azide produces nitrogen gas that expands the nylon air bag. The actual inflation takes 20 to 40 ms. The force exits and inflates the air bag at approx-

imately 200 mph. The nylon air bag provides a high strength/weight ratio and is abrasion resistant with good elongation properties allowing for uniform stress distribution along seams with equally distributed forces. The driver's side air bag is smaller and circularly shaped. It has less time and distance in which to inflate due to the steering wheel. Passenger side air bags are rectangular and three to five times larger than those on the driver's side.

Air bag tethers limit intrusion of the air bag into the driver's space and allow for more lateral expansion (untethered bags extend 250 to 300 mm toward the driver and untethered bags extend 380 to 510 mm). Air bags deflate in about 80 to 100 ms through vent holes in the back of the bag. The diagnostic circuitry has three main functions: evaluating the entire system every time the vehicle is turned on, continuous monitoring, and operating a backup power source for inflation should there be system power failure.

Soft tissue injuries resulting from air bag inflation are common. Air bag injuries result from both direct and indirect trauma. They include abrasions and contusions to the head neck and chest, as well as abrasions and burns to the hands. Transient/permanent paresthesia of the chin is common as are injuries to the TMJ and supporting structures such as teeth fractures and avulsions. Cervical injuries including sprain/strain and more especially cervical facet inflammation, occipital neuralgia, myospasms, myofascial trigger points, compression neuropathies, paresthesias local to the impact site, and sphenopalatine ganglion neuralgia seem to be commonplace, as is closed head trauma.

"Smart" air bags that adjust their performance characteristics based on the environment present at the time of the collision are being used in many newer vehicles and are likely to be refined even further. They are designed to "sense" the occupant's seat position, the size of occupant (including whether the occupant is a child or infant), and adjust the deployment according to the severity of crash (closing speed). There is a tremendous need for clinical case studies of injuries resulting from air bag deployment. Observations need to be documented and published by treating clinicians so engineers can have accurate information from the field.

SAFETY BELTS

Seatbelts are not perfect but nevertheless are among the most effective and simplest devices that help save lives. Although 49 states have seatbelt laws, it is estimated that only 69% of U.S. citizens use seatbelts even when mandated. Seatbelts are designed to comfortably fit 80% of the U.S. population. Seatbelts are designed to protect the occupants by controlling the ramp up of the seat back, reduce the velocity of the occupant relative to the vehicle interior, and thus reduce injuries resulting from occupant contacts.

The regular use may minimize the potential of occupants to be out of position at the time of impact and allow the driver to be in position to remain in control of the vehicle after an impact. They may be effective in controlling forward rebound of the occupant while keeping the occupant within the vehicle. In frontal impacts, they tend to extend the time of "ride down," thus effectively reducing the force on the occupant. This is accomplished by both structural design and stretching of the fabric. Overall they tend to reduce the frequency and severity of occupant impact with the vehicle's interior (second collision), although occupants can still strike the vehicle's interior including dashboard, steering wheel, and windshield.

Most injuries from lap belts fall into the category of AIS I but can still cause permanent injury or death. The occurrence of certain injuries has increased since the appearance of mandatory seatbelt laws. Such injuries include sternum fractures, neck sprains, thoracolumbar spine injuries, as well as serious cervical spine injuries (SAE #912913). The occurrence of certain injuries appears to be directly related to the type of seatbelt. A lap belt can cause internal injuries upon frontal crashes or rebound from REMVA if the belt is positioned superior to the superior iliac crest of the pelvis. At the very least, severe strain on the lower back due to external forces is likely and may result in "flailing" injuries of the lower extremities. The use of lap belts alone will not stop occupants from striking the dashboard, steering wheel, or windshield with their heads. One of the most important considerations is that use of a lap belt can increase acceleration of the head/neck upon rebound in a REMVA, thus result in greater injury to the head and neck.

A three-point shoulder harness, which is said to be essential for air bag safety, can also cause increased forces to the neck in a MVA even if properly positioned. It will tend to add rotational forces to the head/neck upon rebound as the occupant rotates toward the door. Although it may actually increase likelihood of cervical injury in low-speed collisions, regular use appears to reduce the incidence of serious injury by >57% (Watts, 2003). Shoulder belts, while very effective in saving lives, can directly affect injury patterns and, in fact, cause injuries in low-speed accidents. Some common injuries include bruising and abrasions of shoulder, chest, neck, and abdomen. It is important to note that even with seatbelts, occupants can still directly contact the car's interior with their heads. This can vary according to the severity of the impact, location of the impact, and occupant body proportions.

BUMPERS

Bumpers were first applied to railroad cars to protect cargo rather than the car. However, bumpers were added to automobiles to protect the vehicle rather than to protect the passenger (Watts, 2003). Bumper design in modern automobiles is intended to lessen structural damage in a collision, to keep repair costs down. Most cars have what is known as 5 mph bumpers. This means that a collision 5 mph or less into a rigid barrier will not cause any permanent body damage (Watts, 2003).

There are two types of bumpers commonly used in cars. One is designed of rigid metal and is attached to the frame with pistons (isolators). These oil and gas filled cylinders absorb the forces, collapsing in the process. Another type is made of high-density polyurethane in a honeycombed or foam design with a plastic outer shell cover. The polyurethane has a viscoelastic and plastic response when energy is added in a collision, acting similarly to a spring. As the bumper collapses and expands back, energy is released in the form of motion and heat. Many times plastic bumpers can completely compress without showing any obvious signs of damage (Watts, 2003).

Trucks, vans, and SUVs often do not have the same bumper systems as cars. In fact there are no government regulations on minimal impact or height with which manufacturers have to comply in these vehicles. With so many of these vehicle types on the road, collisions with cars are inevitable. Often in low-speed collisions involving a truck and car, there is more damage to the car than the truck. There can be several reasons for this. The bumpers of the truck are often welded directly to the frame without any shock-absorbing material such as pistons or plastic foam. When contact is made in a truck/SUV–car low-impact collision, the energy absorbed and/or transmitted is different between vehicles because trucks and SUVs have much stiffer frames, making them in essence stronger than the cars. The bumper height is often higher than those in cars, yielding differences in striking heights and force vectors. When an SUV bumper collides with an automobile bumper, more forces can be transmitted to the automobile occupants producing greater occupant injury potential than if the bumper hits the soft bodywork, which is designed to collapse and absorb collision energy (Watts, 2003). The difference in costs of repair would be much greater if the automobile body was struck at the same low speed by the SUV bumper as compared with a bumper-to-bumper contact at the same speed. This scenario supports the fact that the cost of automobile repair, automobile damage, or lack thereof does not correlate with injury potential and energy transfer to the occupants. In fact according to Watts: "Even with the typical low-quality SUV bumper, the heavier and stronger vehicle usually wins when it collides with a typical car, and the SUV occupants rarely suffer injuries in low-speed impacts" (Watts, 2003, p. 126). It is important to note that it is not possible to look at bumper damage and determine if an occupant has been injured, nor is bumper damage a predictor of injuries in a given collision.

TABLE 38.2
Abbreviated Injury Scale (AIS)

0   No injury
1   Minor (may not require professional treatment)
2   Moderate (nearly always requires professional treatment, but is not ordinarily life threatening or permanently disabling)
3   Serious (potential for major hospitalization and long-term disability, but normally not life threatening)
4   Severe (life-threatening and often permanently disabling, but survival is probable)
5   Critical (usually requires intensive medical care, survival uncertain)
6   Maximum (untreatable, virtually unsurvivable)

ABBREVIATED INJURY SCALE

The AIS was developed in 1971 by the Association for the Advancement of Automobile Medicine and the Society of Automobile Engineers to statistically track injury categories. Injuries for each body region area are placed into seven levels (0 to 6). The AIS level (Table 38.2) is based on the level of injury revealed by an examination shortly after the crash by doctors trained in its application (Gennarelli et al., 1998).

As the AIS increases, the cost of medical support greatly increases. However, the purpose of the AIS is for statistics only. No level is supposed to be used as a predictor of final outcome or to estimate the cost of treatment. It is possible for injuries at any AIS level to subsequently prove fatal, although the threat to life potential of the injury increases steeply with increasing AIS level (Evans, 1992).

ADDITIONAL FACTS ABOUT MVAS AND THE RESULTING BIOMECHANICS AND KINEMATICS

1. *Biomechanics is an unpredictable science.* Mathematically, scenarios can be predicted via computer modeling, etc. and information can be gathered following an accident by extensively monitored crash test dummies or other surrogates, but one little change in an almost endless supply of variables can result in dramatically different resulting forces and injury potential. In fact, measurements may differ between individual test subjects in the same carefully monitored crash test, rendering predictions of outcome totally inaccurate. Not everyone is hurt in a low-speed REMVA. Conversely, not everyone escapes uninjured either. Applying the measured outcomes from crash test studies to predict an individual's chance of physical harm in a completely different accident is impossible. In fact, valid scientific papers are quick to point out that the gathered data cannot and should not be used in this manner (SAE #930211).

2. *There is no correlation between the costs of repair of an automobile as a predictor of occupant injury.* If there is truly a cost/injury ratio, then the higher the cost of repair, the more extensive the injuries to the occupants. In fact, often the opposite is true. Whenever a nonbumper impact to a vehicle occurs, large amounts of upper body damage occur to the vehicles involved. Vehicular panels are meant to crush, dispersing energy transfer over a longer period of time, and thus reducing the forces applied to the occupants. In today's vehicles with computerized components, the cost of repair can be quite high with very little energy transfer to the vehicle itself. In fact, a recent crash test demonstrated the cost of repair to the same vehicle at the same impact speed varied by more than $1,000, depending on the angle of impact. In bumper impacts a great amount of force can be transferred to the occupants with little or no vehicular damage. As has been previously discussed, bumpers are not designed to reduce impact to the occupants; they are meant to reduce the costs of repair in a collision (Kauffman et al., 1993).

3. *In no instances does the amount of energy transfer and resulting injury involving humans directly correlate with the cost of repair to plastic, metal, and other materials composing the vehicle.* Each individual vehicle has what is called a critical speed. This term means a speed at which permanent damage occurs. All makes of cars are different and respond differently when comparing types of collisions. Vehicles that respond well (with little cost of repair) in rear-end collisions may not do well in side or frontal impacts. There is not a material, component, or vehicle that responds equally under every circumstance or force vector. People have their own "critical speed" at which they become injured. This "speed" will vary and can only be determined after the fact, not mathematically in advance. People are not made of plastic and metal. Their tissue responses are not the same nor can they be compared. This is easily demonstrated by watching a football game. When a player is hit in the head, do the managers look at the helmet and determine if an injury has truly occurred based on the amount of damage to the plastic helmet? On the other hand, when a person has an internal injury from a fall, is it correct to examine the floor upon which he or she landed and determine if an injury has occurred by the amount of damage to the floor? Of course not, yet this is attempted routinely in injuries resulting from MVAs. The only plea for this correlation is emotional and usually in an effort to deny a claim of bodily harm. There is no scientific basis to back this up.

4. *Each accident must be analyzed as its own separate entity.* When attempts are made to understand injuries that result from motor vehicle accidents, many factors have to be included. The more the treating clinician understands about the forces involved, the more accurately treatment can be rendered. The cost of repair to the vehicles involved, however, is one factor that may be of interest

for academic and epidemiological reasons but cannot be used as a yardstick for measuring the extent of injuries or the length of treatment time, or estimating the cost of service provided.

SUMMARY

Understanding the biomechanics and occupant kinematics in MVAs is essential for the clinician who treats soft tissue injuries. New car safety has dramatically decreased car accident fatalities in the United States. The result, however, is a new challenge to our health care system. People who would have died in the past are now living, but often with extensive injuries. Soft tissue injuries are often dismissed as an annoyance or something that you have to learn to live with. The truth is that they often can be debilitating and greatly affect the quality of life of victims and their families. Learning to live with it is not the answer. The answer lies in partnerships among victims, their families, treating clinicians, and third-party payers based on education and understanding. Too often a battleground is formed with experts representing vested interests lining up on each side. The result is a "double victim": one who is a victim of trauma from the automobile accident and also of the trauma of enduring medicolegal confrontations.

Treating clinicians can also become victims of sorts. It is commonly reported that carefully and thoroughly treating MVA victims may be looked upon with distrust by third-party payers. Suggestions are being made that the practitioner cannot solely govern the formulation of a treatment plan (Farnham, 2001). Treating clinicians can become discouraged by the constant conflict of trying to help the patient heal and being castigated for trying to do so at the same time. As automobiles become more efficient in reducing deaths, the complexity of the injuries of the survivors will increase. Clinicians must strive continually to increase their diagnostic and treatment skills, keeping the best interests of the patient first and foremost.

> "It is one of the most beautiful compensations in life that no person can sincerely try to help another without helping themselves."

Diagnosis and Management of Electrical Injury

Raphael C. Lee, MD, ScD, PhD, FACS, Elena N. Bodnar, MD, and Katherine E. Rojahn, MD

INTRODUCTION

Electrical forces can inflict injury in various ways that include both thermal and nonthermal mechanisms. Nonthermal mechanisms include membrane electroporation and electroconformational denaturation of membrane proteins. Nonthermal injury mechanisms produce destructive changes on the timescale of milliseconds or less. Thermal burn mechanisms require field exposure on the scale of seconds or more. Nerve and muscle are prime targets for nonthermal mechanisms of injury. Pain and disability are frequent manifestations expressed by survivors. The injury resulting from the combination of thermal and electric effects depends on several variables, including the tissue field strength, duration of exposure, frequency, and current path. This chapter reviews the destructive changes to cellular structure resulting from exposure to commercial electrical power sources and the resulting manifestations at the organ system level. Several important new therapeutic approaches to treat and possibly reverse the molecular alterations of electrical shock are discussed.

Injury caused by contact with electrical power sources started to become a significant public health problem at the beginning of the 20th century, corresponding to the commercialization of electrical power. It became clear that commercial frequency (i.e., 50 to 60 Hz) electric force was capable of producing very severe and complex injury. Most major electrical injuries occur in the workplace (Hunt, 1992; Lee, Burke, & Cravalho, 1992; Rouge & Dimick, 1978). There are approximately 1000 annual admissions to U.S. burn centers that have been a result of electrical shock (Hunt, 1992). The death rate for individuals that require hospital admission following accidental electrical injury ranges from 3 to 15% (Rouge & Dimick, 1978) and most of the fatalities are due to high-voltage (> 1000 V) electrical shock (Hunt, 1992). Typically, low-voltage accidents requiring hospitalization involve use of electric panels, power hand tools, or industrial machines that use 220 to 440 V (Lee et al., 1992).

Electrical injury involves multiple biophysical mechanisms. To understand the pathophysiology of electrical injury one must consider the effects of Joule heating (Lee & Kolodney, 1987a), electroporation of cell membranes, and electroconformational protein denaturation (Chen & Lee, 1994; Chen et al., 1998; Gaylor, Prakah-Asante, & Lee, 1988; Lee & Kolodney, 1987b; Lee et al., 1988). Injury is also a function of the anatomical distribution of the electric field. If the electrical contact is arc-mediated (no direct mechanical contact), then acoustic blast forces may also add to the magnitude of the injury (Capelli-Schellpfeffer et al., 1998). Injury manifestation is also influenced by the relative susceptibility of tissue to injury. Tissues that communicate by electrical signals, specifically nerve and muscle tissues, are more susceptible to injury. Neuromuscular problems dominate the clinical problems of survivors, with pain being a nearly universal complaint (Pliskin et al., 1998).

This chapter is a review of the pathophysiology and clinical manifestations of injury by electric fields in the extralow frequency (ELF) range (0 to 1 kHz). Current

approaches to management of pain are discussed, as well as new methods. This will introduce several of the emerging and potentially effective strategies for the treatment and therapy of electrical trauma that may correct the complex pathophysiological interactions that accompany electrical shock (Lee et al., 1992).

ELECTRIC FIELD TISSUE INTERACTIONS

CURRENT FLOW IN THE BODY

Direct mechanical contact is usually required for electrical contact when the voltage is less than 1,000 V. Arcing usually initiates the electrical contact for high voltages (>1,000 V). Mobile salt ions are the primary charge carriers within the body and the passage of current at the interface is mediated by electrochemical reactions. Heat and toxic chemical by-products are generated by these reactions, which contribute to local tissue injury. The human body is practically a resistive load when in contact with a 50 to 60 Hz power source (Poppendieck et al., 1966).

The epidermis is the outer layer of skin that serves as a transport barrier purpose and is the largest resistive barrier to current flow through the body. However, as voltage applied across the skin increases, skin insulation is at first partially and then ultimately completely destroyed (Freiberger, 1933). The electrical resistance on the epidermis begins to decrease at voltages as small as 20 V. The skin of the palms and soles is able to withstand voltages up to approximately 100 V. It is reported that the magnitude of the voltage applied across the body has negligible effects on internal body resistance until heat denaturation, electrical breakdown of cells, or dehydration occurs. When exposed to an electrical field above the skin breakdown voltage, the body impedance from one hand to one foot is about 1,000 Ω. The internal body impedance between two hands or between two feet is about 500 Ω.

Within tissues, ionic current passes around the cells. As a result of the extracellular water content of the body being 40% of the total body weight and the electrolyte concentrations being highly regulated, the current distribution between the tissues is reflective of the relative volume of the tissues. This is demonstrated by how in the extremities the bulk of the current passes through the skeletal muscles. Because cell membranes are highly resistive, most of the ELF current is shielded from the intracellular fluid. This does not hold true for strong electrical fields that disrupt the cell membranes or for longer cells, which leak current into the cytoplasm.

ELECTRICAL STIMULATION OF MUSCLE AND NERVE

Biological cells utilize transmembrane ion current as a control signal for intracellular and intercellular communication. This is particularly true for muscle and nerve cells

---

TABLE 39.1
Reported Thresholds for Nerve, Muscle, and Injury Responses to Passage of 60 Hz Electric Current Through the Body

Electrophysiological Response	Threshold Current[a]
Sensation of pain (fingertip)	1.0 mA (M)[b]
	0.5 mA (F)
"No-let-go": involuntary contraction of forearm muscles	16 mA (M)
	11 mA (F)
Cardiac: Arrhythmia	60 mA
Ventricular fibrillation	100 mA
Electroporation of forearm muscle (hand contact)	1,500 mA

Note: Electroporation injury threshold pertains to forearm skeletal muscle and nerve tissue exposed to current passing from an electrical contact point in the hand.

[a] Assumes current path in the upper extremity.

[b] (M) = males; (F) = females.

---

and a strong example is brain–muscle communication and control. Skeletal muscle contraction is normally triggered by electrical depolarization of the membrane by nerve-mediated signals. Artificially imposed electric fields can also stimulate muscle contraction, as well as alter brain and peripheral nerve function. The magnitude of these effects is dependent on field strength and frequency.

Several distinct effect thresholds may be observed as ELF sinusoidal current passing through tissues is increased. These are listed in Table 39.1. The threshold for human (male) sensitivity to current passed into the finger is approximately 1.0 mA. If the current traveling through the forearm is raised to 16 mA, skeletal musculature of the forearm is stimulated to contract causing involuntary muscle spasm (Dalziel, 1943). During current passage, the hand cannot be voluntarily opened to "let-go" of an object in the palm. This has been called the "let-go" threshold. Because the forearm flexor muscles are more powerful than the extensor muscles, the hand becomes rigidly closed in a fist position.

If electrical current passes through the chest along the path from extremity to extremity (e.g., the hand-to-hand path), a much larger current is required to interfere with breathing and heart function because the current is spread over a wider area in the chest. Therefore, the current density and corresponding electric field strength are much smaller than in the extremity (Figure 39.1). The area available in the thorax for current conduction is greater than in the extremities, and thus the current density will be less. For victims subjected to total currents of approximately 60 mA hand-to-hand, 50% will experience cardiac rhythm disturbances within approximately 30 s (Dalziel, 1960).
FIGURE 39.1 For a fixed amount of current passing across the body, the current density is quite variable because of variations in anatomical dimensions and, to a much lesser extent, tissue electrical properties.

Electrical current can start and stop cardiac arrhythmias. Ventricular fibrillation is the most life-threatening cardiac arrhythmia. It has been established that ventricular fibrillation can be induced by electric fields of sufficient magnitude during certain phases of the cardiac cycle. It is believed that if the excitable areas of heart muscle are stimulated to contract again before other areas have fully recovered from the previous heartbeat, then the contraction will propagate through the excitable areas and into the other areas of the myocardium that are regaining excitability in time. This leads to an abnormal conduction path and an extremely ineffective discordant muscle contraction. The window for ventricular fibrillation is in the end stage of ventricular contraction systole, which coincides with the most rapid reacquisition of membrane excitability. Electrical shocks to the heart that are strong enough to completely reset the timing of all cardiac cells can result in defibrillation (Wiggers & Wégria, 1939).

THERMAL INJURY

Thermal burning is a well-recognized mode of tissue damage that occurs in electrical shock victims and, until recently, was considered the only mechanism of tissue injury in these patients. Exposure of tissue to supraphys-

iological temperatures in excess of 43°C leads to tissue injury at a temperature-dependent rate (Diller, 1994; Pennes, 1948; Tropea & Lee, 1992). The cell membrane appears to be the cellular component that is the most vulnerable to heat injury.

Tropea and Lee (1992) developed a three-dimensional model of the human arm to address the issue of the relative significance of thermal to nonthermal mechanisms of damage during electrical shock. This preserved basic anatomical details for simulating the thermal response to electrical trauma under worst-case conditions. This worst-case electrical shock scenario assumed perfect mechanical contact with the power source and all current passage was hand-to-hand. The simulation indicated that the rate of heating during contact with 1 to 10 kV was many times faster than circulatory cooling (Pennes, 1948). Blood-flow (tissue perfusion) was observed to be the most important mechanism for transporting thermal energy from Joule-heated tissues (Lee & Kolodney, 1987a; Pennes, 1948). The extent of heat-mediated tissue damage was calculated on the basis of these predicted tissue temperature histories over a range of contact voltages (Pliskin et al., 1998). These Joule heating simulations have also been supported by predictions using a one-dimensional tissue model (Diller, 1994).

Tropea and Lee (1992) also included probability of thermal injury in the model by convolving calculated tissue heating history with damage accumulation rates. Several authors have published damage accumulation rates as a function of high-temperature exposure. Despite the complexity of the process, experimentally measured thermal injury accumulation kinetics seems to obey a first-order chemical reaction process. Therefore, experimental data are reasonably described by the Arrhenius equation. Tropea and Lee (1992) used this approach to arrive at a lethal electrical contact time (LT) in which most of the tissue was lethally heat damaged. Their LT parameter was a function of contact voltage and the location within the extremity. Using the authors' rate constants, contact with a power distribution line (~10-kV contact) requires approximately 0.4 s to cause 50% muscle damage in the distal forearm tissue, 0.9 s in the mid-forearm, and 1.7 s in the mid-arm.

ELECTROPORATION INJURY

Cell membranes are designed to support transmembrane electrical potential differences in the range of 0 to 150 mV, corresponding to normal physiological operating conditions. Cell membranes do not support transmembrane potential magnitudes that are greater than 200 to 300 mV. Once the voltage drop exceeds this magnitude, the membrane becomes hydrated and the transport barrier mechanism of the membrane is lost. This membrane disruption process is called "electroporation" (Lee & Astumanian, 1996), and it is an important mechanism of tissue injury (Block et al.,
FIGURE 39.2 The cell membrane serves as a transport barrier. This means that the electrical current passes more readily around the cell. The consequence is that most of the voltage drop across the cell is imposed across the cell membrane unless the cell is so large that the resistance of the cytoplasm is equivalent to the membranes.

1995). Electroporation can be transient or permanent, depending on many variables including the magnitude of the field-induced transmembrane potential and the duration of the imposed field (Lee, Canaday, & Hammer, 1993).

To understand the physics of electroporation, the interaction between the electric field and the cells has to be considered. The distribution of current in tissues is governed by the electrical properties of the tissue and the electric field distribution. Cellular membranes are the most resistive of tissues in the body. Cell membrane conductivity is characteristically 10^6- to 10^8-fold less than the intracellular fluid under normal operating conditions. A cell essentially comprises an insulating shell with a highly conductive interior. Electrical current established in the extracellular space by low-frequency fields is to a variable degree shielded from the cytoplasm by the electrically insulating cell membrane. The voltage dropped across the cell by the surrounding current occurs mostly across the cell membrane (Figure 39.2). This induced transmembrane potential is sensitive to several factors including the geometry of the cell and its orientation in the field. For a nonspherical cell, the maximum induced transmembrane potential is dependent on the cell's orientation with respect to the electric field.

The long axes of most skeletal muscle cells and nerve axons in the extremities are oriented approximately parallel to the direction of the field lines (Figure 39.3). These cells have significantly larger transmembrane potentials induced on the membranes than those experienced by skeletal muscle cells in any other orientation or experienced by smaller cell types such as blood cells or tissue fibroblasts. A more precise quantitative appreciation for the magnitude of the induced transmembrane potentials suffered by cells in the current path can be gained by examining the predictions of the basic linear electrical cable model (Gaylor et al., 1988).

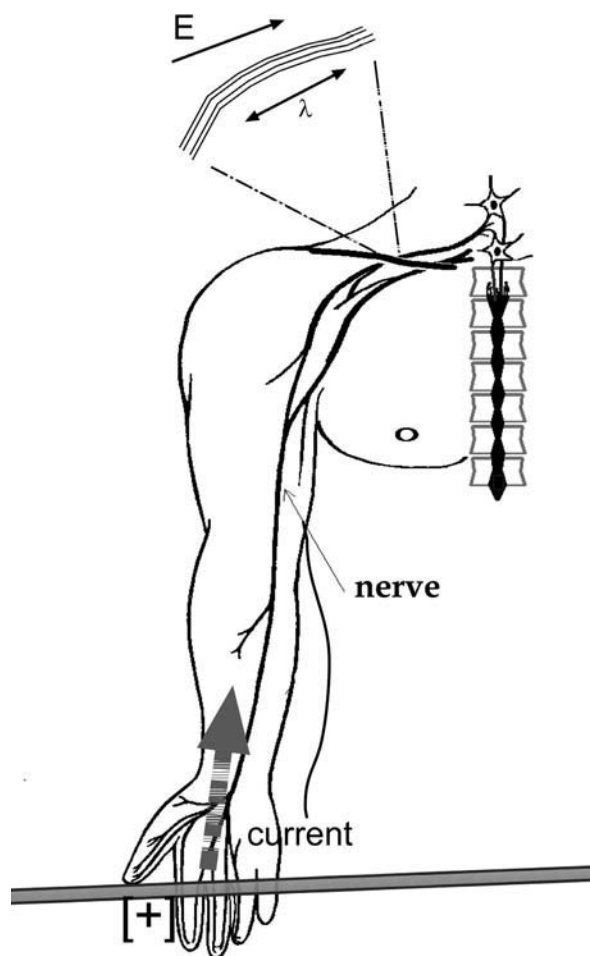
The cable model describes both the spatial distribution and kinetics of induced changes in the transmembrane


FIGURE 39.3 The physical projection of peripheral nerves and skeletal muscle in direction of current flow is much larger than the electrical space constant of these cells. As a consequence, the voltage imposed across the cell is more dependent on nerve diameter, degree of myelination, and electrical properties of its membrane.

potential. From this basic model two deterministic parameters emerge: the electrical space constant λ and the charging time τ. Dimensionally, λ is in units of distance and τ is in units of time (Figure 39.3). These parameters are very important in understanding the electroporation of skeletal muscle and peripheral nerve cells because the physical dimensions of these cells in the direction of the imposed electric field is much larger than their respective λ. This means that the maximum imposed transmembrane potential of nerve and skeletal muscle while acted upon by an imposed electric field will not exceed the product of the field strength and λ. It also means that the time required for the applied electric field to redistribute the charges across the cell membrane to reach that maximum potential is characterized by τ. For large skeletal muscle cells and large myelinated nerve fibers, the electrical space constant may reach several centimeters. These parameters are only useful in predicting the probability of electroporation

injury. Both λ and τ are dependent on the resistance and capacitance of the cell membrane as well as on the physical size of the cell. If the imposed membrane potential reaches values sufficient to electroporate the cells, then both λ and τ change.

It should be noted that the several different types of peripheral nerves differ in diameter and degree of myelination. Thus, they have different space constants and charging times. Small unmyelinated fibers are less susceptible to injury than large heavily myelinated fibers because the large myelinated fibers have larger space constants and shorter charging times. Larger space constants and shorter charging times suggest a higher induced transmembrane potential and increased rate of electroporation.

ELECTROCONFORMATIONAL DENATURATION OF PROTEINS

In addition to disruption of the lipid bilayer component of cell membranes by strong field pulses, the conformation of membrane proteins can also be altered by imposed fields. More than 30% of mammalian cell membranes is composed of proteins. These proteins are composed of amino acids with acidic and basic side groups that can be acted upon directly by an intense intramembrane electric field (Chen & Lee, 1994; Chen et al., 1998; Tsong & Astumian, 1987, 1988). In addition, amino acids of these proteins are electrical dipoles that can align along the length of the transmembrane protein to create a large electric dipole, which can also be acted upon by the field. Many small peptide dipoles in the structure of protein are aligned to effectively form a larger dipole. Generally, a molecule under a strong electric field will tend to shift to having a greater dipole moment in the direction of the field. Hence, membrane proteins will change their conformation in the presence of a strong electric field in a direction to make the effective dipole strength larger.

Effects of this can be observed in several ways, including induced dissociation of ionizable side groups, reorientation of permanent dipoles on the protein within the direction of the field, and other mechanisms. Because voltage-gated ion channels are designed to be sensitive to transmembrane voltage differences, they are the most likely target for this effect. Chen et al. measured the consequences of electrical shock on muscle ion channels (Chen & Lee, 1994; Chen et al., 1998) and found potassium channels to be more susceptible to electroconformational damage than sodium channels (Chen & Lee, 1995). The consequences of this effect may underlie the transient nerve and muscle dysfunction post-shock.

SHOCK WAVE INJURY

If the electrical contact involves high voltages in excess of several thousand volts, the current is likely to be arc-mediated. The arc is a hot ionized plasma reaching tem-

peratures of $10^4 °C$ or greater instantaneously (Capelli-Schellpfeffer et al., 1998). The resulting pressure pulse results in an acoustic shock wave that can produce serious injury, particularly to someone in a closed space environment. In addition, the shock wave transmits hot plasma directly to the victim resulting in thermal injury as well.

FACTORS INFLUENCING INJURY PATTERN

Factors that determine the anatomic pattern, extent of tissue injury, and relative contribution of heat versus direct electrical damage include the amount of current, anatomic location, contact duration, physical environment of the contact if an arc blast occurs, and health history of the victim. The type of clothing, use of protective gear, and the power capability of the electrical source also contribute to the wide range of clinical manifestations observed in electrical shock victims. In a small enclosed space, a very high-energy electrical arc can produce a strong thermoacoustic blast force leading to significant barotraumas (Capelli-Schellpfeffer et al., 1998). Associated falls and skin burns are frequent, exacerbating the injury. Cataracts characteristically occur following rapid and brief exposure of the eyes to heat and arc-mediated electrical current (Lee et al., 1992).

Electroporation of extremity skeletal muscle and nerve cell membranes should be expected when more that 0.5 to 1 A is passed through the extremity (Lee & Kolodney, 1987b). Electroporation damage accumulates in the timescale of milliseconds. With more prolonged contacts on the range of seconds, thermal damage in the subcutaneous tissues becomes substantial. Because the vulnerability to supraphysiologic temperature exposure is similar regardless of tissue type, when pathological levels of heating occur, all tissues in the current path are burned. Extensive disruption of cell membranes leads to release of myoglobin and hemoglobin, which enter into the circulation. Acute renal failure can result from intrarenal deposition of these iron-containing molecules.

When heat damage predominates, the injury is not only limited to the cell membrane, but other intracellular membranes also are involved, so the damage is likely to be irreversible. These parameters also determine the pattern of injury. Damage by Joule heating is not known to be dependent on cell size, whereas larger cells are more vulnerable to membrane breakdown by electroporation. Cells do survive transient plasma membrane rupture under appropriate circumstances (Block et al., 1995; Lee & Astumian, 1996; Lee et al., 1993). If electroporation is the primary mechanism of damage, then injured tissue may be salvageable and the challenge for the future is to identify a technique to promptly reseal the damaged membranes.

If the electrical contact time is brief relative to the LT parameter defined earlier, cell damage is more likely to be electroporation related. If the contact time is longer than the LT time, both Joule heating and electroporation

would be important. Significant membrane permeabilization can be expected to occur in average-sized human skeletal muscle cells exposed to 60 Hz sinusoidal fields with peak amplitudes greater than 25 V cm^{-1} for any contact time more than 20 to 40 ms. However, the extent of the Joule heating mediated damage depends on the duration of the contact. The Tropea-Lee model (1992) predicts that if the field strength is less than 25 V cm^{-1}, the Joule-heating rate is insufficient to produce a significant tissue temperature rise.

PAIN IN ELECTRICAL INJURY SURVIVORS

Peripheral Nerve Pain

Pain is a very common symptom and a complex problem in electrical injury survivors (Mankani et al., 1994; Pliskin et al., 1998; Solem, Fischer, & Strate, 1977; Wilbourn, 1995). Headaches, paresthesias, and dysesthesias within the distribution of peripheral nerves included in the current path are typical. In addition to these problems, many electrical injury survivors experience nerve compression symptoms. This may simply correlate to their occupation. But in our experience, most of the patients do not recall having carpal tunnel or other compression neuropathies before the injury. Complex pain syndromes and causalgia are occasionally reported as well.

Most victims of electrical shock experience transient numbness and weakness, followed by pain. The pain usually subsides over time, particularly with adequate medical help. However, some patients have persistent symptoms. The factors that determine whether the pain resolves remain to be determined. As mentioned previously, heavily myelinated fibers are more susceptible to electroporation than unmyelinated fibers, whereas there should be no difference in their relative susceptibility to heat injury. Figure 39.4 shows a plot of the second action potential as a function of the time interval between the second stimulus and the left (top) and right (bottom) ulnar nerves of an electrical injury survivor. The survivor experienced the shock in the right upper extremity. Note that the faster myelinated fibers are not functioning in the electrically injured extremity. This pattern of abnormality is quite common (Abramov et al., 1996).

In our experience (unpublished), we have often found that the peripheral pain experienced by electrical injury survivors seems to respond to a combination of anti-inflammatory cyclooxygenase inhibitors and vitamin antioxidants (ascorbate and tacopherol). We are currently preparing a clinical trial for further verification.

Emotional and Cognitive Consequences

Electrical injury is associated with a high rate of psychiatric morbidity including major depressive disorders, anx-
FIGURE 39.4 Refractory period spectral analysis of electrician who received an electrical shock with a current path of left arm to back and legs. Note the loss of fast conducting sensory nerve fibers in the left ulnar nerve.

iety disorders, and post-traumatic stress disorder (Kelley et al., 1999). These problems are commonplace regardless of whether there is direct brain exposure to the electrical shock current. Anxiety and depression certainly have a significant role in pain perception. These psychiatric issues must be managed simultaneously with establishing various approaches to pain management. This requires considerable coordination of effort. A team approach is recommended so that a scheduled dialogue between treating physicians occurs. The treating physician is unlikely to be successful in managing pain related problems without successfully managing the psychiatric problems.

Scar Inflammation and Pain

Lingering effects of wound scar pain is also common in electrical injury survivors (Pliskin et al., 1998). Survivors of major electrical injury heal with scars, which are stiff and often entrap nerves. In addition, burn scars often remain inflamed for a prolonged period leading to painful, pruritic, and hypertrophic scars. The mainstay of clinical management is to reduce inflammation and mechanical tension (Quinby et al., 1978; Roseborough, Grevious, &

Lee, 2004). Topical nonsteriodal agents with an occlusive barrier to increase scar moisture and temperature seem to be effective (Bier et al., 1999). Reconstructive surgery may be necessary to resurface a stiff, scarred, and painful skin surface.

SUMMARY AND CONCLUSIONS

The pathogenesis of electrical injury is now understood to be more complex than the traditional diagnosis of exterior thermal burns (Lee & Astumian, 1996). Treatment and recovery require full comprehension of the mechanism of electrical injury. Injury results by the actions of direct electric force on tissue components and the indirect effect of Joule heating. The kinetics of these injury processes differs so that the clinical presentation depends on the duration of field exposure (Bier et al., 1999). Electrical shock continues to be an important cause of human injury in the workplace. Many victims die immediately from cardiac manifestations, and survivors experience the effects of burn wounds and extensive muscle and nerve damage. Because of increased life support effectiveness, more victims are surviving but with disabling conditions. New diagnostic (Hannig et al., 1999; Hash et al., 1988; Karczmar et al., 1994; Tuch & Lee, 1998) and therapeutic (Basakaran et al., 2001; Lee, 2002; Lee, Capelli-Schellpfeffer & Kelley, 1994) strategies to reduce the tissue loss have been reported by multiple labs. Effective utilization of these strategies will rely on improved diagnostic imaging and on reversing the fundamental problem of cell membrane damage. If successful, these efforts should greatly improve the prognosis of surviving victims following electrical trauma.

Section IV

Diagnostic Tests and Evaluations

A. Elizabeth Ansel, RN, Section Editor

Psychological Assessment Tools in Clinical Pain Management

Kathleen U. Farmer-Cady, PsyD

INTRODUCTION

Assessment tools for the psychologist are as vital as the stethoscope and blood pressure cuff are to the physician. Patients' scores on these tools provide a backdrop for understanding them and setting hypotheses to help them unlock maladaptive behaviors. Individuals with chronic pain are doing the best they can. When they seek treatment in a pain management program, they most likely have failed self-management efforts and are subjugating themselves to the rigors of a pain management program out of a sense of desperation. They do not know what else to do, and they fear that pain will continue to force them into a sub-optimal life in which relief is questionable and being able to function normally, out of reach.

The most effective way to intervene is to see the dilemma through the eyes of the patient. If patients are depressed and at the end of their ropes, the psychologist needs to help them find a stake in life, someone or something that will motivate them to change their perceptions and let go of self-defeating habits. They see themselves as failures and hunger for therapists to say something positive about them. They yearn for hope that this walk through the valley of the shadow of death is nearly over and there is bright sunshine around the next bend. Psychological assessment provides these cues into the inner workings of the patient.

The goal of a psychological evaluation is to learn the best approach for the patient to ameliorate the pain syndrome. It is an investigation of the milestones in that person's life that helps the psychologist hone in on an area that may be especially sensitive to the patient: a married,

menopausal woman who is childless; a 23-year-old female, abandoned by her mother at birth and raised by her maternal grandmother; a police officer who retired after his home was burned and his family assaulted by criminals seeking revenge. These are the barriers to healing that assessment tools uncover, setting the stage for interdisciplinary treatment.

These tools are primarily diagnostic. They are sensitive to disorders that would make active participation in an interdisciplinary program unlikely. These tools include

1. Intelligence: Average intelligence is necessary; a person with an IQ of 89 or below thinks in concrete terms. Abstract ideas, goal setting, and visualizing a brighter future are often incomprehensible to such an intellect.

2. Cognitive functioning: The individual who has suffered a head injury, even whiplash, should be administered neuropsychological testing to identify possible cognitive impairment. Typically, these individuals will attempt to cover-up their inability to make change, follow directions, or read highway signs. Even though they know they are confused, they are ashamed that they cannot function at the level they were pre-injury. Cognitive retraining may be necessary for the person to gain compensatory skills before enrolling in a pain program.

3. Thought disorder: A basic goal of pain management is to change the individual's perception of the discomfort that is interfering with daily

functioning. However, when that person has grossly distorted perception (hallucinations) or believes physical problems have occurred through a convoluted thinking process (delusions), there exists no common ground on which to begin the process of therapy and healing. In these cases, the patient needs to be stabilized on a neuroleptic medication before being accepted into a pain program.

4. Personality disorder: The central feature of people with personality disorders is that they accept no responsibility for their behaviors and project blame onto those around them. Within an interdisciplinary pain program, they greatly admire whoever they are with but criticize other members of the staff. In other words, they split the staff. When disagreements arise about a patient at a team meeting, that patient most likely has a personality disorder. To identify such a person ahead of time allows the staff to prepare to treat this individual with firm boundaries and limits and resist requests for special treatment. The diagnosis relies on evaluating the individual's long-term patterns of functioning that are inflexible and maladaptive but stable and cause significant functional impairment. They seek attention (negative as well as positive) to boost self-esteem and they display inconsistency between words and behaviors. They often do not follow through with treatment plans or medication contracts. They also tend to procrastinate and be noncooperative when confronted with a condition or rule of the program. They may be oppositional and self-righteous. Psychological tests designed specifically to identify personality disorders usually yield too many false positives. On the Minnesota Multiphasic Personality Inventory-2 (MMPI-2), an elevated Scale 6, 7, or 8 with a conversion V (Scales 1 and 3 at T-score of 65 or above) is often predictive of a personality disorder.

5. Analgesic rebound headache: An individual who has headaches 15 or more days per month and takes medicine on these days to treat these headaches probably has analgesic rebound headache. That means the medication taken for the headaches is actually perpetuating them. The dilemma is that no other medication will help the headaches until the offending medication is stopped. If the person is taking an opioid or butalbital combination, a tapered withdrawal is indicated; other classes of medication can be stopped abruptly. The patient should not be admitted into the pain program until withdrawal symptoms have subsided, which may take several weeks. A preventative medication (such as an antiepileptic drug) and a clonidine patch are often prescribed to assist the patient through this difficult time of detoxification.

STRUCTURED CLINICAL INTERVIEW

The interviewer has a list of questions to ask the individual directly. However, at the same time, there are questions to be answered covertly through behaviors displayed during the interview and through elaboration of the answers. The following is a list of covert questions in the back of the psychologist's mind during the interview and while interpreting the assessment measures.

COVERT QUESTIONS

1. Is the pain real? Does the patient show obvious or exaggerated signs of being uncomfortable? Does the patient appear well-groomed, smiling during descriptions of excruciating pain, and seemingly unscathed by the reported discomfort?

2. Does the patient have hope or resources for the process of recovery? Does the patient indicate a desire for a new direction or a broader horizon? When hopelessness is reframed as an opportunity, what is the person's reaction? Anger? Ridicule? Excitement?

3. What does pain mean to the patient? Often the person has never considered this question. During the interview, summarize the answers into a formula that may become the focus of treatment.

Meaning of Pain	Focus of Treatment
Punishment/atonement	Self-forgiveness
Strength/taking on others' pain	Set protective boundaries
Victimization	Affirmations: independence
Focus of life	Create other interests
Destruction of quality of life	Define new life path
Numbing to life/emotion	Get in touch with body
Physical pain disguises emotional pain	Identify/release pain memories

4. What are the patient's strengths/resources?
   Supportive relationship with spouse/family
   Employed/desire to return to work
   Impaired but not incapacitated
   Sense of humor
   Religious conviction/faith
   Willing to try new approach
   Able to participate in therapy
   Positive outlook

5. Can the patient give up pain or must residual pain remain?

6. The number of years that pain has been part of the patient's life has taken a toll. Regardless of the years that the current pain has existed, often there is a history of earlier bouts with pain, which were overcome or healed, indicating a positive prognosis. However, the longer that the patient has attempted to cope with chronic pain, the more likely that psychological maladaptations have developed. These include fear that nothing can help, anger at the medical system for being unable to help/fix patient, outrage that God has forgotten him or her, despair over ever functioning "normally" again.

7. Things will get worse before they get better. A breakthrough psychologically will increase pain level temporarily.

STRUCTURED PAIN INTERVIEW

1. When and how did the pain start: injury, illness, assault, spontaneously?
2. What else was going on at that time?
3. How have you coped since then?
4. What medications and treatments have you taken? What worked and what didn't?
5. Education/employment
6. Hobbies
7. Religion
8. Describe typical day

TRENDS THAT DIRECT TREATMENT

During the structured clinical interview, the psychologist listens for themes that direct further investigation and may become the focus of the treatment plan. There are five dominant themes among pain patients from a psychological perspective:

1. *Theme*: Cold hands, cold feet, cannot relax, no power over pain
   Intervention: Temperature biofeedback

Finger temperature is an indicator of the level of stress the individual is carrying within the body. Those with a chronic condition usually have a finger temperature in the 70s, compared with the average finger temperature of 85°F. Biofeedback is the process of training the body to regulate an automatic physiological function. Under the assault of pain, the body responds automatically with the fight-or-flight sympathetic reaction. By warming the finger to 96°F, the emergency response is replaced by the relaxation response. By incorporating biofeedback into daily living, the parasympathetic system balances the sympathetic response to pain and maintains physiological

homeostasis. In this way, the process of thermal biofeedback lowers the overall rating of pain and provides the individual with at least a brief reprieve from chronic pain. Biofeedback is a tool that gives the person a level of control over pain. (Finger thermometers or "Plain Stress Meters ST60" can be ordered from www.cliving.org; Conscious Living Foundation, P.O. Box 9, Drain, OR 97435; 800-578-7377.)

2. *Theme*: Negative self-talk. Puts self down. history of abuse. difficult childhood
   Intervention: Cognitive behavioral, using positive affirmations

Negative self-talk is an automatic private conversation that goes on inside a person's mind in response to an occurrence in the environment which degrades or berates the individual. Often these negative evaluations of oneself are unconscious. Under guidance from a psychologist, the individual identifies and records in a diary the downgrading messages that occur. The patient composes positive affirmations to replace the negative self-talk and repeats these affirmations frequently enough to delete the negative self-talk. With patients with pain, the first affirmation is often, "I forgive myself for being imperfect."

3. *Theme*: People pleasers who measure self-worth in terms of acceptance by others
   Intervention: Learn to say no

These individuals believe that by saying "no" or standing up for themselves, they will be rejected, abandoned, or confronted. They actually fear aggression, both from themselves and others, and confuse assertiveness with aggression. They believe the only way to avoid aggression is to be passive and compliant, often to the detriment of their health. They require assertiveness training. The first step is to identify those behaviors that are asked of them but they do not want to do, which is usually signaled by feelings of guilt, anxiety, ignorance, or dread. They are given the assignment to say "no" in unimportant situations, such as to the cashier in a supermarket. The third step is to say "no" to those who will understand, such as a friend. And finally, to successfully achieve assertiveness, they need to say "no" to the person who demands behaviors that they do not want to do.

4. *Theme*: Feels only pain
   Intervention: Get in touch with body; go beneath pain to feel other feelings and sensations

After the onslaught of pain, the body may shut down to other feelings. What's left is a sense of numbness. To begin re-sensitizing the body, the patient needs to attain a state of relaxation, both of the body and the mind. Biofeedback,

meditation, yoga, or other mind-clearing exercise helps the body and mind reach a state of detachment. The patient is led through the process of imagining where the body carries various feelings, such as joy, envy, love, jealousy, and anger. One feeling at a time is identified and located. As other feelings surface, the overall level of pain is usually reduced.

5. *Theme*: World is upside down: Existential crisis
Intervention: Answers to following questions: Who am I? What am I doing here? Where am I going?

Pain forces us to recognize our vulnerability and our lack of control over our lives. It reshuffles our beliefs and pushes us to reevaluate our worth. Often a patient has to give up a profession or a way of life that has served him or her well. There is a sense of being adrift without direction and being drawn into a downward spiraling whirlwind. Can the person regain a stable foundation? A knowledge that better things are ahead?

The three major questions of existence — Who am I? What am I doing here? Where am I going? — are asked of the patient, one at a time. The task is to write "Who am I?" on the top of a sheet of paper and list everything that comes to mind without editing, without censoring. This process takes at least 1 day, sometimes as much as 1 week. The insights and lessons are discussed with the psychotherapist who challenges the patient to greater depth into searching the self for answers.

ASSESSMENT TOOLS

The standard procedure of many interdisciplinary pain programs is to mail background and demographic questionnaires to the patient before the first visit. The patient returns the completed forms to the clinic by mail or at the first visit. The process allows for clinicians to review the data and structure their time with the patient. It is also educational for patients to have them prioritize complaints, summarize previous treatments and their effects, and consider the association among stress, psychological issues, and lifestyle habits on pain. Of the following psychological assessment measures, half of them are administered by a psychologist in the clinic; the other half are sent with the information packet for the patient to answer at home. These are Zung Depression Inventory, Visual Analog Scale, HIT-6 and MIDAS if headaches are part of the pain problem, diary to be filled out until the first visit, and the Symptom Check List.

1. Intelligence test (Wechsler Abbreviated Scale of Intelligence, WASI; Wechsler, 1999) when the patient is having obvious difficulties reading, interacting, comprehending, retaining

information. The WASI is similar in format and highly correlated with the Wechsler Adult Intelligence Scales (Goebel & Satz, 1975; Tulsky & Zhu, 2000). This short form provides a valid and reliable measure of intelligence and includes four subtests, two verbal and two performance indicators. These are Vocabulary, Similarities, Block Design, and Matrix Reasoning. Vocabulary measures verbal knowledge and fund of information. It is the single best predictor of general intelligence. Similarities measures verbal concept formation, abstract reasoning, and general intellectual ability. Block Design measures nonverbal concept formation, visual-motor coordination, and perceptual organization by requiring the person to put together geometric designs using two-color cubes to match a picture of the design. Matrix Reasoning measures nonverbal fluid reasoning by requesting the individual to complete a missing portion of an abstract, gridded pattern.

2. Mental Efficiency Workload Test (MEWT), programmed on a Palm 130, is a neuropsychological measure of cognitive efficiency. The score is reported as throughput, which is the number of correct responses over milliseconds. Two tasks, Simple Reaction Time (SRT), which measures the speed of the hardwiring of the nervous system, and Continuous Performance Test (CPT), which measures short-term memory, focus, attention, concentration, were derived from the Automated Neuropsychological Assessment Metrics (ANAM), Version 1.0 (Reeves, Kane, Winter, Raynsford, & Pancella (1994). Developed by the military, the ANAM consists of 30 computerized neuropsychological tests, from which SRT and CPT were chosen specifically to measure the cognitive efficiency of individuals suffering from disabling headaches but have been shown to measure the effects of any type of pain on cognition. However, all 30 tests are highly sensitive to central nervous system integrity and are designed for the repeated-measures paradigm. Through repeated measures, each trial is rated against the baseline performance of the individual. A drop in performance indicates a drop of cognitive efficiency due to a compromised nervous system.

The MEWT takes only 5 minutes to complete and is especially effective for measuring the impact of different modalities, especially biofeedback and opioids, on patients' performances. Often, even though they may believe they can function better using opioids, they discover that their reaction time is so slow, they

cannot tap the button on the Palm 130 to indicate they saw a stimulus on the screen. This is an objective indication that their cognitive performances are being negatively affected by medication. Likewise, biofeedback has the potential to enhance cognitive efficiency, which motivates patients to practice biofeedback every day. Using the Palm, mental efficiency can be tracked daily.

3. Zung Depression Inventory (Zung, 1965, 1973) is a self-rating depression scale for quantifying symptoms of depression. Depression is defined operationally as a syndrome comprising coexisting signs and symptoms that signify the presence of pathological changes in the areas of mood (sad, tearful) and physiological (sleep, libido, appetite, fatigue), psychomotor (agitation, slow moving), and psychological functioning (suicidal, confusion, emptiness). The response to each of the 20 statements of the Zung may be "None or little of the time;" "Some of the time;" "Good part of the time;" or "Most or all of the time." Patients are asked to respond according to how well the statement describes their perceptions during the past week. Half of the statements are worded symptomatically positive and half are presented negatively to interfere with the patient's ability to discern a trend in answers.

The raw scores are converted into an index. An index below 50 indicates no psychopathology; 50 through 59, minimal to mild depression; 60 through 69, moderate to marked depression; and 70 and over, severe to extreme depression. Validation studies compared the scores of depressed versus nondepressed patients as well as depressed patients versus normal subjects ages 20 to 64. The majority of patients with chronic daily headache scored between 60 and 70.

4. Halstead-Reitan Trails A and B are a quick neuropsychological measure of the overall level of functioning of the brain in terms of problem solving. The tasks require an ability to scan the environment quickly and put the stimuli in proper sequence. Trail A consists of 25 circles, each containing a number (1 to 25), printed on a sheet of white 8×11 in. paper. The person is asked to connect the circles in numerical order without lifting the pencil. If there is a mistake, the examiner immediately asks the individual to correct the error. Trail A is the "warm up" test to Trail B, which also consists of 25 circles but half contain numbers 1 through 13 and the other half are lettered A

through L. The task is to connect the circles, alternating from numbers to letters, i.e., A, 1, B, 2, etc. The scores for Trails A and B represent the number of seconds required to complete the tests. A normal score for Trail B is 85 seconds or less; 86 to 120 seconds means mildly impaired; more than 120 seconds, seriously impaired (Reitan & Wolfson, 1985).

5. Visual Analog Scale (VAS) of pain severity is presented graphically with a 10-cm line and end point adjective descriptors ("The Worst Imaginable Pain" on one end and "No Pain" on the other). The patient is asked to place a mark along the line to indicate the current pain level. A difference of 13 mm between consecutive ratings of pain is the minimum change in a pain rating that is clinically significant (Gallagher, Liebman, & Bijur, 2001).

6. Verbal Numeric Analog Scale: On a scale of 0 to 10, with 0 being no pain and 10 being the worst pain imaginable, what would the patient rate his/her current pain? This measure is asked and recorded in the patient's chart before and after each treatment modality in the pain program.

7. Many patients with pain complain of headaches. Because there are migraine-specific medications other than analgesics that can treat headaches effectively, it is important to differentiate the impact of headaches from other somatic symptoms on the overall rating of disability associated with pain. The Headache Impact Test (HIT-6™) (Kosinski, Bayliss, Bjorner, Ware et al., 2003) lists six questions by which to measure the impact that headaches have had on the person's life over the past 4 weeks. Scores range from less than 50, little or no impact, to 60 or more, very severe impact. The HIT-6 score has been correlated with the number of hours of lost workplace productivity over the previous 4 weeks; those with no or mild impact lost 2 hours of workplace productivity; some impact, 3 hours; substantial impact, 8 hours; and those with very severe impact (score 60 or more) lost 18 hours of workplace productivity over the previous 4 weeks. In this way, disabling headaches affect not only the individual but also colleagues, employer, family, and others depending on the individual to function at a certain level. The U.S. population mean for recent headache sufferers is 50 with a standard deviation of 10. A score difference as little as 3 points is noteworthy; 5 points is highly significant. The Migraine Disability Assessment (MIDAS) Questionnaire (Stewart,

Lipton, Kolodner, Liberman, & Sawyer, 1999) measures headache-related disability based on five disability questions from three domains of activity: employment (job or school), household work, and family, social, and leisure activities. The score is obtained by summing the number of days of missed activities and reduced productivity over 3 months. Scores range from Grade I (0 to 5), minimal or infrequent disability; Grade II (6 to 10), mild disability; Grade III (11 to 20), moderate disability; and finally Grade IV (21+), severe disability. The drawback of the MIDAS is that headache sufferers often fail to remember or admit that they missed as much of work or other activities as they did.

8. Diary or calendar: Daily log of pain rating, medication taken, and ability to function scale. (See the Headache Care Center Diary in Appendix 40.A at the end of this chapter.)

9. Symptom Check List is essentially a review of systems developed by Headache Care Center personnel for patients to report somatic complaints (see end of this chapter). There is evidence that the more areas of the body with pain, the lower the prognosis for rehabilitation (Freedenfeld, Bailey, Bruns et al., 2002).

10. Minnesota Multiphasic Personality Inventory-2 (MMPI-2) (Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989; Piotrowski & Lubin, 1990) provides an objective, reliable appraisal of an individual's behavioral adaptation to the current life situation. It consists of 567 true-or-false statements, which usually takes a patient 1 1/2 to 2 hours to complete. The biggest challenge for the psychologist is to motivate the patient to answer all the questions. It is preferable for the patient to complete the inventory in one sitting while at the clinic under supervision. However, patients with pain may require several time periods before completion. The test may be administered by computer or using an answer sheet and pencil. The results can be either scanned or entered by hand into a computer. A computerized report is then produced. A computer printout objectifies the results, making an interpretation of the results to the patient more palatable. The response graphs are explained to the patients as how they scored in relation to the normative sample; that is, they were either high or low on each scale. By expanding the test results into potential goals of the treatment program, the patients are steered toward changes that they may never have previously considered.

MMPI

The MMPI (Graham, 1987; Hathaway & McKinley, 1943) is the most studied objective behavioral assessment tool in the history of psychological testing. The interpretative data available on the MMPI have spanned countless research projects over more than 50 years of clinical use. The MMPI has been the clinical assessment tool most frequently administered in the United States (Lubin, Larsen, & Matarazzo, 1984) and some 12,000 books and articles on the inventory have been published. In addition, the MMPI has been translated into more than 115 languages and is used in 45 countries (Butcher, 1985).

In 1989, the MMPI was revised; 14% of the original items were rewritten and 154 new items were included to measure additional personality dimensions and problems. The MMPI-2 normative data were based on 2,600 subjects randomly solicited from several regions of the United States (Butcher, 1990).

Even though, initially, the MMPI results were categorized into 4 validity scales and 10 basic clinical scales, the MMPI-2 has additional scales and indices that delve deeper into the finer aspects of the person's motivation, much like peeling the proverbial onion. When patients are limited in or lack insight into their maladaptive ways of adjusting to their pain syndrome, the divergence between the results of the MMPI-2 and the patients' histories and backgrounds can become the focus of intervention. Often, these individuals have the "fix me" mentality, where they expect to invest little of themselves yet free themselves from pain. At other times, the MMPI-2 may categorize patients' responses as falling "within normal limits" (no standard validity or clinical scale T-score equaling 65 or higher). This means that their pain syndrome is neither distressing nor upsetting to them, which points to a poor prognosis for intervention.

A computerized interpretation of the MMPI-2 (Greene, Brown, & Kovan, 1998) has a database of 295 code types and corresponding interpretations to which a specific MMPI-2 profile can be matched. Interpretations are possible for 55 spike and two-point codetypes, and 238 three-point codetypes that occurred at least 20 times in the research data set ($N = 32,716$). Data from the MMPI-2 are admissible as evidence in a court of law.

Because patients with pain often score a conversion-V (codetype 1-3/3-1) on the MMPI-2, it is interesting to note that this is the third most popular configuration within the MMPI-2 database, making up 65% of the sample. However, the interpretation of this profile is much different for the pain patient than for the psychiatric patient. The assumption of the 1-3/3-1 codetype is that the individual has somatic complaints that have no basis in reality. These include headaches, chest pain, back pain, and numbness or tremors of the extremities. Eating disorders are common as are complaints of weak-

ness, fatigue, dizziness, and sleep disturbance. These individuals express emotional distress through physical symptoms and generally feel minimal levels of anxiety and depression. They show little concern about their physical problems.

By contrast, the answers by patients with pain that produce a conversion-V accurately portray their experiences. Scale 3 has 60 items that cover two general areas: physical problems and social facility, for example "My sleep is fitful and disturbed" [T]; "I feel weak all over much of the time" [T]; "I am bothered by an upset stomach several times a week" [T]; "It is safer to trust nobody" [F]; "At times I feel like swearing" [F]. For these reasons, after scoring a conversion-V on the MMPI-2, verification of the patient's history is paramount before assuming that the patient's problems are not real.

In terms of pain management, elevated validity scales (lie, L, 15 items; infrequency, F, 60 items; and subtle defensiveness, K, 30 items), paranoia (Scale 4, 40 items), negative work attitudes (WRK, 33 items), and negative treatment indicators (TRT, 26 items) are especially important. The validity scales indicate attitudes that invalidate the test scores and suggest that the person is attempting to present himself or herself in a false manner. The truthfulness of the individual is questioned. Scale 4 measures the patient's trust in interpersonal relationships and the belief that he or she is a target for bad events. These misinterpretations are very difficult to undo during a pain management program because they are based on a lifetime of experiences. This extreme defensive posture is in fact an effort to control and protect the individual. Those with a negative work attitude would not want return to work as a goal. Those with a high negative treatment indicator may not fit into an interdisciplinary treatment program.

The possibility of a personality disorder needs to be further investigated.

CONCLUSIONS

Psychological assessment tools involve more than tests. Central to the process is active listening to the patient, incorporating verbal and nonverbal communication, covert and direct messages, and using the patient's language to reinforce what the psychologist heard. Interpretation of test data is more than reporting scores (Rapaport, Gill, & Schafer, 1986). It is integrating the findings into an understandable, accurate picture of the patient. It also involves sharing the findings with the patient in a therapeutic manner, which helps the patient accept self-attributes or issues that were previously unknown, such as a behavior pattern of ignoring emotional stressors. For this person, the goal of identifying and facing emotional stressors would be an important part of the treatment plan. While scores reflect a slice of a person's response repertoire at the present moment, these are taken from a much richer background of the individual. There are also formal aspects, such as answering all the questions or writing in responses instead of answering True or False. In addition, verbalizations during the testing period should be recorded as well as behaviors, such as affect and expressive style.

Pain is an assault on the individual and as such it produces physical, mental, and spiritual repercussions. Pain invariably changes the person's life, perception, and belief system. The purpose of an interdisciplinary pain program is to reframe these changes into an opportunity for growth and positive redirection. Assessment helps navigate these attempts into channels within the patient that have previously been blocked or are misguided.

APPENDIX A: SYMPTOM CHECK LIST

PLEASE CHECK <u>YES</u> OR <u>NO</u>

YES		NO	
Now	In the past		**GENERAL**
			Decrease or increase in appetite
			Fever / night sweats
			Hypoglycemia: shakiness/weakness
			Recent weight change _____ pounds ⇧ ⇩
			Skin disorder
			Snoring
			Weakness / fatigue

			HEAD AND NECK
			Cataracts / blindness
			Change in vision
			Injury to eye/ ear
			Ear infections
			Hearing loss
			Ringing in ears
			Frequent colds or sinusitis
			Nasal / sinus congestion
			Frequent nosebleeds

			BLOOD
			Anemia
			Blood transfusion(s): date_____
			Easy bruising / bleeding
			Swollen glands / mononucleosis

			BONES AND JOINTS
			Back pain / injury
			Gout
			Joint pain
			Morning joint stiffness
			Nightly leg cramps or jerking
			Swollen, red, or warm joints

			LUNGS
			Blood in sputum
			Daily cough
			Exposure to TB / Positive TB skintest
			Falling asleep while working or driving
			Lung disease / emphysema
			Pleurisy
			Shortness of breath
			Wheezing / asthma

YES		NO	
Now	In the past		**KIDNEY AND BLADDER**
			Blood in urine
			Difficulty starting stream
			Discomfort with urination
			Frequent daytime urination
			Hernia in groin area
			History of kidney stones
			History of urinary tract infections
			History of venereal disease
			Loss of bladder control
			Loss of sexual interest
			Nighttime urination:_____ times per night
			Practice birth control: Method _____
			Sexually active

			HEART AND CIRCULATION
			Ankle or foot swelling / leg swelling
			Chest discomfort / tightness / pain
			Heart attack
			Heart murmur / rheumatic fever
			High blood pressure
			Irregular heart beat / palpitations
			Leg pain when walking
			Mitral valve prolapse
			Shortness of breath when lying down
			Varicose veins / phlebitis

			NERVOUS SYSTEM
			Difficulty speaking
			Difficulty walking
			Difficulty with memory
			Difficulty writing
			Dizziness / vertigo
			Double vision
			History of head injury
			Loss of consciousness / blacking out
			Meningitis
			Numbness / tingling
			Paralysis / stroke
			Sciatica
			Seizures / convulsions
			Severe headaches
			Tremors / shakes

Name: _____   Date: _____   MR#:_____

PLEASE CHECK **YES** OR **NO**

YES		NO	
Now	In the past		**STOMACH AND BOWELS**
			Abdominal pain /discomfort
			Black or bloody stools
			Change in bowel habits
			Colon problems
			Constipation
			Crohn's disease / ulcerative colitis
			Diarrhea / frequent loose stools
			Difficulty with swallowing
			Diverticulosis
			Gallbladder disease
			Heartburn / indigestion
			Hemorrhoids
			Jaundice / hepatitis
			Nausea orvomiting
			Pancreatitis
			Poor eating habits
			Ulcers / vomiting blood
			Use antacids: How often?_____

WOMEN

MENSTRUAL HISTORY

Age of onset_____ Last period_____

Last pap smear_____Normal / Abnormal

Number of pregnancies _____

Number of miscarriages _____

Number of abortions _____

			Heavy menstrual flow / clotting
			Hot flashes
			Irregular periods
			Menopause
			Painful intercourse
			Severe menstrual cramps
			Vaginal itching
			Vaginal spotting

BREASTS

			Had mammogram: date of last exam_____
			Lump in breast
			Nipple discharge
			Perform monthly self-exam

MEN

			Hernia / rupture
			Impotence
			Penile sores or discharge
			Prostate infection
			Testicular pain or lumps

YES		NO	
Now	In the past		**OTHER SYMPTOMS**
			A wish to be dead and away
			Alcohol overuse
			Crying spells
			Depression / frequent unhappiness
			Difficulty falling asleep or staying asleep
			Drug overuse
			Panic attacks
			Severe exhaustion / fatigue
			Stress
			Trouble concentrating
			Trouble sleeping
			Use diet pills

Name: _____   Date: _____   MR#:_____

MY DISCOMFORT REPORT CARD

Directions:

1) Evaluate level of discomfort that you treat.
2) Record results of treatment:
      Y= I obtained the goals outlined.
      N= I did not obtain my goals.
3) Record all medicines used on your calendar.
4) Bring this calendar with you to your next doctor's visit.

Goals:

1) Be able to function.
2) Use medicines as prescribed.

Monday	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday	Was I able to function? Y or N

Treatment Plan:

1) Treat all discomfort as soon as you know it is likely to interfere with your function.
2) Treat discomfort before the pain is moderate to severe.
3) Rest for 30 minutes after taking meds.
4) Other_____

Tips for Success

1) Keep your discomfort medicines with you.
2) Do not skip meals.
3) Establish consistent wake & sleep schedules.
4) Do something for yourself everyday, ex. go for a walk, relaxation.
5) Analyze each "No" response on the diary and make notes about why your goal was not achieved.

Laboratory Testing in Pain Disorders

W. John Diamond, MD

INTRODUCTION

Our most primitive indicator of tissue injury, or of a threatening noxious stimulus, is the sensation of pain. Pain is a very subjective symptom employed by our biology to bring attention to a harmful stimulus in our inner or outer environment. As a protective mechanism of homeostasis, pain is defined by the individual patient as to its presence, significance, acuteness, quality, or intensity. Because pain is so personal and nonlinear in its presentation, therefore, does the laboratory have a role in the measurement of pain, or can the laboratory even help in the assessment and management of pain? Young (1979) listed the reasons for ordering laboratory tests in the course of patient care:

- To diagnose disease
- To screen for disease
- To determine the severity of disease
- To determine the appropriate management of the patient
- To monitor progress of the disease and to monitor therapy
- To monitor drug toxicity
- To predict response to treatment

ROLE OF THE LABORATORY IN PAIN MANAGEMENT

Certainly, we cannot diagnose or screen for pain in the clinical laboratory. But we can make underlying diagnoses, that are not normally encountered in everyday practice and that, by their pathophysiology, produce atypical pain, such as the abdominal pain of porphyria or sickle cell anemia. The laboratory can determine the severity of disease or response to treatment, such as monitoring the urine for the quantity of *N*-telopeptide cross-links as an indicator of the rate of osteoporosis or assessment of antiresorptive therapy. Drug screening and therapeutic drug levels of narcotics and anti-inflammatory drugs are now commonplace.

LABORATORY ASSESSMENT OF PAIN SYNDROMES

Margoles (1990) routinely orders the following screening tests for all patients with pain problems and possible underlying perpetuating factors:

- Comprehensive metabolic panel
- Lipid panel
- Complete blood count, platelets, and white cell differential count
- Erythrocyte sedimentation rate
- Urinalysis
- TSH, T_4, and Free T_3

These tests are probably the least one should order and will probably cover the majority of general diseases associated with, or aggravating, a pain syndrome.

The laboratory tests to diagnose or exclude not often encountered specific pain syndromes are listed in an anatomical order below.

1. *Headache*
   - Erythrocyte sedimentation rate (temporal arteritis)

- 24-hour urinary metanephrines (phaeochromocytoma)

2. *Chest pain*
   - Coxsackie B virus (1-6) Antibody (epidemic myalgia and pleurodynia, myocarditis and pericarditis)
3. *Abdominal pain*
   - Lipase and amylase (pancreatitis)
   - Sickle cell hemoglobin (sickle cell anemia)
   - Porphobilinogen and quantitative porphyrins in urine (porphyria)
   - Serum beta hCG (ruptured ectopic pregnancy, hydatidiform mole)
4. *Back pain*
   - Bence-Jones protein in urine (myeloma)
   - Serum electrophoresis, cryoglobulins (malignant gammopathy, Waldenstrom's macroglobulinemia)
   - HLA-B27 (ankylosing spondylitis)
5. *Joint pain*
   - Lyme disease antibodies
   - Uric acid or calcium pyrophosphate dihydrate crystals in synovial fluid (gout and pseudogout)
   - Serum iron and ferritin (hemochromatosis)
6. *Muscle pain*
   - Creatine phosphokinase, lactate dehydrogenase, urinary myoglobin (myopathy, storage disease)
7. *Bone pain*
   - Serum calcium, phosphorus and alkaline phosphatase (Paget's, sarcoidosis, primary, secondary, tertiary hyperparathyroidism, osteoporosis)

HOLISTIC LABORATORY ASSESSMENT IN PAIN SYNDROMES

The clinical laboratory, however, may be much more useful in a more holistic sense by assessing what other global functional disturbances of the entire body affect pain and make its experience all the more distressing or chronic. The body operates as a whole and any disturbance or imbalance in one part of the body will affect the whole body, including the appreciation and perception of pain.

LABORATORY EVALUATION OF PERPETUATING FACTORS

Any time there is an increase in perceived pain or a suboptimal response to adequate treatment in a patient with a pain syndrome, one of the perpetuating factors should be looked for and corrected (Travell & Simons, 1983). These factors include the following.

NUTRITIONAL DEFICIENCIES

- **Vitamins** — Less than optimum levels of the soluble B vitamins: B_1 thiamine, B_2 riboflavin, B_3 niacin, B_5 pantothenate, B_6 pyridoxine, folic acid, B_{12} cobalamin; vitamin C ascorbic acid; and vitamin D cholecalciferol. Travell and Simons (1983) make the point that more than half of patients with chronic myofascial pain syndrome have vitamin deficiencies that require resolution for lasting pain relief. An excess of vitamin A is possible with an excessive vitamin A supplementation.
- **Minerals** — Less than optimum levels of potassium (for rapid membrane repolarization), calcium (for the excitation–contraction mechanism of actin and myosin filaments), magnesium (for the contractile mechanism of the myofilaments), iron, and ferritin (oxygen transport as hemoglobin and myoglobin).

METABOLIC DISTURBANCES

- **Hyperuricemia** — Myofascial trigger points and muscular rheumatism are aggravated by absolute or relative hyperuricemia (Travell & Simons, 1983). Dr. Paul St. Amand (1993) has advocated the use of guaifenesin treatment as a uricosuric in the treatment of fibromyalgia.
- **Low-Grade or Frank Anemia** — Reduced oxygen tension in blood supplied to muscles, fascia, or soft tissue make trigger points more irritable.
- **Hypoglycemia** — Myofascial trigger point activity is aggravated and response to therapy is shortened or reduced by hypoglycemia.
- **Acidosis** — Lactic or metabolic acidosis will cause less efficient muscle contraction, stiffness, and pain.

HORMONAL DISTURBANCES

- **Hypothyroidism** — Absolute low or relative low thyroid levels cause irritable myofascial trigger points and low ATP levels and decrease the concentration of intracellular potassium. Laboratory levels of TSH, free T_3, and free T_4 should all be obtained. In many patients the TSH and T_4 will be normal, while the T_3 will be low. These patients have difficulty in converting T_4 to T_3 and should be supplemented with mixtures of T_4 and T_3 (Armour®, Westhroid®) or supplemented with T_3 (Cytomel®) as well as T_4 (Levoxyl®). In fact, many patients require large supratherapeutic doses of T_3 in order for their

intracellular thyroid receptors to respond (Lowe, 2000).

- **Menopausal Syndrome** — The most common pain symptoms attributed to menopause in women are dyspareunia, formications (crawling sensations), mastalgia, paresthesia, myalgia, headache, and arthralgia. These manifestations are relieved by the judicious supplementation of either estradiol and/or micronized progesterone. These symptoms are best explained in a Traditional Chinese Medicine paradigm, where the Liver Blood and Qi become stagnant or deficient and cause an energetic blockage in the organs and structures that Liver controls — the breasts, uterus, muscles, tendons, and joints.

INFECTIONS

All occult or chronic infections will produce a slew of inflammatory proteins and mediators that will ensure ongoing systemic irritation and aggravated myofascial trigger points. The most important *bacterial infection* sites include the tonsils, sinuses, teeth and jaws, and urinary tract. Laboratory measurement of C-reactive protein, sedimentation rate, a urinalysis, and a complete blood count with differential will usually point to these problems. Infected teeth and jaws will often produce clinical pain at an anatomical site distant from the head and neck depending on the energy meridian line being affected by the infected tooth.

Viral infections often worsen underlying chronic pain syndromes such as arthritis and fibromyalgia. Although all viruses can produce these exacerbations, herpes virus type I and coxsackie B virus are the worst culprits. Coxsackie B is often implicated in stressed males with atypical chest pain and unremarkable EKGs. The recent finding of "post polio syndromes" brings into sharp focus many clinical happenings long since forgotten including tertiary syphilis and the sequelae of imprudently administered hepatitis B vaccine and influenza A shots.

Infestations are uncommon, but the increased Western habit of consuming sushi has led to an increase in the incidence of the fish tape worm. *Diphyllobothrium latum,* a worm located in the jejunum, may consume 80 to 100% of all ingested B_{12} and deprive its host of the vitamin.

ALLERGIES

Environmental allergies are not commonly associated with pain syndromes, but Travell and Simons (1983) mention allergic rhinitis as a cause of nonresponsiveness to trigger point therapy due to the release of histamine. Much more common is the effect of food allergies on painful inflammatory conditions such as arthritis. The nightshade family of potatoes, tomatoes, and peppers is implicated in wors-

ening arthritis and should be avoided. Allergies to wheat, gluten, corn, soy, milk, citrus, and eggs are common food intolerances or hypersensitivities that cause a generalized inflammatory diathesis and exacerbate inflammatory pain syndromes. Individual patients will exhibit idiosyncratic reactions to specific foods or food groups and should be screened by an IgG enzyme-linked immunosorbent assay (ELISA) test for those food groups that seem to cause problems. A 4-day rotational diet, or adherence to a caveman diet, will often confirm a clinical impression of food sensitivity. Patients with chemical sensitivity, especially to petrochemicals, will often experience headaches after exposure to smoke and perfumes.

FUNCTIONAL LABORATORY TESTING OF NUTRIENTS, TOXICANTS, AND CELL REGULATORS

INTRODUCTION

Laboratory testing has moved from static one-time snapshot levels of serum or urinary analytes, to dynamic functional testing and screens of associated metabolic pathways and bodily constituents. These new tests enable clinicians to have an overview of the metabolic deficiencies and excesses in a patient and to logically correct them using dietary information, supplements, and phytonutrients.

VITAMIN STATUS

There are many ways of assessing a patient's vitamin status. Vitamin concentrations can be measured in serum and blood cells, or the excretory products formed from vitamins may be measured in the urine. Changes in enzyme activity in response to added vitamins may be measured in leukocytes in cell culture. Measurement of vitamin-dependent, specific metabolic intermediates in the urine may demonstrate the functional adequacy of a particular vitamin. Liquid chromatography and gas chromatography of serum or urine can give very accurate readings of vitamin levels in the body. Vitamins A, D, E, and K are all fat soluble and may build up to toxic levels, as they are not excreted in the urine to any extent but are dissolved into the fat deposits of the body. Vitamin C and all B group vitamins are water soluble and do not usually present a toxic buildup, as any excess vitamin is excreted in the urine.

MINERAL AND TOXIC METAL STATUS

Laboratory testing has the ability to reveal mineral deficiencies and metal toxicities in the human body. The health risks linked to inadequate intakes of nutritionally essential minerals and to increased exposure to toxic ele-

ments in industrialized societies are well documented in the scientific literature (Bralley, 2001).

Low concentrations of 13 trace elements are known to be essential for human health. These are iron, copper, zinc, iodine, selenium, boron, cobalt, chromium, molybdenum, manganese, vanadium, silicon, and nickel. The more important minerals present in very large concentrations are calcium, magnesium, and phosphorus. Sodium, potassium, and chloride are classified as electrolytes.

The most important toxic metals, for which exposure is a possibility, are aluminum, lead, mercury, cadmium, and arsenic.

Most mineral action is characterized by a bell-shaped dose–response curve. Low intake results in a deficiency state while over dosage results in a toxic state. The optimal amount of trace element intake is in the middle of the curve where function is maximized and toxicity is minimized.

Selection of what sample to use to assess a mineral's level depends on the clinical situation and the question to be answered. Tissue distribution of most elements is determined by the existence of specific protein factors that bind, transport, and store each element under hormonal or other type of homeostatic control. An ideal sampling tissue for mineral status measurement is one whose mineral stores are exchangeable with other major body pools, with a rate of exchange sufficient to provide the best sensitivity with respect to changes in dietary mineral intake.

The most popular specimens for assessing therapeutic elements are serum and plasma. Whole blood is used in emergency situations to establish acute, toxic heavy metal poisoning. Red blood cell mineral levels tend to follow the individual's general mineral levels and have proved to be popular and useful. Hair is the most popular sample for testing toxic metals in the body.

Chelation challenge or provocation tests are used to mobilize toxic elements from the tissue into the general circulation which are then measured in the urine. EDTA (ethylenediamine tetraacetic acid) in an intravenous drip, or oral DMSA (meso-2,3-dimercaptosuccinic acid) may be used in these provocation tests to reveal sequestered heavy metals in the tissue.

AMINO ACID STATUS

Nine amino acids are considered to be the essential amino acids that must be supplied by our diet. These amino acids are arginine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.

Advances in amino acid measurements now enable more than 40+ analytes to be measured, providing information on a wide spectrum of metabolic and nutritional disorders, including protein inadequacy, gastrointestinal insufficiencies, inflammatory responses, vitamin and mineral dysfunctions, detoxification impairments, cardiovas-

cular disease, ammonia toxicity, neurological dysfunction, and inborn errors of metabolism.

Amino acids are measured by high-performance liquid chromatography. The measured analytes are grouped into functional categories, including the nutritionally essential and semi-essential amino acids, dietary peptide-related analytes, the non-essential protein amino acids, and the intermediary metabolites, providing information on nutrient cofactor status and disorders relating to their imbalances.

LIPIDS AND ESSENTIAL FATTY ACIDS

A constant supply of fatty acids from the diet or hepatic synthesis is needed for the demands of energy production, cell membrane function, hormones, and eicosanoid synthesis. Changes in the modern diet are largely responsible for the increasing incidence of essential fatty acid (EFA) imbalances and deficiencies. The ratio of omega-6 to omega-3 fats has changed dramatically due to the widespread use of vegetable oils (mostly n-6 fats) in cooking and to the processing of oils to alter omega-3 fats to improve shelf life and eliminate their stronger taste (just think of the distinctive tastes of cod liver or flax oil). In fact, historical estimates place the ratio of n-6 to n-3 oils at nearly 1:1 for prehistoric humans, but by the turn of the 20th century, the ratio had increased to about 4:1.

Current estimates for Americans place the ratio in the range of 20:1 to 25:1! The sharp rise is due to increased vegetable oil consumption: from 2 lb per year in 1909 to 25 lb per year in 1985! The ideal dietary ratio should probably be in the range of 3:1 to 5:1, with a minimum of 1% of our daily calories coming from omega-3 oils. A recent study looked at eight essential fatty acid metabolites in 847 consecutive patients, aged 50 to 70. Of those tested, 322 had at least one EFA outside the normal range, and of those 322 patients, 57% had at least two abnormal values and 7% had five to seven fatty acid deviations (Shamberger, 1997). General trends observed included an increase in abnormal values with age and increased abnormalities in patients with heart disease and cancer.

Many of the chronic inflammatory conditions that accompany an EFA imbalance are currently treated with symptom-specific pharmaceutical drugs such as steroids, prednisone, aspirin, and other nonsteroidal anti-inflammatory drugs (NSAIDs), sulfasalazine, and colchicine. The problem with such drug therapies is that they prevent the formation of "good" anti-inflammatory eicosanoids as well as the "bad" proinflammatory eicosanoids, or they shift production of one type of eicosanoid to another. For effective, long-term management, eicosanoid production should be modified through dietary changes (balancing dietary intake of specific fats, as indicated by testing) and by controlling insulin levels in the circulation.

Maintaining a proper balance between the various families of dietary fats (omega-3, omega-6, omega-9, sat-

urated, and cholesterol) may be one of the most important preventative measures a person can take to reduce the likelihood of developing one of the chronic diseases of modern civilization, such as diabetes, heart disease, obesity, irritable bowel syndrome, and autoimmune disease. And for patients who may already have one of these diseases, EFA testing and therapy has been demonstrated to reduce both morbidity and mortality associated with these diseases.

ORGANIC ACID STATUS

Organic acids are formed in various tissues or by intestinal microbes as metabolic intermediates and end products. Accumulations of organic acids in urine can indicate metabolic dysfunction, hormonal stimulation, or even microbial overgrowth. Abnormal levels of organic acids can be traced to inherited enzyme deficiencies, buildup of toxicants, specific nutrient deficiencies, or drug effects. Every cell is affected when a metabolic pathway is interrupted. Clinical expression is unique to each patient, determined by genomic characteristics, medical history, and recent toxin exposures. Organic acid testing allows one to view the impact of all these factors.

Organic acids in the urine can demonstrate problems in fatty acid oxidation, carbohydrate metabolism, the citric acid cycle, B-complex vitamin activity, detoxification markers, neurotransmitter metabolism, and dysbiosis markers.

TOXIN AND DETOXIFICATION STATUS

One of the body's primary self-defense mechanisms is the conversion and neutralization of metabolic products and toxins into soluble and safe by-products that can then be eliminated. Many challenges to this system — a leaky gut, repeated exposure to food-borne toxic chemicals, environmental pollutants, bacterial endotoxins, and other substances — can increase the detoxification burden. This overload can lead to greater production of free radicals and damage to many body systems. Assessing multiple pathways with challenge substances provides clinical information about individuals with imbalanced detoxification.

All ingested and microbiologically produced toxins are presented to the first-pass clearance system. First-pass clearance involves the biotransformation and clearance of a chemical from the body before it reaches the systemic circulation. This clearance may take place in several organ tissues including the intestinal mucosal wall and the liver.

The liver is the body's primary detoxifying organ. Here, detoxification is carried out in two related processes known as Phase I and Phase II. Phase I serves to biotransform substances through oxidation, reduction, or hydrolysis, using the cytochrome P450 mixed-function oxidase enzymes. This process increases the solubility of molecules and prepares them for Phase II reactions, which will further increase their solubility.

The Phase I reactions are necessary for detoxification, but the resulting production of reactive oxygen species can at times be very damaging. Thus, the liver needs to be able to generate oxidation capacity when needed, yet at the same time generate no more than what is needed. Perhaps this is why Phase I systems are inducible by different compounds.

In Phase II, conjugation reactions add a polar hydrophilic molecule to the metabolite or toxin, converting lipophilic substances to water-soluble forms for excretion and elimination. Phase II reactions may follow Phase I for some molecules or act directly on the toxin or metabolite. Major Phase II pathways include glutathione, sulfate, glycine, and glucuronide conjugations. Individual xenobiotics and metabolites usually follow one or two distinct pathways. While the modification of Phase I and II enzyme activities has its basis in the research setting, there is growing appreciation of the clinical applications of such strategies.

In Phase I, the family of P450 enzyme systems is quite diverse, with specific enzyme systems being inducible by particular drugs or metabolites. Caffeine is a substance capable of testing a number of P450 systems simultaneously.

Measurement of salivary caffeine clearance provides a noninvasive procedure for quantifying hepatic microsomal function, as caffeine is almost completely absorbed by the intestine and is metabolized in the liver by P450 enzymes. Levels are affected only slightly by the presence of liver disease, although they are substantially reduced in patients with cirrhosis. P450 activity and caffeine clearance is reported to be upregulated by smoking. A variety of drugs and xenobiotics are oxidized by the P450 system. Thus, this system plays a crucial role in the detoxification and removal of many potentially toxic substances.

In Phase II pathways, a 650-mg dose of acetaminophen taken in the evening is converted to various conjugation products overnight, and the levels in the urine reflect the respective activities of pathways utilizing glutathione, glucuronic acid, or sulfate as conjugating agents. A 650-mg dose of salicylic acid (aspirin) if taken in the evening can be used as a marker of oxidative damage protection.

OXIDANT STRESS STATUS

Oxidation is a chemical process that allows life for aerobic organisms. It enables the conversion of glucose to carbon dioxide and water with the formation of energy. This action is not harmful to the rest of the cell. In other reactions of oxidation, compounds can enter into unregulated non-enzymatic chemical bond formation, which

damages the cell. These oxidation reactions are caused by reactive oxygen species or free radicals. These include the superoxide radical, hydrogen peroxide, and the hydroxyl radical. These reactive species are the responsible for most of the degenerative and chronic diseases in the body. The oxidant stress status of the body can be measured by the following:

Markers of Oxidant Damage
- *Lipid Peroxidation* — Lipid peroxides in serum and urine, serum isoprostanes, HNE (4-hydroxy-2-nonenal), oxidized low-density lipoproteins in plasma: all high.
- *Protein Oxidation* — 3-Nitrotyrosinein plasma and methionine sulfoxide in serum: all high.
- *Nucleotide Oxidation* — 8-Oxoguinasine in serum and white cell DNA strand breakage: all high.

Antioxidant Nutrient Testing
- *Glutathione* — Urinary sulfate (low) and pyroglutamate (high)
- *Fat-Soluble Vitamins* — Vitamins A, E, beta carotene, and serum coenzyme Q_{10} (all low)
- *Antioxidant Minerals* — Selenium, zinc, copper in red blood cells, hair, and urine (all low)

Note: The above information, details, and rationale of testing can be found in the literature, books (especially *Laboratory Evaluations in Molecular Medicine*, by Bralley and Lord), notes, lectures, and Web sites of the following two excellent laboratories:

THERAPEUTIC DRUG MONITORING IN PAIN MANAGEMENT

The application of therapeutic drug monitoring to optimize drug therapy in individual patients should be considered as an adjunct to the physician's clinical judgment in assessing the course and effectiveness of treatment. Always remember that each patient is an individual and no one size fits all. If the serum drug concentration does not fit the clinical picture, it may be that the effects of disease and age, or drug interactions, are responsible for alterations in the pharmacokinetic disposition of the drug.

Therapeutic drug monitoring is inappropriate for acute drug usage and in clinical situations where the clinical end point is easily followed, e.g., blood pressure measurements. For drugs with poor dose–response relationships and with a narrow therapeutic range and a low therapeutic index, and for which toxicity is a problem at upper therapeutic levels, therapeutic drug monitoring is very advantageous to patient safety and clinical drug effectiveness.

PHARMACOKINETIC ISSUES

The time course following administration of a drug is characterized by individualized patterns of absorption, distribution, metabolism, and elimination.

- *Absorption* is the crossing of drugs from the skin, muscle, or gut into the general circulation. Most orally administered drugs have rapid absorption across the gastrointestinal mucosa and reach peak concentrations in 1 to 2 hours. Drugs with limited solubility, or that bind to foods or other drugs, may exhibit poor absorption characteristics.
- *Distribution Phase* is dependent on the degree of plasma protein binding of the drug and the amount of free drug available to stimulate its appropriate receptor. Alterations in the degree of protein binding have been reviewed by Longa and Cross (1984).
- *Metabolism and Elimination* determine the duration of the drug's pharmacological activity and are the result of biotransformations that take place primarily in the liver and are followed by excretion in the bile or by the kidneys. Drugs may undergo activation by the liver or undergo transformation and detoxification into a more soluble substance for renal clearance. Clearance of a drug by glomerular filtration is reduced in patients with reduced renal function, especially in elderly individuals, and this will affect the elimination of the drug and its biological half-life. Appropriate modification of drug dosage in these patients will avoid toxic reactions to increased plasma levels of the drug.
- *Steady-State Concentrations* of the drug provide the best correlation between serum drug concentrations and clinical status. At steady state the amount of drug being eliminated from the body is equal to the amount administered. The steady-state drug concentration is usually achieved after three to five half-lives of a given

drug. Loading doses circumvent the necessity of waiting three to five half-lives to achieve a maximum therapeutic effect.

TIMING OF SPECIMEN COLLECTIONS

In an ideal world, the therapeutic drug specimen should be collected after a steady state has been achieved. For drugs with short half-lives, both a steady-state peak and a trough level should be obtained. Each drug has a different peak collection time, but all trough levels should be taken just prior to the next dose of the drug. A toxic drug evaluation level may be collected at any time.

ALTERED PHARMACOKINETICS

The *in vivo* disposition of drugs varies with age and disease and with drug–drug interactions. These factors are responsible for the intra- and interindividual variations encountered in clinical practice.

- *Age* — There are age-related pharmacokinetic differences among the neonate, infant, child, pubescent child, adult, and geriatric adult, which can be attributed to changing metabolic functions, body composition, and protein-binding characteristics. As a general rule, children metabolize drugs twice as fast as adults. In elderly patients, drugs are cleared at a slower rate than in adults due to a combination of reduced metabolic activity and reduced renal function. As people age, total-body water decreases, lean body mass is reduced, and the percentage of body fat increases. Lipid-soluble drugs will tend to build up and saturate the fat stores and temporarily decrease the serum level of the drug. As the fat compartment becomes saturated with the drug, the serum level will suddenly rise and therapeutic monitoring will alert one to the situation.
- *Disease Processes* — Renal glomerular disease reduces the clearance of drugs and drug metabolites and increases biological half-lives. Diseases that alter the albumen concentration will cause the active drug fraction to alter dramatically. Reduced liver or cardiac functional capacity will cause increased serum levels of administered drugs.
- *Drug–Drug Interactions* — The practice of polypharmacy to treat multiple disease processes, especially in elderly patients, creates the potential of drug–drug interactions with difficulties in interpreting drug levels and adjusting dosages.

THERAPEUTICALLY MEASURED PAIN-ASSOCIATED DRUGS

- *Acetaminophen (Tylenol®)* — Peak plasma concentrations in 30 to 60 minutes; steady state in 10 to 20 hours; therapeutic levels 10 to 20 µg/ml, toxic levels >200 µg/ml. For toxicity, take first sample 6 hours postingestion and a second sample 3 to 4 hours later. Normal half-life is 1 to 3 hours; > 4 hours indicates possible hepatic necrosis.
- *Amitriptyline (Elavil®)* — Peak plasma concentrations at 2 to 6 hours after oral dose; steady state in 3 to 8 days; therapeutic level depends on use. Elavil has significant drug–drug interactions. Elderly patients are prone to postural hypotension, urinary retention, and sedation.
- *Carisoprodol (Soma®)* — Therapeutic levels 6 to 12 µg/ml.
- *Gabapentin (Neurontin®)* — Only 3% bound to plasma proteins and not appreciably metabolized; is cleared by the kidneys and has a half-life of 5 to 7 hours; steady state at 1 to 2 days; for therapeutic monitoring draw trough levels; very little drug–drug interactions.
- *Meperidine (Demerol®)* — Maximum analgesic effect in 30 to 50 minutes after intramuscular injection; duration of action 2 to 4 hours; therapeutic level 50 to 500 ng/ml; 95% efficacy at 700 ng/ml; potentially toxic at levels >1000 ng/ml.

DRUG TOXICOLOGY PROFILES

Every laboratory offers drug toxicology profiles for medical, medicolegal, and preemployment use. Each laboratory has a slightly different menu for blood, urine, and gastric contents. The most important issue is to be in compliance with company, state, or local guidelines or collective bargaining agreements when ordering and collecting samples. Chain-of-custody issues and confirmation of presumptive positive specimens by gas chromatography/mass spectroscopy should be automatic (LabCorp, Directory of Services 2004; Quest Diagnostics, Directory of Services, 2003).

Functional Capacity Evaluations

Barbara L. Kornblau, JD, OT/L, FAOTA, DAAPM, CCM, CDMS,
Max Ito, PhD, OTR/L, and Pam Kasyan-Itzkowitz, MS, OTR/L, CHT

INTRODUCTION

This chapter looks at current practices in functional capacity evaluations as part of the return-to-work process for patients/clients with pain. After describing current practice, the authors provide a discussion of the literature with respect to evidence regarding concerns for the effectiveness, validity, reliability, and limitations of the use of functional capacity assessments.

CASE PRESENTATION

Bill, a 49-year-old airline pilot, was struck by lightning while helping passengers deplane from a corporate jet. The lightning hit the umbrella he was holding, entered his body through his right hand, and exited through his belt buckle. Bill passed out on the tarmac hitting his head and lower back on equipment accidentally left out by one of the airline catering contractors.

Following his acute medical recovery, Bill continued to complain of chronic pain in his lower back and numerous muscles, as well as general fatigue, weakness, and swelling in his right arm. He is not sure what he can and cannot do since he has been out of work for a few months. Although very motivated to return to the workplace, eventually doctors diagnosed Bill with fibromyalgia. He is assigned a case manager by his workers' compensation carrier, and his attorney is pursuing a third-party claim against the catering contractor, who it turns out violated the airport's policies by leaving the equipment on the tarmac. His physician expects Bill to reach Maximum Medical Improvement (MMI) shortly. Once he reaches MMI, his attorney expects to settle his workers' compen-

sation case and Bill is anxious to settle his third-party claim against the caterer.

Bill's situation raises many questions. Will he be able to return to his job safely? Can he work in spite of his pain? How do we know what he is capable of doing? Does he need accommodations in the workplace in order to return to work? Can he benefit from a work conditioning program? Does Bill need a work conditioning program? If so, what kind?

FUNCTIONAL CAPACITY EVALUATION

Functional capacity evaluations attempt to answer these questions by providing specific information about how Bill is functioning in relationship to his work's demands in spite of the pain he experiences. Functional capacity evaluations (FCEs) measure physical abilities or functional capacities through a systematic process of assessment, using a standard protocol (Kornblau, Dahl, Armstrong, Ellexson, & Larson, 1998; Matheson, 1996). Readers will find several related terms for FCE, which are sometimes used interchangeably. These include *work capacity evaluation* (Matheson, 1989), *functional (or physical) capacity assessments* (FCA) (Key, 2004), and *physical capacity evaluation* (Harrand & Hoffman, 1980).

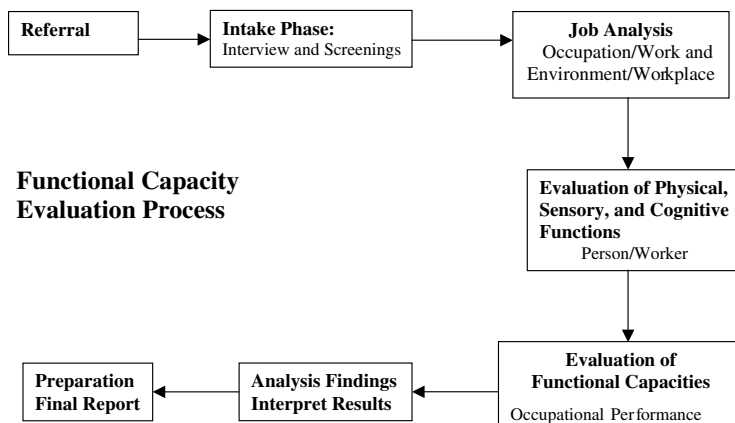
FCEs may contribute valuable information to help in determining job placement, job accommodation, return-to-work assignments after injury, and extent of impairment. Employers, insurance adjusters, rehabilitation specialists, and others have looked to FCEs to help them determine if work restrictions, job modifications, or reasonable accommodations could assist in returning an indi-


FIGURE 42.1 Functional capacity evaluation process.

vidual to the workplace or help prevent further injury (Kornblau et al., 1998). FCEs have also been used to predict potential ability to perform work tasks following work conditioning or work hardening programs (Kornblau et al., 1998).

FCE tools have long been used to examine the relationship between the individual's abilities and specific job demands through a formal process that involves lengthy and intensive one-on-one contact with the evaluator/clinician. Comprehensive FCEs may take a few hours to a few days to complete, and the time commitment can place a high demand on resources in terms of staffing, training and expertise, equipment, and facility. These factors can lead to high costs of conducting FCEs (Gross, 2004; Matheson, 1996).

FCEs are provided by clinicians or trained evaluators skilled to perform work-related evaluations in free-standing clinics, at job sites, in outpatient and hospital-based rehabilitation programs, and in private practices (Kornblau et al., 1998). Readers may find FCEs performed by multidisciplinary teams of therapists, exercise physiologists, vocational evaluators, rehabilitation professionals, individual occupational therapists or physical therapists, and others. The evaluator/tester or team must possess the necessary skills to assess the physiological, psychophysical, cognitive, and biomechanical functioning of the individual. Clinicians performing FCEs must possess the observational skills, training, and experience necessary to perform complex job and task analysis and assess environmental factors that may affect work performance (Kornblau et al., 1998).

The results of an FCE evaluation may contain objective information that can be used to assist in determining disability status, disability benefits, and whether maximum benefit from rehabilitation and medical interventions has been reached. FCEs may be used as a baseline and final evaluation for work rehabilitation, to determine appropriate job placement, and to confirm an injured worker's self-report of work limitation. Appropriate job placement

reduces the risk of reinjury, which makes the FCE an important component of an injury prevention program.

FUNCTIONAL CAPACITY EVALUATION PROCESS

The FCE involves a seven-step process that allows the evaluator to take a comprehensive look at the fit among the person, the environment, and the everyday occupations that contribute to his or her participation as a worker (Stewart et al., 2003). In other words, the functional capacity assessment looks at the worker, the workplace, and the work tasks and seeks to make a match between them to facilitate safe work performance (Kornblau & Ellexson, 1992).

The FCE process for our airline pilot, Bill, will begin with a referral for the evaluation (Figure 42.1).

REFERRAL

A referral for a functional capacity assessment makes sense for Bill for several reasons. He is approaching MMI shortly, he is motivated to return to work, and he is not sure what he can and cannot do at this point. He wants to settle both his workers' compensation and third-party claims as soon as he can.

Clients are generally referred for FCEs to determine a baseline of what they can do or to compare what they can do with what a given job requires (Kornblau et al., 1998). A client might be referred for an FCE because he or she has reached MMI but continues to have work-related issues interfering with reentry into the workplace (Kornblau et al., 1998). An FCE can provide data needed to initiate settlement in a workers' compensation case or provide evidence of a social security claimant's residual capacity to help determine his or her ability to work. An FCE can provide an individual with information to quantify his or her functional status to facilitate an enlightened,

realistic job search (Kornblau et al., 1998). All of these situations may apply to Bill, our hypothetical airline pilot.

Referrals can come from several sources. A rehabilitation professional, such as a rehabilitation counselor or, in Bill's case, a case manager, may refer a client for an FCE. This is the first step in the return-to-work process following discharge from the medical phase of rehabilitation following an accident or injury. Baseline information about one's level of functioning or information comparing the level of function to the job's demands give rehabilitation professionals invaluable information for the return-to-work or job search process. Rehabilitation professionals and/or employers (human resource personnel or risk mangers) may initiate a referral to obtain information about reasonable accommodations the client may need in the workplace to facilitate return-to-work.

Representatives from workers' compensation insurance or disability insurance carriers may refer a client for an FCE to gather information to facilitate claim settlement or to investigate whether the client's claim is legitimate. Referrals from insurance representatives also serve to expedite the return-to-work process.

A physician may refer a patient for an FCE because a case manager, rehabilitation counselor, or attorney desires specific information about how the patient is functioning with the goal of trying to settle a workers' compensation or disability claim. The information from the FCE can provide the physician with the specific details he or she needs to assign the client an impairment rating (American Medical Association [AMA], 1993).

Clients are often referred for functional capacities assessments by physicians who receive a form from the rehabilitation nurse, case manager, or insurance adjuster that asks for information similar in nature to Figure 42.2.

Knowledgeable physicians, physician assistants, and nurse practitioners understand that they can report only on information for which they have knowledge from observation, examinations, or consultations from other practitioners. "Guessing" at the answers to specific questions regarding a patient's physical restrictions and limitations will not sufficiently support their decisions should an attorney question them in detail during a deposition. Finding oneself at a deposition or in court defending a restrictions and limitations form is not unusual considering many clients referred for FCEs are involved in litigation or administrative claims. Readers will find individual state workers' compensation forms potentially more complicated and very specific in the questions they ask (examples: Florida Division of Workers' Compensation form DWC-25, available online at www.fldfs.com/wc/pdf/DWC-25.pdf, and the Texas Rehabilitation Commission form TRC106, available online at http://www.rehab.state.tx.us/forms/trc106.dot).

Attorneys, both plaintiff/claimant and defense/employer, may seek FCEs to obtain information to support their cases in court or in administrative proceedings. These may include workers' compensation claims, social security disability determinations, disability retirement controversies, disability insurance claims, and others. Bill's attorney could certainly benefit from the FCE results in settlement discussions.

Once a referral is made, the clinician will want to confirm that the referral is appropriate for the client, medically and vocationally, and that the client has medical clearance to participate in the FCE. Safety is a feasibility concern, and clients referred for an FCE must not be subjected to an unacceptable risk of injury or an adverse event from testing. Additional safety guidelines should be established and strictly complied with when administering an FCE on clients with medical conditions. Pretest orientation, safety briefing, test procedure training, and warm-up physical exercises may assist in reducing the risk of adverse incidents.

The clinician will review all available records, medical, vocational, and legal; gather pertinent information about the client; evaluate the purpose for the referral; and determine the expected outcome. The clinician should obtain a copy of the client's current or intended job description. What kind of information does the referral source want from the FCE? Is there a job waiting for the client at the end of the process? Does the client have a desire to return to work? Does the client have a realistic vocational goal he or she wishes to work toward? In addition to the answers to these questions, the clinician will also want to know the reimbursement source for the FCE.

Workers' compensation and disability insurance carriers as well as self-insured plans will often pay for FCEs because the information acquired through the assessment helps determine future direction of the claim. In some instances, health insurances may exclude what it considers vocationally related services and may need to be convinced that the functional capacity assessment is a medically necessary intervention, before it will agree to pay for the FCE (Kornblau et al., 1998).

State departments of vocational rehabilitation and other state or local agencies may also reimburse for functional capacities assessments of their clients. Any or all of these reimbursement sources may subject their reimbursement to a set fee schedule. Individuals may also choose to pay privately for an FCE (Kornblau et al., 1998).

INTAKE PHASE

During the intake phase, the clinician will gather information from the client regarding specific past medical history and past vocational and work history through a structured and standardized interview process. Using the job description as an initial focal point for discussion, specific job-related information is collected through inter-

FIGURE 42.2 Restriction and limitations.

view and/or checklists to acquire a sense of what tasks the client must perform in his or her job as precursor to a preferred onsite job analysis.

The clinician also asks the client about performance of activities of daily living and participation in everyday, non-work-related occupations (*Williams v. Toyota Motor Mfg.,* 534 U.S. 184 [2002]). As part of this phase, the clinician might use forms and checklists, which will help establish how the client perceives his or her own limitations. The format of the intake interview may depend on the specific FCE protocol used.

This step in the process gives the clinician an opportunity to administer psychological tests, pain questionnaires, personality inventories, educational or literacy screenings, and other assessments thought to screen for maximal or submaximal effort. This step in the process

also allows the clinician to discover the client's goals for his or her future and establish mutual goals for the FCE. The clinician can begin to observe pain behaviors and establish a rapport with the client.

Many individuals come to the FCE via a work-related injury or non-work-related accident. Because of the source of the injuries, clinicians may find that many individuals who present themselves for FCEs are often involved in administrative claims or civil litigation. Clients may perceive secondary gains in the form of higher settlements or other non-injury-related benefits should their performance on the FCE show greater than actual limitations. Clinicians have expressed concerns about whether participants are putting forth their true effort. This inquiry has become an integral part of most FCE protocols in one form or another and usually begins during this phase of

the process (King, Tuckwell, & Barrett, 1998; Lemstra, Olszynski, & Enright, 2004).

In performing FCEs, test administrators attempt to determine whether the individual tested is putting forth maximal effort or is exaggerating or magnifying his or her symptoms in an effort to "throw" the test in his or her favor. Commercial or proprietary FCE protocols and the therapists who perform FCEs often include a variety of assessments they believe will look at the client's effort and cooperation with the test in an effort to determine the reliability of the client's performance. These may include, among others, the Ransford Pain Drawing and other similar pain drawing scales (Hildebrandt et al., 1988; Ransford, Cairns, & Mooney, 1976), the McGill Pain Questionnaire (Melzack. 1975), Waddell's signs or distraction tests (Waddell, McCulloch, Kummel, & Venner, 1980), visual analog pain scales (Carlson, 1983; Salo et al., 2003), Somatic Amplification Scale (Korbon, DeGood, Schroeder, Schwartz, & Shutty, 1987), EPIC Hand Function Sort (Matheson, Kaskutas, & Mada, 2001), and the Beck Depression Inventory (Beck & Steer, 1984).

Some clinicians have used the rapid grip strength exchange test or other grip or pinch strength tests to try to detect submaximal effort of FCE subjects. They have used them with a variety of diagnoses such as lower back pain but these tests are often performed during the evaluation of physical, sensory, and cognitive functions stage in the FCE process (Mathiowetz, Nelson, Sadoff, & Sadoff, 1984; Smith, 1989).

JOB ANALYSIS (OCCUPATION/WORK AND ENVIRONMENT/WORKPLACE)

The job analysis phase in the process focuses on occupation and the environment or, in other words, the work and the workplace. Job analysis plays a key role in the FCE process. The intended outcome of the return-to-work process, which often begins with an FCE, is a match of some sort between the individual's abilities and work. The work may include the person's preaccident or preinjury job, a different job with the same employer, or a different job with another employer. One must compare the demands of the job with the abilities of the person to accomplish the outcome.

An important aspect of FCE is that the measurement of work capacity is specific to the job demands. This requires a job analysis, an evaluation of specific job tasks. A job analysis then becomes a key part of the overall assessment (Pransky & Dempsey, 2004; Trombly & Radonski, 2002). Work requirements specify components of work along with the requisite skills and abilities to successfully perform work tasks.

The job analysis looks at the skills and abilities the job demands or requires (Kornblau, 1996). Kornblau and Ellexson (1992) describe a job analysis designed to give the evaluator a wealth of information about the job while abiding by requirements of the Americans With Disabilities Act 29 CFR §1630.2(n).

This job analysis incorporates the *Dictionary of Occupational Titles* (DOT) *Physical Demands,* and it also takes a much more comprehensive approach. It goes farther than merely physical demands and looks at cognitive, environmental, and psychosocial demands of work (Ellexson, 2000; Kornblau & Ellexson, 1992).

While the DOT and its intended successor O*NET provide extensive information about jobs and their requirement, these sources do not provide comprehensive information about the work in the specific environment in which the work is performed (O*NET, 2004). Using the methodology described in Figure 42.3, the authors believe one must conduct an onsite job analysis before performing the FCE to truly analyze the job and the environment in which the worker must perform the job. For example, one of the authors performed a job analysis on Jose at a warehouse. Prior to the onsite job analysis, the injured worker was interviewed extensively about the job to look at how injuries could be prevented in the future. Jose reported that one of his job tasks was to open boxcars on the loading dock. He explained that he used his arms to reach the wheel-like mechanism to twist the boxcars open. This did not explain his low back injury. It was only when the occupational therapist went to the worksite did the therapist discover that in order for Jose to reach the boxcars to open the doors, he had to straddle a 28-in. gap between the loading dock and the boxcar. Neither O*NET and the DOT nor the interview with the worker prepared the therapist for the actual, onsite, boxcar scenario. Only with the specific worksite information in hand can clinicians begin to make a close comparison and a match for the person, task, and environment or worker, work, and workplace and proceed to do so with the FCE.

A close match to the specific job demands plays a key role in compliance with the Americans with Disabilities Act (ADA) Title I, 29 C.F.R. §1630.1 *et.seq.* Congress passed the ADA of 1990 to reduce discrimination against individuals with disabilities and promote their inclusion into the workforce and independent life (29 C.F.R. §1630.1 *et.seq*). Employment-related medical testing is one of the areas in which Congress sought to discourage discrimination against individuals with disabilities. The ADA sets specific requirements for tests such as FCEs that may tend to screen out individuals with disabilities. To prevent unnecessary disqualification of an individual with disabilities from employment consideration based on a test such as the FCE, the ADA requires three things: (1) the test be job related, (2) the test must be consistent with business necessity, and (3) the person performing the test on the employer's behalf must provide the subject with reasonable accommodations during the testing process, or

Step	Job Analysis Task
1.	Determine essential functions of the job.
2.	Determine the marginal functions of the job.
3.	Break down each essential function into sequential steps describing the work the worker will perform (task analysis)
4.	Observe and record the physical requirements necessary for the worker to perform the essential function. This includes: • Documenting specific motions, e.g., walking, standing, reaching, climbing, handling, talking, etc. (DOT Physical Demands) (U.S. Department of Labor, 1986) • Measuring the distance, force, and repetition required to perform the physical activities.
5.	Measure the weight, dimensions, pressure required for operation, temperature, and vibration of specific tools, equipment and material used at the worksite.
6.	Record the frequency with which workers perform individual activities.
7.	Document the number of employees available to perform each task.
8.	Document the percent of time spent performing each essential function.
9.	Document the degree of skill or specialization required.
10.	Document psychological considerations
11.	Document physiological considerations.
12.	Record environmental considerations.
13.	Describe cognitive considerations in detail.
14.	Document workplace accommodations or modifications employers can readily make.

FIGURE 42.3 Fourteen point job analysis.

the employer must be able to show that performance of the essential functions of the job cannot be achieved with the provision of a reasonable accommodation (29 C.F.R. §1630.14 (a); EEOC, 2000). By assuring the closest match between the job tasks obtained from the comprehensive onsite job analysis and the FCE tasks, the evaluator/clinician strengthens evidence of the compliance of the FCE with the "job-related" requirements for testing under the ADA.

EVALUATION OF PHYSICAL, SENSORY, AND COGNITIVE FUNCTIONS (PERSON/WORKER)

The evaluation of physical, sensory, and cognitive functions focuses on the person/worker. This part of the evaluation together with the screenings previously mentioned during the intake process focuses the clinician/evaluator on the whole person rather than the impairment or physical limitations.

During this phase, the clinician/evaluator performs a musculoskeletal exam, looking at, among other things, strength, range of motion, flexibility, cardiovascular fitness, and posture. The range of motion evaluation plays an essential role in providing the physician with information he or she will need to assign the patient a permanent impairment rating (AMA, 1993). The comprehensive strength testing provides the clinician/evaluator with significant information regarding weakness following an illness or injury. Weakness can serve as a major contributor to loss of work capacity (Matheson, 1996).

The clinician may use some of the tests for submaximal effort as part of the strength assessment (Mathiowetz et al., 1984; Smith, Cunningham, & Weinberg, 1989). During this phase, the clinician/evaluator will look at endurance, also called sustained activity tolerance, that combines aerobic, metabolic, and strength capacities (Matheson, 1996).

Pain often plays a major role in interfering with one's ability to return to work. During this stage and throughout the entire FCE process, the therapist/clinician will continue to observe and record the patient's pain behaviors, psychosocial behaviors, and use of body mechanics. Specific methodologies for any or all areas for assessment mentioned herein may be prescribed by the particular FCE protocol in use, proprietary or otherwise.

During this phase, the clinician/evaluator will also look at gait, coordination, balance, sensory abilities, and hand use and dexterity. Some clinicians use coordination tests during this phase such as the Adult 9-hole Peg Test or the Jebsen-Taylor Test of Hand Function (Jebsen, Taylor, Triescsmann, Trotter, & Howard, 1969; Mathiowetz, Weber, Kashman, & Volland, 1985). Other individual tests may be prescribed by the standardized protocol used by the clinician. Clinicians may find the need to do further investigation of activities of daily living during this stage based on results obtained during the intake interviews, written questionnaires, or inventories and the sensory and hand dexterity testing.

One cannot stress enough the need to look at the whole person and those everyday activities of significance to everyday life including those outside work, such as activities of daily living. The U.S. Supreme Court brought this issue to light in the ADA case, *Williams v. Toyota Motor Mfg.* 534 U.S. 184 (2002).

When the ADA originally became law, Title I provided broad protection to individuals with a substantial limitation in their major life activities from discrimination in the employment context, 29 C.F.R. §1630.1 *et.seq.* As the courts interpreted the ADA, judges have narrowed the scope of its coverage to a more limited population of individuals with more involved disabilities.

The Supreme Court set forth the current standard in *Williams v. Toyota Motor Mfg.,* 534 U.S. 184 (2002). Mrs. Williams had cumulative trauma syndrome and tendonitis. She claimed she was limited in the major life activity of performing manual tasks, which interfered with her ability to perform her job.

In examining the facts and applying the law, the Supreme Court explained the broad scope of manual tasks and the importance of looking at how limitations in the performance of manual tasks affect one's participation in everyday activities. The Court said "[m]anual tasks to any particular job are not necessarily important parts of most people's lives. As a result, *occupation specific tasks may have only limited relevance to the manual task inquiry*" *Williams v. Toyota Motor Mfg*, 534 U.S. at 693. "When addressing the major life activity of performing manual tasks, the central inquiry must be *whether the claimant is unable to perform the variety of tasks central to most people's daily lives,* not whether the claimant is unable to perform the tasks associated with her specific job" (emphasis added).

By putting forth this standard, the Supreme Court reminds those guiding clients through the FCE process that one must look at the "variety of tasks central to most people's daily lives" as part of a comprehensive assessment. Translated into the FCE terminology domain that means participation in one's activities of daily living.

Finally, this phase of the FCE process will give the evaluator a picture of the subject's impairments and limitations. It will also provide an indication of the client's physical safety to proceed to the next level, the evaluation of functional capacities.

EVALUATION OF FUNCTIONAL CAPACITIES (OCCUPATIONAL PERFORMANCE)

There are two types of FCEs, the Baseline FCE and the Job Specific FCE (Kornblau et al., 1998). The Baseline FCE, upon which most of the proprietary products rely, looks to develop a baseline of how the individual functions in relation to the physical demands of work, usually based upon the DOT descriptions (Kornblau et al., 1998).

The Job Specific FCE evaluates the individual worker's ability to function within the specific task demands of his or her job or specific proposed job (Kornblau et al., 1998). This assessment is based on the essential functions of the job identified in the job analysis (Kornblau et al., 1998).

Evaluating functional capacities with the Job Specific FCE involves looking at occupational performance, the interplay among the work, the worker, and the workplace, and often using simulated work tasks in a simulated work environment. The evaluator looks at the subject's occupational performance by analyzing the client's functional capacities within the context of simulated work activities.

Baseline FCEs may involve commercially available or proprietary FCE protocols or the "home grown" variety, a standard protocol developed by the clinician, practice, academic institution, or facility (Gibson & Strong, 2002). Some examples of commercially available or proprietary FCEs include, among others, Blankenship Functional Capacity Evaluation (Blankenship, 1994), EPIC (Matheson, Mooney, Grant, Leggett, & Kenny, 1996), ERGOS Work Simulator (Dusik, Menard, Cooke, Fairburn, & Beach, 1993), Isernhagen Functional Capacity Evaluation (Isernhagen, 1995), Key Method Functional Capacity Evaluation Assessment (Key, 2004), and Ergoscience Physical Work Performance Evaluation (Lechner, Jackson, Roth, & Straaton, 1994).

Although the U.S. Department of Labor intended to replace the DOT with O*NET, an online database of occupational information, the Physical Demands from the DOT still remain a part of the Social Security Federal Regulations, job analysts tools, vocational counselor's repertoire, and many Baseline FCE and some Job Specific protocols that rely on it (King et al., 1998; O*NET, 2004; 20 C.F.R. §404.1567). Most of the commercially available functional capacity systems as well as those "home grown" varieties draw from the physical demands enumerated in the DOT for the functional capacities portion of the process (Fishbain et al., 1994; Jones & Kumar, 2003; King et al., 1998). See Figure 42.4.

Clinicians may evaluate the physical demands using different methods depending on the protocol they employ for their FCE. However, all of the FCEs involve evaluating a variation of the DOT Physical Demands (King et al., 1998; U.S. Department of Labor, 1991). The DOT classifies work into five categories of strength factors, based on lifting, carrying, pushing, and pulling, which the Social Security Administration and some workers' compensation systems use to assist with determining a client's status and future work classification or ability. See Figure 42.5 and Figure 42.6.

During this part of the process, the clinician can make the determination regarding the client's strength factor category to help quantify return-to-work choices available to him or her.

Virtually all FCEs have a lift capacity component in their protocols (King et al., 1998; Matheson, 1996). Many commercially available FCEs and Baseline FCEs include lifting assessment components that seek to determine a

Standing	Stooping
Walking	Kneeling
Sitting	Crouching
Lifting	Crawling
Carrying	Reaching
Pushing	Handling
Pulling	Fingering
Controlling (hand/arm)	Feeling
Controlling (foot/leg)	Talking
Climbing	Seeing (including acuity & visual field)
Balancing	Depth Perception

FIGURE 42.4 *Dictionary of Occupational Titles:* Physical Demands.

Sedentary Work — S

Exerting up to 10 pounds of force occasionally and/or a negligible amount of force frequently to lift, carry, push, pull, or otherwise move objects, like ledgers and small tools and including the human body. Although a sedentary job is defined as one which involves sitting, a certain amount of walking and standing is often necessary in carrying out job duties. Jobs are sedentary if walking and standing are required only occasionally and all other sedentary criteria are met.

Light Work — L

Exerting up to 20 pounds of force occasionally, and/or up to 10 pounds of force frequently, and/or a negligible amount of force constantly to move objects. Physical demand requirements are in excess of those for Sedentary Work. Even though the weight lifted may be only a negligible amount, a job should be rated Light Work: (1) when it requires walking or standing to a significant degree; or (2) when it requires sitting most of the time but entails pushing and/or pulling of arm or leg controls; and/or (3) when the job requires working at a production rate pace entailing the constant pushing and/or pulling of materials even though the weight of those materials is negligible. NOTE: The constant stress and strain of maintaining a production rate pace, especially in an industrial setting, can be and is physically demanding of a worker even though the amount of force exerted is negligible.

Medium Work — M

Exerting 20 to 50 pounds of force occasionally, and/or 10 to 25 pounds of force frequently, and/or greater than negligible up to 10 pounds of force constantly to move objects. Physical Demand requirements are in excess of those for Light Work.

Heavy Work — H

Exerting 50 to 100 pounds of force occasionally, and/or 25 to 50 pounds of force frequently, and/or 10 to 20 pounds of force constantly to move objects. Physical Demand requirements are in excess of those for Medium Work.

Very Heavy Work — V

Exerting in excess of 100 pounds of force occasionally, and/or in excess of 50 pounds of force frequently, and/or in excess of 20 pounds of force constantly to move objects. Physical Demand requirements are in excess of those for Heavy Work.

FIGURE 42.5 *Dictionary of Occupational Titles:* Strength Factor and Social Security Administration physical exertion requirements.

DOT/SSA Term		Definition
Occasionally	O	0–33% of the work day
Frequently	F	34–66% of the work day
Constantly	C	67–100% of the work day
Exerting Force		Lifting, carrying, pushing, and/or pulling

FIGURE 42.6 Key to strength factor and physical exertion terminology.

subject's maximum lift while monitoring heart rate changes and/or biomechanical changes during the test, which can also include the subject's report of pain or discomfort during the test. The tests usually involve lifting a standardized item with light weights and progressing to heavier weights (Matheson et al., 1988; Mayer, Barnes, Kishino, Nichols, Gatchel, Mayer et al., 1988). These assessments often include the use of the NIOSH standards or the National Institute for Occupational Safety and Health (NIOSH) equation for the design and evaluation of manual lifting tasks as an element of their lifting assessment (Waters, Putz-Anderson, Garg, & Fine, 1993).

Evaluators who take a Job Specific FCE approach use tools and materials from the worksite for the lift and other areas of the evaluation. With tools and materials from the

actual work performed, evaluators can look at whether the individual can lift the items he or she needs to lift to perform his or her job task, or if the lifting can be eliminated as a reasonable accommodation if necessary.

The Job Specific FCE derives the tasks evaluated, such as lifting, from the job tasks gathered from the job analysis. The subject participates in simulated job tasks with the frequency, weights, measures, and repetitions of the tasks taken directly from the real-life job demands. It is inherently "job-related" within the meaning of the ADA and gives subjects an idea of whether they can perform their own jobs (29 C.F.R. §1630.14 (a); EEOC, 2000).

With both FCE approaches, the clinician must select the task for evaluation based on protocol, job analysis, the subject's physical and psychosocial condition, and professional judgment. The clinician must also use that professional judgment to prevent any further problems from occurring that might injure the test subject and stop the test should the subject experience physical, cardiac, or other problems.

ANALYZE FINDINGS

During this phase, the clinician analyzes and integrates the results of the functional capacity assessment and job analysis with the medical impairment and limitations to determine recommendations for job limitation, safety considerations, job placement, or disability determination. The baseline physical capacities, if performed, must be documented along with recommended work restrictions and/ or reasonable accommodations.

Bill, our airline pilot, may have reached maximum medical improvement, but still experiences lower back pain, general discomfort, fatigue, and right arm weakness. It is determined that he is physically unfit to fly commercially, and no reasonable accommodation is available under the guidelines for commercial pilots. The clinician must determine from documented assessment findings and medical reports Bill's specific medical impairment, functional abilities and limitations, physical capacities or abilities, and job-specific limitations. This information will be used by his case manager and attorney in determining his claims against workers' compensation and his pending litigation against the catering contractor. The information will further assist in Bill's decisions and plans for work conditioning programs, future job placement, or a career change.

PREPARE FINAL REPORT

Professionals who administer FCEs should make sure they write their reports in plain English, understandable to all potential readers. Clinicians should use clear, concise sentences that do not use jargon, medical terminol-

ogy, and other terms of art unfamiliar to those outside. Use of technical language and jargon should include definitions of the terms so the reader can understand them. For example, suppose one reported that Bill could abduct his right shoulder to 90° and externally rotate his right shoulder to 25°. The writer should follow this up with an example to illustrate what this means. One might say, for example, that because of this limitation, Bill could not comb his hair and could not pull down the lever on the presser machine.

Reports should tell a story and paint a picture that readers can understand and explain to others if necessary. Individuals reading these reports, such as attorneys, judges, administrative hearing officers, human resource personnel, and insurance adjusters, do not necessarily have a background in the subject matters and, therefore, use of jargon, minutiae, and technical terminology has the potential to frustrate the reader. Similarly, overly long, computer-generated reports, filled with charts and graphs meaningful only to the writer, may not contribute useful information to those concerned with the client.

The reports should summarize the important information on the first page in plain English. The summary should stress the client's strength and weaknesses as well as the evaluator's recommendations. Clinicians should keep in mind that realistically, in many situations, the summary may be the only part of the report that anyone actually reads and decisions may be based on this summary.

Clinicians should report the sources of their information (i.e., test results, reports by the patient/client, etc.). Objective data should play a significant role in the summary as well as in the body of the report to the extent the writer can abide by the "plain English" rule. Report writers should use well-labeled headings in the body of the report to provide ready access to information.

Clinicians should relate test results directly to recommendations. To whatever extent possible, inclusion in the report of any evidence-based literature references regarding the assessment may assist fact finders (judges or administrative hearing officers) should the FCE subject find himself or herself involved with social security, workers' compensation, insurance disability personal injury, and/or other claims. See, e.g., *Daubert v. Merrell Dow Pharmaceuticals,* 509 US 579 (1993).

FACTORS TO CONSIDER IN SELECTING OR DEVELOPING FCES

Ideally, when selecting an FCE to use or when developing one's own, referral sources and clinicians should consider six basic factors: safety to the test subject, reliability, validity in predicting safe future job performance, content validity, practicality of test administration, and the ability to predict future risk of injury (King et al., 1998). How-

ever, while one can consider these six factors, according to the current literature, it is difficult to find or create an FCE that meets all of these criteria.

SCIENTIFIC AND PRACTICAL LIMITATIONS OF FCES

There are scientific and practical limitations to FCEs. Human behavior and performance are not always predictable and accurately measurable, especially when the complex phenomena of motivation, response and tolerance to pain, external environmental, and other internal psychosocial factors may influence task performance. An instrument that measures functional capacity for return-to-work determination should be reliable and valid with the sensitivity and specificity to measure job specific capacities (Innes & Straker, 1999a, 1999b). Most FCEs do not achieve these scientific standards; however, they do have value in documenting progress and performance limitations in relation to a job and in identifying factors influencing abilities (Pransky & Demsey, 2004). FCE results may contribute to job status or disability determination, but one should view these results as part of a broader assessment program that evaluates injury prevention and return-to-work issues. Other limitations identified by Matheson (1996) include the lack of formal or adequate training by clinicians and evaluators in evaluation procedures and test methodologies, availability of standardized test equipment, and reactivity to testing or testing effect.

The nature of FCEs makes them a difficult subject to study. Many of the FCE protocols are proprietary or commercial in nature and, thus, have not appeared in the peer-reviewed literature (Jones & Kumar, 2003). Most studies in the literature review "parts" of a battery of assessments included in an overall FCE, such as lifting or grip strength. This makes it difficult to craft a general statement about a given FCE and virtually impossible to craft statements comparing one FCE with another (Innes & Straker, 1999a). Because protocols vary from FCE to FCE (or FCA or physical capacity assessments [PCA]), and the literature fails to adequately reveal the contents of the evaluations, looking for overall generalizations about "FCEs" is also difficult.

PREDICTING RETURN TO WORK

FCEs may contribute valuable information to help determine job placement, job accommodation, return-to-work assignments after injury, and extent of impairment. FCE tools have long been used to determine the level of work an individual can safely perform. However, while functional capacity theory has long promoted FCEs as an aid to help predict work performance following postinjury rehabilitation (Kornblau et al., 1998; Matheson, 1996;

Smith, Cunningham, & Weinberg, 1986), recent research raises questions about the validity of the FCE's ability to identify those individuals who are "safe" to return to work. One retrospective study (Gross & Battie, 2004) that looked at the prognostic value of sustained recovery in individuals with low back pain showed that better performance on the FCE was associated with a *higher* risk of recurrence and thus not necessarily predictive of those "safe" to return to work.

While the literature indicates the predictive value of the FCE needs more research in terms of return to work as an outcome, the literature does support the ability of the FCE to provide the tools and procedures necessary to quantify present functional capacities (King et al., 1998). In other words, although the FCE might not be able to predict the airline pilot's long-term safe return to work, the FCE would provide quantifiable and qualitative information about his present functional capacities, including the impact of pain on his performance.

VALIDITY AND RELIABILITY

Subjective self-reporting of functional limitations serves as an important element of the evaluation process, but the information provided lacks validity and reliability. FCEs provide a process that may confirm or refute a claim of a functional limitation. The recipients of FCE outcome data (referral sources, insurance companies, workers' compensation case managers, and the injured worker) need some degree of confidence in order to rely on the FCE results. Decision makers need to base return-to-work and disability determinations on accurate and dependable objective measures. These issues point to concerns of validity and reliability of FCE measures and protocols.

Although the literature continues to report additional studies, most commercial FCEs lack adequate documentation of validity (Innes & Straker, 1999a). Validity concerns may stem from inadequately or too broadly defined job demands or inaccurate measures of actual performance capabilities. Further, FCEs based on job simulation test only the physical components of a job and may not include extraneous but significant factors such as the work environment and psychological components (Pransky, 2004). Predictive and concurrent validity are judged the most relevant for FCEs. Currently, the scientific literature does not support predicting return-to-work exclusively on FCE results (Gross, 2004).

Reliability of FCEs also raises concerns in the literature. Reliability threats include motivation, pain, fear, evaluator and equipment, and protocol application. Inconsistent use of practice or training sessions, intratesting, and interrater testing are also concerns related to FCE reliability (Matheson et al., 1996). Innes and Straker (1999a) conducted an extensive literature review of the existing evidence of the reliability of 28 work-related

assessments that included components of FCE batteries. They conclude that older tests that lack sufficient reliability data remain in use simply "because they are there" (Innes & Straker, 1999a). However, the developers of the newer FCE batteries place more emphasis on conducting and reporting reliability studies. Finally, Innes and Straker conclude that a limited number of work-related assessments have an adequate amount of evidence from which to draw conclusions, and they show a moderate to good degree of reliability, with only a few work-related assessments demonstrating reliability sufficient for clinical use. This study points to the need to improve reliability of existing work-related tests and for further reliability studies for other available tests, which need more evidence to prove their worth (Innes & Straker, 1999a).

IDENTIFYING SUBMAXIMAL EFFORT

Those who refer clients for FCEs often seek evidence of whether the client is putting forth full effort in cooperating with the evaluation. The literature suggests significant shortcomings in the effectiveness of the current menu of tests available that are thought to evaluate whether a client is putting forth submaximal or insincere effort. For example, some of literature suggests several shortcomings in the exchange grip strength test and other grip measures used as a means of testing submaximal effort in FCEs. First, no generally accepted standard protocol exists for submaximal effort testing based on grip strength tests (Taylor & Shechtman, 2000), and their reliability is questionable. Westbrook, Tredgett, Davis, and Oni (2002) findings suggest that the exchange grip strength test could not reliably detect submaximal effort. Shechtman and Taylor (2000) found that the rapid grip exchange test may not be sensitive or specific enough to detect insincere effort. The authors warn readers of the likelihood and consequences of mistakenly labeling subjects as putting forth less than a sincere effort, based solely on the rapid exchange grip test (Shechtman & Taylor, 2000).

Gutierrez and Shechtman (2003) found that grip strength testing with a Jamar dynamometer was strength dependent and potentially biased against those with weak hands who were presented with this method to assess sincerity of their effort. They found the Jamar five rung-test less effective with women than with men, another potential bias. In light of all of their findings, Gutierrez and Shechtman (2003) recommend against using the five-rung test to assess sincerity of effort.

Lemstra, Olszynski, and Enright (2004) evaluated the effectiveness of 17 tests commonly used to detect maximal effort during FCEs. They found that only 5 of 17 commonly used tests of maximal effort could individually differentiate between subjects' maximal effort and submaximal effort. The five effective tests included 3 of the 6 commonly used hand grip measurement tests presented

to the subjects (Lemstra et al., 2004). In reporting their findings, the authors remind readers of the complexities of determining maximal effort and the medicolegal and ethical implications in labeling a test subject as exerting maximal, or less than maximal, effort and that caution should be taken in relationship to asserting these labels (Lemstra et al., 2004). This study also suggests the need for more effective assessment tools for evaluating maximal effort during FCEs.

LEGAL AND ETHICAL ISSUES

FCEs raise many legal and ethical issues for those who practice in this area. Because the clients referred for FCEs are often already involved in litigation and administrative claims, clinician/evaluators should make sure they maintain comprehensive malpractice insurance. They should put policies in place that promote prevention of client injuries. Documentation plays a key role in protecting one's professional self should something happen during the course of the FCE that puts clients at risk.

With FCE validity and reliability an issue, some question whether courts will accept the results of functional capacity assessments as evidence in court proceedings. One of the reasons for this concern is the case of *Daubert v. Merrell Dow Pharmaceuticals*, 509 U.S. 579 (1993). *Daubert* limits expert witness testimony to theories or techniques the court considers scientific knowledge that will assist the trier of fact or judge.

In *Daubert*, the U.S. Supreme Court articulated four factors for judges to consider in deciding whether to admit scientific expert witness testimony under the Federal Rules of Evidence, *Fed. Rule Evid.* § 104(a).

1. Has the theory or technique been tested?
2. Has the theory or technique been subjected to peer review and publication?
3. In the case of a particular scientific technique, is there a known or potential rate of error, and standards controlling the technique's operation
4. Is the underlying technique generally accepted in the scientific community?

Should the expert not pass muster according to these guidelines set forth in *Daubert*, his or her reports would be considered non-evidence and inadmissible and the FCE professional would not be allowed to testify. Although many pieces of FCEs have appeared in reliability and validity studies in the literature (see, e.g., Brouwer et al., 2003), the literature is certainly not conclusive by any means (Innes & Straker, 1999a, 1999b). However, FCEs have been mentioned in the occupational therapy literature as a part of the return-to-work process since World War I (Crane, 1927; Cranfield, 1947; Office of the Surgeon General, 1968; Reuss, Rawe, & Sundquist, 1958). FCEs have

been studied for more than 50 years and are accepted as an integral part of the return-to-work process. The information gathered through FCEs provides fact-finders with objective, quantifiable data.

Federal and state courts have accepted expert witness testimony regarding FCEs and have allowed other experts to give testimony based on results of FCEs that these witnesses relied upon in forming their opinions. (See *Thigpen v. Retirement Board of Firemen's Annuity & Benefit Fund*, 317 Ill.App.3d 1010, 251 Ill.Dec. 682, 741 N.E.2d 276 (2000); *Brennan v. Reinhart Institutional Foods*, 211 F.3d 449, 54 Fed. R. Evid. Serv. 535 (8th Cir., 2000). Clinicians should prepare themselves for court by gathering publications that reference FCEs positively and prepare themselves to defend against those that are not so favorable.

Another significant issue involves the question, "Who is the client?" A typical FCE referral scenario involves a third party — the insurance carrier, defense or claimant's attorney, or case manager — referring our pilot Bill for the FCE and in some cases another party — his employer, for example, paying for the services. In providing occupational therapy interventions in work practice, the professional standards support the concept of client-centered care or intervention. In this situation, one must decide whether the "client" is Bill, our test subject, or the workers' compensation defense attorney representing Bill's employers' workers' compensation insurance carrier — the one who made the referral — or Bill's employer who is ultimately paying the bill. What if the evaluator perceives that Bill is underestimating his subjective complaints and trying too hard because he is so motivated to return to work? With his safety questionable under the circumstances, should the evaluator disclose this information if Bill feels disclosure of the information is not in his best interest? On the other hand, does the evaluator owe a duty to the referral source or the employer to report this information about Bill's risk of safety should he return to work?

One might look at this scenario and think, "Does it really matter?" Doesn't the clinician/evaluator owe a duty to all three parties? However, this situation presents an ethical dilemma to the clinician/evaluator because the three parties may have different interests and one cannot readily determine to whom the tester owes a duty beyond the actual test subject (Kornblau & Starling, 2000).

SUMMARY

Functional capacity evaluations are systematic assessments that measure physical abilities and functional capacity related to work demands. FCEs provide objective information from a trained evaluator to the injured

worker/claimant, clinicians, case managers, insurance adjusters, employers, and other payers of compensation or benefit systems. The evaluation findings can verify or refute a worker's subjective report of work limitations resulting from an injury or illness. FCE results provide useful information to assist in determining job placement, recommendations for accommodations, and other return-to-work options. When used together with an injury prevention program, FCEs may be to determine safety guidelines and limits. FCEs serve as a baseline for function and a final evaluation for work rehabilitation programs; they also contribute information to help determine when one has reached maximum medical improvement.

Two types of FCEs have been described: the Baseline and the Job Specific FCEs. The Baseline FCE looks more generally at the baseline of individual function in relation to the physical demands of work. The Job Specific FCE evaluates the worker's abilities within the specific demands of the job. With either type of FCE, a job analysis is seen as an important if not crucial element of the evaluation process. An evaluation with a job analysis better matches the worker to the demands of his or her job or a possible alternative job. An onsite job analysis will, of course, provide more specific job demand information than looking at job descriptions or databases such as the DOT or O*NET.

Clinicians/evaluators use different methodologies depending on the FCE protocol used, but most FCEs assess physical abilities or function, as well as sensory and cognitive functions. The authors stress that clinicians and evaluators look at the whole person and the effect the impairment may have on other aspects of the worker's life in addition to the worker role.

The FCE, as it currently exists, remains the only tool that can provide quantitative and qualitative data about how the individual functions in relationship to work performance and the work environment. The literature paints the FCEs as a necessary but less than perfect system of determining the level of work-related abilities and limitations that result from injury, accident, or illness. The interest in objective measures of functional capacity related to work is expected to continue to rise as more parties demand accurate and reliable information to help with decision making in workers' compensation or other benefit claims, disability determination, work placement, reasonable accommodations, and litigation issues. Ongoing FCE development work and research will continue to improve the reliability and validity of FCE systems and methodologies. The injured worker evaluation process will continue to evolve to better integrate functional assessments from the perspective of the injured individual as a whole, rather than fragmented working parts.

Diagnostic Musculoskeletal Ultrasound

Kelly Black, MD, and David Chapman, MD, MS

INTRODUCTION

Ultrasound shows musculoskeletal anatomy from a new and unique perspective (Van Holsbeeck & Introcaso, 2001). Musculoskeletal sonography is an advanced application of an established technology to evaluate the acute or chronic painful condition. Diagnostic musculoskeletal ultrasound has been used since the 1970s throughout the world, in the Olympics, and with professional and collegiate athletes, and is recently becoming accepted in the United States (Chapman & Black, 2003). The capability of ultrasound to demonstrate fluid with great sensitivity and specificity proves extremely useful in the diagnosis of osteoarticular diseases (Van Holsbeeck & Introcaso, 2001).

This is a brief introduction to musculoskeletal ultrasound; it is not our intent to make this an exhaustive review of musculoskeletal ultrasound but to point out its uses and benefits. We cover some of the most common uses along with some rare clinical entities.

SONOGRAPHY VERSUS OTHER MODALITIES

The availability, ease of examination, and low cost of sonography in contrast to magnetic resonance imaging (MRI) make follow-up of healing lesions practical. Sonography can provide all the information available with MRI and more with regard to muscle pathology. Its spatial resolution and definition of muscle structure are usually superior to those provided by MRI (Van Holsbeeck & Introcaso, 2001). The basic problem with MRI is that only subtle contrast differences of nerves and surrounding tissues are demonstrated; further, the resolution of MRI is still far below that of sonography. Another reason for the low impact of MRI for diagnosis of peripheral nerve disease is the oblique course of nerves in the extremities — while it is easy to follow a nerve with a longitudinal sonographic scan, this is barely accomplished at all with MRI (Peer, 2003). The interaction with the patient during a sonographic examination helps determine possible pathology and allows for a focused investigation. The examination is easily tailored to the exact location of a patient's pain sensations, or areas of possible coexisting trauma. It is quick and lacks the discomfort caused by pricking with needles during electrodiagnostic studies or by positioning in MRI (Peer, 2003).

Serial ultrasound can be useful in following healing processes, and it provides essential feedback to the athlete and clinician. Real-time ultrasound offers the best dynamic study currently available and allows for prompt image-guided procedures such as aspiration of fluid collections. Bilateral examinations can be performed expeditiously. There is no risk to patients with pacemakers or cochlear implants, and artifacts due to ferromagnetic implants do not occur. Use of Doppler further allows depiction of tissue inflammation and vascularity (Torriani & Kattapuram, 2003). Besides being inexpensive and commonly available, sonography spares the patient from ionizing radiation and is an interactive and nondiscomforting method, which makes it the first choice from a patient's viewpoint (Peer, 2003). Although electrodiagnosis is able to definitely confirm and in many cases localize a nerve lesion, to define the nature of the underlying pathology is often beyond its reach (Torriani & Kattapuram, 2003). The information from the ultrasound examination has a major impact on decision making in competitive athletics, disability, medicolegal cases, and sports injuries in the authors' practice.
FIGURE 43.1 A normal median nerve (between the x's) in the forearm.

NORMAL NERVES

For inspection of the peripheral nerve, sonography may be regarded as the number one imaging modality. Peripheral nerves are in most cases superficially lying structures easily accessible with sonography, they show a typical and quite distinct sonographic texture, and recent studies have revealed characteristic findings in various disease entities. In comparison with MRI, which is the only competing imaging modality for the workup of nerve compression syndromes, sonography is low cost and generally available. At the same time sonography is nondiscomforting, quickly performed, and easily adjusted to a patient's complaints in static as well as dynamic examinations. The latter are an important adjunct to the standard evaluation of peripheral nerve diseases, and especially valuable for the diagnosis of functional disorders such as the snapping triceps syndrome with ulnar nerve dislocation. This functional evaluation is beyond the abilities of the MRI. A huge advantage of sonography in comparison with MRI is its ability to image longer nerve segments in a single study and its superior resolution. One of the major advantages of sonography compared with other imaging modalities, such as MRI, for example, is its ability to acquire images in virtually every orientation along the course of a peripheral nerve (Peer, 2003).

Figure 43.1 is a longitudinal view of a normal nerve. Nerves have a characteristic appearance on ultrasound. The examination of a peripheral nerve should include transverse and longitudinal scanning (Peer, 2003). At dynamic examination with active or passive movements, the mobility (or immobility) of the nerve in relation to the surrounding musculotendinous structures is assessed. Normal nerves appear as markedly echogenic tubular structures with parallel internal linear echoes on longitudinally oriented scans and as an oval or round echogenic section on transverse scans, occasionally with internal punctate echoes (Fornage, 1988).

NORMAL MUSCLE

Real-time examination available only with ultrasound elucidates some types of muscle lesions that are occult on
FIGURE 43.2 The bipennate structure of the normal biceps muscle.
FIGURE 43.3 A normal posterior tibialis tendon.

static examinations. Serial sonographic examinations can accurately evaluate the rate and stage of healing, significantly decreasing the likelihood of reinjury (Van Holsbeeck & Introcaso, 2001).

Figure 43.2 is of normal muscle on a longitudinal view. The typical normal architecture of muscle as seen on longitudinal sections is generally evident; i.e., there is a "herringbone" pattern of hypoechoic skeletal muscle bundles separated by longitudinally aligned echogenic connective tissue (epimysium). In the transverse section the epimysium is seen end-on and therefore appears as an echogenic "dot" (Bohndorf & Kilcoyne, 2002).

NORMAL TENDON

Figure 43.3 shows the appearance of a normal tendon. Tightly packed, longitudinally arranged collagen bundles result in a brightly echogenic structure with a fine internal fibrillar pattern (Gibbon, 1996).

NORMAL JOINT

Figure 43.4 is a longitudinal view of a finger joint. Ultrasound is dramatically changing our approach to the evaluation of joint disease. In Europe, ultrasound has already established its place as the primary means of evaluating periarticular disease of synovial joints. The principal advantage of ultrasound over arthroscopy and MRI is its ability to examine the periarticular soft tissues with a more useful structural and anatomical detail. Many pain syndromes do not originate in bone or articular cartilage.
FIGURE 43.4 A normal metacarpal-phalangeal joint.
FIGURE 43.5 A normal medial meniscus of the knee.

Until now, these were presumptive clinical diagnoses. Sonography can be used to diagnose disease of the peri-articular tissues with great sensitivity and specificity. The densely packed fibers of fibrocartilage result in a relatively homogeneous structure, although occasionally a subtle fibrillar pattern may be identified along the axis of the annularly arranged fibers (Gibbon, 1996). Figure 43.5 is a longitudinal view of the medial meniscus, which is composed of fibrocartilage.

Although hyaline cartilage, subchondral lamellar bone, and trabecular bone can be considered separately, they are now seen increasingly as a functional unit (Bohndorf & Kilcoyne, 2002). Hyaline articular cartilage is anechoic in young adults but its echogenicity slowly increases with age especially if there is chondrocalcinosis. Figure 43.6 is a

FIGURE 43.6 The normal hyaline cartilage in the shoulder joint, also note the circular hyperechoic biceps tendon on the left-hand side of the image.
FIGURE 43.7 An intact anterior talofibular ligament bridging the talus and the fibula.

transverse view of the shoulder joint. In bone, the surface is usually brightly echogenic with profound posterior acoustic shadowing.

NORMAL LIGAMENTS

The advantages of ultrasound over MRI are the short examination time, the ability to provide a dynamic examination, reasonable cost, and availability. Computed tomography (CT) lacks sufficient contrast resolution to define ligamentous structures.

Figure 43.7 is a longitudinal view of the anterior talofibular ligament. Ligaments are composed of dense, regular connective tissue similar to that of tendons. Their structure differs from that of tendons in that more interweaving of collagen fibers is observed in ligaments, giving them a less regular histological and sonographic appearance (Van Holsbeeck & Introcaso, 2001).

NORMAL CLINICAL SONOGRAPHIC ANATOMY

In the soft tissues of the neck, many of the diagnostic problems that present to the clinician can be managed with maximal efficiency using ultrasound. The detail that can be seen in lymph nodes is superior to and more clinically useful than that obtained by either CT or MRI. In many cases one is able to make a confident diagnosis before fine needle aspiration cytology or histology, but in those cases where this is still indicated, ultrasound is the imaging technique of choice in guiding the needle to its best target. When one considers that the majority of structures and associated pathology in the neck lie only between 1 and 5 cm below the skin surface, and given the superior resolution that high-resolution ultrasound can attain, it is not surprising that ultrasound is gaining in popularity in the field of head and neck imaging. Ultrasound lends itself to biopsy techniques in the neck, being far superior to MRI and CT in this respect (Ahuja, Cozens, & Berman, 2000). Figure 43.8 shows a transverse view of the neck.

Several pain syndromes can be imaged and guided with ultrasound to help with proper diagnosis and to decrease risks with interventional procedures. Eagle's syndrome is caused by pressure on the internal carotid artery
FIGURE 43.8 An example of normal structures in the neck.
FIGURE 43.9 A normal supraspinatus tendon.

FIGURE 43.10 A normal growth plate in a 12-year-old female.

FIGURE 43.11 An example of the posterior aspect of the shoulder joint.

FIGURE 43.12 A normal biceps tendon overlying the proximal humerus.

FIGURE 43.13 Transverse view of a normal biceps tendon.

and glossopharyngeal nerve, by an abnormally elongated styloid process and/or a calcified stylohyoid ligament. Injection of the attachment of the stylohyoid ligament to the styloid with local anesthetic and steroid will serve as a therapeutic maneuver (Waldman, 2003). In our practice, we use dynamic ultrasound to evaluate the temporomandibular joint, surrounding musculature, and nerves. We also evaluate the vasculature with Doppler ultrasound. Ernest's syndrome is an insertional tendonosis of the stylomandibular ligament.

The subacromial-subdeltoid bursa lies superficial to the supraspinatis tendon and deep to the deltoid muscle. A thin layer of peribursal fat surrounds the bursa forming an echogenic (white) line between the deltoid and the supraspinatis (Chhem & Cardinal, 1999). The supraspinatus tendon has an outline that has been likened to that of a parrot's beak (Van Holsbeeck & Introcase, 2001). Figure 43.9 is a longitudinal view of a normal supraspinatis tendon.

Figure 43.10 shows a normal humeral epiphysis. Ultrasound has been used to diagnose Salter–Harris fractures in pediatric patients. Hubner et al. (2000) suggest the use of ultrasound in particular cases such as suspected bulge fractures or mildly displaced, simple fractures of the long bones of the forearm, humerus, femur, lower leg, and clavicle (Hubner et al., 2000).

Figure 43.11 shows that the fibrocartilaginous glenoid labrum can be visualized at ultrasound as a triangular, homogeneously hyperechoic structure that caps the bony rim of the glenoid (Sofka & Adler, 2002).

Figure 43.12 shows a longitudinal image of the normal biceps tendon. The tendon will appear as hyperechoic parallel lines (Mack & Matsen, 1995).

Figure 43.13 is a transverse image of a normal biceps tendon. When viewed transversely, the bicipital groove, which contains the tendon of the long head of the biceps

FIGURE 43.14 Normal extended view of the elbow. This type of view makes anatomic recognition more familiar to the clinician.
FIGURE 43.15 This view traces the perimeter of the median nerve to determine the cross-sectional area
FIGURE 43.16 Visualization of the normal or abnormal glide of the median nerve and its interaction with the surrounding anatomical structures on dynamic examination.

brachii muscle, appears as a concavity in the bony surface of the humerus (Mack & Matsen, 1995).

Figure 43.14 is a panoramic view of a normal elbow. Sonography allows complete evaluation of the elbow and surrounding musculature. At all ages, a frank breach in the cortex is detectable with ultrasound. Children with suspected dislocations at the elbow may benefit in particular from sonography because the unossified cartilage is visible (Barr, 1995).

Figure 43.15 is of a normal carpal tunnel transverse view. Figure 43.16 is a longitudinal view of a normal carpal tunnel. Sonographic guided injection could improve the clinical efficacy of the intralesional treatment of carpal tunnel syndrome by allowing corticosteroid injection into the most appropriate target area. High power resolution plays a key role in ensuring the "step by step" control of needle placement in the target area (Grassi et al., 2002).

De Quervain's syndrome is a stenosing tenosynovitis that causes entrapment of the tendons of the muscles that abduct and extend the thumb. High-resolution ultrasound shows thickening of the tendon sheath of the abductor
FIGURE 43.17 This view allows determining if each tendon shares a sheath or has a separate sheath, so that accurate injection of medication can be performed.
FIGURE 43.18 Scapholunate ligament connecting the scaphoid and lunate bones.
FIGURE 43.19 Dynamic imaging of this finger joint can reveal pulley tears or small tendon tears.

pollicis longus tendon and the extensor pollicis brevis tendon and color Doppler shows hypervascularity of those tendon sheaths (Lin et al., 2000). Figure 43.17 represents a longitudinal view of normal tendons mentioned above.

The scapholunate ligament is one of the important stabilizers of the wrist; abnormalities of this ligament may cause scapholunate dissociation, and rotary subluxation of the scaphoid bone (Totterman & Miller, 2000). The dorsal aspect of the ligament is seen in Figure 43.18.

Figure 43.19 is a longitudinal view of a finger flexor. Dynamic ultrasound with the fingers extended and with the fist clenched enabled excellent visualization of extensor tendon subluxation and dislocation at the metacarpal-phalangeal joint (Lopez-Ben, Lee, & Nicolodi, 2003). Ultrasound is a feasible imaging modality for measurement of the response of rheumatoid small-joint synovitis to therapy (Ribbens et al., 2003).

FIGURE 43.20 The extended view aids the clinician in observing a large segment of the infrapatellar region and then concentrating on the injured area.

FIGURE 43.21 The peripheral portion of the medial meniscus is readily visualized.

Figure 43.20 represents a panoramic view of a normal infrapatellar ligament. The patellar tendon appears as a cylindrical structure on sonography passing from the inferior pole of the patella to the tibial tuberosity. The normal tendon measures 4 to 5 mm in anteroposterior thickness and broadens at both insertions (Carr et al., 2001).

The meniscus appears as a homogeneous hyperechoic triangle interposed between hypoechoic layers of articular cartilage (Strome, Bouffard, & Van Holsbeek, 1995). Figure 43.21 is a longitudinal view of the knee joint.

The Achilles tendon is the common tendon of soleus and gastrocnemius muscles. The anterior and posterior margins of the tendon should be parallel to each other without fusiform expansion or gap in the tendon. The normal tendon has a uniform fibrillar appearance (Thain et al., 2001). Figure 43.22 is a longitudinal panoramic view of the Achilles tendon.

The normal plantar fascia has a fibrillar echotexture and measures about 3 to 4 mm in thickness (Cardinal et al., 1996). Ultrasound diagnosis of plantar fasciitis includes thickening of the plantar fascia and fat pad edema (Sofka & Adler, 2002). Figure 43.23 is a longitudinal view of the plantar fascia.

FIGURE 43.22 Panoramic view of the Achilles' tendon, the cursors depict the width of the tendon.
FIGURE 43.23 The x's show the width of the plantar fascia.

FIGURE 43.24 Full thickness tear of the supraspinatus tendon.

PATHOLOGIC SONOGRAPHY

Musculoskeletal ultrasound is particularly useful in the evaluation of tendons following surgical repair, assessment of soft tissues adjacent to orthopedic hardware, assessment of joint effusion, guidance of procedures and joint aspirations, evaluation of neoplasms, and sonographic assessment of osseous healing as well as focused investigation in stump pain in the amputated limb. Ultrasound offers a fast, effective, and relatively radiation-free method of assessment of postoperative musculoskeletal complications, free of some artifacts encountered on other modalities, including CT and MRI (Jacobson & Lax, 2002).

A full thickness tear is diagnosed when the disruption extends from the articular to the bursal surface of the tendon (Lin et al., 2000). In Figure 43.24, a full thickness tear of the supraspinatis tendon with peribursal fat and deltoid muscle herniation is noted. Also, note the cortical irregularity of the humerus that may accompany a full thickness tear. Sonographic findings of a partial thickness tear include a focal hypoechoic defect reaching either the bursal or articular surface, but not both (Lin et al., 2000). In Figure 43.25 note how the tear does not bridge the bursal and articular surfaces.

Figure 43.26 is a cyst located in the spinoglenoid notch. Suprascapular nerve follows a Z-shaped pattern with two fixed points: the first situated at the suprascapular notch and the second at the spinoglenoid notch. When nerve entrapment occurs at the suprascapular notch, both the infraspinatis and supraspinatis muscles are denervated. When compressed at the base of the scapular spine,

FIGURE 43.25 Partial thickness tear of the supraspinatus tendon.

FIGURE 43.26 Spinoglenoid cysts can be drained and injected under ultrasound guidance.

infraspinatis denervation occurs while the supraspinatis remains intact (Ludwig et al., 2001) Ultrasound can detect muscle atrophy and fatty infiltration of the affected muscle. Also, a labral cyst can be detected and aspirated by ultrasound guidance.

Figure 43.27 depicts shoulder impingement test, which is best visualized on dynamic scanning. Stretching of small nerve fibers within the thickened bursal tissues results in pain upon motion and provides less space for the rotator cuff during movement because of the thickened, inflamed tissues (Van Holsbeeck & Introcaso, 2001).

FIGURE 43.27 Dynamic imaging can reveal impingement of the supraspinatus tendon or peribursal fat as it attempts to go under the acromion.

FIGURE 43.28 Large amount of fluid in the subacromial-subdeltoid bursa. In addition to bursitis, this can be a finding in rotator cuff tears.

FIGURE 43.29 Curser on a large subacromial-subdeltoid bursitis. Ultrasound-guided aspiration revealed a traumatic hemorrhagic bursitis.

Bursal thickness should be no greater than 2 mm (Van Holsbeeck & Introcaso, 2001). The bursal space may be a potential space or may be seen as a thin hypoechoic (dark) band (due to a small amount of fluid) in normal individuals (Winter et al., 2001). Figure 43.28 shows a longitudinal ultrasound image of fluid in the bursa just inferior to the greater tuberosity and distal to the insertion of the supraspinatus tendon. Figure 43.29 is a transverse view of bursitis.

Figure 43.30 is an epidermal cyst. This cyst is the most common type found in the head and neck. It is surrounded by a fibrous capsule and has an epithelial lining (Ahuja et al., 2000). Ultrasound can help visualize and guide aspiration of loculations of the cyst and help prevent injury to nerves and blood vessels adjacent to the cyst.

Ulnar nerve dislocation represents an abnormal movement of the ulnar nerve out of the cubital tunnel and anterior to the medial epicondyle during flexion of the elbow, which is caused by an absence of the cubital tunnel retinaculum. Neuropathy is induced by abnormal friction and tear to the nerve during recurrent dislocation (Childress, 1975). Snapping triceps syndrome is medial dislocation of the medial head of the triceps muscle

FIGURE 43.30 An epidermoid cyst with no loculations or significant vasculature near the cyst.
FIGURE 43.31 Ulnar nerve.
FIGURE 43.32 Ulnar nerve subluxation.

(Spinner & Goldner, 1998). Dynamic ultrasound allows direct visualization of the ulnar nerve and/or triceps dislocation during active flexion of the elbow (Jacobson et al., 2001). Figure 43.31 is of the ulnar nerve at the medial epicondyle in extension. Figure 43.32 is of the ulnar nerve dislocated anterior to the medial epicondyle with the medial head of the triceps muscle in flexion. This is an example of ulnar nerve dislocation with snapping triceps syndrome.

Figure 43.33 shows a tear and severe tendonosis of the flexor tendon origin of the elbow. Dynamic ultrasound also provides a rapid means for evaluating the anterior band of the ulnar collateral ligament in professional baseball pitchers (Nazerian et al., 2003).

Figure 43.34 demonstrates a horizontal tear of the medial meniscus. Sonography reliably demonstrates posterior and peripheral meniscal tears, which are not well demonstrated with arthroscopy (Casser, Sohn,

FIGURE 43.33 Flexor tendon tear of the elbow.

FIGURE 43.34 The black line above the asterisk is a tear.
FIGURE 43.35 Ultrasound-guided aspiration and injection simplify procedures.

Kieckenback, 1990). Sonography is also able to identify injuries of the collateral ligaments or periarticular bursae that may mimic meniscal lesions clinically (Casser et al., 1990).

Figure 43.35 shows a suprapatellar bursitis. The suprapatellar bursa acts as a window to intra-articular knee pathology. Inflammatory and noninflammatory arthritis, infections, rheumatoid arthritis, osteoarthritis, gout, spondiloarthropathies, crystalline arthropathies, and trauma all manifest in some way in the suprapatellar bursa (Grobbelaar & Bouffard, 2000).

Figure 43.36 depicts an infrapatellar bursitis. Ultrasound is very sensitive for detecting joint and bursal fluid. An effusion may consist of clear fluid, pus, or blood (Ptasznik, 1999).

Figure 43.37 shows tendonosis of the infrapatellar tendon. Note the increased Doppler signal signifying neovascularization. It may be impossible to distinguish between small intratendon tears and increased gelatinous substance deposition within the tendon because of mucoid degeneration (Grobbelaar & Bouffard, 2000).
FIGURE 43.36 Cursors on distal infrapatellar tendon.
FIGURE 43.37 Doppler activity representing neovascularization.

FIGURE 43.38 A 2-year-old trocar scar from arthroscopy.

FIGURE 43.39 Fetus-like image of a Baker's cyst.
FIGURE 43.40 Peroneal tenosynovitis.

Hoffa's infrapatellar fat pad can become inflamed with irritation or injury or after arthroscopic surgery. The fat pad may swell, and it may become hyperechoic (Thain et al., 2001). A normal fat pad contains two small vertical arteries with two or three horizontal arteries connecting them (Jacobson et al., 1997). On power Doppler images, a higher number of vessels represents inflammation of the fat pad (Thain et al., 2001). Figure 43.38 shows scar tissue filling in the path of a trocar through the infrapatellar tendon and Hoffa's fat pad from an arthroscopic procedure.

Figure 43.39 shows a Baker's cyst, which is the most commonly described cyst in the knee. The cyst is a pathologic distension of the semimembranosus-gastrocnemius bursa. The most important feature for identifying a Baker's cyst with ultrasound is visualization of the stem of the cyst, which originates in the medial aspect of the popliteal fossa,

between the semimembranosus tendon and the medial gastrocnemius head (Grobbelaar & Bouffard, 2000).

Peroneal tenosynovitis is a common cause of periarticular pain at the ankle joint (Wang et al., 1999). In Figure 43.40, note the fluid distending the peroneal tendon sheath.

Morton's neuroma is a benign mass of perineural fibrosis affecting the plantar digital nerve (Rawool & Nazarian, 2000). The most common location is the third web space of the foot. On ultrasound, Morton's neuroma appears as a hypoechoic mass with an average size of 5 to 7 mm. Its relationship to the digital nerve can be established with ultrasound (Pollak et al., 1992). Figure 43.41 is a longitudinal view of the digital nerve going into a large hypoechoic mass. Figure 43.42 is a transverse view of a Morton's neuroma.

FIGURE 43.41 Morton's neuroma.
FIGURE 43.42 Morton's neuroma.
FIGURE 43.43 Plantar fascial ligament tear.

FIGURE 43.44 Achilles' tendon tear.

In Figure 43.43, note the hypoechoic gap in the plantar ligament representing a tear. In plantar fasciitis, ultrasound-guided injection allows accurate placement of medication and improved recovery.

Figure 43.44 is an acute complete rupture of an Achilles tendon. Achilles tendon tear or rupture is frequently caused by sports-related activities, but may also occur with systemic diseases that include inflammatory arthritis, autoimmune disease, diabetes, and gout (Fessell & van Holsbeek, 1999). Rupture most often involves a zone of relative avascularity located 2 to 6 cm proximal to the insertion of the tendon on the calcaneus (Winter et al., 2001). With an acute tear, a hematoma fills the gap
FIGURE 43.45 Pectoralis major muscle tear.

between the torn ends. The mechanism that causes pain in chronic Achilles tendonosis is not known (Astrom, 1997). However, high-resolution color Doppler ultrasound has shown that neovascularization may be involved. Ohberg et al. (2002) have found that sclerosing neovessels appears to be an effective treatment for painful chronic Achilles tendonosis.

Figure 43.45 is a muscle tear with hematoma filling the gap between the torn muscle ends. Ultrasound is also used for guided injection of myofascial trigger points as it can provide accurate placement of the needle and medication into the target tissue. Botulinum toxin can also be injected more accurately with ultrasound assistance with fewer adverse effects.

CONCLUSION

Diagnostic musculoskeletal ultrasound is used by physicians as an extension of the physical examination. Diagnostic musculoskeletal ultrasound can aid the physician in accurate diagnosis, treatment, and monitoring effects of therapy. It is our hope that ultrasound-guided interventions that are videotaped may decrease malpractice premiums for physicians performing office-based procedures. As advances in technology, such as three-dimensional and panoramic musculoskeletal ultrasound, improve we will have an even better and more user-friendly tool in our hands to evaluate patients with pain syndromes. We have given a very brief introduction of the many uses of musculoskeletal ultrasound in pain management.

Electrodiagnosis

Ross E. Lipton, MD, and David M. Glick, DC

INTRODUCTION

The experience of pain is unique to each individual. In spite of the immense strides that have been made in objectively defining the causes and pain perception, there is still much to learn of its pathways and mechanisms. The recording of brief bioelectrical potentials evoked after application of noxious stimuli in humans has aided in the effort to elucidate nociceptive pathways and mechanisms, and simultaneously augmented the clinical and radiological assessment of patients in acute pain. It is not atypical to distinguish acute from chronic pain by its more easily identifiable mechanism (generator). In contrast, chronic pain is far more challenging to characterize, as its localization and pathology tend to be more elusive. Despite these differences, electrodiagnostic assessment is valuable in characterizing both subtypes of pain.

Careful history and physical examination remain the most important tools used to evaluate the patient who complains of pain. The clinician then relies on his or her knowledge and experience to narrow the differential diagnosis and consider the possible underlying causes. It has become routine to consider other forms of assessment to assist in determining a more definitive diagnosis. Laboratory, imaging, and electrodiagnostic studies, whether considered as a group or individually as circumstances may dictate, are relied upon to identify, characterize, and quantify the presence of pathology and the likely cause of pain. In routine clinical practice, imaging studies, such as x-ray and magnetic resonance imaging (MRI) are often considered as the first adjuctive study for evaluating the patient with pain. These provide valuable structural data. While structure and function may overlap, imaging studies alone may not definitively reflect whether a pathology or abnormality is clinically relevant.

All pain has a neurological component. As the technology of physiologic assessment evolves, a means to assess each component of the pain pathway will likely develop. In the mean time, most electrodiagnostic procedures assess general nerve function and play an important role in characterizing neuropathogy. It is the goal of this chapter to provide discussion of those studies, which are considered routine, as well as those that are efficacious, but often overlooked. This chapter is not intended to serve as a comprehensive reference for electrodiagnostic procedures. Rather, it is meant to provide a basic introduction to the clinical utility, method of recording, and understanding the clinical significance of various electrodiagnostic studies.

INSTRUMENTATION

The central issue concerning instrumentation is safety. Vigilance and attention to detail, with respect to grounding, wiring, shielding, and patient-related issues (implantable electronic devices, etc.), goes a long way to ensure a safe laboratory. Once lab safety is secured, the examiner can concentrate on technical excellence and accuracy. To this end, the examiner must understand the capabilities and limitations of each electrodiagnostic testing device. For all of this, a basic conceptual understanding of electricity is key.

We take advantage of the unique characteristics of resistors and capacitors to configure electronic circuits that strategically either permit or block electronic signals. This configuration takes advantage of the difference between high-frequency and low-frequency bioelectric alternating current (AC) signals from the human body, as well as

615

direct current (DC) signals (not biological). Ultimately, the filtering system permits one to manipulate the recorded bioelectrical signal by configuring the electrodiagnostic device to accept or reject specific potentials, based on signal characteristics, such as frequency and amplitude. When it works, the result is a computer screen (oscilloscope) devoid of extraneous noise, leaving a smooth baseline and an accurately assessed bioelectrical signal.

A variety of surface or needle electrodes act to interface between the machine and the patient. The electrode picks up the biological signal (alternating voltage current). Each electrode has inherent impedance (resistance to alternating current). "Good" system impedance is considered to lie in a range between 1,000 and 5,000 ohms. This will confer good signal conduction from the body to the machine. Lower impedance is better. However, if the impedance is too low, one should be suspicious of an unwanted pathway between electrodes on the skin's surface — essentially a "short circuit." This may be caused by imperfect electrode wiring, excessive patient perspiration, or excessive conduction paste (salt bridge). If impedance is too high, it adversely affects conduction, especially of the smaller potentials, such as somatosensory evoked potentials (SEPs). Mismatched impedances can result in a buildup of charge resulting in a battery effect or permit 60 Hz noise (from the power supply) to pollute the signal, masking the electrical potential.

To acquire a bioelectric signal, the active electrode is placed near the expected current source of the action potential (near field) — e.g., the motor point during motor nerve stimulation. When the reference electrode is placed close to the active electrode (i.e., close to the action potential), a bipolar montage is created. This montage is useful for accurate signal localization. Electrodes in a bipolar montage send "like" data to the amplifier. When filtered, like data are subtracted during the processing — leaving the actual signal of interest. The bipolar potential is relatively small, e.g., a sensory nerve action potential (SNAP).

A referential montage is created when the reference electrode is placed a relatively significant distance from the active electrode. Compared with the bipolar system, the referential montage generates a comparatively large potential, as the signal is registered from a relatively larger current field, with little in common between electrodes. This montage is useful for elucidating hard-to-find signals. An example of this montage is seen in electroencephalography (EEG), configured to reference each side of the brain to the ipsilateral ear to propagate the signal.

In either type of setup, the bioelectric potentials of interest remain small in size, necessitating amplification. A signal is amplified when it passes through a system that multiplies it by a fixed factor (gain) that is characteristic of the equipment. Once the signal is amplified, extraneous signal (noise) is removed (filtered). In most machines, the signal is ultimately converted from its original analog characteristic to digital characteristic. The digital representation of the analog signal is then displayed on the cathode ray tube or computer screen.

PHYSIOLOGIC BASIS OF ELECTRODIAGNOSTIC STUDIES

Volume conduction is key to understanding electrophysiology and is defined simply as the propagation of electrical currents from external sources within the body. The human body is a very good volume conductor. As electrical current is conducted along excitable tissue (e.g., nerve), its characteristics can be recorded. The actual individual electrical impulse that is associated with a corresponding phenomenon (e.g., sensation or muscle twitch) may be too small or too far from an electrode to be recorded. But, because of volume conduction, electrical phenomena can be assessed and quantified. Volume conduction occurs because of the characteristics of the excitable tissue (nerve or muscle) and the surrounding ion-rich fluid (Dumitru, 1991a).

In a typical nerve, the lipid-rich semipermeable membrane acts as a barrier to compartmentalize the cell. This membrane is rich in channels and pumps, conferring selectivity to that which can and cannot pass through it. This selectivity of passage is based on ion charge and molecular size. In a typical nerve axon, large negatively charged anions are trapped inside the cell, creating a constant negative intracellular charge. Potassium, a major positively charged ion involved in tissue excitability, moves freely in and out of the cell through the membrane, its direction of flow depending on the relative concentration of the ion on either side of the membrane, as well as the charge difference between the inside and the outside of the cell at any given moment. Sodium, unlike potassium, does not move freely across the membrane. This property permits momentary variations in voltage (charge differences) across the membrane. When the resting state of ion separation is perturbed by the action potential, a complex array of ion flux occurs locally as the action potential (depolarization) and is then reset (repolarization) — on the basis of charge and molecular equilibrium, as well as the specific characteristics of the membrane channels and the ambient charge. These characterize the basis of local charge generation. The action potential is the critical adjacent voltage large enough to stimulate the necessary changes in membrane pumps and channels (Kandal, Schwartz, & Jessell, 2000).

The existence of a transient charge difference between the interior and exterior of the membrane (transient voltage difference) is the key to the generation of a local capacitive current dipole, residing on the extracellular surface. The channels downstream from the local dipole respond to that dipole by generating another series of ion flux, a bit farther "down the membrane."

The dipole represents a local "capacitive current" on the outer surface of the cell membrane. As the dipole effects a contiguous segment of nerve, causing another series of ion fluctuations, further dipoles are generated, and so on. This phenomenon travels incrementally along the nerve (or muscle), giving birth to transmission (Kandal et al., 2000).

Benjamin Franklin postulated that current flowed from positive to negative. This is opposite of what actually occurs, with electrons flowing from the negative to the positive pole. By convention, and based on the polarity of recording electrodes, flow that occurs in the direction of the current is designated as positive, and is represented by a downward deflection of the waveform. Signals propagated along excitable tissue in the human volume conductor have distinct electrical characteristics that translate into the signal that is seen on the computer (oscilloscope). As the biological signal (moving along nerve or muscle) approaches the recording needle, the needle "sees" the approaching edge of the signal. As the signal continues to pass under the needle, the needle records the middle of the signal, followed by the trailing edge, which is moving away. Each component of the biological signal, recorded by the electrode as it passes, is translated into a corresponding component of the waveform seen on the computer screen (oscilloscope). The approaching and trailing signals generate phasic components. Transition zones are associated with wave inflection points. Direction of waveform phase depends on the position of the electrode. By convention, upward (above baseline) is negative and downward (below baseline) is positive (Dumitru, 1991a, b).

In myelinated nerve, an action potential leads to uninterrupted signal transmission of capacitive current along a significant stretch of the insulated axon, without needing any further action potentials until the signal wanes at the next unmyelinated spot (node of Ranvier). This so-called salutatory conduction acts like a slingshot, making transmission along a myelinated axon much faster than that noted along an unmyelinated axon. The classic pain sensory fibers are small and lightly myelinated or unmyelinated. Therefore, transmission along pain fibers is relatively slow.

The speed of pain fibers is exemplified by the situation in which one places a hand on a hot stove. The expectation of pain is realized before the actual pain is felt (Kandal et al., 2000).

Conventional electrodiagnostic studies (e.g., nerve conduction velocity studies) assess the larger, faster myelinated nerves, whereas assessment of smaller fibers that are lightly myelinated or unmyelinated is exacted by indirect means. Painful conditions are often diagnosed by electrodiagnostic studies that reflect the state of large nerve fibers despite the fact that it is small fibers that classically transmit pain signals. It is less common to find small nerve fiber pathology in isolation (Kandal et al., 2000).

ELECTROENCEPHALOGRAPHY

EEG signal reflects activity at the level of the cerebral cortex. Deeper generators of cerebral signal, such as the thalamus and brainstem, are indirectly reflected by these signals (Wyllie, 1997). The EEG signal is of relatively low amplitude because the recorded bioelectrical signal must first pass through dense intervening tissue, to include the scalp. In addition, the cortical convolutions are associated with specific regional geometries, which may be associated with phase cancellation effects, causing a spurious reduction in net regional amplitude. The ability to assess this low-amplitude signal is enhanced by strategic placement of electrodes in geometrically advantaged fields that optimize the capturing of this activity. During acquisition of data, the position of the evenly spaced recording electrodes remains unchanged. Machine-generated variations in polarity and reference points correlate with specific sets of dipoles that characterize each montage. Each montage, in turn, corresponds to a different plane of assessment, each with its own distinct advantage in characterizing different types of regional signal. For example, a transverse montage will more clearly demonstrate stage II sleep activity when compared with that seen in the referential montage (Andriola & Epstein, 1983). Typically, multiple two-dimensional montages are assessed in a single study, to approximate a three-dimensional assessment.

EEG has been used in pain research to map the cerebral topographical perception and modulation of pain, to characterize the processing of nociceptive signal in the central nervous system. EEG augmented with spectral analysis has demonstrated that signal obtained from muscle is processed differently from signal obtained from skin, with both within similar neural matrices of the brain (Chang et al., 2004). As well, brain maps generated by EEG/EMG are used in tandem with PET/fMRI (positron emission tomography/functional MRI), significantly adding to the diagnostic yield. Clinically, EEG is mostly used in the setting of headache (Niedermeyer, 1999).

EMG

The abbreviation EMG has more than one meaning. EMG literally stands for electromyogram, a study that features insertion of a needle into muscle to assess activity during rest, as well as during voluntary contraction. In a broader sense, EMG is the combined study that includes needle EMG when performed in conjunction with nerve conduction velocity (NCV) studies. To help distinguish between the two definitions of EMG, the phrase "needle EMG" is

used to describe the specific testing of muscle, whereas "EMG" is used to refer to the entire study.

Surface EMG

Diametrically opposed to needle EMG, the electrode interface of surface EMG (sEMG) does not penetrate the skin, rendering this test unable to directly measure spontaneous activity, insertional activity, motor unit morphology, and motor unit recruitment. Despite its limitations, sEMG plays a role in the diagnosis of muscle impairment syndromes such as fibromyalgia, myofascial pain, muscle injury, and muscle spasms (Cassisi et al., 2000; Pullman, 2000; Nederhand et al., 2003; Wimalaratna et al., 2002). Experimental kinesiology has also proved to be a valuable application of sEMGs (Mannion et al., 1997). A detailed discussion of sEMG can be found elsewhere in this text.

Needle Electromyography

The needle EMG study is complemented by NCV. For example, the abnormal motor NCV in polyneuropathy may be further qualified by severe axonal changes, found on needle EMG. EMG can also help distinguish between neuropathy and radiculopathy or may confirm their coexistence. The information derived from the needle EMG examination also aids in localization of the spinal level(s) of radiculopathy. Irritability of muscle, as exemplified by fibrillations, sharp waves, or myotonia can be demonstrated by needle EMG in a variety of painful muscle disorders. Needle EMG examination also reveals the current state of nerve or nerve root healing after injury and helps approximate the precise date of injury. The latter is particularly valuable in cases where prior injury or pathology is concurrent with new clinical abnormalities.

Needle EMG assessment features both sight and sound. A variety of potentials generate characteristic sounds as well as characteristic waveforms. Audiometric assessment augments visualization. Routine needle EMG is performed using either a monopolar or a concentric needle. The monopolar needle needs a separate ground. Because it is smaller in caliber, the monopolar needle causes relatively less discomfort than does the concentric needle. The concentric needle, which comes in various sizes and is larger than the monopolar needle, contains its own ground (Walker et al., 2001).

Bioelectrical signals obtained during needle EMG are categorized by activity noted at rest versus active muscle contraction. Resting muscle EMG reveals two subtypes of activity: spontaneous activity (that activity noted while the needle is resting in muscle after cessation of insertion) and insertional activity (that activity noted during crisp short insertions). Needle insertion causes a burst of short-lived relatively high frequency activity. Silence immediately follows in normal muscle. Both the examiner and the subject must hold still after each insertion, to avoid movement artifact. This artifact is sometimes responsible for misdiagnosis of abnormal insertional activity by a less-experienced examiner. Normal insertional activity should last no longer than 0.5 ms. Activity lasting beyond 0.5 s suggests irritability. This may be the earliest evidence of increased insertional activity, especially if coupled with a sharp wave or fibrillation potential (Bromberg, 1993). Needle insertion into the neuromuscular junction begets normal "end plate" activity, exemplified by the miniature end plate potential (MEPP), a tiny sharp monophasic negative wave (less than 10 microvolts, less than 3 ms duration) that occurs randomly and is difficult to isolate, due to coalescence with end plate noise. End plate noise appears as many end plate spikes with an irregular baseline. This activity produces the characteristic "seashell" murmur. Miniature end plate potentials are random, monophasic, upward-deflecting (negative) waves, occurring spontaneously with irregular rhythm representing presynaptic calcium release, leading to subthreshold levels of acetylcholine. Therefore, no action potential is generated (Dumitru, 1991a, b).

Another spontaneously generated potential from muscle is the end plate spike, a potential that is a bit more substantial than the MEPP. It occurs in distinct intervals, approximately every 50 ms. Unlike the miniature end plate potential, the end plate spike results from a suprathreshold action potential, propagating an irregularly fired biphasic waveform: negative–positive. End plate spikes generate a characteristic sound, reminiscent of "sputtering fat in a frying pan." That needle assessment of the neuromuscular junction is particularly painful acts, which is a distinct diagnostic feature.

Abnormal spontaneous and insertional activities are represented by the fibrillation potential and positive sharp wave. The fibrillation potential is a spontaneously generated action potential that is sharp in morphology, owing to its relatively short duration. The potential is characterized by a positive downward deflection followed by a low-amplitude negative upward deflection. It may be triphasic. The potential is about 20 microvolts or higher in amplitude and is 1 to 5 ms in duration. The fibrillation occurs as a result of spontaneous depolarization, a periodic rhythmical twitch excitation of a single sensitized muscle fiber potential (Denny-Brown & Pennymaker, 1938). This activity reflects a muscle fiber that has lost its nerve supply, causing so-called irritability.

Resting muscle membrane of denervated muscle is unstable and irritable, acting as an oscillator that spontaneously depolarizes. The fibrillation may be morphologically similar to an end plate spike, but is classically rhythmic and lower in frequency. Rarely, an end plate spike may demonstrate features of a fibrillation potential, causing confusion for the novice electrodiagnostician. Irritable muscle is seen in many conditions, to include certain

myopathies (e.g., necrotizing type), neuropathies with large fiber axonal involvement, and radiculopathy. Needle EMG of paraspinal muscle will confer the best yield for fibrillations and positive sharp waves found in painful irritable myopathies because most myopathic processes preferentially affect the proximal and truncal muscles (Katirji, 1998).

A positive sharp wave carries the same clinical significance as the fibrillation potential (reflecting denervation). The positive sharp wave, like the fibrillation potential, is generated spontaneously. Its significance is thought to equal that of the fibrillation potential, differing only in its point of origin, with its biphasic appearance reflecting electrode position (Dumitru, 1991a, b).

Distinguishing end spikes from fibrillations hinges on rhythm and morphology, the former of relatively high frequency, the latter of lower frequency and regular in rhythm. As well, the deflection of the fibrillation potential is positive, whereas that of end plate spike is negative. Although previously thought to be a rule without exception, characterization by deflection direction is not without potential error (Herbison, 1991).

Other examples of spontaneous needle EMG activity include the complex repetitive discharge (CRD) and the myotonic discharge. Both discharges are prolonged, at times for many seconds. A complex repetitive discharge is generated spontaneously as a result of a nonsynaptic (ephaptic) muscle fiber pacemaker. This is essentially a short circuit of normal synaptic transmission, occurring between groups of adjacent injured nerve fibers, causing repetitive spontaneous firing of the same exact muscle groups, resulting in the production of a complex polyphasic potential, each repetition being identical in morphology. This usually very high frequency rhythmic firing does not waiver in frequency or amplitude. The CRD reflects chronic denervation (Katirji, 1998).

Myotonic discharges are sometimes found in myotonic disorders, but are not exclusive to those disorders, e.g., painful conditions such as myotonia congenita (Sunohara et al., 1996); proximal myotonic myopathy, also called PROMM (Kress et al., 2000); and myotonic dystrophy. The pain experienced as a result of these disorders is mostly due to cramp generation, with cramp discharges a separate issue. Although the CRD is rhythmic, the myotonic discharge waxes and wanes in both amplitude and frequency, generating the characteristic "dive bomber" sound with needle insertion (Bromberg, 1993). Spontaneous activity notwithstanding, myotonic activity obtained during insertion tends to be morphologically sharp. True myotonic discharges last for more than 0.5 s (Daube, 1996).

A fasciculation represents spontaneous activity obtained from an entire motor unit action potential (MUAP), to include the motor neuron and the muscle that it innervates. Fasciculations are noted both in normal sub-jects and in states of diseased motor neuron. Physiological accentuation of fasciculations can be seen secondary to benign exogenous (caffeine) or endogenous (stress) alterations. Fasciculations are usually associated with amyotrophic lateral sclerosis, a classically painless disease. Myokymic discharges are spontaneous, rhythmic to semirhythmic discharges seen with muscle rippling. Myokymia is found in radiation-induced brachial plexopathy, as well as multiple sclerosis (MS), Guillain-Barre syndrome (GBS), pontine tumor, and timber rattlesnake poisoning (Gutmann, 1991).

The neuromyotonic discharge is quite complex, producing bizarre sounds mimicking soldiers marching with sirens ringing. These high-frequency discharges can be sustained or can occur in bursts. They are associated with sustained muscle activity and are unaffected by voluntary movement. This activity is considered to be quite painful, as seen in Isaac's syndrome, anticholinesterase poisoning, achondroplastic dwarfism, tetany, and spinal muscular atrophy (Daube, 1996).

MOTOR UNIT ASSESSMENT

Unlike the aforementioned spontaneous and insertional activity, assessment of the motor unit is performed during voluntary contraction. The motor unit consists of a motor neuron and all of the muscle fibers that it innervates generated by active contraction of skeletal muscle. Assessment of the motor unit aids in the diagnosis of many neuromuscular disorders that are associated with pain, including radiculopathy, plexopathy, and mononeuropathy and characterizing morphology and recruitment pattern. The interference pattern is generated with increasing muscle contraction toward maximal. A full interference pattern is a gross reflection of normal muscle activity but not a sensitive parameter for less obvious motor dysfunction.

Our nervous system responds to gradually increasing muscle contraction by generating a motor unit and increasing its firing frequency. The normal motor unit starts out firing at about 2 to 3 Hz. With further contraction, the first motor unit appears at a higher frequency, toward 10 Hz. Before or at 10 Hz, normal muscle produces a second motor unit. That is to say, once the critical firing frequency is reached, the muscle should produce a second unit that starts at about 2 to 3 Hz, seen concurrently with the first faster unit. This pattern of motor unit recruitment continues with further muscle contraction. By the third or fourth unit, the screen may be filled with so many potentials that it is difficult to identify each individual motor unit (Daube, 1996). The presence of multiple waveforms can create the erroneous impression that some potentials are high in amplitude, by virtue of phase addition. Reduced motor unit recruitment is the earliest electrodiagnostic finding of neurogenic weakness, which is seen concurrently in many painful states, such as plexopathy, radiculopathy, and com-

pressive mononeuropathy. Assessment of motor unit recruitment depends on the ability to isolate a single motor unit, which depends on the cooperation of an alert subject's ability to maintain required muscle tension. Reduced recruitment is synonymous with neurogenic recruitment. In this pattern of recruitment, the initial motor unit fires at an abnormally higher frequency before the next unit is recruited. In severe cases, the second unit may never show and the single unit fires at a very high rate. The most severe recruitment abnormality is characterized when no motor units are obtained, with severe weakness. A lack of fibrillations in the setting of severely reduced recruitment suggests conduction block from a demyelinating lesion, rather than axonal motor nerve damage. However, if the needle EMG study is performed less than 2 to 3 weeks after axonal injury, then fibrillations that are due to develop may not have done so that early, necessitating a follow-up study in about a month.

Myopathies are associated with pain. The electrodiagnostic features of myopathic muscle tend to be inconsistent. Diametrically opposed to neurogenic change, motor unit potentials in myopathic muscle are said to be shorter in duration (thinner) due to fiber loss within the motor unit. They also tend to be polyphasic, due to desynchronization of firing within the unit. Reduced amplitude, a "classic" and most debated myopathic characteristic, is the least reliable feature of myopathy. Myopathic recruitment is marked by many early appearing (fast-onset) muscle fibers of low amplitude (fatigued), in the 50 microvolt range. Recruitment pattern varies, but is usually normal in less severe cases. Increased (early) recruitment is thought due to both weakness and effort, as though the muscle contracts enough to generate potentials, but it does so using several motor units jumping into the fray together, appearing as several suboptimal motor units occurring simultaneously some of which are too "early." Early recruitment is the most common electrodiagnostic finding in myopathy. Neurogenic recruitment is seen in severe late stage muscle disease. Irritable myopathies demonstrate fibrillations and/or sharp waves. This category of myopathy can be due to inflammation, acid maltase deficiency, myotonic dystrophy, myotonia congenita, and many other causes (Katirji, 1998). Pain is a major characteristic of many muscle diseases within this subclass.

Factors that can influence recruitment must be considered to avoid spurious diagnosis. These include pain (inhibition of motor unit activation), co-contraction of antagonist muscle (yielding false assessment of muscle contraction force), electrode movement during muscle contraction (loss of motor unit "focus"), and poor subject cooperation (Petajan, 1991). To accurately assess the motor unit, one must be assured that it is not a distant unit, but the one closest to the needle electrode. The closest units will have the shortest duration and rise time

(pointy morphology) and will be of greater amplitude than more distant units (Figure 44.1).

NERVE CONDUCTION VELOCITY STUDY

The motor nerve action potential is more aptly named the compound muscle action potential (CMAP) because it reflects activity from muscle after stimulation by nerve — a combination of both. After motor nerve stimulation, there is a synapse at the neuromuscular junction, where muscle fibers are activated by a calcium-dependent action potential. In a sense, this represents amplification of the motor nerve signal. This also explains why the amplitude of the CMAP (measured in millivolts) is typically 1,000 times larger than that of the SNAP, which is typically measured in microvolts. SNAP morphology is usually "thinner and sharper," marked by a short rise and fall time. The compound muscle action potential is usually biphasic. CMAP amplitude is lost faster than SNAP amplitude after injury.

A stimulated motor nerve has a distal latency and a proximal conduction velocity. The distal latency cannot be referred to as the distal conduction velocity because it involves muscle as well as nerve. The distal motor latency is accounted for by nerve, neuromuscular junction, and muscle conduction combined.

The amplitude of the average adult MUAP ranges from a few hundred microvolts to about 2 millivolts. High amplitude polyphasic motor units suggest reinnervation of muscle after injury. This combination of findings is most consistent with chronic neurogenic change. Denervation caused by an irritable myopathy can be distinguished from that caused by a neurogenic process by distinct morphological and recruitment features. Amplitudes of neurogenic muscle tend to be normal or higher in amplitude, particularly after the healing period. These units may be of longer duration and may also be polyphasic, indicating the healing of motor nerve. The extra phases reflect the sprouting nerve fascicles that have reinnervated new muscle fibers (Bromberg, 1993; Katirji, 1998).

Because of its relatively diminutive size, the normal SNAP is more susceptible to obliteration by artifact, which may be due to improper grounding technique, movement caused by muscle tension, or overstimulation. When a nerve is overstimulated, a component of the CMAP may be incorporated into the SNAP, wiping out that portion of the SNAP or the entire SNAP. In a subject with substantial girth, action potentials may be difficult to obtain, especially the SNAP, leading to higher stimulation current/voltage, which can cause obliteration of the SNAP by the CMAP.

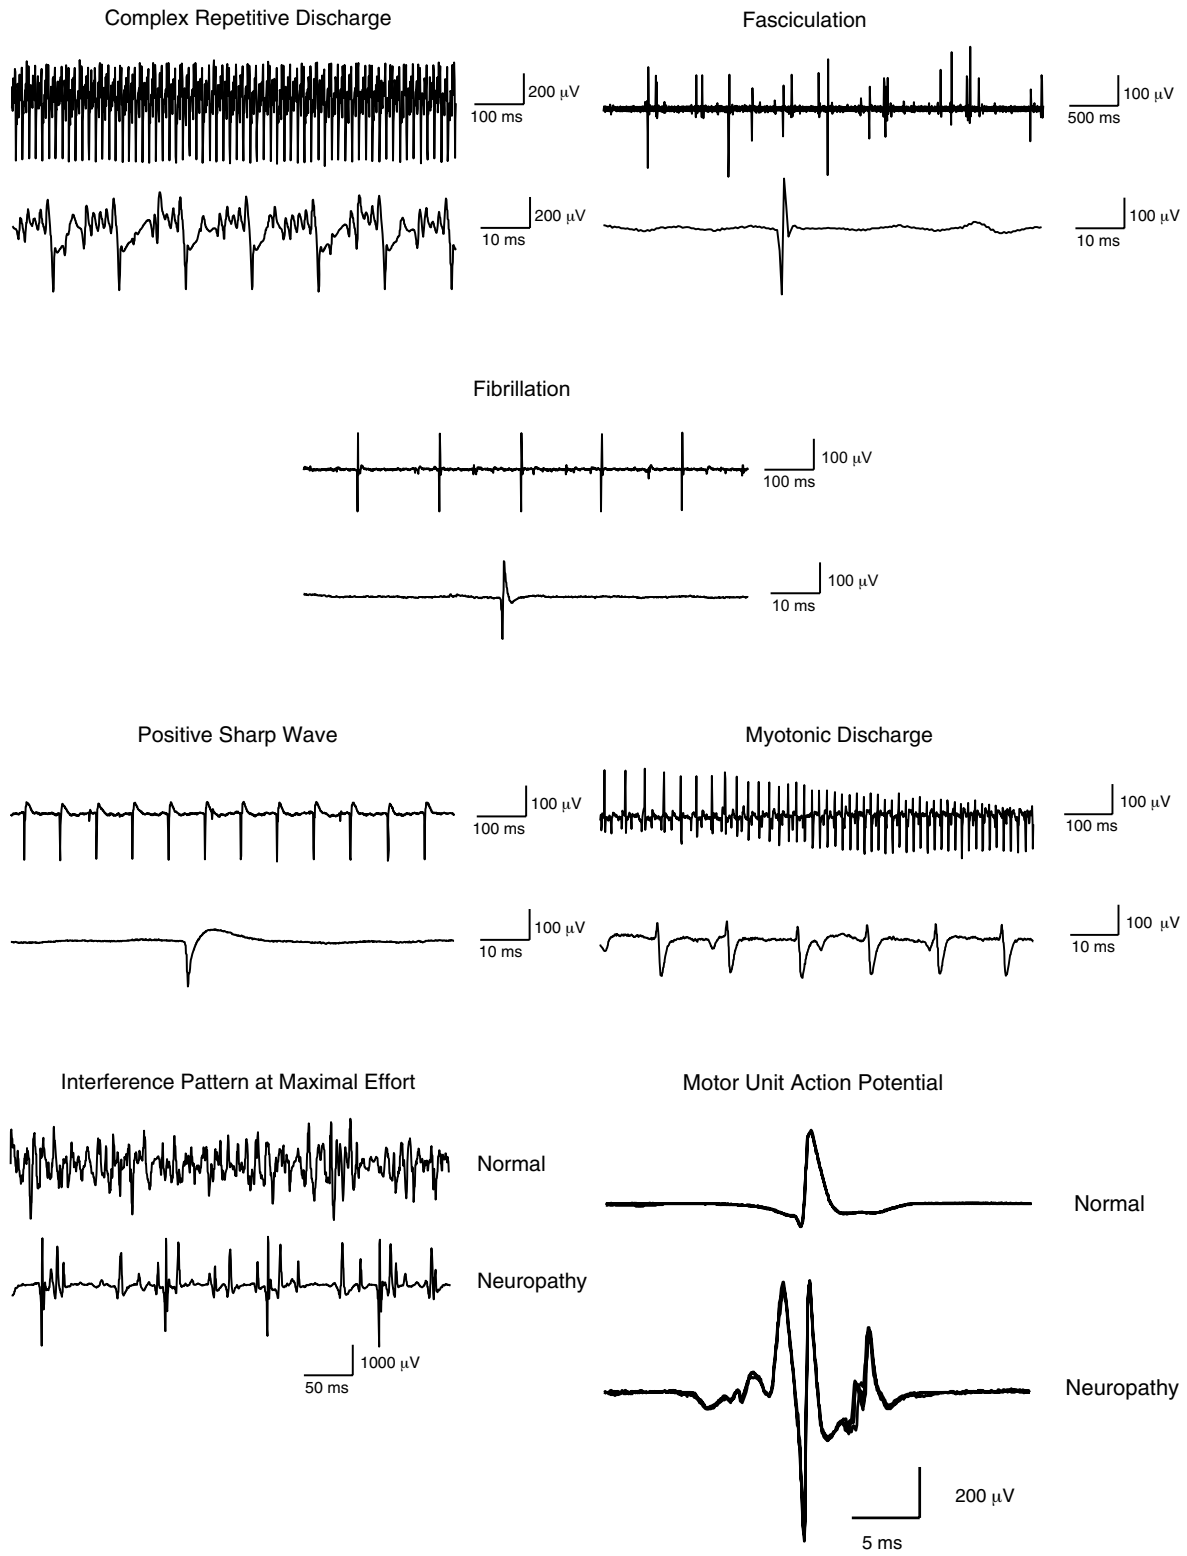
The SNAP is obtained by stimulating the sensory nerve and recording information from that nerve in either the *orthodromic* direction (the same direction in which the nerve naturally propagates its signal) or in the *antidromic*


FIGURE 44.1 Sample EMG waveforms demonstrating common normal and abnormal patterns. (Courtesy of Oxford Instruments.)

direction (normal). Therefore, one may stimulate the sensory nerve from either a distal-to-proximal or proximal-to-distal direction. The potential should essentially be the same, unless motor nerve artifact is obtained with stimulation at one end but not at the other end. With respect to the CMAP, only the orthodromic-derived CMAP is considered. With stimulation in the distal-to-proximal (antidromic) direction, one will obtain a large amplitude *M-wave* (CMAP) that is generated by the signal traveling backward. However, a volley also travels proximally, hitting a dead end in the cell body of the motor neuron (in the spinal cord), ultimately being propagated back down the limb to the active electrode. This potential, known as an *F-wave,* is considered a late potential because it arrives many milliseconds after the M-wave is recorded. The F-wave represents conduction through the full course of the motor nerve, up and back (Oh, 1993).

The proximal extent of the F-wave response permits localization of disorders in those regions, e.g., the brachial plexus. Under normal conditions, a series of "rastered" F-wave responses produces a clustered group of late potentials, each differing slightly from one another in both morphology and latency. The variability in latency and morphology is explained on the basis of the signal being propagated along a different component nerve fascicle each time the nerve is stimulated as well as the fact that the local stimulation artifact affects a refractory period for some of the returning F-wave responses during their descent back down the limb.

The *H-wave* (Hoffman reflex) is another type of late response. Stimulation of the tested nerve, usually the tibial nerve at the popliteal fossa, is directed proximally toward the hip girdle, with a descending response expected. Unlike the F-wave response, which spans its entire length in motor nerve, the H-wave signal travels up the afferent sensory component, synapses in the spinal cord, and descends in an efferent motor component, ultimately generating a CMAP at a muscle belly, usually at the medial calf. In most circumstances, the amount of current/voltage used to generate an H-wave is low, whereas the stimulation time is relatively long, usually set at 1 ms. The tibial H-wave reflex recapitulates the clinical muscle stretch tendon reflex (ankle jerk/S1 root). It is performed with the patient lying in the prone position. The H-wave should be triphasic in morphology and should demonstrate little side-to-side latency variation. Unlike the F-wave, the H-wave is nearly invariant in its morphology and latency. Whereas the F-wave is clinically useful in the study of many accessible nerves, the utility of the H-wave in adults is restricted to the tibial nerve, used primarily to aid in diagnosis of an S1 radiculopathy. The median nerve H-wave reflex may be useful in children (Oh, 1993).

Whereas the SNAP is obtainable when the sensory component of a mixed nerve is stimulated in isolation (e.g., median digital branches), the SNAP is obliterated when the sensory and motor components are close to each other. As well, the machine settings (e.g., band-pass filter) and the electrode set up (e.g., ring electrodes on digits that contain no motor nerve component) are modified to "capture" waveforms of various latency and amplitude. Sensory and motor nerve potentials are both affected by the state of the axon, as well as the state of myelination. With a reduction in the quantity of motor fibers, the amplitude of the potential will be reduced proportionally to quantity of fiber loss. When enough fibers are lost, that number will include a percentage of the faster-conducting fiber population. Therefore, with axonal loss, not only does one lose amplitude (expected), but one also loses velocity (Triggs, 1997).

Conduction velocity of demyelinated nerve is slowed due to myelin loss. However, distal stimulation of a demyelinated motor nerve will also show reduced compound muscle action amplitude, not due to axonal injury, but due to temporal dispersion and phase cancellation. When a nerve loses its myelin insulation, it does so unevenly. As a result, different parts of the nerve will conduct signal at different velocities. Dispersed signal loses its synchrony by definition, where fewer fibers to fire at the same time. Phase addition is reduced, and phase cancellation occurs more frequently, both acting to diminish the signal (Daube, 1996). Isolated temporal dispersion (without conduction block) has not been established as a cause of motor or sensory deficits (Olney et al., 1999).

Nerve disorders are either predominantly axonal in nature or predominantly demyelinating in nature. In the setting of so-called conduction block, this distinction has significant prognostic ramifications, as a focal nonpathological demyelinating lesion tends to have a better outcome when compared to conditions of axonal loss. Conduction block of an intact nerve may be axonal in nature, demyelinating, or both (Katirji, 1998). Conduction block is associated with a variety of sensorimotor symptoms. One may also experience pain in a clinical scenario that includes conduction block (e.g., severe carpal tunnel syndrome). Complete conduction block may cause severe weakness along with pain, as exemplified by traumatic injury. Criteria for defining partial conduction block hinge on latency and amplitude. More than one set of accepted criteria to define partial conduction block exists in the literature, revealing the difficult nature of this chore (Olney et al., 1999). Pain is a common symptom experienced by patients with conduction block who suffer acute inflammatory demyelinating polyradiculneuropathy (AIDP) and mixed axonal and demyelinating polyneuropathy, such as that seen in renal disease and diabetes mellitus. Classically, a hereditary predisposition to pressure palsy is not painful, although both nerve compression and secondary nociceptive pain may both play a role in some cases. The finding of conduction block aids in the accurate identification of a primary demyelinating disorder, which

is more than an academic exercise, as debilitating disorders such as AIDP and diabetic radiculoplexopathy may be ameliorated with immunotherapeutic intervention, via intravenous immune globulin or plasmaphoresis. Cerebrospinal fluid assessment may be obtained to augment the electrodiagnostic and clinical information in this type of case.

EVOKED POTENTIALS

An evoked potential (EP) is generally defined as an electrical manifestation of the central and peripheral neural pathways in response to an external stimulus. In simple terms, when an electrical, mechanical, visual, auditory, or other stimulus is applied, the body responds in a predictable manner, propagating electrical impulses. These impulses can be recorded and assessed for speed and volume of conduction, as well as aberrance. For the most part, these studies evaluate sensory pathways, including both peripheral and central components, with the exception of motor evoked potentials (MEPs). The three most common EPs in daily clinical practice are (1) somatosensory evoked potentials (SEPs), (2) brainstem auditory evoked potentials (BAEPs), and (3) pattern-shift visual evoked potentials (VEPs). Each of the studies provides an objective measurement of function relating to their respective sensory systems. Although each study is best suited for specific clinical purposes, the clinical benefits of all EPs lie within the ability to demonstrate aberrant function within the sensory systems when clinical examination is equivocal, define the anatomic distribution of a neural pathology, and even monitor the affected pathways over time.

The ability to record EPs is not new. Chiappa (1983) is generally credited with compiling much of the early literature relating to EPs. Although there had been references dating back to the early 1900s with the first EP recorded by Richard Caton in England, it is Dawson (1947) who is responsible for the techniques in use today. Dawson is credited with having made the first systematic recordings of EPs from the human sensory cortex using surface electrodes over the scalp. The initial work was done superimposing photographs of faint traces. He then devised the first mechanical–electric averaging device (Dawson, 1954). Nowadays, signal response averaging and the recording of EPs are taken for granted thanks to electronic and computer technology. For the purposes of this chapter, the detailed discussion of SEPs is felt to be of greater value based on the ability to assist in the differential diagnosis of musculoskeletal pain disorders. Conversely, BAEPs and VEPs are of greater value in assessing loss of function, not necessarily associated with pain, with the exception of intracranial mass, where headache is likely a symptom.

SOMATOSENSORY EVOKED POTENTIALS

SEPs are obtained through direct stimulation of structures in the peripheral nervous system, primarily in the upper and lower limbs, as well as the torso. The acronym SSEP is common to literature, and refers to the term "short-latency" SEPs, in which responses largely occur within 50 ms for nerves stimulated in the upper extremities and 100 ms for the lower. The major clinical application of SEPs is in the detection of physiologic impairment of the sensory pathways including the peripheral nerve, plexus, nerve roots, spinal cord, brainstem, and cerebrum. As one would imagine, these studies are particularly valuable in evaluating conditions that are primarily sensory in nature. For example, in the case of a preganglionic sensory radiculopathy, an SEP is more likely to identify the lesion than the more routine EMG.

An SEP, as are EPs in general, is best understood as a mere continuity check, in this case involving the sensory afferent pathways from the extremities to the sensory cortex. A concise series of waveforms is generated that reflects sequential activation of neural structures along the way. These waveforms can be recorded at specific intervals, most commonly the peripheral nerve, spine, and cortex. If the signal arrives at the cortex at the correct time, with adequate intensity, the study is felt to be normal, reflecting unhindered continuity. If, on the other hand, the signal is late arriving at the cortex, or is attenuated with respect to the volume or strength, the study is abnormal. Localization of the lesion is possible by reviewing the potentials generated along the way, noting where the block or delay first occurred.

Although the term SEP is generally used to describe all types of peripheral nerve stimulation, current literature makes a distinction between the classic stimulation of mixed nerves, such as the median, ulnar, tibial, and peroneal, and other more specialized studies. One of the principal limitations of SEPs that likely contributed to the primary use of EMG for the diagnosis of radiculopathy was the innervation of multiple roots that innervate mixed nerves. To address this problem, several authors described the use of dermatomal SEPs (DSEPs or DEPs) as a means of increasing the sensitivity and specificity of SEPs primarily for radiculopathy (Aminoff & Goodin, 1988; Aminoff et al., 1985a, b; Dvonch et al., 1984; Katifi & Sedgwick, 1987; Liguori, Taher, & Trojaborg, 1991; Machida et al., 1986; Scarff et al., 1981). As the name implies, DEPs are obtained following stimulation of a cutaneous nerve having innervation of a particular nerve root. Credit is largely given though to Slimp et al. (1992) for a paper delineating normative data for dermatomal stimulation from C4 to S1, as the others were primarily limited to distributions such as L5 and S1. There were isolated studies representing the dermatomes of the hand (La Joie & Melvin, 1983). Today the volume of references reporting

directly on the clinical utility of SEPs or that rely on SEPs for access to the outcomes or effectiveness of therapeutic interventions or instrumentation is quite extensive.

Before elaborating further on clinical utility of SEPs, there is another term that the literature commonly neglects to differentiate: segmental SEPs (Eisen, Hoirch, & Moll, 1983). Segmental SEPs have factors that are common to both mixed nerve and dermatomal stimulation. Segmental studies involve the direct stimulation of peripheral nerves that have a primary innervation of one nerve root. The most classic of these nerves are the superficial peroneal and the sural, representing the L5 and S1 distributions, respectively. The techniques involving the evaluation of segmental nerves address the limitations regarding sensitivity and specificity related to mixed nerve stimulation, as well as the perceived difficulty in recording the smaller potentials generated with DSEPs, not to mention the overlapping of adjacent dermatomes (Glick, 2001).

The clinical utility of SEPs is highly dependent on the criteria set for abnormality. The classic criteria are well described by the most recent edition of Chaippa's text (1997). The limits of normal are typically portrayed from a statistical standpoint as 2.5 to 3.0 standard deviations (SD) from the mean, as determined from a laboratory set of normal studies by each laboratory. *Latency* is defined as being the time it takes for the potential to travel from the stimulation to the recording side. In practical terms, most clinicians have grown to accept the fact that it takes approximately 19.0 ms for the volley of electrical impulses to reach the cortex following stimulation of the median nerve at the wrist. Coincidentally, 1 SD typically equals 1.02. The normative range assuming 3.0 SD from the mean latency of 19.0 ms would yield a range of 16.0 to 22.0 ms. It should be said that many clinicians rely on the upper limit of 2 SD as clinically significant. To this end, if the left to right side-to-side difference is greater than 2.0 ms, an abnormality is suspected. Localizing this abnormality would be dependent on assessing interpeak latencies, those obtained at the other recording site along the pathway, typically over a peripheral site and the spine. This would be best described by comparison with a road rally, in which the first determination of a problem is reflected by the arrival at the final checkpoint. In this situation, the entire pathway would have to be intact as there are defined limits to the propagation of an electrical impulse along a nerve or neural pathway, and each will function normally. If the potentials recorded over the final destination, i.e., the cerebral cortex, were delayed or late, it is possible to examine the intermediary recording sites or checkpoints to determine the origin of the problem, essentially localizing the pathology.

When it comes to determination of abnormality, most authors concur that latency is clinically diagnostic. There is a notable difference of opinion in the literature regarding the reliability of amplitude measurement. All potentials that are generated and subsequently recorded are manifested as a waveform. The occurrence of a peak in the waveform is recorded as the latency. In simple terms the height of the waveform is defined as the *amplitude*. The difficulty in relying on amplitude measurements is inherent in factors associated with the recording parameters of the instrumentation, as well as the impedance (reflecting the connection between the patient and the recording instrument) and location of the recording electrodes. As amplitude is a measure of volume conduction, the intensity of the electrical stimulation is also important. From the analytical standpoint, common sense would dictate that by maintaining consistency in recording parameters, and ensuring adequate stimulation of nerves, including when assessing dermatomes, much of the variability is addressed and amplitude variations could be considered more reliable. This would be especially true when comparing nerves evaluated on the ipsilateral side, such as the left median to the left ulnar.

When Slimp et al. (1992) proposed normative data for dermatomes, especially in the thoracic level, they relied on a Z-score concordance analysis to help compare responses from one level to another, as it seemed apparent that comparing a response cephalad and caudal with the level in question could assist in identifying pathology. Their observation was that the response at one level could essentially predict the value of another. This is a very important concept when structuring a study or defining abnormity.

The last consideration in discussing the reliability of SEPs is portrayed in the literature associated with intraoperative monitoring and the predictability of a successful surgical decompression. Early mention of SEPs intraoperatively (Brown, 1983; McCallan & Bennet, 1975) seemed more than promising. That led to further studies such as one by Herron et al. (1987) that acknowledged the ability of DSEPs to determine the adequacy of decompression. The ability of the DSEPs to be sensitive to various surgical events was reported by Toleikis et al. (1993). Other authors presented data that increased the level of confidence in the DSEPs intraoperatively by reporting that the test results at closing could predict the adequacy of decompression (Cohen, Major, & Huizenga, 1991). Studies such as this served well to also demonstrate the clinical significance of small changes in latency as clinically significant by comparing baseline presurgical, intraoperative, and postsurgical studies. Among the early advocates for DSEPs was a study that reported DSEPs as clinically diagnostic of lumbosacral root entrapment in 92% of 300 patients evaluated for the study, suggesting greater diagnostic sensitivity than myelography, without false positives (Scarff, 1981).

No introduction to SEPs would be complete without acknowledging the controversy associated with the studies: the criteria relied on to determine which abnormality is at the forefront, including whether to rely on amplitude

measurements. Oddly enough, those that are most critical seem to conclude that SEP and DSEP techniques do not yield clinical information greater than other forms of clinical assessment. Because the studies are efficacious, safe, and cost-effective, logic dictates their use, especially when other methods of examination have not proved effective to identify and treat neuropathic pain.

RECORDING SEPs

The actual performance of SEPs requires a skilled, experienced clinician. To best understand the role of SEPs in the assessment of a patient with pain, it is best to have a basic familiarity as to how SEPs are elicited and recorded. The SEP is first elicited by direct electrical stimulation of a peripheral nerve. The initial volley of electrical impulses is felt to be large-diameter myelinated fibers. In mixed nerve and certain segmental studies they are largely afferents (Ia) from muscle spindles. In dermatomal studies and most segmental studies, cutaneous afferents (IIa) are activated. The electrical volley travels proximally along the nerve entering the cord, then ascends through the dorsal columns. At the cervicomedullary junction, the nucleus gracilis receives signals from the upper extremities, while those from the lower are received by the nucleus cuneatus, more medially. The signals are then carried by the second-order neuron to the opposite side through the medical lemniscus to the ventroposterolateral nucleus of the thalamus. Third-order neurons then project the impulse to the primary sensory cortex, corresponding to the area receiving signals from the stimulation site.

The most important recording site is the final checkpoint over the primary sensory cortex. At least one recording should be made over the proximal portion of the peripheral fibers to help identify or exclude peripheral pathology, as well as to better localize pathology to the plexus or nerve roots. Routine clinical studies seem to show a preference for Erb's point (over the supraclavicular fossa) and the cervical spine for upper extremity studies. Lower extremity studies usually record over the spine at the lower thoracic or upper lumbar.

Although this task might sound trivial, the problem is that these electrical potentials are comparatively small, and are essentially buried with background electrical noise. Endogenous noise (from within the body) comprises electrical potentials associated with muscles, including the heart, as well as the brain, as recorded with EEG. The largest source of exogenous noise can be from the power supply. To this end, there are two considerations that are important to enable the isolation of the comparatively small evoked potentials from the background noise. Improving the signal-to-noise ratio is first and foremost. This is done by ensuring the best possible connection between the recording electrodes and the patient. Adequate stimulation of the nerve is also essential. All too often the clinician does not adequately stimulate the nerve as a result of the discomfort expressed by the patient. It should be noted here that the inverse square law applies. Essentially to make the waveform look twice as good, one would have to stimulate four times as long. This leads to the discussion of signal averaging cited earlier. Modern computers fill the role of sampling EP through the averaging process in a manner very similar to that first accomplished by Dawson (1954). During this process, the nerve is stimulated a constant rate, triggering the computer to record at the same rate. Any electrical potentials that are synchronized to that rate are superimposed or averaged, while all other electrical noise or artifact logarithmically approaches zero. The greater the amount of noise, the longer the averaging necessary for an adequate study. Similarly, the better the signal-to-noise ratio, the shorter the period required to generate and record a potential. Stimulation frequencies are carefully chosen not to coincide with other time synchronized events, such as the 60 cycle sine wave of electrical current. Repetitive stimulation through the averaging process is then replicated to ensure reliability of the test results (Table 44.1).

BASICS OF SEP INTERPRETATION

Although the interpretation of SEPs may require proper experience and training in both recording techniques as well as the pathophysiology of conditions affecting the sensory nervous system, there are fundamental basics that most any clinician can rely on to understand SEP test results. As previously stated, the most important part of the test result is the generation of the cortical potentials. The resultant waveforms from evaluation of nerves in the upper extremities have a pattern that has the appearance of a "mountain-valley" with the peak of the mountain the cortical potentials. By convention, as determined through standardized placement and polarity of recording electrodes, upward deflections are reflected as negative reflection, labeled "N," while deflections downward are positive, labeled "P." For median nerve stimulation, the classic period for the signal to travel from the point of stimulation at the wrist to the cortex is 19.0 ms. On a linear scale measured in milliseconds, the peak of the mountain would appear at approximately 19.0 is the therefore labeled "N19" for the cortical latency.

In looking at test results, even a patient often recognizes the waveform and likens it to a bell curve. That is an appropriate analogy, as the generated waveform represents that sum total of averaged stimulations over time and the average of individual nerve fibers firing synchronously. From the physiologic standpoint, a decrease in the number of individual neurons firing would result in a lower-intensity signal and therefore decreased amplitude. From the technical standpoint, the same effect could occur with poor or inadequate stimulation or with one of the

TABLE 44.1
Sample Evoked Potential Waveforms

Test	WAVEFORMS	POSSIBLE GENERATORS
BAEP		I — distal VIII nerve II — proximal VIII or cochlear nucleus III — lower pons (superior olivary complex) IV — mid-upper pons V — upper pons or inferior colliculus
Upper extremity SEP		N20 — primary sensory cortex N13/p13 — cervicomedullary junction N11 — root entry zone (cervical region) EP — Erb's point, entry of volley into distal brachial plexus
Lower extremity SEP		P40 — primary sensory cortex N20 — lower thoracic potential PF — afferent volley as it passes the popliteal fossa
Pattern shift VEP		P100 — striate and pre-striate occipital cortex with contributions from the thalamocortical volleys

various factors that adversely affect the signal-to-noise ratio. Once again, here lies the controversy in relying on amplitude measurements as a diagnostic criterion. In the hands of a skilled clinician with a properly structured study, amplitude deficiencies may be clinically diagnostic and highly informative in quantifying a neuropathy. Nerve compression is among the most common causes of diminished or attenuated amplitudes. Given this fact, one could argue it would be neglectful to ignore the diagnostic value of such measurements.

Similar to the waveforms generated with upper extremity nerve stimulation, those generated during stimulation of the lower extremities have a pattern that appears as a "W." The first downward deflection of the "W" is the cortical potential. For the tibial nerve this typically occurs at 40.0 ms, as such it is referred to as "P40."

Simply knowing the values for median and tibial nerve evaluation in a normal individual, along with the concept that nerves stimulated more proximal will have a shorter latency and those more distal will have a greater latency, the normative values for any other nerves evaluated can be estimated. It is also important to have a familiarity with nonpathological factors that influence the propagation of SEPs. Among them is patient height. A taller individual with a longer extremity length will require a greater amount of time for the signal to travel, although at approximately 60 m/s the time difference is measured in milliseconds. Gender, temperature, and age represent other factors when considering the test results in the context of a population normal. These variables are less important when considering a patient normal by comparing the results of one nerve with another on the ipsilateral as well

as contralateral side of the same patient as described by Slimp et al. (1992). The most basic example of an ipsilateral comparison can be demonstrated by observing median and ulnar SEP in a normal individual, with stimulation sites equidistant from the cortex. If the medial cortical latency is 19.0 ms, the ulnar will approximate 19.0 ms as well. If the ulnar latency measures 21.0 ms, within the limits of normal when relying on population normal, minor pathology affecting the distribution of the ulnar nerve may be overlooked. Clinical correlation should be the deciding factor when considering the significance. An example where such a finding might be clinically important would be in the differential diagnosis of complex regional pain syndrome (Hendler, 2002).

Before leaving the subject of SEPs, although the assessment of typical nerves is commonly discussed, most any nerve accessible to peripheral electrical stimulation can elicit a response. Trigeminal (Soustiel, Feinsod, & Hafner, 1991), facial (McMenomey et al., 1994), glossopharyngeal (Fujii et al., 1994), and pudendal nerve (Haldeman et al., 1982) and even the distal esophagus (Aziz et al., 1995) stimulation are common to literature. Uncommon studies can play an important role in evaluating a patient with an unusual or atypical presentation. In these cases normal values may be gleaned from an unaffected side or ipsilateral adjacent nerves.

BRAINSTEM AUDITORY EVOKED POTENTIALS

Brainstem auditory evoked potentials (BAEPs) are generated by the auditory nerve (CN VIII) and brainstem in response to an external stimulus, in this case a "click." As with SEPs, a waveform is generated. In the case of the BAEP, also commonly referred to as BEAR or BSEAR (brainstem auditory evoked response), the potentials occur within a period of 7 ms from the onset of stimulus. The most common clinical applications are for the evaluation of acoustic neuromas, brainstem tumors, hearing disorders, coma, brain death, strokes, and demyelinating disease (Chiappa, 1983; Donohoe, 1988). There is also much literature regarding the assessment of hearing in children and patients that are unable to provide voluntary response to traditional hearing tests. The resultant waveform comprises five primary components, labeled I through V. The generators responsible for each component of the waveform are the action potential of CN VIII, the cochlear nucleus, the ipsilateral superior olivary nucleus, the nucleus or axons of the lateral lemniscus, and the inferior colliculus, respectively. Determination of the anatomic site of pathology is based on which components of the waveforms are absent or delayed. For the most part, this includes interpeak latencies of I–III, III–V, and I–V and interside comparisons as are amplitudes ratios of I/V or I/IV–V. Absolute latency measurements of III and V are considered when there is difficulty in measuring interpeak

latencies (Chiappa, 1983; Hood & Berlin, 1986). Although there seem to be many BAEPs ordered for the assessment of headaches, especially following motor vehicle accidents involving closed head trauma, abnormal studies are rarely found. Recent literature describes changes in BAEPs during acute attacks of migraine reflective of physiologic change, yet the changes were found to be reversible (Kochar et al., 2002). Given the varying findings cited in the literature and described throughout texts such as Chiappa and Hill, BAEPs seem to fill more of a supporting role in the diagnosis of many conditions where brainstem involvement is suspect.

VISUAL EVOKED POTENTIALS

As the name implies, VEPs primarily assist in the investigation of visual pathways from the retina to the occipital cortex. As one would assume, the method of stimulus is visual and the primary clinical application is in the evaluation of optic nerve function. The preferred method in clinical practice is the pattern reversal method accomplished through an alternating reversal of a checkerboard pattern or pattern shift without change in luminance. Other techniques include pattern offset (also called pattern shift) and flash (also called strobe). The most common use of flash stimulation involves the assessment of patients experiencing compromise to the visual pathway from the retina to the visual cortex or with an uncooperative patient. As with SEPs, repetitive stimulation results in a waveform that can be obtained by recording over the cortex. The same basic principles outlined for SEPs apply to VEPs. The test results comprise a waveform that has a characteristic pattern with the first downward deflection typically occurring at 100 ms. As such, it is referred to as "P100." Recording from several sites on the cortex, in certain cases, can better assist in the assessment of visual disturbances. Many early studies report intraocular latency differences largely seen in MS and other nervous system disorders, as well as tumors, infarctions, and migraines, in addition to abnormalities of the visual field (Chiappa, 1983). Clinical applications involving tumors and migraines are among the most prevalent. Rather than yielding a definitive diagnosis, authors investigating transient changes in VEPs during acute migraine attacks (Afra et al., 1998; Drake et al., 1990; Kochar et al., 2002) or comparing differences in patient with and without aura (Bockowski et al., 2003) are leading to a better understanding of the involved pathophysiology.

MOTOR EVOKED POTENTIALS

While EMG and motor NCVs are commonly relied on to assess the motor system, they are primarily useful in identifying lesions in the peripheral nervous system. With the exception of indirect evidence of pathology reflected by

abnormal motor unit firing, routine electrodiagnosis was limited in the ability to identify pathology in the central motor pathways. The development of MEPs likely dates to Penfield and Boldrey (1937). They observed that by directly stimulating the human brain with small electrical current in conscious patients undergoing surgery, mapping of the cortex was possible. This work led to the familiar caricature, the homunculus.

During the next 40 years several other authors reported on stimulation of the exposed motor cortex in both human and animal studies. For obvious reasons, such techniques are not useful in routine clinical practice. In 1982 Merton and Morton designed a high-voltage transcranial electrical stimulator that excited the motor cortex using cutaneous electrodes directly over the scalp rather than on an exposed brain (Merton, Hill, Morton, & Marsden, 1982). This was the first report of non-invasive stimulation of the motor cortex to quantitatively assess central motor conduction. A notable disadvantage was the significant discomfort created by the stimulus. The ability to more readily rely on MEPs for routine clinical assessment is largely credited to Barker et al. (1985) for the devolvement of a transcranial magnetic stimulator (TMS). Thus far, the techniques have proved safe and painless.

An MEP may be generated by magnetic or electrical transcranial stimulation. The stimulus activates the cortical motor neuron pathway, which in turn excites spinal motor neuron and generates a CMAP. The CMAP is easily recordable with a surface electrode in a manner similar to a routine nerve conduction study. As the muscle response is a comparatively strong signal, averaging required with other EPs is not necessary to record and measure the potential. The global motor conduction can be measured, and represents the time it takes for the signal to travel from the cortex to the muscle. It is presented as having two distinct components representing central conduction time (CCT) and peripheral conduction times (PCT). The CCT is typically determined by calculating the motor conduction time less the PCT, determined through stimulation at the spine.

The recording of MEPs is accomplished by recording over target muscles with surface electrodes. Needle electrodes are also occasionally used, especially in a research setting. As with other EPs, at least two recordings are obtained to ensure reliability. There is a proper orientation for the current traveling through the coil during magnetic stimulation of the cortex: clockwise when stimulating over the right hemisphere, counterclockwise for the left. Magnetic stimulation directly over the cervical and lumber spine is also possible. Coil current is also important in this application, clockwise for the right, counterclockwise for the left. It is worth mentioning that amplitudes and latencies of MEPs tend to vary over time during repetitive stimulation of relaxed target muscles. It is presumed that this occurrence is indicative of an element of the nervous

system that guarantees the consistency of excitatory input to the neural elements, which is theorized to be fluctuations of resting threshold (Keirs et al., 1993). Amplitude and latency measurements of MEPs generated with intensity of the stimulation being constant also vary with the degree of contraction or relaxation by the muscle. With tonic contraction of the target muscle, the latency shortens and amplitude is increased. This process is referred to as facilitation of MEPs. Among the explanations offered was the tendency of a subliminally excited motor neuron to fire more readily when the phasic excitation elicited by the TMS reaches the motor neuron (Hess et al., 1987).

As with other EPs, MEPs are considered essentially safe, although there has been anecdotal mention regarding the risk of seizure. This seems to be limited to a small fraction of the already negligible incidence of seizure following strobe stimulation in EEGs (Pascual-Leone et al., 1993). Conversely, several authors such as Tergau et al. (1999) found that low-frequency transcranial stimulation may actually offer therapeutic benefit in treating epilepsy.

LASER EVOKED POTENTIALS

Among emergent technology is the ability to perform laser evoked potentials (LEPs). SEPs have generally been limited to the evaluation of tactile and proprioceptive pathways. Although SEPs are a sensitive measurement of the somatosensory pathways, many lesions in the sensory system were not detectable. Many recent clinical studies are suggesting that LEPs will permit the assessment of pathways that fall under historical limitations of SEPs (Kakigi, Wananabe, & Yamasaki, 2000; Lefaucheur et al., 2002; Treede, 2003; Treede, Lorenz, & Baumgartner, 2003). Stimulation of receptors associated with temperature and pain perception is accomplished using a pulsed laser. In this case the signal travels along small fibers in the peripheral nerve and the anterolateral spinothalamic tract in the spinal cord and brainstem. The most obvious clinical application will be to assist in differentiating between large and small fiber neuropathies (Kakigi et al., 2000; Treede et al., 2003). While early literature leaned toward the evaluation of peripheral neuropathies and central pain syndromes (Casey et al., 1996; Kakigi et al., 1992), other applications are quickly being reported, such as in the evaluation of painful temporomandibular disorders (Romaniello et al., 2003). LEPs may offer insight into spinal and peripheral sensitization in fibromyalgia (Lorenz, Grasedyck, & Bromm, 1996). Recent literature described the role LEPs may play in the assessment of patients with dorsal root pathologies (Quante et al., 2003). As with other EPs, the study is completely objective. LEPs overcome the subjective component of other tests that have been used to evaluate the small fiber system in the past. For this reason, it is likely LEPs will play a significant role in helping to assess the patient with pain as the technology develops.

ADJUNCTIVE TESTING

There are several other electrodiagnostic studies that are not necessarily considered mainstream for routine clinical assessment. However, there is adequate mention in the literature to warrant discussion in this chapter. It is important to understand that these studies may still aid in the assessment of certain painful conditions, despite inconsistent data concerning their role as diagnostic tools.

QUANTITATIVE SENSORY TESTING

Quantitative sensory testing (QST) comprises a heterogeneous group of tests employed to assess sensory nerve fiber function, although QST is used mainly to assess sensory nerve function of small-caliber sensory nerve fibers. The subgroup of lightly myelinated and unmyelinated small-caliber nerve fiber types includes those which transmit pain signals from the peripheral nervous system to the central nervous system, making QST particularly useful in the realm of pain assessment.

Thermal thresholds are commonly used in quantitative sensory tests. A thermal threshold represents either the lowest perceptible warm temperature or the highest perceptible cool temperature. Assessment is accomplished by comparing age-matched normal values and side-to-side differences. Incremental changes in temperature are called *just noticeable differences* (Siao & Cros, 2003).

The major limitations of QST include its psychophysical subjective nature and the inability to distinguish central and peripheral lesions. Poor performance may be willful or attentional, or may represent a misinterpretation of the instructions (Mendell, Kissel, & Cornblath, 2001). The American Academy of Neurology's 2003 report, *Quantitative Sensory Testing: Report of the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology*, corroborated the utility and shortcomings of the test, while noting that QST is more valuable when used to augment the validity of another test, and is less useful when used as the sole electrodiagnostic modality. The report clearly noted that QST could not be used in the medicolegal arena (Shy et al., 2003). Despite these limitations, QST has been a valuable tool in the electrodiagnostic assessment of peripheral nerve disease. Abnormalities must be interpreted in the context of a thorough neurological examination and other appropriate testing such as the EMG, nerve biopsy, skin biopsy, or appropriate imaging studies.

QUANTITATIVE SUDOMOTOR AXON REFLEX TEST

Certain painful neuropathies, such as hereditary sensory and autonomic neuropathies (HSAN) and those associated with porphyria, have a prominent autonomic component. The quantitative sudomotor axon reflex test (QSART) assesses autonomic (small) fiber dysfunction via the sweat response and is considered to be a reliable test with good reproducibility. Acetylcholine (ACH) is the key to QSART. It is used as an exogenous stimulator of the sweat response as well as the endogenous mediator of that response. Iontophoresed (exogenous) ACH activates antidromic axonal transmission, which eventually becomes orthodromic after turning at a branch, ultimately stimulating release of synaptic (endogenous) ACH. The released synaptic ACH that binds to the M3 muscarinic receptor on the sweat gland is quantified by a "sudometer" reading of the multicompartment sweat capsule that collected the released ACH (Jaradeh & Prieto, 2003). In neuropathy, multiple sites are tested. Small fiber nerve damage may be reflected by a reduced or absent sweat response. As well, a small fiber neuropathy may be characterized by an excessive or a persistent sweat response. The sweat response also has a latency, which is measured from commencement of iontophoresis to the moment of sweat secretion. Prolonged latency suggests small fiber dysfunction. Conversely, relatively shortened sweat response latency, less than 1 minute, is consistent with sympathetic overactivity.

THE NEUROMETER®

The Neurometer is a portable constant-current sine wave stimulator, used to quantify peripheral nerve dysfunction by measuring thresholds of constant current stimulation. Stimuli are applied through surface electrodes at three frequencies, with the so-called forced-choice method (as seen in some QST testing) used to determine the minimum detected current amplitude. An investigation by Masson and Boulton (1991) compared neurometric results to those results obtained using more conventional nerve tests, including thermal and vibration detection thresholds in the case of diabetic neuropathy. Their observations suggested that this technology may be useful as a screening instrument, providing a fairly comprehensive assessment of the functional integrity of different nerve fiber populations. A full exam is comparatively short, encompassing 10 to 15 minutes. Although most electrodiagnostic clinicians do not commonly rely on the Neurometer, it may be helpful in the assessment of small fiber pathology. An abundance of clinical research is planned.

BLINK REFLEXES

Terminologically, the clinical blink reflex is distinguished from the electrodiagnostic blink reflex. The clinical blink reflex is carefully elicited by the examiner by lightly touching the cornea of one eye. The electrodiagnostic blink reflex is performed by electrical stimulation of the supraorbital nerve on one side of the face while recording the obicularis oculi muscle response on both sides. Unilateral sensory information is carried from one side of the face, via the supraorbital nerve branch of the V1

segment of the trigeminal nerve. This afferent signal reaches the principal trigeminal nucleus in the pons (Meckel's cave). After pontine nuclear synapse, the efferent limb of the reflex is mediated by the facial nerve (VII) on both sides of the face, resulting in bilateral obicularis oculi muscle contraction.

The so-called ipsilateral R1 response correlates with early efferent signal transmission, occurring after brainstem synapse. The clinical significance of the R1 response remains unclear. The bilateral R2 response correlates with the bilateral blinking of eyes. The normal R1 latency is about 13 ms and is found on the same side of the stimulus. The normal bilateral R2 latency is about 40 ms on each side with potentials noted on each side. The ipsilateral R2 response occurs approximately 3 ms sooner than the contralateral R2 response (Daube, 1996).

The blink reflex test is performed in a variety of suspected disorders that cause pain, such as AIDP (cranial neuropathy) and cerebellopontine angle lesions (e.g., schwannoma or neurofibroma) (Tanaka, Takaki, & Maruta, 1987). Trigeminal neuralgia (TN) is a debilitating syndrome of lancinating pain, which is associated with abnormal blink reflex results. In some cases, TN is associated with a vascular loop that presses the nerve near its nucleus at the skull base (Jannetta, 1980). TN may be caused by connective tissue diseases, such as scleroderma (Serratrice, Pouget, & Saint-Jean, 1986). Blink reflexes are oftentimes abnormal in MS (Novatschkova-Spassova, 1983), with TN the presenting symptom of MS in a minority of cases. Many cases of TN remain idiopathic. The blink reflex may be normal in TN, but when abnormal, the affected component is usually the afferent portion.

NERVE ROOT STIMULATION

The nerve root stimulation (NRS) procedure involves discrete stimulation of a single nerve root using relatively low levels of current/voltage passed through a needle electrode, to assure that only the nerve root of interest is stimulated. This procedure is mostly used to precisely localize the abnormal spinal myotome. NRS is often performed in conjunction with SEP assessment, especially in the context of intraoperative monitoring. NRS is also used to assess atypical neuromuscular disorders, such as bladder abnormalities due to detrussor muscle dysfunction (Markland et al., 1972). NRS is a safe procedure, albeit more invasive than routine EMG. In 2002, Zileli et al. reported the utility of nerve root stimulation to be similar to that of dual diagnostic assessment with needle EMG and NCVs suggesting that the role of NRS will remain limited.

APPROACH TO THE PATIENT

Before performing an electrodiagnostic study on the patient with pain, one must define a diagnostic goal for the investigation. The hypothesis drives the choice of study. Electrodiagnostic findings may, at times, alter the course of the study in midstream if an alternative diagnosis is suggested by those findings. For this reason the examiner must be both prepared and flexible. In some cases, it is vital to know the temporal details of the patient's history. For example, a needle EMG performed 10 days after an apparent axonal injury may show reduced recruitment and be otherwise normal. In this case a repeat study must be performed a few weeks later to assess for delayed onset of axonal injury, as abnormal insertional and spontaneous activity are not apparent until about day 15 after injury.

Before one endeavors the performance of an electrodiagnostic study, normal values and anthropomorphic data should be known, or at least available for reference. Temperature effects must be taken into account during NCV studies. The normal upper limb skin temperature should range from 34 to 36°C, although 32°C is acceptable. The lower limb skin temperature should range from 32 to 34°C, although 30°C is acceptable. Temperature is most important for sensory nerves and in the assessment of symmetrical processes. If a warming apparatus is not available, correction factors may be used, but their use tends to have less accuracy than warming, especially with pathological nerve (Rutkove, 2001). An electrodiagnostic laboratory is considered incomplete if it lacks a temperature probe. Cool limbs can be warmed with direct moist heat. However, in this chapter's first author's opinion, heat from an infrared light is clearly superior. With direct moist heat, the surface is warmed better than deeper tissue, its effects relatively short lasting. Cooling of normal excitable tissue has several effects. It tends to increase amplitude, prolong latency, and slow conduction velocity of nerve responses. Fibrillations are diminished in numbers. Fasciculation amplitude increases, whereas its frequency diminishes. Cooling also reduces compound muscle potential amplitude and initially increases myotonic discharges in paramyotonia (myotonic discharges abate with further cooling). Effects of warming include worsening of conduction block as well as worsening of neuromuscular junction decrement in myasthenia gravis. In PROMM (proximal myotonic myopathy), myotonic activity increases with warming. The effect of temperature on other potentials is not well defined (Rutkove, 2001).

Laboratory safety issues include screening the patient for a history of electronic device implantation, such as a cardiac pacemaker. The American Association of Electrodiagnostic Medicine guidelines for performing studies in patients with implantable electronic devices confirm that NCV, needle EMG, and EP studies are relatively safe, as long as attention to grounding detail is meticulous. Proximal limb studies (e.g., brachial plexus stimulation) may increase the risk of an untoward cardiac event with cardiac pacemaker present. Performance of NCV studies in patients with external cardiac pacemaker is not recom-

mended. Repetitive stimulation can be problematic in the case of sensed-rate triggered implantable defibrillators. Intra-arterial catheters present a significant current-related risk, increasing with current leaks. The patient should be screened for anticoagulant use and for history of coagulopathy, platelet disorder, visceral disease, or proclivity to bruise easily. Universal precautions and protocols are in play at all times. Needle EMG of the chest and abdominal wall musculature carries puncture risks, which should be discussed with the patient and consented to before examination. Electrical safety in the laboratory depends on the proper grounding of the machinery. A low-resistance pathway from the machine to the ground is usually provided through the electrical line in the wall plug. One must never directly ground the patient or permit the patient to make contact with grounded objects while connected to any biomedical equipment. This includes avoiding a scenario in which the patient is hooked up to two different machines simultaneously, as in the case of electrocardiography (EKG) with EEG. Extra care must be taken with electrically sensitive patients who are critically ill (Daube, 1996).

COMMON PAINFUL CONDITIONS

HEADACHE

Hurdles to define the EEG features of migraine include variability in defining migraine as a nosological entity. Inconsistent normal criteria, concurrency of nonmigrainous headache, inclusion of criteria associated with neurologically significant symptoms (e.g., hemiplegia with migraine), age-related differences, and variability in EEG interpretation all contribute to this variability. The interictal EEG is usually normal in migraine, although focal slowing, sharp wave transients, pronounced posthyperventilation delta activity, and hypersynchronous bursts are noted as well. Alpha depression may be noted in the initial (ophthalmic) phase of migraine with aura. Lateralized alpha asymmetry has strongly correlated in common migraine without aura. For the most part, the EEG of patients with migraine does not differ significantly from the EEG of normal individuals (Niedermeyer, 1999).

In the experience of these authors and others, the migraineur demonstrates an occipital driving response at higher flash frequencies (at or above 20 flashes/s) during application of intermittent photic stimulation. This phenomenon is fairly specific for migraine (Golla & Winter, 1959; Slater, 1968; Smythe & Winter, 1964). This premise has been further established by spectral analysis (Simon et al., 1982).

Basilar migraine, common in children and young adults, has a variety of associated EEG findings, depending on the study. Loss of consciousness in basilar migraine is associated with either diffuse or lateralized slowing on EEG. Status migrainosus is not highly corre-

lated with any one particular finding on EEG. Acute migraine is commonly associated with a normal tracing. Predictably, lateralized slowing in the delta and theta frequency range has been noted over the involved hemisphere in cases of hemiplegia that accompanies migraine. Distinguished from adult migraine, childhood migraine is commonly associated with abdominal symptoms and obtundation, either of which may occur without headache. The abdominal component has been shown to be associated with so-called 14 and 6 positive spikes (Niedermyer, 1999).

Intracranial lesions are associated with headache, as well as with seizure. Adults and children with intracranial lesions suffer from headaches. Identified lesions, such as stroke, tumor, and herpes encephalitis are associated with periodic lateralized epileptiform discharges on a fairly consistent basis (Lipton, Chaudry, & Andriola, 1998).

Rolandic spikes have been noted in childhood migraine. Rolandic epilepsy and migraine are relatively common entities, begging the question of linked pathophysiology versus coincidence in this set of patients. An assessment based on extensive data collection was unable to support the theory of a shared genetic susceptibility between migraine and epilepsy (Lipton & Ottoman, 1996). An entity noted as migraine-triggered epilepsy has been described (Niedermeyer, 1999). In this clinical entity, the interictal EEG is mostly normal. Conversely, an epilepsy-triggered migraine has been postulated (Jacobs, Goadsby, & Duncan, 1996).

MONONEUROPATHY

Electrodiagnostic findings in suspected mononeuropathy include prolonged sensory and/or motor nerve latency, reduced SNAP, and reduced CMAP. Significant axonal involvement begets neurogenic changes found on needle EMG. Certain anatomical regions confer a higher susceptibility to compression. The flexor retinaculum at the volar wrist may be the most infamous of those regions (carpal tunnel syndrome, CTS). Entire texts are dedicated to entrapment. Peroneal mononeuropathy may be caused by compression in the thigh (sciatic peroneal), at the fibular head, or at the ankle. Needle EMG study of the biceps femoris short head muscle (the only peroneal-innervated muscle above the knee) helps localize the site of peroneal nerve compression to either above or below the fibular head. An SEP may also be effective in identifying a peroneal nerve entrapment at the piriformis muscle. Axonal changes are common in peroneal mononeuropathy at the fibular head (Katirji & Wilbourn, 1988, 1994; Wilbourn, 1986).

Susceptibility to nerve compression may be conferred by metabolic dysfunction associated with diabetes, likely by microvasculopathic mechanisms involving the vaso nervorum (Dellon, Mackinnon, & Seiler, 1988). Diabetic

susceptibility is commonly manifested in median mononeuropathy at the wrist (CTS). Genetic mutation of Connexin-32 causes a hereditary susceptibility to pressure palsy (HNPP). Whereas most other forms of compressive neuropathy are usually painful, HNPP is not (Chance & Lupski, 1994). Vasculitis is a common cause of painful mononeuropathy associated with systemic disease (David, Peine, Schlesinger, & Smith, 1996).

Compressive peripheral neuropathies may coexist with either radiculopathy or plexopathy (double-crush). Limitations in routine electrodiagnostic testing necessitate specialized techniques to identify atypical compressive neuropathies, as in the case of digital mononeuropathy secondary to repetitive finger trauma, as seen in bowlers, hence the term "bowler's thumb" (Nasr & Kaufman, 2001).

The use of SEP studies in the evaluation of peripheral entrapment or injuries is not new (Eisen, 1982; Peterson & Will, 1988; Trainer et al., 1992). SEPs are particularly helpful in the setting of a suspected mononeuropathy that occurs in a region that is difficult or impossible to assess using routine NCV studies. Cordato et al. (2004) demonstrated the reliability of SEPs in identification of lateral femoral cutaneous nerve entrapment in meralgia paresthetica. SEP testing predicts the outcome of surgery that is performed to correct such conditions (Siu & Chandran, 2004).

Carpal Tunnel Syndrome

CTS is the most common peripheral mononeuropathy. In the Western world, CTS is infamously due to repetitive use. Hypothyroidism, rheumatoid arthritis, acromegaly, Lupus, hyperparathyroidism, and diabetes mellitus are felt to account for secondary causes. Brachial plexopathy and cervical radiculopathy may affect a downstream loss of median nerve integrity, increasing susceptibility to compression. This so-called double-crush phenomenon is also seen with involvement of the proximal median nerve (Osterman, 1988; Upton & McComas, 1973). Bilateral CTS is more common than not and, in older males, may be due to amyloid protein deposition, which commonly occurs with multiple myeloma.

Normal electrodiagnostic findings in what appears to be a clinically apparent case of CTS may suggest subclinical CTS or, possibly, another clinical diagnosis, such as de Quervain's tenosynovitis, posterior interosseous (radial sensory) neuropathy, neurogenic thoracic outlet syndrome, cervical radiculopathy, or arthritic changes in the limb. Proximal median nerve lesions are less common (e.g., pronator syndrome). A routine electrodiagnostic assessment includes finger ring electrode stimulation, recording at the volar forearm. One may choose any of the four median-innervated digits to stimulate. The index finger is commonly used. Some experts in the field prefer

the middle digit, likely because this digit is autonomously innervated by the median nerve, with no gross contribution from the radial or ulnar nerves.

Routine laboratory assessment of the median nerve includes the sensory nerve, the motor nerve at the wrist and elbow (some prefer to also stimulate the nerve at the axilla), and the F-wave response. Assessment of the ipsilateral ulnar sensory and motor nerves studies, an ipsilateral radial (posterior interosseous) sensory nerve study, and testing of the contralateral median sensory and motor nerves round out the NCV study. Needle EMG assessment is performed to rule out concurrent cervical radiculopathy and to define, when applicable, the extent of an axonal median nerve lesion. The high incidence of bilateral CTS begs assessment of the median nerve contralateral to the symptomatic side. Prolonged median sensory nerve latency with no other abnormal findings constitutes mild CTS. Involvement of the median motor nerve is consistent with moderate CTS. Although not common, median motor involvement may be seen without concurrent sensory dysfunction. Abnormal needle EMG study suggests severe CTS, usually associated with some level of abductor pollicis brevis (APB) muscle weakness and thenar eminence atrophy. Subtle or focal lesions of the median nerve may not be detected with conventional electrodiagnostic methods, necessitating supplemental techniques of higher precision, including comparison of the median and ulnar mixed nerve latencies (Kaufman, 1996), palmar short segment assessment (Katirji, 1998), and the antidromic inching technique (Kimura, 2001). SEPs are also used to assist in the diagnosis of CTS, or the lack thereof (Glick, 1992; Kawasaki, Saito, & Ogawa, 1995).

Other Mononeuropathies

Radial nerve compression at the humerus (Saturday night palsy) is the usual cause of wrist drop, which is mostly a motor phenomenon, although it may cause pain. The ulnar nerve is classically compressed at the elbow (cubital tunnel syndrome). This is diagnosed when ulnar motor nerve slowing is found with stimulation above the elbow. Ulnar nerve lesions at the wrist are usually noted at Guyon's canal in the wrist or at the pisohamate hiatus in the hand. SEPs can be helpful in confirming an ulnar neuropathy, as well as in ruling out a more proximal medial cord plexopathy or preganglionic C8/T1 radiculopathy.

Although commonly discussed in the electrodiagnostic literature, tarsal tunnel syndrome, as a clinical entity, remains controversial (Dumitru, 1991a). The tarsal tunnel is the site where the descending tibial nerve divides into the calcaneal sensory branch, the medial plantar mixed nerve, and the lateral plantar mixed nerve. Inconsistent ability to obtain mixed and motor plantar nerve potentials necessitates stimulation in both lower limbs for comparison (Katirji, 1998). A routine tibial motor nerve response

at the ankle, as well as needle EMG assessment of the adductor hallucis and abductor digit quinti pedis muscles, will improve the diagnostic yield of plantar neuropathy. Plantar neuropathy is also evaluated using SEPs (Dumitru, Kalantri, & Dierschke, 1991).

In suspected piriformis syndrome, the sciatic nerve is thought to be compressed by the piriformis muscle. The literature reveals that compressive denervation of the sciatic nerve is usually due to aberrant myofascial bands, rather than piriformis muscle. NCV studies are rarely corroborative in this setting. A notable percentage of the population demonstrates an anatomical anomaly in which the peroneal division of the sciatic nerve passes either superior to the piriformis muscle or directly through the muscle, piercing it as it goes, increasing the risk of nerve compression (Brazis, Masdeau, & Biller, 1996). In this situation, SEPs can provide a unique means of quantification and confirmatory diagnosis, and are commonly used introperatively to avoid malpositioning injury (Glick, 2001).

Weight loss, crossing of the legs, and trauma are major causes of peroneal mononeuropathy at the fibular head, which may be associated with pain (20% of cases), paresthesias, numbness, and motor findings (e.g., foot drop). The tibialis anterior muscle is the major foot dorsiflexor, conferring functional prognostic value in its assessment. As well, the more distal extensor digitorum brevis (EDB) muscle is commonly atrophic due to "wear and tear," rather than due to pathology, limiting its diagnostic value. Tight footwear may cause denervation (Katirji, 1998). The tibialis anterior muscle is innervated by the L4 and L5 spinal nerve roots and is the only L4-innervated muscle below the knee.

PLEXOPATHY

There are several plexi in the human body. The lumbar plexus is clearly important in the clinical settings of diabetes mellitus, surgical trauma, and pelvic tumors. However, the brachial plexus is the touchstone for electrodiagnostic assessment. Disorders of the brachial plexus include those involving birth trauma (Erb's palsy and Klumpke's palsy), radiation plexopathy seen in breast cancer, Parsonage-Turner syndrome (idiopathic disease of the brachial plexus), a variety of traumas (e.g., avulsion), and neurogenic thoracic outlet syndrome (NTOS). NTOS is due to an abnormality of the lower plexus trunk, associated with local anatomical variations, such as cervical rib and scalene anticus syndrome (Brazis et al., 1996). Plexus lesions tend to be extraordinarily painful. Volume conduction-related error is common with stimulation of Erb's point, causing one to interpret these results with a grain of salt (Herbison, 1996).

Because of its complex anatomy, successful electrodiagnostic assessment of the brachial plexus necessitates solid knowledge of its regional anatomy. Plexus lesions are classified according to lesion level: root, ramus, division, trunk, cord, or terminal nerve branch. Upper plexus lesions (C5, C6, upper trunk) tend to be demyelinating in nature, with or without conduction block, and are more likely. Upper plexus lesions are more likely extraforaminal, i.e., more amenable to surgical repair. Lower plexus lesions tend to be preganglionic and axonal in nature, demonstrating denervation. Neurogenic changes in the lower plexus tend to affect muscles that are distant from the lesion. This feature confers a generally poorer prognosis for lower plexus lesions (Ferrante & Wilbourn, 2002). NTOS affects the lower trunk. However, dysfunction of ramified nerve roots (C8 and T1) and multiple peripheral nerves (median and ulnar) should be considered. Clinically, NTOS features thenar atrophy, hypoesthesia in an ulnar distribution, paresis of the intrinsic muscles of the hand, and pain in the affected limb. Electrodiagnostic findings include low or absent ulnar sensory nerve SNAP, low median CMAP, borderline low ulnar CMAP, and normal median SNAP. Needle EMG will show neurogenic changes in the distal upper limb muscles, more compelling in those innervated by the median nerve (Katirji, 1998). Routine electromyographic plexus evaluation is augmented by SEP studies. The literature demonstrates that SEPs are superior to routine EMG in both localizing plexus injury and assessing the extent of that injury (Brudon et al., 1989; Date, Rappaport, & Ortega, 1991; Stohr, Riffel, & Buettner, 1981; Sugioka, 1984; Synek, 1987a, b; Yilmaz et al., 2003).

RADICULOPATHY

Nerve root pathology (radiculopathy) is considered in the setting of spine- and limb-related pain, as noted with protrusion of disc material, degenerative vertebral changes, arthritis, and fractures of the boney elements. Pathological fractures may occur in the setting of cancer, infection, and rheumatoid arthritis. Muscle, ligament, and tendinous dysfunction often occur with or without deeper spine pathology. The scope of painful root pathology extends to systemic disease, such as that seen in zoster-related root disease and AIDP.

The term *nerve root* refers to a neural bundle contiguous with the spinal cord. The sensory bundle is the *dorsal nerve root*. This extends laterally from the dorsal portion of the spinal cord. The motor bundle is the *ventral nerve root,* which extends laterally from the ventral portion of the spinal cord. The dorsal and the ventral roots meet at a point lateral from the spinal cord, in the vicinity of the neural foramen, where they eventually form the *mixed spinal nerve,* which contains both motor and sensory tissue, as well as autonomic tissue that enters the mixed spinal nerve beyond the neural foramen. As it emerges

from the neural foramen, the ramified mixed spinal nerve branches into the primary rami.

The *dorsal primary ramus* extends posteriorly to innervate the axial muscles and the skin of the posterior trunk, whereas the *ventral primary ramus* extends anteriorly to supply the limbs, appendicular skeletal muscles, and the skin of the lateral and anterior trunk and neck. By virtue of the relative volume of innervated structures, the ventral primary ramus is more substantial in size than is the dorsal primary ramus. The dorsal and ventral *roots* are distinguished by functional tissue type — sensory versus motor. The rami are distinguished by their anatomical distribution, i.e., dorsal or ventral structures (Brazis et al., 1996). The dorsal root ganglion lies just proximal to the junction of the sensory root and the mixed nerve. A chemical synapse at the ganglion separates sensory information transmitted from the periphery to the ganglion from the sensory information transmitted from the preganglionic region to the brain. A lesion, therefore, proximal to the dorsal root ganglion, will not affect the sensory nerve distal to it. This relationship reveals an extremely important clinical pearl that describes a clinical scenario in which a painful dorsal root lesion is associated with a completely normal sensory nerve conduction velocity study. As well, if the dorsal root is affected in isolation, without ventral root involvement, the needle EMG and motor F-wave evaluations will be normal.

In this special circumstance of an isolated preganglionic lesion, only the SEP can diagnose this lesion, as the SEP is the only study that assesses the sensory system in continuity and is superior to EMG (Aminoff et al., 1985a; Dvonch et al., 1984; Pape, Eldevik, & Vandvik, 2002; Rodriquez et al., 1987; Slimp et al., 1992; Snowden et al., 1992; Talavera-Carbajal et al., 2003). Therefore, SEPs should be considered when more routine electromyography is equivocal and when a preganglionic radiculopathy is suggested.

One study assessing EMG in radiculopathy revealed that a six-muscle limb screen confers "good" yield for neurogenic activity, limiting the need for a more extensive muscle study (Hong, Lee, & Lum, 1986). Although each muscle is innervated by different nerve roots, each muscle is considered to have one predominant level of innervation. An upper limb nerve root screen should include needle EMG assessment of at least one representative muscle from each nerve root level. For example, C5 is represented by the deltoid muscle. As well, the proximal-to-distal gradient should be appropriately assessed by testing two anatomically separate muscles that represent the same predominant nerve root, e.g., triceps (proximal) and the extensor digitorum communis (distal) muscles, both predominantly innervated by C7.

To help localize cervical spinal nerve root pathology, one should understand that the C1 nerve exits the spine above the C1 vertebra. This pattern of the nerve exiting above the vertebral level of the same number continues until the T1 vertebral level, at which point the C8 nerve root exits on top and the T1 root exits below. From this point, as one descends the spine, the root exits below the corresponding numbered vertebra. The anatomical consistency of this pattern breaks down at the L1 vertebra, where the distance between the spinal cord levels shortens, but the intervertebral distance does not. Thus, proximal bunching of lumbar nerve root egress is noted; the result is the cauda equina. The longer the distance a motor neuron nucleus lies from its synapse with muscle, the more time it takes to generate neurogenic activity after injury. As well, it takes that much longer for that nerve to heal after injury. In addition, proper healing is less likely with increased nerve length. Therefore, by virtue of its midline axial location, the paraspinal muscles are more apt to demonstrate normal EMG activity after a monophasic injury than are limb muscles. Evidence of radiculopathy may be masked by the overlapping of paraspinal nerve root levels. Paraspinal neurogenic activity manifests by about day 7, but may be gone, if mild, by the time that activity shows in the limb. The tibial nerve H-wave reflex examination may augment needle EMG in the setting of an S1 radiculopathy, especially if it is unilateral. In the setting of polyneuropathy, the H-reflex is typically prolonged symmetrically, assuming no other focal lesion (Johnson & Pease, 1997).

SPINAL STENOSIS

Clinically speaking, spinal stenosis represents tightening of the spinal and foraminal spaces due to congenitally small size and/or abnormal changes in spinal tissue. Spinal stenosis can produce pain and reduced mobility and may also cause neurological dysfunction (Benini, 1992). Clinically, spinal stenosis is recognized as a generic entity of heterogeneous pathology, but is entertained as a singular electrodiagnostic construct. Recent literature suggests that compared with MRI, paraspinal needle EMG is a superior study in the diagnostic assessment of symptomatic spinal stenosis (Haig et al., 2001). In the asymptomatic elderly patient with spinal stenosis, the sural sensory nerve action potentials and tibial nerve H-wave reflexes tend to be absent, causing potential false electrodiagnostic positives for polyneuropathy. The most common EMG finding associated with lumbar stenosis is bilateral symmetrical L5, S1, and S2 radiculopathies. The literature shows that SEPs augment electrodiagnostic assessment of spinal stenosis, especially in the setting of surgical decompression for this clinical entity (Herron et al., 1987; Kraft, 2003; Norcross-Nechay, Mathew, Simmons, & Hadjipavlou, 1999; Seyal et al., 1992; Snowden et al., 1992).

POLYNEUROPATHY

Entire texts are dedicated to the classification and categorization of this diverse group of disorders, with a plethora

of subtypes. Many polyneuropathies cause pain, either due to small fiber involvement or secondary to other causes that are characteristic of a particular pathological process (e.g., inflammation or susceptibility to compression). The length-dependent polyneuropathy is common and is exemplary of the bunch. The length-dependent polyneuropathy affects the most distal portion of the limbs first, that is, the toes. In diabetic neuropathy, it is thought that both metabolic and microvascular pathology play a role. The process progresses with a gross symmetry characterized by abnormal sensation slowly ascending the lower limbs. If motor fibers are involved, the most distal foot muscles are affected first, i.e., toe extensors, explaining why "hammertoes" develop in polyneuropathy (unopposed flexion). Early nerve conduction velocity study findings include slowing of sensory nerve conduction velocity, along with reduced SNAP and CMAP amplitudes. Significant motor dysfunction begets neurogenic changes on needle EMG. Atrophy of the extensor digitorum brevis muscle is a classic motor sign of polyneuropathy. Besides pain, small fiber manifestations may include autonomic changes such as postural syncope, as well as an array of dermatological changes (Periquet, Mendell, & Kissel, 1999).

The most common cause of symmetrical painful polyneuropathy in the Western world is diabetes mellitus. Alcohol polyneuropathy is second, associated with the direct toxic effect or nutritional deficiency or both. Genetic factors play a role in predisposition to alcoholic neuropathy (Kucera et al., 2002). Other painful neuropathies include those secondary to B vitamin deficiency, hypothyroidism, renal insufficiency, paraneoplastic (variety), HIV, treatment for HIV (didanosine, zalcitabine), Lyme disease, sarcoidosis, amyloidosis (familial or acquired), dysproteinemia (e.g., multiple myeloma), INH (isoniazid without B_6), vincristine, cisplatin, paclitaxel, D4T, porphyria, vasculitis, cryoglobulinemia, Fabry's disease, Tangier's disease, multiple myeloma, Sjögren's syndrome, cancer, macroglobulinemia, lapromatous compression, perhexiline poisoning, hereditary sensory and autonomic (HSAN), idiopathic, and cryptogenic causes, just to name a few (Mendell et al., 2001). Early detection of diabetes mellitus is correlated with improved outcome, but it must be looked for. A simple sensory examination followed by electrodiagnostic assessment may lead not only to the discovery of diabetes, but also to the recognition of other serious illnesses associated with neuropathy, such as multiple myeloma, lung cancer, and connective tissue disease.

Painful Hereditary Neuropathies

HSAN is a group of congenital neuropathies associated with abnormalities of neurotrophin. There are five major types, many of which cause burning and lancination pain. Subtypes vary clinically and electrodiagnostically, with

respect to motor, large fiber sensory, and small fiber sensory changes on EMG. Amyloid neuropathies may be congenital or acquired, such as those that occur with multiple myeloma. Genetic testing and nerve biopsy are usually not needed for family members who are already classified. Electrodiagnostic findings include large fiber axonal changes. The small fiber electrodiagnostic studies (QSART, QST) may corroborate the painful and autonomic symptoms, respectively.

The spectrum of Charcot-Marie-Tooth disease (CMT) exemplifies an inherited large fiber polyneuropathy, originally referred to as peroneal muscular atrophy by Dyck and Lambert (1968). Experience reveals that abnormal sensory symptoms associated with inherited polyneuropathy are associated with pain that is both nociceptive (e.g., cramps, hammertoes) and neuropathic, although CMT is not classically considered a painful neuropathy. In a prospective study of 52 patients with CMT, positive sensory symptoms were reported by 28 of those patients (54%), including neuropathic pain in 6 of those patients. Pain, either neuropathic or nociceptive, was present in 29 patients (56%) and in 15 patients as a main symptom (Gemignani et al., 2004).

Sensory Ganglionopathy (Neuronopathy)

Sensory neuronopathies represent impaired function of the unipolar sensory neurons that reside in the spinal dorsal root ganglia or trigeminal ganglia of the pons. The large fiber component is well documented, but the painful component is less obvious. Sensory ataxia is typically profound, as is the gravity of etiologies, such as cancer (e.g., paraneoplastic from lung cancer) and autoimmune disease (e.g., Sjögren's syndrome). Treatment tends to be more academic than efficacious (Bryer & Chad, 1999).

Myopathy and Neuromyopathy

Muscle pain secondary to myopathy has many causes. Myopathies can be myotonic, inflammatory, metabolic, and storage disorder categories. Recruitment patterns of myopathic muscle may vary and are usually abnormal in more severe cases. Because myopathic processes preferentially affect the proximal and trunk muscles (Katirji, 1998), needle EMG of paraspinal muscle confers the best yield of abnormal activity manifested through denervation potentials found in irritable myopathies (fibrillations and positive sharp waves).

Rhabdomyolysis is an acute, painful, and life-threatening myopathy, associated with a disturbance of thermoregulation. Fibrillation potentials abound; high CPK levels cause concern for renal failure. The three classic inflammatory myopathies (polymyositis, inclusion body myositis, and dermatomyositis) have their own distinct pathologies. Dermatomyositis features classic skin lesions, to include periorbital edema with an upper eyelid

heliotrope, Grotten's dorsal hand nodules, and fiery erythema of the chest, representing telangectasias (Fitzpatrick et al., 1992). Needle EMG findings reflect denervation due to inflammation. Specific EMG features of dermatomyositis include fibrillations, pseudomyotonic discharges, and positive sharp waves. In this particular disease, evidence of denervation portends occult tumor. Myopathy, whether acquired (e.g., HIV, alcohol) or congenital (e.g., Duchenne's muscular dystrophy, McCardle's disease), irritable or non-irritable, and with or without myotonic or dystrophic components, comprises a vast heterogeneous group of entities, many causing pain and amenable to electrodiagnostic assessment.

Muscle disease associated with alcohol abuse is more common than previously realized. The acute painful variety is associated with swelling, hyperalgesia, cramps, and weakness. This typically occurs after a binge and may be difficult to differentiate clinically from deep vein thrombosis. Ethanol and its metabolite acetaldehyde exact direct pathologic effects on skeletal muscle (Ford, Cadwell, & Kilgo, 1984).

Syringomyelia and Myopathiosis

A syrinx refers to a pathological expansion of the central spinal cord canal (syringomyelia), which may extend to the brainstem (syringobulbia), associated with Chiari malformation. Burning pain is typically localized to the trunk and limbs. Myelopathic signs and symptoms, such as urinary incontinence and lower limb paresis, may be noted. The complaint of burning trunk and/or limb pain is not uncommon. Traumatic syringomyelia is common, although most cases are associated with tumor or are noted as congenital variants.

A study of 48 subjects with syringomyelia revealed that 70% suffered from pain, many of them localizing that pain to the neck and upper extremities. In 68.7% of these subjects, an associated cervical *myopathiosis* was found to be the principal cause of the manifestations. This phenomenon was noted in subjects with no evidence of cervical osteochondrosis. The myopathiosis was electromyographically characterized by a persistent mixture of shortened and prolonged motor unit potentials noted during cervical spinal needle EMG assessment. Regional upper extremity circulatory changes correlated with the intensity of muscle pain. Segmental massage was found to be effective in helping reduce and eliminate local myopathiosis (Ivanichev, Khasanova, & Aleeva, 1982). SEP may be useful in the electrodiagnosis of syringomyelia (Wagner et al., 1995).

Pseudomyopathy (Hypophosphatemia)

Painful proximal muscle weakness that clinically simulates polymyositis can be found in cases of hypophos-

phatemia, which may result from antacid overuse. CPK (creatine phosphokinase) and muscle enzymes are normal. This metabolic "pseudomyopathy" exemplifies the myriad of rheumatic diseases that may be mimicked by hypophosphatemia (Searles et al., 1977).

Cramps

Cramps can be profoundly painful, especially if they are sustained. Cramps are benign in subjects with no known pathology. They may be idiopathic or associated with stress, as well as exogenous substances, such as theophylline. They are also seen in a litany of systemic disorders. Individual potentials resemble motor unit potentials. They fire rapidly at 40 to 60 Hz, usually with abrupt onset and cessation. These potentials may fire irregularly, in a sputtering fashion, especially just before termination. Typically, increasing numbers of potentials that fire at similar rates are recruited as the cramp develops. Those potentials, then, drop out as the clinical cramp subsides (Daube, 1996).

Landry–Guillain–Barre–Storhl Syndrome

Landry–Guillain–Barre–Storhl syndrome, commonly known as GBS, is an umbrella term for the array of idiopathic inflammatory disorders that subacutely affect the nerves and nerve roots. The flagship disorders under this group are AIDP and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). Both of these disorders are associated with pain, which can be debilitating. AIDP is considered a monophasic illness, marked by the clinical hallmark of ascending weakness. Its onset, clinical nadir, and recovery phase occur over a span of weeks. Despite its motor flavor, the pathological process affects both large and small nerve fiber types, affecting a variety of sensory symptoms, with pain prominent. Classic presentations of AIDP may feature low back pain as the presenting symptom. Dysautonomia may have grave consequences, including cardiovascular instability. Intensive care admissions are not uncommon. Electrodiagnostic confirmation of AIDP expedites immunotherapy. Early recognition leads to early treatment. Mitigation of the autoimmune process improves long-term motor prognosis as well as potentially preserving life.

The usual targets of the inflammatory attack against mixed fiber populations in AIDP are characterized electrodiagnostically, being clustered at the anatomical extremes of the peripheral nervous system. That is, the foci of pathology tend to cluster proximally, at the nerve root, as well as at the distal extents of the peripheral nerve. Involvement of the nerve root sleeve confers a high cerebrospinal fluid protein level, noted without a rise in cerebrospinal fluid white count (the so-called cytoalbuminemic dissociation). Criteria for diagnosis include EMG evidence of primary demyelination (including significant slowing of conduction and/or conduction block), with clinical findings

such as lower limb areflexia and ascending paresis. Axonal involvement, as reflected by low CMAP amplitude at clinical plateau, portends a poorer prognosis for recovery of motor function. Other electrodiagnostic characteristics of AIDP include absent H-waves, prolonged or absent F-waves, reduced SNAP amplitude, and temporal dispersion (which causes lower amplitude but does not affect volume under the curve). An electrodiagnostic pearl for AIDP is the finding of a reduced median nerve SNAP accompanied by a normal sural nerve SNAP. Specific electrodiagnostic criteria differ among authors (Katirji, 1998).

PORPHYRIA

Porphyria refers to a set of disorders caused by a defect in heme metabolism. Clinical symptoms mimic those of AIDP. Paroxysmal attacks of debilitating pain, as well as specific urine findings, aid in distinguishing between the two disorders. The paroxysmal attacks of hepatic porphyria, due to neuropathy, are precipitated by stress, drugs, dietary indiscretion, and endocrinological factors. Porphyric neuropathy affects the small, lightly myelinated or unmyelinated nerve fibers, mediating visceral autonomic dysfunction along with regional pain. Besides distinct patterns of pain, proximal limb weakness and the persistence of the muscle stretch tendon reflexes help distinguish this disorder from AIDP (Mendell et al., 2001). A study of 115 patients with acute intermittent porphyria, seen during a 20-year period, revealed that 11 of them suffered an acute episode of quadriparesis. Nerve conduction studies performed on 8 of these 11 patients demonstrated low-amplitude compound action potentials with normal velocity measurements. Needle EMG demonstrated prominent fibrillation potentials, especially in proximal muscles. The changes in these findings with time confirm that this disorder, at least a major component of this disorder, is an acute axonal neuropathy with proximal predilection (Albers, Robertson, & Daube, 1978).

POST-POLIO SYNDROME

Post-polio syndrome tends to cause pain. Electrodiagnostic findings of polio include giant motor units and tiny fibrillations. The large-amplitude motor unit represents the large population of muscle fibers that are reinnervated by the motor neurons that survived the viral infection. Years after motor function has stabilized, a later-life motor decompensation becomes manifest as weakness, fatigue, and myalgias. Tiny fibrillation potentials suggest ongoing denervation and reinnervation. This post-polio phenomenon may be secondary to the collateral sprouting of motor neurons that do not actually fully stabilize. Denervation becomes more prominent with time. A post-infectious autoimmune syndrome is suggested in late-onset destabilization of motor dysfunction (Younger, 1999).

DIABETES MELLITUS

Neurological manifestations of diabetes mellitus are diffuse and well defined. From cerebral stroke to muscle hemorrhage, the entire neuraxis is fair game for the assault by metabolic and vascular pathology. Lesions associated with pain are usually those that are involved with polyneuropathy (which secondarily predisposes to painful mononeuropathy), plexopathy, and radiculopathy. Serum glucose control, weight loss, and blood pressure control contribute to a favorable outcome. Several types of neuropathy are seen in diabetes, and more than one type may manifest in the same patient. The length-dependent, so-called "dying-back" polyneuropathy is one of the more common types and may involve multiple fiber types. Polyneuropathy in diabetes may be primarily axonal, but may also be mixed demyelinating/axonal. Isolated painful small fiber polyneuropathy cannot be diagnosed using conventional EMG/NCV studies. Thermal threshold QST, QSART, and skin biopsy are appropriate studies in the diagnostic assessment of isolated small fiber painful polyneuropathy. Length-dependent neuropathy correlates with a stocking-glove sensory loss, as well as weak distal lower limb muscles. Hammertoes are formed when the most distal foot muscles, the extensor muscles, become affected before the toe flexors, which contract unopposed. Sensory nerve studies are more sensitive than motor nerve studies for diagnosing polyneuropathy. Needle EMG changes may precede nerve conduction study changes. The comparison of central and conduction times recorded by SEP in a group of diabetic patients revealed what had been an unapparent lesion of the spinal cord in addition to peripheral nerve involvement (Varsik et al., 2001).

Other painful neuropathies such as CTS and meralgia paresthetica (entrapment of the lateral femoral nerve at the anterior hip) are common in patients with diabetes. The later causes pain and numbness in the anterolateral proximal lower limb. Obesity further increases the risk of this phenomenon, as it does the risk for diabetes. Femoral neuropathy, distinguished from lateral femoral cutaneous nerve, tends to occur as part of diabetic lumbosacral radiculoplexopathy (Mendell et al., 2001). Diabetic truncal neuropathy can be very painful and may present as symptoms of a myocardial infarction, an ironic assertion, due to the proclivity of patients with diabetes to suffer from painless infarction of heart muscle. Diabetic amyotrophy (Brun-Garland syndrome) is a distinctly proximal lower limb phenomenon in which electrodiagnostic studies tend to reveal concurrent large fiber polyneuropathy. Fibrillations in proximal and distal lower limb muscles are seen. Cranial neuropathies are also seen in diabetes mellitus. Oculomotor neuropathy, which can be painful, is diagnosed on clinical grounds. In this so-called diabetic third nerve, it is key to differentiate between a vaso nervorum stroke and a compressive third nerve aneurysm. Painful hemorrhagic muscle infarction can also be seen in diabetes

mellitus. MRI assessment supports the characterization of this entity as a primary infarct, associated with secondary hemorrhage (Sharma et al., 2000). Literature also suggests as association with immune defects (Ali et al., 2003).

Lyme Disease

Neurological abnormalities in Lyme disease result from the direct effect of *Borrelia burgdorferi* as well as from the effect of the host's immune response. Lyme vasculitis has been implicated in painful peripheral Lyme neuropathy. Electrodiagnostic tests suggest peripheral nerve demyelination in Lyme neuropathy. An autoimmune etiology is implicated. Subarachnoid inflammation is implicated in both spinal radiculitis and cranial neuritis (e.g., trigeminal neuralgia) caused by Lyme disease. In Lyme radiculopathy, EMG usually reveals axonal involvement in both nerves and nerve roots, in a pattern reminiscent of AIDP. Peripheral nerve findings include slowing of conduction velocity and prolongation of distal latency. Sensory and motor nerve potentials may be reduced in amplitude. F-waves are prolonged in as many as 50% of patients. Lyme radiculoneuritis tends to improve spontaneously within a few months of onset. Painful muscle disease due to Lyme disease is associated with stiffness, cramps, swelling, and myalgias. The symptoms begin between 1 to 6 months after tick bite. Significant weakness is rare. EMG findings in Lyme myositis include short-duration, low-amplitude polyphasic potentials (myopathic potentials), positive sharp waves, and fibrillation potentials. Early manifestations of neurological Lyme disease also include syringomelia, cauda equine syndrome, mononeuropathy multiplex, isolated painful radiculitis, and ulnar nerve entrapment. Late neurological sequelae of Lyme disease include "late" polyneuropathy, CTS, and radiculopathy (Coyle, 1993). Radiculoplexitis and focal nodular myositis round out an array of painful late onset neurological syndromes of Lyme disease (Coyle, 1993).

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is an extraordinarily painful condition, which varies in its presentation, etiology, and progression. Definitive pathophysiology and nosology of CRPS are yet to be accepted by the scientific community. EMG may rule out CRPS by virtue of diagnosing an ulterior entity, such as an occult plexopathy. QSART can help verify an autonomic component, although is not specific for the sympathetic nervous system. SEP can confirm a preganglionic radiculopathy that mimics CRPS. CRPS is discussed in greater detail elsewhere in this text.

CONCLUSION

The information contained within this chapter addresses merely the tip of the iceberg. Electrodiagnostic studies augment the clinical analysis by reflecting neuronal function while concurrently providing information regarding anatomical localization. A well-crafted, well-performed study is invaluable. Although these studies confirm and characterize the clinical hypothesis, they may also divulge important prognostic information. The reader should have obtained a framework for understanding the basic electrophysiological underpinnings of electrodiagnostic tests, particularly those crafted for patients in pain. A grasp of the major clinical entities that cause pain is key to choosing the appropriate electrodiagnostic study or studies to provide a differential diagnosis and localize pathology. Ultimately, the reader should develop a flavor for the utilization pattern for these tests.

SEMG: Objective Methodology in Muscular Dysfunction Investigation and Rehabilitation

Gabriel E. Sella, MD, MPH, MSc, PhD (HC)

INTRODUCTION

Surface electromyography (SEMG) is a methodology discovered in the 1930s and used more and more in the clinical field since the 1950s. The advent of the computer allowed for an exponential development of its use since the 1980s. John Basmajian and collaborators were major early contributors to the field (Basmajian, 1974). The Association of Applied Psychobiology and Biofeedback (and its predecessor) was the leading research society, which disseminated the research results of the researchers across the past 30 to 40 years in the field of SEMG. The medical field needed further development of the clinical applications of SEMG beyond the original contributions (Fernando & Basmajian, 1978). Development of clinical dynamic protocols and their standardization was an awaited event. The author has contributed to the field since the early 1990s and continues to perform clinical and applied research and dissemination thereof.

THE INVESTIGATIVE ARM OF SEMG

SEMG aims to assess the muscular electric tonus during rest or during activity (Sella, 2000b).

Muscle functions in two modes, the resting and the active modes. During the resting mode, it does not move a joint or body region through any segment of motion. The muscle is actively reenergizing while using action potentials only to maintain the body part against gravity in the resting position and to maintain the "alertness state" tonus required by the sympathetic nervous system at any given moment in time. The energy consumption is generally minimal compared with that needed for any motion.

During the active mode, the muscle works together with the other muscles in its primary myotatic unit and vector to move a joint or a body region in space, with or against gravity. The body musculature as a whole works on a "saving mode" system in which multiple muscles are active at the least level of force or electrical potential effort such that no muscle is particularly prone to fatigue (and, by extension, pain) for a determined action.

THE RESTING TONUS

The muscular tonus at rest comprises the alpha-motor neuron component and the sympathetic system input component. The muscle has to sustain the body part it pertains to against gravity. It must also maintain the turgor of the particular body part, such that the vascular and neural components or visceral components should not be compressed and damaged. In addition, even when the body does not move, such as when supine at rest, all the muscles of the trunk are still participating, even if minimally, in the act of breathing and in the slow movement of the abdominal visceral components.

The electrical potentials used during rest are generally 2 to 3 µV rms, except in the case of the muscles of expression. More likely than not, the sympathetic tone contributes to maintain a more elevated resting potential level (>2 and <6 µV rms). The resting tonus electric potential can be modulated by the individual who has

learned basic relaxation techniques. As such, it can be decreased to levels <1 μV rms in any given muscle.

THE ACTIVITY TONUS

The electrical potentials used by an active muscle vary with the intensity of the activity. SEMG measures mainly the amount of effort that any active muscle contributes to the overall motion or motions in space, with or against gravity. The muscles that move a given joint or region work together in a well-orchestrated fashion to promote, modulate, and effectuate the motion in such a way that each one provides the least amount of effort. The activity amplitude level is a number of times the multiple of the action potentials needed to maintain the resting tonus. The ballistic muscles, i.e., the limb muscles, have an *A/R* (activity/rest) ratio >10:1 on the average while the postural muscles have an *A/R* ratio on the average of <5:1 (Sella, 2000a, 2000d). The ratio increases with the amount of energy expended both in the postural and in the ballistic muscles. The resting tonus remains rather constant, provided that the muscle returns to rest for an appropriate amount of time (i.e., >3 seconds). Dysfunctional muscles activity disrupts the natural modulation. If the resting tonus increases while the activity tonus stays rather stationary, the *A/R* ratio will decrease. If both the resting and the activity tonus increase proportionately, the *A/R* ratio may not change.

Pain occurs usually following the advent of muscular fatigue (De Luca, 1985). It also occurs in conditions of muscular spasm and hypertonus or in conditions associated with repeated co-contractions or co-activation (Donaldson et al., 2001a, 2001b). This subject is developed later in this chapter.

The activity tonus is normally an electric potential multiple of the resting tonus. The *A/R* ratio is usually 2 to 3 in the components of the axial skeleton and between 5 and 18 in the components of the appendicular skeleton. This fact corroborates the principle that the axial muscles function mainly as "postural" muscles while the appendicular muscles function mainly as "ballistic" muscles.

Muscles may be hypoactive or hyperactive, according to the level of control imparted by a number of physiological or pathological conditions, as well as the result of dysfunctional learning. This subject will be developed further later in this chapter.

STATIC SEMG PROTOCOLS

A number of protocols have been developed to enable the assessment of axial muscles electric potentials in a given static position against gravity (Sella, 2002b). While the intent was commendable, such protocols suffer, at present, principally from a technical limitation: only a pair of homologous contralateral muscles can be assessed simul-

taneously. The subsequent pair, usually tested from a cephalad-to-caudad direction, is tested a number of seconds later. Thus, the idea of static testing suffers from the fact that the body may change posture, in a physiological or pathological sense, over time.

Nonetheless, after having considered this limitation, one can test repeatedly the paraspinal musculature and observe if the same electric potential static pattern occurs over time, and one can gather the statistics of the average potentials at each paraspinal level and compare contralateral potentials over a number of trials in a number of ways.

DYNAMIC SEMG PROTOCOLS

A number of dynamic protocols have been written and standardized (Sella, 2002b, 2003b; Sella & Donaldson, 1996; Sella & Finn, 2001). All dynamic protocols involve testing a number of homologous contralateral muscles through a given number of segments of motion, within a well-defined clinical and neuroanatomic context.

According to the standard protocols, muscles may be tested simultaneously bilaterally or in a sequence of one side at rest while the other is moving through well-defined segments of motion in space.

Although the number of potential dynamic protocols is quite large, the following protocols have been written and standardized by the author.

ROM PROTOCOLS

This is a series of protocols following the standard range of motion (ROM) of the joints and regions of the body. The dynamic protocols follow closely the inclinometry derived degrees of motion from a standardized text (Gerhardt & Sella, 2002).

The joints tested with SEMG dynamic protocols are the following:

1. Shoulder (6 to 7 segments of motion)
2. Elbow (4 segments of motion)
3. Wrist (4 segments of motion)
4. Hand/fingers (7 segments of motion)
5. Hip (6 segments of motion)
6. Knee (2 segments of motion)
7. Ankle (4 segments of motion)
8. Foot (4 segments of motion)

The regions tested are the following:

1. Cervical (6 segments of motion)
2. Trunk (6 segments of motion)
3. Pelvis (2 segments of motion)

Each dynamic protocol follows an identical pattern:

1. Screen 1 involves initial rest, pretesting rest in the neutral position for 30 seconds
2. Screen 2-n represents the number of screens following the number of segments of motion. Thus, the elbow SEMG dynamic protocol requires testing through elbow flexion, extension, pronation, and supination. Each screen is performed identically: Starting with the particular activity for 7 seconds of sustained motion and 2 seconds of returning to the original resting position, with 9 seconds of resting in the neutral position following the activity. The sequence of activity and rest is repeated five times or more, if necessary. Thus, any screen of activity and rest will take 90 seconds or longer.
3. Final rest or post-exercise resting of 30 seconds in the neutral position.

Statistics are compiled from the quantitative data accumulated from the test through activity and rest. Those statistics involve gathering data for the average activity (x) (μV rms) of any muscle tested through any segment of motion five times. This will involve calculating the standard deviation (SD) of the average described above, the coefficient of variation (CV) derived from the SD/x ratio, and other statistics, as necessary (Sella, 2001d). Such statistics may involve contralateral comparisons, regression analysis, etc. The most valuable statistic of the resting tonus is that of the minimal resting tonus, derived from the average of the central 3-second period of the 9-second resting interval. The first 3 seconds of the resting period are "biased" by the returning to rest momentum and the last 3 seconds are "biased" by the tendency to start the motion again, i.e., anticipatory movement.

The overall purpose of the ROM dynamic protocols is to identify the muscular response through any given segment of motion. The particular myotatic unit tested or any muscular component of it may respond with "normal" amplitudes of electrical potentials through a given segment of motion and "abnormal" amplitude through other segments of motion. Thus, performing only one segment of motion of a given joint or region may not reflect the true picture of functional or dysfunctional muscular behavior. The performance of several segments of motion allows also for the identification of any degree of dysfunction of any given muscle through the test, as performed bilaterally. Furthermore, it allows for the identification of unilateral dysfunction with the muscles at rest while the contralateral muscles are performing any given segment of motion, i.e., ruling out the presence of co-contractions or co-activation.

The SEMG dynamic protocols allow also for the identification of improvement of amplitude electric potentials at rest or through motion during the period of neuromuscular rehabilitation following the diagnostic testing. Figure 45.1 exemplifies the process of testing with SEMG
FIGURE 45.1 Average SEMG amplitude potentials of the five muscles tested with SEMG through elbow region ROM segments. From Sella, G. E., 2004. Presentation given at the 8th Annual BFE (Biofeedback Foundation of Europe) Meeting & Workshops. Winterthur, Switzerland. February 24–28. Reprinted with permission.)

through a given joint classic ROM segments of motion (Sella, 2003a).

NEUROMUSCULAR PROTOCOLS

The neuromuscular protocols follow in format the ROM protocols described above in terms of the type of screens and statistics. The aim of these protocols is to rule out any neurological abnormality that may affect a muscle or a muscle group, ranging from central to peripheral neuropathy (Sella, 2003b). The following examples aim to clarify the general protocols.

The musculocutaneous nerve (C5–C6–C7) innervates the following muscles: coracobrachialis, biceps brachii, and brachialis. The first muscle is anatomically located too deep for SEMG testing at the present time. The testing is performed on the biceps and brachialis, in the appropriate segments of motion, i.e., the segment of motion with the highest and lowest activity found from the database for each muscle. If only one muscle is affected, the diagnosis will lead to mononeuropathy, whereas if both muscles are affected, the diagnosis will lead to musculocutaneous neuropathy as a whole. Because the nerve has a three-root innervation, one may need to proceed with differential diagnosis of radiculopathy. In this case, the deltoid muscle may be tested for C5 radiculopathy, the brachioradialis may be tested to rule out C6 radiculopathy, and the triceps may be tested to rule out C7 radiculopathy. In each case, testing for each muscle needs to be done in the clinically chosen segments of motion, most often those found in the database to produce the highest and lowest amplitude potentials. Thus, neuromuscular testing can serve to rule out mononeuropathy or radiculopathy with no invasiveness, in an effective and efficient manner, with quantitative analysis. The procedure can be quite useful in the overall diagnostic process, as well as in the process of neuromuscular rehabilitation.

The neuromuscular protocols follow the anatomic outline of 29 nerves and include also the differential diagnosis for all the roots. The only limitation is the ability to test muscles that are too deeply located anatomically for the SEMG testing at the present time. SEMG neuro-

Highest	Abduction	54.1	Lat. flex.	61.2	Post. flex.	38	Ext. rot.	10
Lowest	Post. flex.	20.5	Post. flex.	17.7	Ant. flex.	12.2	Int. rot.	6.2

Note: From *Surface Electromyography: A Neurological Clinical Approach,* by G. E. Sella, 2003. Martins Ferry, OH: GENMED Publishing. Reprinted with permission.

muscular testing allows for the finding of pathological signs such as fasciculations. Thus, the testing can help to distinguish central from peripheral or mixed neuropathy without invasiveness (Sella, 2003b). Table 45.1 shows the process of differential diagnosis used with SEMG neuromuscular protocols.

The examiner can use the knowledge from the database and Table 45.2 through Table 45.4 to assess the normalcy of the electric potentials amplitude through the segments of motion representative of the expected highest and lowest activity for each muscle described. In general, the confidence interval (CI) of 95% is within 20% of the averages of μV rms cited above. Therefore, results, which would be above those values, would be indicative of loss of strength, more commonly resulting from peripheral neuropathy, including radiculopathy. The testing needs to be done bilaterally following the general outline described in the dynamic SEMG joint ROM protocols section. Because most neuropathy is unilateral, that should provide a good frame of reference in the sense that the expectation would be that the asymptomatic side values would fall within the reference values frame of reference. Thus, SEMG is an objective electrophysiological modality that can be applied in a noninvasive fashion in the differential diagnosis needed for neurologic workup.

MYOFASCIAL PROTOCOLS

Myofascial pain syndrome (MPS) is a common clinical occurrence in the muscular pain field (Sella & Finn, 2001). The authors have devised at least 75 SEMG dynamic protocols to be used in the diagnostic and rehabilitation process of the MPS. The SEMG dynamic testing or biofeedback can be used simultaneously with physical testing or myofascial trigger points massage treatment or trigger point injections.

The testing procedure is similar to that described for the ROM testing. In terms of the diagnostic findings and the rehabilitation process, the ranking sequence of amplitude potentials through the classic or functional ROM is of relevance in MPS or other such conditions (e.g., fibromyalgia). This involves comparing the patient's results with those in the database. Figure 45.2 exemplifies this point. As Figure 45.2 indicates, there is a "ranking" of all

the segments of motion of the muscles tested through the elbow joint ROM. The clinician will note that the highest amplitude of motion (normalized to the average of the group) is that of the anconeus muscle in pronation and the lowest amplitude is that of the triceps in supination. It stands to reason that the rehabilitation sequence of the elbow joint myotatic unit should be performed "from easy to hard," i.e., from motions that require the least amount of energy to those requiring the highest amount of energy. Thus, the clinician will choose the triceps muscle and work with that muscle first in supination to enable the person to regain appropriate proprioception and muscular control of energy expenditure. This will avoid fatigue and unnecessary pain. As the patient progresses through the different muscles/segments of motion from "low to high," the elbow region is more exercised and enabled to proceed with higher and higher energy requirements for motion. By this token, the pronation of the anconeus muscle will be last in the rehabilitation sequence. This is the general situation obtained from the database of 373 muscles tested through the elbow joint ROM (Sella, 2001a).

Any particular patient whose elbow myotatic unit muscles are tested through the elbow joint ROM may show a different ranking pattern of amplitude potentials. The clinician is enabled to compare that pattern with the expected pattern from the database.

FORENSIC PROTOCOLS

SEMG dynamic testing can be used in the field of forensic sciences or legal medicine (Sella & Donaldson, 1996). The testing results can help to rule out objectively a number of features of muscular behavior of relevance in the forensic field (Sella, 1997a, 2001c, 2002d). The principle of internal consistency of muscular behavior through given joint classic segments of motion can help rule out symptom magnification, functional overlay, or malingering (Sella, 2000c) The author uses protocols of bilateral simultaneous testing of four homologous contralateral muscles through the classic joint/region ROM. In the forensic arena, one may have to add any number of functional motions relevant to the target case. It is expected

that if a person performs the testing consistently, i.e., without a secondary agenda to show "pain" or any other symptom, the coefficient of variation for any given segment of motion of the eight muscles tested should be ≤10% (CV ≤ 0.10).

The literature shows that this is the case in >93% of the tests done on more than 2,800 muscles (Sella, 2000a). Furthermore, it may be expected that if one muscle is dysfunctional, it will be the only muscle that may show a CV > 10% through any given motion or at rest. The author has shown that persons who intend consciously or unconsciously to magnify their symptoms will show aberrant types of muscle motions and electrical potentials thereof with high coefficients of variation.

The presence of a number of asymptomatic muscles acting in an aberrant fashion through any given segment of motion is indicative of functional overlay or symptom magnification (Figure 45.3). In the case of malingering, by definition, the claimant should not have any muscular symptom or sign because there was no involvement in any actual injury. The pattern described above shows that muscular behavior is subject to voluntary control aimed at deceiving the examiner and will show a generalized pattern of CV > 10% for any given muscle and segment of motion.

Forensic testing with SEMG may also be useful to rule out muscle weakness. In general, muscles that suffer from loss of strength show a high-amplitude electrical potential pattern through any given segment of motion (Sella, 2003d). This is the result of the need to recruit a higher number of myofibrils to produce that given motion. Thus, it may be expected that if the right biceps is weak, it may show an amplitude potential at least 20% superior to the expected 36.9 μV rms in elbow flexion (CI < 95%, >95% 29.9 to 43.9 μV rms). If the asymptomatic left biceps of the claimant shows an amplitude potential within 29.9 to 43.9 μV rms, while the right symptomatic muscle shows a value above 43.9 μV rms, the symptom of weakness may be credible. On the other hand, the credibility factor is decreased if the flexion value is within the expected range for asymptomatic biceps in flexion. If there is any question, the credibility may be enhanced if the weakness can be demonstrated on all the classic segments of motion and also on a functional motion such as ball throwing. Thus, SEMG testing and the ability to compare
FIGURE 45.3 Symptom magnification: there is no pattern of activity to either muscle through five identical repetitions of motion and rest. Based on Sella, 1997b; Sella, 1999.

amplitude potential values of a given claimant with those of the asymptomatic population can help in the diagnosis process of symptom magnification.

The forensic testing may have to rely also on the presence or absence of a number of electric dysfunctions of symptomatic muscles. Those dysfunctions may involve spasm, hypertonus, loss of mirror image, fasciculations, co-contractions or co-activations, the presence of myokimia, etc. Those electric dysfunctions are defined and discussed later in the chapter.

To summarize, normal findings rule out against the presence of muscular symptoms. Internal inconsistency shown by CV > 10% rules in favor of symptom magnification, functional overlay, or malingering. Findings of weakness rule against unfounded complaints. Findings of abnormal electric potential patterns in the target muscles preclude the performance of adequate statistics and rule in the favor of the plaintiff.

ERGONOMIC PROTOCOLS

Those protocols may follow the outline of the joint/region ROM protocols, the neuromuscular protocols or the myotatic protocols. The performance procedure during the investigation is similar to that described for the SEMG dynamic ROM protocols (Sella, 2002d, 2002e). The ergonomic requirements of motion are usually above and beyond those of the classic ROM segments of motion. The procedure will usually require the performance of the classic joint/region ROM tests to allow the clinician or ergonomist to compare the electric potential amplitude results derived from the client to those from the database (Sella, 2001b, c, d). The overall aim of ergonomic SEMG testing, including athletic utilization is to assess the fitness of any given muscle and myotatic unit to prepare them through SEMG/biofeedback reeducation to give optimal function.

The SEMG meaning of optimal function is that of utilization of the least amount of action potentials for the active myofibrils in the most efficient and effective manner, in unison within the myotatic unit and primary and secondary vectors in order to achieve the best rendition for the longest period of time without fatigue. This can be achieved by training each individual muscle involved and then the entire primary myotatic unit and vectors above to act within the lowest possible amplitude of activity and greatest control and possible effort and strength.

The muscles of a given myotatic unit are assessed at first and then ranked according to a "high to low" ranking fashion. The examiner has to compare the values of any given client to those of the existing database (Sella, 2001a). Then, the muscles are trained from "low to high" at the minimal effort level of activity. Finally, they are trained at the level of activity that is necessary for the objective target work function or athletic endeavor.
FIGURE 45.4 Wrist joint ROM: sequential activity potential tonus of the muscles and motions tested. The normalization (%) is performed as a ratio of each muscle/motion by the average of the whole group (19.7 μV rms). (From Sella, G. E., 2004. Presentation given at the International Symposium of Cerebral Palsy. Munich, Germany, March 17–20. Reprinted with permission.)

Figure 45.4 and Table 45.5 illustrate the point of ergonomic/athletic SEMG testing and neuromuscular reeducation procedure. The examiner will modify the ranking of the muscular retraining per muscle and motion after training the client to proceed in harmony with the muscle segmental motions at the least amount of effort. The new or modified engram of the participant will help in the ergonomic retraining procedure. Thus, different ergonomic or athletic needs will determine different patterns of muscular utilization either for the classic wrist segmental motions described above or for any functional motions such as needed for the purpose of the training. The final aim is to utilize the least amount of energy to provide the best rendition with the least fatigue. The database allows the ergonomic/athletic trainer to modify different ergonomic protocols within a solid framework, which would avoid fatigue, pain, or injury.

THE THERAPEUTIC ARM OF SEMG/BIOFEEDBACK

The SEMG modality can be used not only for investigative or diagnostic purposes but also for neuromuscular retraining or reeducation (Basmajian, 1981; Schwartz et al., 1995). With the diagnostic framework in mind, the clinician can proceed to establish a rehabilitation program (Sella, 2000b). The first step is to compare the results of any given muscular activity with those of the database. The next step needs to be to establish a program that, in most cases, will involve a plurality of therapeutic methods and SEMG/biofeedback.

The main aim of the addition of the SEMG/biofeedback is to modify and improve the existing neuromotor engram (Donaldson et al., 2001c; Sella, 2002e). It is taken for granted in most cases, except for very small children, that the individual has learned a movement pattern involving a given number of muscles or myotatic units through life. Because of the injury or other causes, this engram

will have been disrupted or disturbed. Consequently, the pattern of movement of the target myotatic unit has been disrupted and the individual had lost some proprioception and ability to control the muscular movements in the most effective fashion.

SEMG/biofeedback can retrain the proprioceptive ability (Sella, 2004b). Although the nerve endings responsible for proprioception reside uniquely or mainly in the capsular apparatus rather than in muscles, muscular movement or controlled resting helps to reestablish the normal proprioception regarding a joint via new learning involving a complexity of visuocorticomotor or audiocorticomotor pathways. The body–brain–SEMG equipment connection needs to be performed by applying the surface electrodes to the skin overlying the target muscles in the vectorial direction of the muscle action's main vectorial direction. The electrode wires, the SEMG equipment, the computer, and the computer screen serve to connect the muscular message with the brain motor terminals. This is usually accomplished via a visual message found on the computer screen. Occasionally, the message may be of auditory or vibratory origin. The final muscle–SMG equipment message is transmitted to the subject's sensory-cortical (and subcortical) brain terminals and is relayed to the homunculus motorius and, via complex pathways, to the corticospinal motor tracts leading peripherally to the target muscles (Sella, 2000c).

The original engram will be modified or actually partially replaced by the new SEMG/biofeedback learning in time, through a number of clinical sessions. The end result will be a better proprioception involving the particular joint or region as well as an improved level of control of the muscles targeted with the learning for either activity or rest. If the new engram is exercised properly, in time

it will remain as the actual functional engram. If it is not exercised properly and the individual returns to old habits and dysfunctional pathways, it will be of little use.

Research done in the past 40 years has shown that the brain is not a "black box" but a vibrant organ able to undergo neuromodulation (Changeux, 1985). This ability enables the individual with dysfunctional muscular activity from neurologic, traumatic, or other etiology to learn anew to utilize the target muscles in the most effective manner. SEMG/biofeedback and other forms of biofeedback are main tools that can be used in the realm of helping the brain in the act of neuromodulation (Donaldson et al., 2001c). This is done, in terms of SEMG/biofeedback, by involving either the ancient motor pathways not used since early infancy or by involving new neuronal associations, which permit adequate muscular behavior through the new learning pattern (Donaldson et al., 2001a, 2001b, 2001c).

Rehabilitation of the resting tonus, the activity tonus, is the main task of the SEMG/biofeedback neuromuscular reeducation program.

The resting tonus has been assessed for more than 180 muscles. The total number of muscles tested is around 7,000 (Sella, 2000d). As described above, the resting tonus as investigated by the author represents the minimal resting value obtained in the central range of the resting period of 9 seconds between any two repeated movements of any given muscle. Overall, the resting tonus of the untrained muscles ranges between 2 and 3 µV rms. The resting tonus of the muscles of expression is usually higher in untrained persons. It may be reduced to below 2 µV rms in any muscle in trained individuals. The resting tonus depends largely on the input of the α-motor neurons and the sympathetic nervous system (SNS) input. The general outline of the clinical assessment of the magnitude of the SNS

component is that it would affect all muscles tested, not only the target, symptomatic muscle. Other factors showing a high sympathetic input of different systems would be ruled out by the demonstration of elevated heart rate, breathing rate, sweat, etc. The α-motor neuron input may be different in the target muscle than in its homologous contralateral, depending on a number of factors. Pain may increase the overall SNS input and the α-motor neuron input. On the other hand, some individuals learn to adapt to pain by reducing the overall muscular tonus.

A normal individual may learn through SEMG/biofeedback to reduce the resting tonus of any given muscle within a matter of minutes and retain the new learning (Sella, 2000b). The lower the resting tonus, the less the energy expenditure required to maintain the target muscle in any given tonic state. It would stand to reason that a higher tonus would be tantamount to a decreased arteriolar and capillary blood and oxygen intake and a decreased appropriate emptying of catabolic substances through the lymphatic and venous channels. The accumulated catabolic products and local edema would be detrimental to the normal metabolism of the muscular tissue (Travell & Simons, 1983). In time, the individual concerned would perceive symptoms, such as pain, muscle sluggishness, and early fatigue. In terms of ergonomic and/or athletic endeavor, it is most appropriate to maintain the muscular tonus at its optimal resting level, usually within 0.5 to 1 μV rms.

In the biofeedback world, there is some confusion between the expression "baseline" and the expression "resting tonus." Baseline is a general, nonspecific expression that has no power of structural definition of the muscle at rest nor of any pathological or functional significance. Resting tonus refers to the dynamic muscular electrical activity of a given muscle that is not moving a joint and is not moved concentrically, eccentrically, or in a rotatory fashion at any given moment of time. The dynamics of the resting tonus depend on the nervous factors above as well as other factors such as temperature and vascular system.

A lot of work has been done in the past in the area of muscle relaxation for a variety of emotional, psychological, or other etiologies (Basmajian, 1981; Schwartz et al., 1995). In general, well-documented therapy has proved successful in relaxing muscles and reducing the resting tonus. A note of caution needs to be added at this point. Some clinicians chose to place electrodes *across* muscles rather than *on* the same muscle. They found that, in time, the amplitude potentials "quieted down" and deduced therefore that the muscles or the region had "globally" relaxed. These hypotheses and conclusions were clinically and electrophysiologically unfounded, as *electromyography* requires specific electrode placements in the main vectorial direction of a particular muscle. They used the volume conduction parameter applicable to SEMG as a substitute for actual *myographic* properties and derived the wrong conclusions, which are simply not applicable clinically. As an example, electrode placements at 2 cm interelectrode distance on the main vectorial direction of a given muscle, e.g., biceps brachii, may result in an electric potential difference of approximately 2 μV rms while the muscle is at rest, compatible with the definition of the resting tonus. If electrodes are placed one on the right biceps and one on the left biceps (with the ground electrode placed elsewhere), and if the resulting amplitude potential is 2 μV rms, that can only happen if the electric potential difference between the two electrodes across the chest volume and the upper limbs volume is 2 μV rms. In other words, if the voltage potential on the right side is 30 μV rms and on the left it is 28 μV rms, the difference would be 2 μV rms, thus not a value compatible with resting tonus. Yet, those clinicians mistakenly believed that the volumetric conduction difference equated that of relaxed resting potential.

It is important for any clinician to understand that SEMG refers to specific muscular measurement and rehabilitation. Volumetric work is not to be equated or confused with SEMG.

ACTIVITY TONUS

The electric tonus of any given muscle during any given activity is a multiple of that of the resting tonus. Table 45.6 illustrates the average activity/rest ratio for different joints and regions through the classic ROM.

Table 45.6 summarizes important data from many studies. The average value represents the average amplitude potential for the number of motions and the number of muscles tested through the ROM segments for each joint or region. The average resting tonus values represent the average minimal resting values during the resting periods as defined above.

It is easy to notice that the limb joint overall activity and the *A/R* ratio are quite larger than those of the axial regions. The hip joint seems to be an exception, save for the fact that the joint motions were tested in the supine position (except for extension). The testing was done at all times at the minimal effort level of muscular contraction. The actual degrees of motion for any given muscular movement followed the pattern described in the standardized text (Gerhardt & Sella, 2002).

The activity tonus required for any movement that needs more effort than to move the muscle/joint/region against gravity is greater than the activity levels described above or in the database (Sella, 2000d, 2001d). Two things need to be stressed again at this point: (1) if a muscle is weak it will require more active myofibrils, thus resulting on SEMG amplitude potentials that are generally at least 20% higher than the amplitude potentials seen at the upper 95% CI of the general sample tested in the database (Sella,

TABLE 45.6
SEMG Testing of the Activity and Resting Tonus in 11 Joints and Body Regions

Joint/Region	No. of Muscles	No. of Segments of Motion	Overall Avg. Muscle/Seg. (μV rms)	Avg. Min. Resting Tonus (μV rms)	A/R

2000d); (2) the amount of conditioning or deconditioning of the tested individual will either decrease the amplitude potential levels of the muscles tested or increase it.

Ergonomic reeducation aims at producing overall activity potentials that are no larger than those found within the upper and lower 95% CI of the asymptomatic persons tested and described in the database. Rehabilitation patients need to be trained to produce activity potentials that reflect the same pattern.

MUSCULAR DYSFUNCTION

MUSCLE SHORTENING

Skeletal muscle gives its best rendition at a length that is at least equal to that of the well-conditioned muscle at rest. All athletes and ballet dancers start with a period of stretching exercises before any given performance. Those exercises actually "warm-up" the viscoelastic elements; improve the arteriolar, capillary, venous, and lymphatic circulation; and prime the muscle fibers for the activity to follow.

Deconditioned muscles, such as related to a number of factors, e.g., joint ROM limitations, lose the optimal length and can actually shorten structurally. Any fascial scar or muscular scar from previous injuries can contribute to the tendency to stretch less and give less of an effort when required to move the joint.

Acute muscular splinting and ensuing protective guarding can promote the muscular shortening. The target engram of the person suffering from such symptoms and signs will undergo changes whereby the muscle tends to use fewer and fewer myofibrils and action potentials. The

joint in question will rely, in time, more and more on other structural elements for motion and the overall effort of motion will decrease accordingly, e.g., in whiplash injuries, a few months after the injury, in untreated cases.

Figure 45.5 shows that the SEMG amplitude potentials of shortened muscles will decrease compared with the expected range found in the database. Simple clinical observation of the individual in motion will note an ongoing fear of motion and tendency toward protective guarding. Shortened muscles fatigue more easily from any level of effort that normal muscles would not. If the muscles are subjected to greater levels of effort, fatigue may be transformed into pain.

Shortening of muscles is a problem that cannot be solved too quickly. A program of exercises aimed at gradual joint/region ROM increase may be given jointly with an SEMG/biofeedback program aimed at increasing the muscular amplitude potentials to reach the range of the asymptomatic muscles described in the database. The process of improvement in the ROM and in the amplitude potentials may take several sessions.
FIGURE 45.5 Muscular shortening: presentation of symptomatic (whiplash) subject.

Loss of Joint ROM

The joint is a complex structure. Whatever etiology may be responsible for joint lost ROM (LROM), muscular, tendinal, capsular, etc., the end result is muscular suffering. The muscle may respond to poor ROM or partial ankylosis with loss of optimal functional strength, deconditioning, early fatigue, or pain. The response is not immediate but can be found very frequently in subacute or chronic joint LROM. The SEMG amplitude is usually higher in a muscle that is subject to joint LROM as compared with its homologous contralateral. This may be expected because the muscular disuse may beget loss of strength (LOS). Such loss of strength may be responsible for the muscle's needing to recruit more contractile elements to effectuate any contraction, concentric or eccentric, of the target joint.

Loss of Strength

This subject has been alluded to in the previous sections. Loss of strength could be defined clinically as a loss of >10% of tensile strength from a given group of muscles compared with the homologous contralaterals. Normally, for example, in the hand grip, there is a difference of ≤6% between the two hands when gripping a Jamar dynamometer. Published studies have shown that the dominant hand is within 6% stronger than the nondominant hand 53% of the time, weaker than the nondominant hand 36% of the time, and equal in strength to the nondominant hand 11% of the time (Gerhardt & Sella, 2002; Sella, 2001a, 2001b, 2002a).

There are no methodologies currently that can rule out loss of strength of one single muscle in a particular group. SEMG is the only methodology that comes close to it. Several studies have shown consistently that a weaker muscle has a higher amplitude potential curve for any given motion performed at the minimal level of effort. This has been theoretically explained by the fact that the weaker the muscle, the higher the recruitment of more myofibrils and the higher the number of action potentials required for the performance of the given activity (Sella, 2000a, 2000b, 2000d). Thus, SEMG can be used in the diagnostic workup to rule out muscular weakness in terms of its characteristic of more elevated amplitude potential curves on the weaker side. By the same token, therapeutic success can be documented with SEMG by showing that the previously weaker muscle performs better in time through the rehabilitation period as it shows a decreasing pattern of amplitude potential curves for given motions and finally the amplitude and pattern fall within the expected range of the database (Sella, 2000b, 2001d).

Muscle Fatigue

Fatigue is a complex phenomenon, partly of physical origin and partly of emotional or even motivational ori-

gin. Muscular fatigue has been shown on the SEMG spectral analysis to correspond most closely with the median frequency (Anderson et al., 1978; Arendt-Nielsen & Mills, 1988; Bigland-Ritchie, 1981; Christensen, 1986; De Luca, 1985). The author has noticed empirically that the median frequency curve tends to lower far earlier than the change in amplitude potentials curves in persons complaining of early fatigue. Spectral analysis is the domain of choice at the present time in terms of investigation and also of therapeutic documentation of rehabilitation success.

Muscle Pain

A number of factors can contribute directly or indirectly to muscular pain. The sensation can be primary or secondary such as in referred pain (Travell & Simons, 1983). Pain may be referred from visceral tissue as well such as in anginal pain referred to either upper limb. The sensation is actually perceived in the muscular tissue. Muscular pain may be direct and acute such as in traumatic etiology. It may coincide with splinting of a joint and/or protective guarding of the same joint. It may be of myofascial origin or of diffuse central nervous system origin such as in fibromyalgia. Muscular pain may be the result of vascular, metabolic, endocrine disease, or more rarely, intrinsic muscular diseases.

Because a person would tend to "protect" a muscle or a group of muscles in pain, the descriptions given above under the sections of "Muscular Fatigue," "Loss of Joint ROM," and "Loss of Strength" do apply fully within the present context. In general, a muscle in pain has a decreased pattern in the median frequency amplitude. It is able to contract concentrically or eccentrically in a consistent manner (Sella, 2000d). It may show a higher amplitude potential through a given ROM than its homologous contralateral (Sella, 2000b, 2000d). It may act in a "protective guarding" mode by performing at a lower amplitude of contraction such as the case in whiplash. When the symptom of pain is reduced via different therapeutic means, the amplitude potentials of contraction tend to normalize (Simons & Mense, 2001). Muscular pain may change from the acute state to the chronic state although the characteristics of intensity or frequency may not change. Generally, the person affected with muscular pain feels more comfort at rest than with motion and that tends to create overall deconditioning.

Muscular pain may also be a characteristic of hyperalgesia and allodynia, such as in fibromyalgia or related disorders. SEMG/biofeedback may be a useful modality not only in terms of investigation and ruling out the presence of electrical dysfunctions compatible with pain (see below), but also in terms of engram modification and neuroplasticity during the rehabilitation program.

MUSCULAR DYSEQUILIBRIUM (LOSS OF NORMAL LATERALITY)

Appropriate posture and gait require equilibrium on both sides of the body. Homologous contralateral muscles function most effectively when they are required to use the least amount of energy for the effort of contraction and when they function in equilibrium, i.e., generally within 25% difference of electric potential activity during motion and rest (Sella, 2000d). This empirical observation applies for the appendicular muscles and for the axial muscles, as well.

Table 45.7 shows that there are striking percentage differences in laterality of amplitude potentials between normal and abnormal values, as compared with the database. The data in the table have been weighed and the results are presented as such. Table 45.8 is a summary of Table 45.7. Of interest is the fact that there are several overlaps in the percentage differences between the normal and abnormal resting and activity amplitude potential values. The median difference and the average differences are quite different between the two groups. At all times, the differences are larger either for the resting tonus or the activity tonus during motion than during rest.

The clinician may interpret the data from Tables 45.7 and 45.8 in terms of assessing myotatic units of the appendicular skeleton or of the axial skeleton.

Table 45.9 shows that the average resting range muscular differences between the right and left side of the body in the normal (asymptomatic) muscles and the abnormal (symptomatic) were generally less, with no overlap between the two groups. The same did not hold true for the similar ranges of the muscles during activity. In general, the differences were less in the asymptomatic groups of the axial and appendicular muscles than in the symptomatic groups. There was significant overlap between the symptomatic/asymptomatic group differences.

SEMG-DEFINED PARAMETERS OF MUSCULAR DYSFUNCTION

SPASM

From a clinical perspective, it is difficult to define the presence of spasm. A very taut muscle or group of muscles could be called "in spasm" during palpation if the person complains of pain at the time of the visit. On the other

FIGURE 45.6 Spasm.

hand, the same palpation in an individual who has no complaints would not be called "spasm." Therefore, the tautness of a muscle or a group of muscles cannot be defined as "spasm" without further documentary proof.

The complaint of pain alone may not be sufficient, especially in the forensic environment. SEMG is the only electrophysiological modality that can throw light onto this problem (Sella, 2000d). Muscles that are simply taut, without the presence of any symptom, will show a normal resting tonus and an activity tonus. Muscles that are indeed in pain show no visible differences in the amplitude potentials during any ROM activity. Figure 45.6 illustrates this point and the SEMG derived definition of spasm.

Figure 45.6, deriving from a whiplash case, illustrates that the right upper trapezius is in spasm from the SEMG perspective. One can see no tendency to increase or decrease the amplitude potential through the five repetitions of neck flexion. The left upper trapezius (shown at the bottom of the graph) has an overall amplitude that is far less than that of the right side of the same muscle. Its activity is likewise mildly abnormal, but there is a tendency to return to normal resting tonus in the first three repetitions of the motion.

HYPERTONUS

From a clinical perspective, it is difficult to define the presence of hypertonus. Many a clinician will define

loosely a very taut muscle or group of muscles as being "hypertonic." This is a very nonspecific term, as it is dependent on the ability of palpation of the clinician involved. If the person complains of pain at the time of the visit, then the taut muscle or group of muscles could be considered symptomatic and the "proof" of it is the tautness. On the other hand, the same palpation in an individual who has no complaints would not be called "hypertonus."

The complaint of pain alone may not be sufficient to consider the tautness of the muscle or muscle group as dysfunctional or pathologic, especially in the forensic environment. SEMG is the only electrophysiological modality that can throw light onto this problem. Muscles that are simply taut, without the presence of any symptom, will show a normal resting tonus and an activity tonus.

The SEMG-derived definition of hypertonus is that of a muscle that performs activity with an increased amplitude, commonly above that of the database range, while in the same time the resting tonus does not return to real resting values (Sella, 2000d). The tendency is commonly there in terms of the return to rest; however, that does not quite happen.

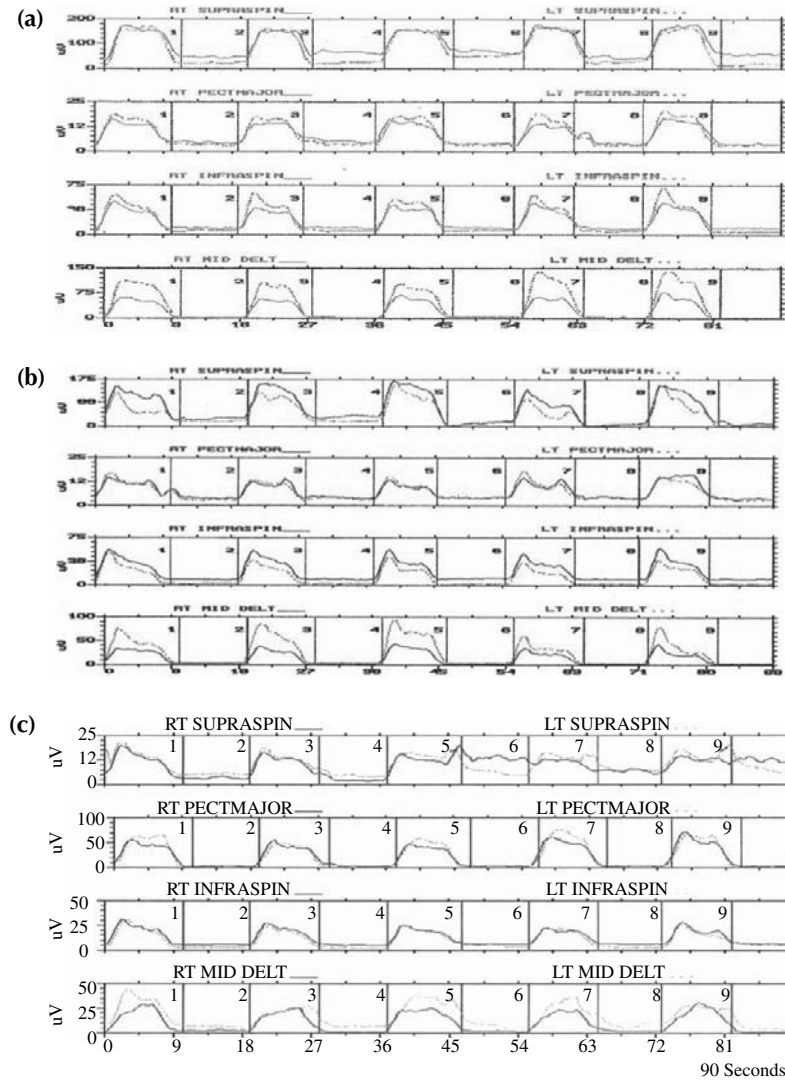
There are three versions of hypertonus: (1) the resting tonus is elevated but rather constant among the five repetitions of a given segment of motion; (2) the resting tonus tends to increase in amplitude within the space of the 90 seconds and the five repetitions of motion, i.e., "scale-up hypertonus"; and (3) the resting tonus tends to decrease in amplitude within the space of the 90 seconds and the five repetitions of motion, i.e., "scale-down hypertonus." Occasionally, it could be seen that scale-up hypertonus may become spasm and spasm may become scale-down hypertonus. Figure 45.7a illustrates the SEMG-derived definition of hypertonus. This figure illustrates at the same time two versions of hypertonus. The left supraspinatus shows a scale up of the hypertonus. The right and left pectoralis major illustrates the "constant" elevated resting


FIGURE 45.7 (a) Hypertonus: constant and scale-up versions; (b) hypertonus: scale-down version; (c) hypertonus and spasm transformation.

tonus through the motions (compare with middle deltoid) on the lower side of the figure. Figure 45.7b illustrates the scale-down version of hypertonus. The right supraspinatus shows a scale down of the hypertonus phenomenon and the five repetitions end with a normal resting tonus.

Hypertonus and spasm are thus phenomena on the same continuum. It is possible that warming up of the muscles through repeated motion improves the symptoms and the muscles tend to act more normally such as in the case of scale-down hypertonus. It is possible that repeated motions irritate the peripheral nerves and/or the muscles, which then act in a more abnormal fashion such as in scale-up hypertonus or spasm. It has been shown that either phenomenon is bound to be more particular in a given segment of motion and may change its aspect in a different segment of motion to follow. Thus, both hypertonus and spasm are functional electric dysfunctions.

Figure 45.7c illustrates the continuum between hypertonus and spasm. One may note on the supraspinatus muscle the change of the resting tonus to that compatible with spasm and then a tendency to normalize via change to hypertonus.

HYPOTONUS

From a clinical perspective, it is difficult to define the presence of hypotonus. Many a clinician will define loosely a "soft feeling" muscle or group of muscles as "hypotonic." This is a very nonspecific term as it is dependent on the ability of palpation of the clinician involved. If the person complains of pain at the time of the visit, then the "soft" muscle or group of muscles could be considered symptomatic and the "proof" of it is the softness. On the other hand, the same palpation in an individual
FIGURE 45.8 Fasciculations.

who has no complaints would not be called "hypotonus." At most, the clinician will consider the muscle or group of muscles as "deconditioned."

The complaint of pain alone may not be sufficient to consider the lack of tautness of the muscle or muscle group as dysfunctional or pathologic, especially in the forensic environment. SEMG is the only electrophysiological modality that can throw light on this problem. Muscles that are simply "soft," without the presence of any symptom, will show a normal resting tonus and an activity tonus. The SEMG-derived definition of hypotonus is that of a muscle that performs activity with a decreased amplitude, commonly below that of the database range, while in the same time the resting tonus does not return to real resting values (Sella, 2000d).

The tendency is commonly there in terms of the return to rest; however, that does not quite happen. Just as in the case of hypertonus, there are three versions of hypotonus: (1) the resting tonus is elevated but rather constant among the five repetitions of a given segment of motion; (2) the resting tonus tends to increase in amplitude within the space of the 90 seconds and the five repetitions of motion, i.e., scale-up hypotonus; (3) the resting tonus tends to decrease in amplitude within the space of the 90 seconds and the five repetitions of motion, i.e., scale-down hypotonus. Occasionally, it could be seen that scale-up hypotonus may become spasm and spasm may become scale-down hypotonus. The author has observed empirically the "transformation" of hypotonus into spasm and spasm into hypotonus, but not that of hypotonus into hypertonus, or vice versa.

FASCICULATIONS

Fasciculations are unconscious paroxystic muscular contractions, usually part of lower motor neuron pathology, but occasionally, an asymptomatic normal variant (Dumitru, 1996). Usually, only one muscle in a group shows fasciculations. Occasionally, they can recur with a certain constancy and the twitch may be visible at the surface level if the amplitude is high enough. SEMG can demonstrate fasciculations with no interference with the neuromotor plate, such as may be the case with needle EMG testing. The fasciculations seen on SEMG may be recorded according to the clinical need of the investigator. Figure 45.8 illustrates repeated fasciculations of the left levator scapulae. Fasciculations may be found more commonly in conditions of muscular irritation and pain.

Myokimia is a form of spasm. The individual cannot control the muscular tremor voluntarily. It occurs more commonly on muscles of expression innervated by the facial nerve, such as orbicularis oris (Dumitru, 1996). The myokimia may last for several minutes or even longer. It may be recorded on SEMG with no fear that the methodology may have induced it. It is more common in lower motor-neuron disease.

CO-CONTRACTIONS/CO-ACTIVATION

It has been observed clinically that when one joint (joint A) moves and the other is at rest, occasionally one muscle becomes active in the contralateral joint (joint B) at rest. The other muscles from the same myotatic unit do not show any change in amplitude from the resting tonus, thus documenting that there is no conscious or unconscious attempt at moving that joint. The contracting muscle that should be resting along with the rest of the myotatic unit is *co-contracting* (Sella, 2003b). It can be shown that most of the time when the previously resting joint (joint B) is moving through any segment of the primary ROM, no muscle on the previously moving joint (joint A). Occasionally, there is likewise a co-contracting homologous contralateral to the muscle initially noted to be co-contracting.

The usual history is that joint B has suffered from central or peripheral neuropathy, e.g., stroke or plexopathy, or a history of diffuse allodynia and hyperalgesia such as found in fibromyalgia. The hypothesis of the author is that the co-contraction takes place as a result of new internuncial associations.

Co-contraction by definition refers to a muscle contracting minimally while supposedly at rest and surrounded
FIGURE 45.9 Co-contraction of right biceps.

by other muscles from the same myotatic unit, while those other muscles show no tendency to contract. It is a situation occurring only when the homologous contralateral joint is going through the primary segmental ROM.

Figure 45.9 shows a co-contracting right biceps while the right upper limb is at rest in the neutral position and the left elbow is moving through flexion. The right upper limb or elbow exhibits no actual movement, but the right biceps shows obvious electric activity, both during elbow flexion of the left side and during rest. This is a situation found in an individual with right brachial plexopathy.

Co-activation is a situation where a contralateral muscle from a different joint (joint C) is active while supposedly at rest when the contralateral different joint (joint D) is moving. This has been observed in situations such as fibromyalgia while the patient was sitting on a chair with a back support and moving one shoulder at a time. There was no co-contraction on the homologous contralateral muscles but there was co-contraction on the contralateral hip.

This could only be explained via a hypothesis whereby the condition, i.e., fibromyalgia, associated with allodynia and hyperalgesia produced a generalized spinal disinhibition of the primitive motor associations, which allowed the co-contraction (Donaldson et al., 2001a, 2001b). The authors' hypothesis relates to the fact that the disinhibition resulted in the activation of primitive impulses of movement of the quadruped type motion, which would have required concomitant motion of one shoulder and the contralateral hip.

Figure 45.10 illustrates the point of the co-contraction. Figure 45.10a shows that when a normal, asymptomatic subject moves the shoulder (upper area of the graph) there is no co-contraction or co-activation of any other muscle. Figure 45.10b shows that in a fibromyalgia sufferer there are multiple co-activation sites, active during a shoulder contraction (Donaldson et al., 2001b).

Loss of Mirror Image

SEMG dynamic testing of the axial skeleton allows for the observation of mirror image of the muscles tested in the segments of lateral flexion or rotation. Logic would say that for the same degrees of motion, the target muscles
FIGURE 45.10 (a) Co-activation: presentation of asymptomatic subject; (b) co-activation: presentation of fibromyalgia subject. (From Donaldson, C. C. S., MacInnis, A. L., Snelling, L. S., Sella, G. E., & Mueller, H. H., 2001. *Neuro Rehabilitation*, *17*. Reprinted with permission.)

should express similar activity in the target motions (Sella, 2000d). For example, the right sterno-cleido-mastoid (SCM) should express an activity of 14.7 to 17.4 µV rms (95% upper and lower CI) in left rotation while the left SCM should express similar activity in right rotation, for the same degree of motion. That would be normal mirror image. If, on the other hand, for the same movement pattern and degree of motion, the activity range is >25% or <25% the upper or lower CI limits described above, that would define loss of mirror image. This may be important within the clinical rehabilitation context and would be even more important in the ergonomic or athletic competition context.

Contracture

By clinical definition, a muscle that loses the trophic nervous factor, such as in poliomyelitis, atrophies in time to become just a fibrous band (McAnelly & Faulkner, 1996). The SEMG aspect of such a contractured muscle would show an amplitude level ≤1 µV rms. This would be the situation both at rest and during any given passive or active activity level of the primary myotatic unit. Of course, in this situation, the clinician needs to rule out the possibility of a technical artifact before coming to the conclusion of "contracture."

SUMMARY

The soft tissue injury and pain field suffered for a long time from lack of credible, objective methodologies of

documentation. Such documentation is necessary within the clinical context where palpation or any other clinical observation could be deemed "subjective" and different from one examiner to the next. Furthermore, very few investigative modalities would be able to focus specifically on one muscle rather than a whole region.

SEMG dynamic testing allows for a much higher degree of objective documentation of various aspects of muscular dysfunction or pathology. It allows for a superior differential diagnosis of upper versus mixed or lower neuron disease, muscle tension derived from sympathetic nervous system hyperactivity, engram changes related to protective guarding or emotional shock, etc. Furthermore, SEMG dynamic studies allow for a much more objective identification of pain and pain-related parameters in soft tissue injury or disease. Moreover, the rehabilitation arm of this methodology allows for a better engram repair or reeducation and consequent improved control on muscles and movements.

Impairment and Disability Determination

Gabriel E. Sella, MD, MPH, MSc, PhD (HC)

DEFINITIONS

The field of disability medicine or forensic evaluation has a number of rules of procedure and definitions, which are functional within the field. Those definitions may differ somewhat from the dictionary definitions of certain words or principles (Garner, 1999).

By definition, *physical* or *mental impairment* refers to the following: (1) a permanent situation whereby an individual is not expected to change substantially in the physical or mental status in the targeted respect within the foreseeable 24 months without the advent of major, unexpected medical discoveries; (2) the impairment refers to the inability to perform one or more activities of daily living commonly necessary for maintaining a normal lifestyle; (3) the impairment may also refer to the inability to perform certain occupational functions, although this part of the definition does not always hold true (World Health Organization, 1980).

The definition of *disability* includes parts 1 and 2 above and will also include part 3 in administrative, legal, insurance, or occupational terms. One example illustrates the differences between impairment and disability. A right-handed surgeon may have the right index finger amputated for a traumatic reason. An amputation is by definition a permanent impairment. The impairment may not be sufficient to impede the performance of most or all activities of daily living around the house. However, the surgeon may not be able to perform any more surgeries because the function of the index finger is essential for such performance. Therefore, that surgeon may be considered permanently disabled in terms of the essential duties of his surgical profession. It is clear that he or she may teach medicine or surgery or perform office kind of

duties. However, that will not change the status of the permanent disability in terms of performance of surgery. The same impairment may be of less consequence to a medical practitioner who does not perform surgery. There is no question that the surgeon may perform quite well most activities of daily living. On the other hand, there are situations where the performance of activities of daily living are impaired and the performance of a working function may not be impaired. Therefore, it is important to consider all the factors within the perspective of any individual requesting an impairment evaluation.

Specialized physicians may perform the duties of impairment evaluation. The complexity of this performance is described summarily below for the remainder of this chapter. The final goal of the performance of an impairment evaluation is to produce a complete report, which would include the conclusions about whether the person has indeed a permanent impairment. If the person has such impairment, then, according to the legal and administrative rules of the evaluation, the specialist may have to give a quantitative assessment of the impairment.

This can be done by following the guidelines of the *Guides to the Evaluation of Permanent Impairment* of the American Medical Association or similar texts (American Medical Association, 1993; Minnesota Medical Association, 1989). This assessment is referred to as the "permanent percentage of impairment" and it is a percentage ranging between 1 and 100%. The administrative, insurance, or legal authorities use that percentage number in their calculation of the disability relative to the governing laws and regulations. Therefore, the physician participates in the process of establishing the range or limits of the *disability* by performing the *impairment* evaluation. The

rest is performed by the accredited administrative, legal, or insurance specialists.

It is common to talk about "disability"; however, in reality, the physician performs only the impairment component of the disability evaluation process.

It may be relevant at this point to describe the activities of daily living commonly evaluated by the impairment-evaluating physician in a historical perspective (LaPlante, 1991). They are as follows:

1. *Communication* — This refers to the ability of the individual to communicate with other persons. The ability to hear or speak is evaluated in a functional way. The ability to write, read, or use a computer or other keyboard may be evaluated by giving the individual a questionnaire to complete.

2. *Sensory functions* — The evaluee is examined for hearing, seeing, and speaking; indirectly or directly, the evaluee is also examined for the touch or, if necessary, for the smell or taste perception.

3. *Hand functions* — The evaluee is examined for the hand grip. As necessary, an individual is also evaluated for the ability to dress and undress or to discriminate between two points, stereognosis, etc.

4. *Physical activities* — The evaluee may have traveled independently to the examiner's office and be able to sit, stand, walk, lift a light weight, and carry the same. Or the evaluee may have traveled in a wheelchair and be unable to perform any of the above ambulation and lift/carry activities. The evaluee may be evaluated for the abilities to push, pull, climb, or perform light exercises.

5. *Travel* — The evaluee is asked about the way he or she traveled to the examiner's office, i.e., driving, being driven, etc. If necessary, one inquires about the abilities to travel by other means such as bicycling, boating, or using an airplane.

6. *Personal hygiene* — As necessary, from the personal appearance, the examiner finds out about bathing, grooming, or dressing habits. As necessary, can inquire about the ability to perform the acts related to hygiene or dressing. The examiner takes the vital signs including the weight of the person. The eating habits are inquired about. Routinely, there are questions about incontinence or constipation/diarrhea problems.

7. *Sleep* — The evaluee is asked routinely if there are any problems with sleeping or changes in the sleeping pattern. The examiner finds out if the evaluee has to take any sleeping medications.

8. *Sexual functions* — The examiner asks routinely if there are any problems with the usual sexual functions related to age, gender, or social status. Furthermore, the examiner may ask questions about sexual habits or need for medication such as Viagra or oral contraception.

9. *Social/recreational activities* — The examiner inquires if there are any changes related to the impairment under question in terms of the accomplishment of personal and family social and recreational activities.

ELEMENTS OF IMPAIRMENT EVALUATION

The Claim

The claim depends on the legal context involved. For example, a claim for similar symptoms may be valid under one type of legislation, e.g., workers' compensation, and not fall within the legal criteria of another legislation, e.g., social security disability. Therefore, at all times the word *claim* should be understood within the exact administrative or legal context to which it pertains.

In general, a claim will refer to some type of body or mental impairment whereby the individual requests a monetary compensation related to that impairment.

The Causality

In some legal perspectives, the claim does not necessarily have to fulfill the clause of *causality*. For example, in terms of social security disability claims, it is irrelevant why a claimant has a condition such as neck pain related to whiplash from a car accident. What matters is the presence of the neck pain and related symptoms and signs, with regard to the diagnostic criteria under the social security disability law. In another context, such as in accident insurance context, the issue of the whiplash and the motor vehicle accident may be quite relevant. For example, at issue may be the question of *fault*. The targeted insurance company may recognize a whiplash claim if the motor vehicle accident could be demonstrated to be caused by its insured but not if the accident was caused by the person who got the whiplash. Therefore, the validity of the claim may be the first issue under consideration. Once the claim is demonstrated to be valid, the next question is that of *causality* (Sella, 1997a). For example, in this case, the issue is the type of impact that may have caused the type of whiplash.

A back-to-front vehicular impact may be compatible with a flexion–extension whiplash but not with a lateral bending or rotation whiplash. Therefore, if the claimant presents with symptoms of lateral bending whiplash in a back-to-front (or front-to-back) collision, then causality may not be established and the claim may not be recognized. Clearly, physical or other type of causality must coincide with the symptoms and signs it produced. One

issue that needs to be addressed as early as possible is that of malingering.

The definition of *malingering* within this context is that of a physical or mental symptomatology presentation of an injury or other valid etiology, when it could be shown that the claimant was not actually present in the location and at the time of the injury (Sella, 1997b). One variant of malingering could be demonstrated to be within the context of a somatoform disorder. There are a number of psychiatric conditions that may present with symptoms of injuries that never occurred as stated. Therefore, it is important to demonstrate for the purpose of the claim that the injured or impaired party was actually present at the time and location of the injury. That is done commonly by presenting physical witnesses who saw the events of the injury and the claimant at that time. Other such "witnessing" could be offered by police officers, tape recordings, or video recordings of the injury events. Within the context of somatoform disorders, such witnessing may be provided by the clinical authorities in favor or in the disfavor of the causality presented in the claim.

There are several types of causality and the interested reader is referred to standard legal texts (Garner, 1999). While they are important to know, they are not necessarily relevant within the context of this chapter. Suffice it to say that the impairment evaluator may need to know those definitions within the working context and also within the potential expert witness context.

CHRONOLOGY OF INJURY — DESCRIPTION OF THE INJURY EVENT

A verbal report is nice; however, in legal terms it may serve only as "hearsay" because the examiner may be cross-examined in court or in deposition to prove that the series of events of the injury happened the way that he or she described in the written report (Sella, 1996c). Taking for granted that the issue of the validity of the claim has been established and that the causality has been determined, the evaluee needs to render a written statement in which the injury event is as fully described as possible. The author advises every impairment evaluator to obtain a written statement from the claimant in terms of the actual description of the events of the injury. Such a statement could be attached to the examiner's report or paraphrased. It can be used in court as documentation of the examiner in the course of one's medical/legal work. If the description is demonstrated not to be truthful or accurate, then the problem cannot be imputed to the examiner but to the claimant. Clearly, in such a case, the claimant would have broken the trust relationship and willfully misled the examiner (unless it can be documented that this occurred within the context of a somatoform disorder).

Usually, the symptomatology presented at the time of the evaluation should fit well the expected development of symptoms/signs resulting from the injury under the claim in the course of time. At times, the situation is rendered more complex and yet it could follow a direct causality pattern. Such is the case where an injury requires surgery, e.g., lumbosacral disk herniation surgery, and the scar resulting from the surgery produces further damage, chronic pain, lumbosacral radiculopathy, etc. Such a series of events may be considered legally acceptable in terms of the final impairment evaluation. However, in other cases, the symptomatic presentation cannot be fairly associated with the original injury or subsequent treatment.

The issues of symptom magnification and malingering need to be touched on again at this point. If there was an injury, one may expect a number of symptoms and signs to exist as a result of that injury. Within the reasonable knowledge and experience of medical practitioners, the intensity (and frequency) of such symptoms will have been known from the experience gathered from other patients with similar conditions. Therefore, if a claimant presents with exaggerated symptoms in spite of lack of physical signs that may corroborate such symptoms, the examiner should be alerted to the possibility of symptom magnification. The same would apply for the possibility of malingering or for that of somatoform disorders. Only a clear review of objective data, including prior medical and other documentation, may help to rule out those possibilities.

CHRONOLOGY OF THE HEALTH CARE TREATMENT RELATED TO THE INJURY UNDER THE CLAIM

By the technical nature of things, an impairment evaluator usually sees an evaluee for a final evaluation at least 6 months after the injury under the claim. This is the general rule because most symptoms following injuries would either disappear or tend to become permanent in at least that period of time. The only major exceptions would be amputations. Therefore, the evaluee has to have a chronology of diagnoses and treatment leading to the time of the impairment evaluation. Most typically, an injured person would be seen immediately after the injury in an emergency department or by the plant physician, family physician, or other such health care provider. That would be followed by a period of investigation of a few days. After the general diagnosis or diagnoses are posed, there follows a period of treatment or rehabilitation. Such a period lasts a number of weeks or even months.

Because most injuries result in soft tissue pathology or dysfunction, the physical/occupational therapy period lasts usually within a range of 3 months. After that, most persons affected by an injury will have returned to work

either in their previous line of duty or in modified duties, if there are any remnants of symptoms. A rather small percentage of persons affected by injury develop chronic pain and related symptoms. These form the bulk of cases seen by impairment evaluators.

The impairment evaluator has to review the documentation available and perform a rather comprehensive physical examination on the claimant (Sella, 1996c). The impairment evaluator does not treat the claimant and does not give medical advice, but may have to report such treatment suggestions or follow-up suggestions in the final written report.

A number of issues merit individual consideration:

1. Was the original diagnosis appropriate for the injury under claim? Were there any additional factors involved that may have affected the presence of the diagnosis? Such factors may include, for example, high habitual alcohol intake and the presence of an injury from a fall from a ladder. The question is, in this case, whether the claimant had a high alcohol level at the time of the injury which may have contributed to the actual fall. The converse would be, of course, that the injury would not have occurred if it were not for the alcohol factor.

2. Were the diagnostic investigations appropriate for the clinical presentation and were they done in a timely manner? One recurrent example, at this point, is the ever presence of the emergency room diagnosis of "sprain/strain" in cases of acute myofascial pain syndrome, in the presence of clear symptoms of trigger points, etc. The lack of appropriate diagnosis more often than not may lead to very expensive and unnecessary diagnostic procedures such as MRIs (magnetic resonance imagings) and unnecessary consults to neurosurgery and even to the practice of neurosurgery in questionable cases. The appropriate diagnosis is very important in itself and in the timeliness of it. The second point is the costly and ineffective radiologic procedures in the presence of documentation, which shows that such procedures do not usually result in useful information for the case under consideration. A case in point is that at least 30% of lumbosacral MRIs of asymptomatic adults are "positive," which represents a very large "false-positive" factor when it comes to interpreting the MRI of an injured person who presents with back pain. Many people with symptoms and such positive MRI results end up with neurosurgery only to be followed by either no change in the original symptoms or complications in time related to the presence of

scar. Many a time, an impairment evaluator has to review or even grant a percentage of permanent impairment in such cases, where no surgery was appropriate to begin with. Practically speaking, such impairment results in an addition of at least 10% more than would have been necessary for the same symptoms in the absence of surgery.

3. The next issue refers to the duration, frequency, and intensity of the treatment. Medical experience shows that most common rehabilitation treatments last 3 to 6 months, start with a frequency of three times a week, and taper off as necessary to once a week, once every 2 weeks, and then once a month for the duration. The intensity may refer to the number of treatment modalities and to the ratio of active to passive modalities. At the same time, the evaluator needs to know if an overall program of reconditioning, mainly a home program with review in the physical therapy department, was part of the overall treatment. The examiner needs to know if the factors of duration, frequency, and intensity applied as well in a proper manner to programs in alternative medicine, as these programs become more frequent in our society. In either case, appropriate objective notes from the treatment providers are very important in terms of the examination of the results of the treatment. Many times, the impairment evaluator is asked to provide an opinion about the appropriateness of the treatment program for the injury under the claim. Such objective notes are paramount for the formation of that opinion. Therefore, the clinicians involved in the treatment program would be well advised to do a quantitative analysis of their treatment results because, in many cases, they may be denied payment unless they can document the effectiveness and efficiency of their program.

4. Factitious treatment must be ruled out. An experienced examiner should know what treatment generally works for a particular injury and resulting symptoms and what treatment could be continued for a very long period of time without any documentation of improvement. It is very important to assess the effectiveness and efficiency of any given program, and alternative medicine programs cannot be an exception to this. At times, the examiner finds evidence of completely unproven treatments, alternative or not, and, of course, no positive results. The examiner needs to report such treatments and the fact that the claimant has been treated with a factitious type of treatment. The question may

arise then whether the symptoms would still be present at the time of the impairment evaluation if the injured person had been treated appropriately. Therefore, the examiner may conclude and opine for a change of venue in the treatment pattern for a given period of time, such as 2 to 3 months, with a treatment modality or combination thereof that is known to work.

5. The principle of maximal medical improvement (MMI) must be considered. According to the governing rules, the impairment evaluator has to decide whether one can grant, at a given time, a permanent percentage of impairment for a given claimant. That granting is dependent on the "MMI factor" (Sella, 1996a). In other words, permanent situations such as amputations result automatically in the MMI simply because there is no further expectation of change, for better or worse. On the other hand, a surgical treatment such as lumbosacral surgery does not result in immediate MMI. A period of rehabilitation usually follows such surgery. It is only after an adequate period of physical rehabilitation, including perhaps work reconditioning, that one could learn if the claimant is at the "plateau" point of rehabilitation where no further improvement may be expected. By definition, if no further improvement in the physical or mental status may be expected within a 24-month time from the date of the evaluation, a person may be declared to have reached the status of MMI. The only condition that the examiner may add to the reporting of the MMI is that of "barring" unexpected medical discoveries or treatments.

6. Determining the principle of permanent impairment. Once the examiner has decided that a person has not attained the status of MMI, no granting of any percentage of permanent impairment can be given. The examiner has to write in the report that the evaluee may have to return for further examination within the number of months when the MMI would have been expected to occur. On the other hand, once the examiner has decided that MMI has occurred, he or she can grant the status of "permanent impairment." Because the MMI was conditional on no change from a "plateau" state within the foreseeable 24 months from the date of the evaluation, the same applies to the granting of the percentage of permanent impairment (% PPI). At that time, the report must contain either no actual percentage of impairment if the governing law requires no such percentage (e.g., civil law) or it must contain a given numerical percentage if the governing law (e.g., workers' compensation) requires such a percentage (Sella, 1996b). In the latter case, the examiner has to obtain and calculate the given percentage from authoritative texts, which give such numerical percentages, such as the AMA *Guides to the Evaluation of Permanent Impairment*. Impairment evaluators are specialized physicians who know how to find and interpret, as well as calculate, the figures necessary for the final percentage of permanent impairment. It is clear that the impairment evaluator needs to support the data of the percentage of permanent impairment either on the report or in deposition, including that of court testimony. A whole case may falter if the impairment evaluator does not give an appropriate percentage or does not support such a percentage (Stamp et al., 1996).

CONSIDERATIONS OF TEMPORARY PARTIAL IMPAIRMENT

In a number of administrative or legal conditions, a person may be granted a "temporary partial impairment." Such conditions usually refer to workers' compensation cases, as part of the continuum leading to the final rendering of the "permanent partial impairment."

A temporary partial impairment may be granted under certain governing laws without the status of MMI and without a percentage of permanent impairment. Under such circumstances, the claimant may have some benefits in the financial sense and may not have to work until declared either free of symptoms and fit for duty or suffering from symptoms related to the injury and such symptoms would have achieved the status of MMI, would be permanent, and may be granted a percentage of permanent impairment. Usually, the temporary partial impairment lasts a number of months, and the impairment evaluator reviews each case at the end of the "temporary period."

CONSIDERATIONS OF TEMPORARY TOTAL IMPAIRMENT

The difference between "partial" and "total" impairment is that of a degree of physical and/or mental dysfunction related to a claim. The actual percentage numbers, which distinguish "total" from "partial," are relative and may vary among different legislations. Suffice it to say that, if an evaluator considers that a person may be granted 75 to 80% PPI or more if the temporary period were to become permanent, that would be compatible with the definition of the word "total." Any percentage below that of the legally accepted definition of "total" would be considered "partial."

A clear example would be a person with an occupational respiratory impairment of Class II (10 to 25%) versus one affected by a Class IV (50 to 100%), calculated to have impaired pulmonary function tests in the range of >80% (AMA, 1993). If, in either case, the pulmonary condition should resolve, the person affected would not be given any particular percentage of impairment in terms of its permanency. Clinically, it would be quite unlikely that this would be the case in the situation of a person with a Class IV impairment and, although the examiner would grant a "temporary" status for a determined period of rehabilitation, e.g., 6 months until the final evaluation, it would be expected that a certain percentage of permanent impairment would be granted at the end of that period.

CONSIDERATIONS OF PERMANENT PARTIAL IMPAIRMENT

Most injured persons who reach MMI can be considered for the purpose of granting a permanent partial (%PPI) or total (%PTI) impairment percentage. In most cases, the injured party may be granted a permanent partial percentage of impairment. This percentage represents what is legally acceptable to grant based on authoritative texts such as the AMA *Guides to the Evaluation of Permanent Impairment*. One must stress at this point that the expression "Guides" refers exactly to what it states.

The textbook is a major compendium based on consensus of opinion and agreement of several medical societies and authorities. It is mostly based on consensus and minimally based on scientific studies of the highest credibility. However, it is the best that the medicolegal and forensic community has at the present time. The fact that the text has undergone five editions and the sixth is on its way shows that the AMA committees are working hard at ever improving the way that one can grant such a percentage of permanent impairment.

The AMA *Guides* is not the only authoritative text on the subject; several states or legal authorities use other texts of a rather similar nature. In general, most U.S. state legislations have adopted the AMA *Guides* to be the basis for granting percentages of partial or total permanent impairment as if the "guides" have become "written in stone." At times, the impairment evaluator has the opportunity to explain, during a deposition or court testimony, that the AMA *Guides* or such other authoritative text means to provide guidelines only, not precise numbers that have to be utilized at all times. Even though that is the case, the legislatures took the concept of "guidelines" and transformed it into a legal obligation (Sella, 1998).

What is the procedure of granting the percentage of partial permanent impairment? As described above, the impairment evaluator has to decide first of all the actual merit of a case. If the decision is positive, then the evaluator

has to decide whether the case has reached the state of MMI. Only when that status has been reached, could one grant a percentage according to the rules in the case. If the person has an injury that could be granted a %PPI deriving from only one source of data from the AMA *Guides* or such other text, then the evaluator has to cite that in the report. To give a simple example, if the person suffered from a lumbosacral impairment compatible with the description of "DRE lumbo-sacral category II: Minor impairment," then the evaluator could grant 5% PPI and state that this was based on the AMA *Guides to the Evaluation of Permanent Impairment*, 4th edition, Chapter 3, Paragraph 3.3g, p. 102. If, on the other hand, the decision is that the %PPI to be granted is to be based on more than one source of impairment data, then the total would be composed either from the addition of the two percentages of PPI if the sum total would be ≤14% PPI or from the combination of such numbers resulting in a PPI ≤ 15% PPI, according to the AMA *Guides*. An example in point would be as follows: A person who had disk surgery at C6 followed by loss of cervical range of motion (ROM), and documented pain and rigidity could be granted 9% PPI according to Table 75, p. 113 of the *Guides* as well as 4% for loss of motion in right rotation and 4% for loss of motion for left rotation. In this case, the first two percentages are added up, i.e., 9% + 4% = 13%. Then 13% is combined with 4%, according to the rules of the Combined Values Chart on p. 322 of the AMA *Guides,* and the resulting combination is 16%. How can that be explained when in reality, the addition of 13% + 4% = 17%? The explanation is quite simple and clear. The person already has 13% whole-body permanent percentage impairment before the last addition or combination. Therefore, the addition/combination of the last 4% is really to the body, which is only at 87% whole capacity. That, combined with the last 4%, comes out to 16% rather than 17%. If a new permanent percentage is to be "added," the combination would take into consideration the fact the body is now at only 84% of the original whole-body full capacity.

For a better and clearer understanding of the issue, an abstract example would be a first permanent impairment percentage of 10%. Therefore, if a second permanent impairment of 10% should occur at a later time, the second impairment would come from 100% – 10% = 90% and would actually count as 10% of 90%, i.e., 9%. The same would apply to any later percentage. Otherwise, if this type of calculation were not done, a successive number of impairments could total more than 100%, which would be impossible.

CONSIDERATIONS OF PERMANENT TOTAL IMPAIRMENT

In theory, a person would be granted "total permanent" impairment only upon a condition such as permanent

coma or complete paralysis. In reality, this is rarely the case. Most workers' compensation legislatures and other such legal bodies define total impairment as 80 ± 5% permanent impairment. That percentage is reached by calculating the pertaining figures in the same way as was described above for the calculation of partial permanent impairment. If the target is attained for the pertinent legislature definition of permanent total impairment, then that can be granted as such. It should be clear that a person receiving a *total permanent impairment percentage* cannot do any kind of activity of daily living, and certainly not any kind of occupational activity. This applies to a number of major organs damage such as advanced chronic obstructive pulmonary disease (COPD), most severe CHF, major paresis, Meniere's disease, etc.

While it is technically possible to review a case granted a permanent partial percentage of impairment after a number of years and be enabled to increase or decrease the original percentage, this is rarely the case with persons who have been granted a total percentage of permanent impairment. The only difference that may apply is that if the percentage of permanent impairment is, say, 80% in one state legislature and the person moves to another state where the definition for total permanent impairment is 85%, that would induce the legal issue regarding which definition should apply to the case. In either situation, however, the impairment evaluator would still find basically the same total percentage.

THE "PAIN" FACTOR IN INJURY

The first principle to be applied in this context is that the pain should be of a chronic and permanent nature under the applicable definition (AMA, 1993). The impairment evaluator will need to take into consideration the injury, its causality, and the presence of pain within the overall symptoms and signs of the issue under claim. The evaluator will also need to consider the chronology of the treatment, especially focusing on specific treatment to alleviate pain and the appropriateness and results of such treatment. It is relevant to document whether the pain factor increased or decreased within the context of the history of the injury and whether the pain has increased in terms of becoming part of a secondary set of symptoms within the context of "chronic pain syndrome." If the latter is the case, then the presence and intensity/frequency of the pain needs to be interpreted within the context of the overall psychiatric evaluation and treatment for the depression component of the chronic pain syndrome. Of course, depending on the legal context, the evolution and presence of the chronic pain syndrome may have to be accepted within the legal framework of the claim. If it is not, although that does not exclude its presence, the evaluator needs to note it as such.

If pain is to be considered in terms of granting a PPI, a number of considerations apply. The first involves a holistic approach. The examiner needs to define the pain of the individual within a number of biological and psychosocial parameters (Sella & Donaldson, 1996). These parameters include the physical context of the injury, the social context involving the claimant and his or her family, the economic context, including factors such as the economic contribution to the family of the claimant before the injury and at them time of the evaluation, the mental status prior to the injury and at the time of the evaluation; and eventually, the spiritual context of the individual with pain within the family and within the community.

If pain is present within the framework of "chronic pain syndrome," then the eight defining factors of this syndrome need to be considered in terms of presence, intensity, and frequency. Those factors refer to the substance dependence and/or abuse, psychological dependence of the claimant on the health care system, the presence of depression/anxiety, the number of contextual diagnoses, the duration of the injury period, and the aspect of dramatization of the pain symptom, as well as factors such as physical deconditioning and physical and mental dysfunction (AMA, 1993).

Should pain be granted its own percentage? That is a question referred to time and again by impairment evaluators when the pain appears more as an autonomous factor rather than a clear and focused component of a particular symptom. The AMA *Guides* 5th edition tries to relate to this question from a slightly different perspective than that of previous guides. In fact, every edition of the text has considered this subject slightly differently. This shows that the complexity of this matter has not been resolved to date.

The author opines in favor of granting specific permanent percentage of impairment for the presence of pain, where such impairment cannot be fit directly and properly within the context of any particular permanent symptom/sign that is considered for granting a particular percentage of permanent impairment. In the author's opinion, the pain percentage would be granted after due consideration of the grid of the usual activities of daily living (ADL), in the format shown in Table 46.1. This format contains two components: (1) the manner in which any ADL component is impeded by the presence of pain and (2) the manner in which the performance of any ADL component affects the intensity/frequency of the pain.

Any item would be considered within 100% for each category of ADL. The total percentage for the involvement of the pain factor in terms of intensity/frequency would be 30% partial permanent impairment. The actual calculations are described in an earlier text (Sella, 1999).

As such, when the presence of pain is relevant as a chronic and permanent factor, not expected to change in

frequency or intensity within the foreseeable 24 months, it should be granted its own percentage rather than trying to fit it as a "square peg in a round hole."

This would fit quite well in cases of malignant pain such as in cancer or in failed back syndrome. Society as a whole and the legal/insurance/administrative authorities have to change their mentality and accept in some cases, where they are well-defined, the presence of permanent chronic pain in a given claim. Of course, the intensity/frequency of the pain and its involvement in the ADL such as shown in Table 46.1 may change in time and should be reevaluated at appropriate intervals within the context of reevaluation of any given claim.

The Biopsychosocial Perspective: Psychiatric Disorders and Related Issues in Pain Management

Raphael J. Leo, MD, FAPM

INTRODUCTION: THE BIOPSYCHOSOCIAL PERSPECTIVE

For psychiatrists and mental health practitioners, the contemporary view of pain adopts a biopsychosocial perspective. In this model, the experience of pain and the patient's presentation and response to treatment are determined by the interaction of biological, psychological, and social/environmental derivatives. There is no dichotomizing between physical versus psychological origins. Rather, the experience of pain and the response to treatment can be influenced by the patient's psychological makeup, the presence of psychological comorbidities, and the extent of social support and extenuating environmental circumstances (Leo, 2003). The array of variables exerting an impact on the patient with pain can exceed the capabilities of sole pain practitioner. Hence, a multidisciplinary treatment approach is advocated (Gallagher, 1999).

Patients with chronic, enduring, frequently recurring, or unremitting pain can report a number of psychological experiences. For many, there is the experience of emotional roller coasters, with hopes for relief dashed by unsuccessful treatment endeavors or only transient relief. They may experience significant losses, e.g., loss of work with resultant loss of income and health insurance. There may be a greater dependency on others and a loss of a sense of self-efficacy, and perhaps even a loss of their customary level of autonomy. There may be a reduction in capacity to maintain their level of activity. Patients may

have less physical energy and emotional reserve to invest in others, and their ability to pursue and maintain relationships may diminish. Other relationships, e.g., those within the home, may require modification as a result of the limitations imposed on the life of the patient with pain. This may lead to increased levels of stress within the home and contribute to strained relationships. Patients may experience guilt for their inability to overcome or master their pain.

While any of the aforementioned psychological and social factors may seem plausible and even intuitive, the pain practitioner must also bear in mind that there are several psychiatric comorbidities that can accompany pain. If present, it is prudent to enlist the support of psychiatric and other mental health practitioners into the comprehensive treatment of the patient with pain.

PSYCHIATRIC COMORBIDITIES

A comorbidity refers to a coexisting disorder that can accompany an index disease or illness (Feinstein, 1970). Common psychiatric comorbidities arising among patients with chronic pain (Fishbain, 1999a; Katon, Egan, & Miller, 1985; Koenig & Clark, 1996) include those listed in Table 47.1. Such psychiatric disorders are likely to contribute to the experience of pain, influencing prognosis and long-term outcome. It is important to remember that the presence of a comorbid psychiatric

TABLE 47.1
Common Psychiatry Comorbidities Accompanying Pain

Disorder	Percent (%) of Occurrence in Various Series
Depression	30–54[a]
Substance abuse/dependence	2–34[b]
Somatoform disorders	16–53[c]
Anxiety disorders	1–62.5[d]

[a] Banks & Kerns, 1996.

[c] Dworkin & Caligor, 1988.
[d] Fishbain et al., 1986.

disorder does not render a patient's pain complaints less credible. Identification of psychiatric comorbidities can influence the selection of, and response to, treatment for the index condition. The rates of psychiatric disorders vary among various studies due to the diversity in patients with chronic pain examined; estimates vary depending upon whether one examines patients in clinic or community samples (Chapman, 1986; Crook, 1986; Crook, Weir, & Tunks, 1989; King & Strain, 1989). The psychiatric diagnostic criteria employed may also vary across the studies. In addition, diagnostic techniques employed in the studies were diverse; e.g., some employed diagnostic interviews, while others employed pencil-and-paper assessments.

MOOD DISORDERS

Most healthy individuals experience a wide range of emotional states and feel as though they have a repertoire of skills to deal with life situations and moods. Disturbances of mood, e.g., depression or anxiety, refer to clinical entities that by virtue of their duration and intensity, are sufficiently severe to adversely influence one's functioning. The mood is so overwhelming that one often feels no control over it. The prevailing mood colors one's existence, limiting the individual's capacity for pursuing interests, pleasure, relationships, work, or other achievements, or maintaining self-care.

The experience of pain is associated with a number of distressing life consequences that are likely to precipitate and exacerbate emotional distress. Patients with chronic pain are often plagued with distress, experiencing unpleasant changes in lifestyle and loss of rewarding activities and interpersonal reinforcement. It would be a fallacy to ascribe the depression and/or anxiety to such circumstances. The potential pitfall is that clinicians might assume the depression and/or anxiety is expected given the pain, overlooking potentially treatable disorders.

Emerging evidence suggests that mood disorders and pain share common physiological substrates. First, mood disturbances (i.e., depression and anxiety) and pain modulation involve common central nervous system (CNS) neurotransmitter systems (Blier & Abbott, 2001; Cross, 1994; Fields & Basbaum, 1999; Nelson, 1999), i.e., norepinephrine (NE) and serotonin (5-HT). The relationship between pain and mood disturbances might simultaneously involve disruptions in the NE and 5-HT neurotransmission.

Second, substance P, a neurotransmitter essential to pain processing and transmission from the periphery (Doyle & Hunt, 1999), has likewise been implicated to have a role in depression and anxiety. Recent evidence has suggested that substance P is abundantly present in limbic system structures, i.e., the repository of emotions within the CNS (Santarelli & Saxe, 2003). Increased activity of substance P centrally may contribute to the experience and expression of emotional distress, e.g., depression and fear. Current efforts are being directed at treating depression and anxiety through the development of centrally acting substance P antagonists (Rupniak & Kramer, 1999).

Third, the opioid system is intimately linked with the development of emotions. Measures of μ opioid receptor binding within the limbic system, as measured in positron emission tomography, revealed that dynamic changes occur in the activity of the μ opioid receptor system during various emotional states. Deactivation of μ opioid neurotransmission has been observed to occur during periods of sadness, presumably reflecting generalized states of dysphoria (Zubieta et al., 2003).

While further clarification is required, the physiological factors that subserve both pain and mood disorders may account for the high co-occurrence rates between them. It is necessary, therefore, to inquire into, accurately diagnose, and treat comorbid mood disorders occurring in the context of pain.

DEPRESSION

Among patients with chronic pain, depression prevalence rates are much higher than in the general population (Banks & Kerns, 1996; Gamsa, 1990). Patients with medical illnesses of sustained duration, e.g., chronic back pain and migraine, were twice as likely to develop major depression than individuals without long-term medical illnesses (Patten, 2001; Sullivan et al., 1992). Therefore, one should keep a high index of suspicion of the possibility of concurrent depression among patients with chronic pain (Ohayon & Schatzberg, 2001). The causal relationships between depression and pain are unclear. Depression may develop as a consequence of pain (Gamsa, 1990) or medical treatment (Massie & Holland, 1990), e.g., from medication use such as opiate use, baclofen use, and treatment

with other medications (Browning, 1996; Sommer & Petrides, 1992). Alternatively, depression may precede the pain and may be related to the maintenance of pain. The biopsychosocial approach recognizes that the relationship between pain and emotional disturbances, e.g., depression, is likely to be reciprocal. Depressed patients tend to focus on several somatic complaints and concerns. Almost 60% of patients with depression report pain symptoms (Magni, Schifano, & DeLeo, 1985; Von Knorring et al., 1983). A number of studies demonstrate that the severity of depressive symptoms predicted the number and severity of pain complaints (Dworkin, von Korff, & LeResche, 1990; Faucett, 1994; Hotopf et al., 1998), but these improve once the depression is successfully treated. Conversely, patients with pain with comorbid depression tend to rate their pain severity higher than those without comorbid depression, a phenomenon referred to as pain scale augmentation (Gamsa, 1990).

Clinical depression is a pervasive sense of sadness, tearfulness, or dysphoria that colors one's existence, with a restricted range in the affective states of the individual. Major depressive disorder is associated with significant dysphoria or sadness, for a minimum of 2 weeks in duration, but often longer. The tearfulness and sadness influences all aspects of life, incapacitating patients from engaging in usual role responsibilities, interfering with academic and occupational functioning. Patients are incapable of taking in any comfort or relief. There may be a commensurate reduction in their ability to take in pleasure, notable as a decline in their pursuit of interests, hobbies, and normally rewarding relationships. Patients may experience a number of symptoms, including sleep disturbances (either too much or insomnia) and appetite changes (either too much leading to significant weight gain or too little intake leading to significant weight loss). The individual may experience energy changes with commensurate fatigue, a sense of restlessness or conversely retardation of activity, and indecisiveness and poor concentration. This can manifest as an inability of the patient to attend to and adhere to prescribed and proscribed treatment measures to treat the pain. Afflicted individuals may report preoccupations with guilt, or an intense focus on their worthlessness, and preoccupations with death and dying, or suicidal ideation (American Psychiatric Association [APA], 2000).

The presence of a depressive disorder can influence one's view of life circumstances, health, and long-term prognosis. Expectations can be jaded by the presence of a depressive disorder, leading individuals to "expect the worst" and view the outlook as bleak, and predisposing them to hopelessness. The depressed patient might conclude that participation in any rehabilitative efforts is futile. The patient might, therefore, be prone to helplessness and passivity, self-blaming, and other self-defeating tendencies, along with a tendency to abdicate responsibil-

ity for self-care, rehabilitation, and recovery. It is essential, therefore, that we consider the depression a serious medical condition that warrants treatment (Leo, 2003).

ANXIETY

Anxiety is also commonly associated with acute and chronic pain states, encompassing a number of distressing symptoms. Anxious people are likely to report apprehension and worry, chest palpitations, chest tightness, dyspnea, chest discomfort or throat closing off, feeling faint, tremulousness, restlessness, muscle tension, a sense of impending doom, a sense that they will not survive or will die, a sense of separation from their body, paresthesias, hot flashes, and cold chills. Such symptoms can be quite distressing, and without a particular means of alleviating these symptoms, patients might be inclined to seek out medical attention, fearing that there is something seriously wrong (Dworkin & Caligor, 1988).

When confronting stressful situations (e.g., taking an exam, encountering an unfamiliar barking dog, racing to avoid being late for an important meeting), it is appropriate for one to experience a heightened sense of arousal. The activity of the autonomic nervous system stimulates one's inclinations for fight-or-flight, serving to mobilize one's defenses to face challenges, forestall danger, and alleviate distress.

On the other hand, pathological anxiety can take on a life of its own, whereby one not only experiences bouts of severe anxiety and distress but becomes apprehensive about the possibility of recurrences. Patients may experience new worries and new reasons to experience fear. Pathological anxiety can become so incapacitating that it interferes with their ability to think, reason, concentrate, and accurately perceive the significance of events.

Anxiety, similar to depression, is associated with an increased incidence of somatic symptoms and may augment pain perception (Beidel, Christ, & Long, 1991). Preoperative anxiety can predict postoperative pain ratings and severity (Thomas et al., 1998), and anxiety may be a powerful predictor of pain ratings among patients with various forms of arthritis (Smith & Zautra, 2003). Anxiety may be related to fears of engaging in activities that precipitate pain. As a result, the patient may be inclined to avoid activity, physical therapy, and even basic self-care activities. This may have the net effect of leading to muscle wasting, deconditioning, and physical weakness with reduced physical endurance, compromising rehabilitative measures (Leo, 2003).

There are a number of anxiety disorders that can accompany chronic pain. Among these, the clinician is apt to encounter:

- Post-Traumatic Stress Disorder — Persistent anxiety associated with intrusive recollections

and reexperiencing of a traumatic event, e.g., motor vehicle accidents, work-related accidents, etc. Often, the experience of anxiety can be precipitated by reminders of the traumatic event, may result in a generalized state of heightened arousal and irritability, with poor sleep and concentration difficulties (McFarlane, 1986).

- Generalized Anxiety Disorder — Relentless apprehension regarding the potential outcomes of events, life circumstances, and the future (often about matters that do not warrant that degree of worry), associated with experience muscle tension, fatigue, sleep disturbances, and irritability. Patients may appear restless, tense, vigilant, and scanning (a watchful feeling and hyperarousal). Patients have difficulty controlling the worry, will often even recognize that it is excessive, but feel an inability to distract themselves from it (Banks & Kerns, 1996).

- Existential Anxiety — Patients with painful terminal disorders may experience anxiety related to end-of-life issues, unachieved aspirations, and failure to leave a legacy. They may come to question the meaning of their life and then question whether their life has been productive and worthwhile (Leo, 2003).

Treatment of Mood Disorders Accompanying Pain

The clinical symptoms of depression and/or anxiety require recognition, accurate diagnosis, and expedient treatment. Psychiatric consultation may be helpful when there is doubt about the patient's clinical presentation and when there are uncertainties about treatment approaches.

There is an array of options from which to select treatment for comorbid anxiety and/or depression. A number of antidepressants have efficacy in treating both anxiety and depression. Selection of an anxiolytic and/or antidepressant agent can be based on a number of factors, including response of the individual (or a member of the individual's family) to prior antidepressant therapy, the tolerability of side effects, concerns related to potential interactions with concurrently administered medications, and medication cost.

In addition, a number of antidepressants can be effective in treating pain. To simplify the medication regimen, it may be prudent to select from among those agents that can treat both pain and the underlying mood disorder. Some antidepressants are thought to have a pain-mitigating effect due to their influence on NE and 5-HT neurotransmission of the supraspinal modulatory systems influencing dorsal horn pain transmission. It is possible that antidepressants that influence both neurotransmitters may have an advantage over those antidepressants exerting influences over a single neurotransmitter system (Max et

al., 1992; Sindrup & Jensen, 1999). Thus, tricyclic antidepressants such as amitriptyline and imipramine, venlafaxine, and a new agent, duloxetine, may hold particular promise in this regard while antidepressants with predominantly NE effects such as despiramine or those with predominantly 5-HT effects such as fluoxetine, citalopram, or sertraline may have less efficacy in pain mitigation (Leo, 2003; Max et al., 1992; Sussman, 2003).

Other ways in which antidepressants can influence pain is by influencing opiate activity (Schreiber, Bleich, & Pick, 2002) and by potentiation of opioid analgesia (Ventafridda et al., 1990). Venlafaxine and mirtazapine have been found to influence μ and κ opioid receptors, in addition to their influences on monamine neurotransmission essential for treatment of depression (Schreiber et al., 2002).

Sometimes the side effects associated with some of these agents can be particularly difficult for patients to tolerate, e.g., anticholinergic side effects associated with some of the tricyclic antidepressants. As such, consideration of alternative agents might need to be explored based on the monitoring of the tolerability of the agents employed. On the other hand, selection of an antidepressant might be based on certain of the side effects, e.g., for patients with insomnia selection of a sedating antidepressant might help to eradicate the dysphoria as well as facilitate sleep.

The influence on mood of antidepressants might not be appreciated for as long as 4 to 6 weeks after initiation and dose optimization. However, the effect on pain can occur much more rapidly. Failure to achieve antidepressant and/or anxiolytic efficacy might warrant psychiatric consultation and evaluation.

Psychotherapeutic approaches might be simultaneously invoked to help patients achieve an understanding of the illness, development of more effective coping strategies, mobilization of their social support network, and modifications in their cognitive appraisals and life view that may have become distorted and disturbed by the prevailing depression. Psychotherapeutic endeavors may exceed the purview and skills available to the pain management clinician. As such, referrals to a mental health specialist, e.g., psychiatrist, psychologist, or social worker, with skills in psychotherapy may be helpful in mitigating some of the sequelae of depressive disorders.

SOMATOFORM DISORDERS

Somatic concerns, including a variety of pain states, bowel disturbances, dizziness, palpitations, fatigue, and respiratory symptoms, account for approximately half of outpatient physician visits. Most of these remit spontaneously or respond to simple treatment interventions; however, as many as one fourth of these symptoms remain chronic.

TABLE 47.2
Common Pain Complaints

Source of Pain Complaint	Estimated No. of Outpatient Medical Visits Annually (in Millions)
Back	19.8
Knee	9.8
Abdominal	12.3
Headache	9.6
Chest	8.4
Neck	8.1
Nonspecific	3.2

Note: Adapted from Schappert, 1992.

As many as one third of symptoms remain medically unexplained (Kroenke, 2003; Kroenke & Mangelsdorff, 1989; Kroenke & Price, 1993; Marple et al., 1997). Pain complaints of a variety of sorts are likely to be the basis for patient presentations to ambulatory medical settings (Schappert, 1992; see Table 47.2).

Clinicians may be apt to question the veracity of the patient's pain when the complaints appear disproportionate to the nature of the pathology of a given disease or the complaints of most others with comparable disease states. Psychological factors are often invoked when complaints persist beyond the expected course of the illness or despite customarily reasonable treatment endeavors. Such complaints are often deemed to be psychogenic or "all in one's head." The reality is, there can be quite a range of diversity in the pattern and experience of pain and distress in response to medical conditions.

A number of psychiatric disorders have long been recognized in which physical complaints, including pain, are the predominant focus, which cannot be reasonably accounted for by a medical condition or disease. Such disorders, broadly categorized under the rubric of somatoform disorders (APA, 2000), can include the following:

- Hypochondriasis is characterized by preoccupations with fears of having a dreaded medical condition, based on the misinterpretation of bodily sensations. The disturbance is a cognitive one, whereby individuals misconstrue the significance of a common, perhaps normal, sensation, e.g., a momentary twinge in the shoulder is believed to signal myocardial disease. Such individuals are characterized by a conviction that they are ill and will seek out medical consultation and diagnostic tests to confirm the suspicion that they are, indeed, ill. Medical reassurances are not well received; the patient is likely to become persistent, perhaps seeking

out other medical evaluations and consultation with specialists, to affirm the suspected disease.
- Somatization disorder involves distortions in physical sensations. Patients seek out medical attention for multiple unexplained symptoms, several of which are pain symptoms, gastrointestinal symptoms, genitourinary symptoms, and even pseudo-neurological symptoms.
- Pain disorder is characterized as a condition in which psychological factors are thought to contribute to the patient's subjective experience of pain by exacerbating the level of pain, maintaining the pain, precipitating bouts of pain, and aggravating it. Currently, there is no stipulation that the pain cannot be accounted for by a general medical condition. However, it is accepted that even pain conditions may not be fully accounted for by our current knowledge of physical conditions.

Generally speaking, patients with somatoform disorders present with bodily preoccupations and concerns, often with vague, sweeping, and confusing features. They frequently and persistently seek out physician evaluations, laboratory, and other diagnostic investigations, and frequently perceive themselves as chronically ill (Barsky, 1996). However, despite the seeming similarity between alleged symptoms and medical symptoms, there is little or no evidence to support a medical diagnosis. It should be borne in mind that any of these conditions can co-occur with medical conditions and chronic pain disorders.

There are controversies about the utility of the psychiatric diagnostic criteria of somatoform disorders (Mayou, Levenson, & Sharpe, 2003). The biggest of these is the contention that the classification of somatoform disorders perpetuates the outmoded dualistic definitions of disease couched in physical versus psychological origins. Another criticism is that the taxonomy outlined by the *Diagnostic and Statistical Manual of Mental Disorders-IV* (DSM-IV; APA, 2000) really is only understood and employed by psychiatrists, i.e., is not widely understood or acceptable. Primary care clinicians may address the same sorts of symptoms and disturbances by employing medical taxonomies, e.g., labeling a constellation of symptoms or syndromes as fibromyalgia, irritable bowel syndrome, multiple chemical sensitivities, or chronic fatigue syndrome.

Even within psychiatry, there are alternative viewpoints of how to conceptualize somatic preoccupations (DeGucht & Fischler, 2002). For example, a broad concept of somatizing is sometimes referred to in the literature, whereby patients with mood disturbances present with preoccupations about physical symptoms. In such conceptualizations, there is less emphasis placed on characterization of the number and type of symptoms as defined in

the DSM-IV, but rather an emphasis on the "function" that the somatic preoccupations serve. For some patients, there may be a vested interest in presenting the worst of their plight. In this way, they may be apt to convince the clinician of the seriousness of the complaints and the legitimacy of their disorder. For some patients, there is much to be gained by focusing on somatic complaints, e.g., to avoid unpleasant tasks, to achieve secondary gains (e.g., compensation, disability payments), to avoid family conflicts (e.g., by diverting attention away from more pressing issues), to communicate displeasure with others in their life (Ford, 1986).

Nonetheless, patients with somatoform disorders and/or manifesting functional somatization can become quite focused on their ailments, to the point of compromising most aspects of their lives, their relationships, and adaptive functioning. Regardless of whether one construes such conditions as predominantly psychological or an as yet unexplained physical phenomenon, psychological treatment may be warranted. Otherwise, the physician may erroneously be caught up in the endless and futile attempts to provide patients with relief from their symptoms, rather than attempting to address adaptation to the physical concerns and the psychological factors underlying the somatic concerns (Barsky, Geringer, & Wood, 1988). Psychological interventions may be particularly helpful in assisting patients to develop strategies with which to take control of many aspects of their lives that had been subterfuged to the focus on somatic concerns, fears, and preoccupations with disability. Psychiatric treatment would attempt to assess and address the impact of the somatic complaints on patients' ability to sustain work, experience pleasure, and improve the quality of interpersonal relationships.

SUBSTANCE ABUSE AND DEPENDENCE

Many clinicians still have a tendency to underutilize opiate analgesics for their patients with pain. For many, this is driven by concerns related to the federal regulation of opiate analgesics and concomitant fears of prescribing agents that will be abused, misappropriated, or diverted (Potter et al., 2001).

Such apprehensions have been fueled by media attention and legal pursuits. In recent years, a great deal of attention has been directed to the abuse and diversion of opiate analgesics, e.g., OxyContin SR abuse (Baumrucker, 2001; Tough, 2001). When crushed, so that its analgesic and euphoric effects become immediate, OxyContin SR has been ingested intranasally or injected intravenously to produce euphoria. As a result, acquisition and illegal distribution of OxyContin SR has become an epidemic in some parts of the country. Clinicians have also been implicated in legal suits related to the emergence of drug dependence from the prescription of analgesic agents (Albert, 2002).

While opiates have been a focus of media attention, there are several other agents used in the armamentarium of pain treatment that are likewise prone to abuse and dependence. These can include the muscle relaxant carisoprodol (Soma®), which, when metabolized, is converted to methocarbamol, a barbiturate-like substance with sedative qualities; ketamine; ergot alkaloids and barbiturates employed in migraine treatment; and benzodiazepines, employed in patients with pain to address insomnia and muscle tension.

Consequently, clinicians may be reluctant to employ optimal analgesia in their patients with pain, especially for patients with chronic, nonmalignant pain. While there are anecdotal experiences with patients abusing the doctor–patient relationship to acquire analgesics for purposes of abuse, the literature has been lacking with regard to accurate estimates of the degree to which such patterns of behavior occur. Estimates of substance abuse and dependence among patients with chronic pain have varied in the literature (see Table 47.1). The difficulty in interpreting such varied results is related to how dependence/addiction was defined; i.e., varying rates of addiction were reported depending on the criteria employed to classify abuse and addictive behaviors (Fishbain, Rosomoff, & Rosomoff, 1992).

According to the DSM-IV, substance dependence has been defined by physiological and psychological symptoms. Physiological symptoms of dependence include tolerance (higher amounts of a substance are required to produce the same effects that previously lower amounts had achieved) and withdrawal (symptoms emerge with abrupt cessation of use) (APA, 2000). Some clinicians erroneously rely on such physiological parameters to define addiction. However, the presence of tolerance and dependence alone does not constitute addiction. For example, any patient with chronic pain who has received an opiate analgesic for an extended period of time is likely to experience a diminution of the analgesic effect over time, requiring higher doses of the analgesic (i.e., tolerance) and can experience withdrawal symptoms upon abrupt cessation of the use of the analgesic. Such physiological reactions to long-standing analgesic use do not necessarily constitute addiction.

Instead, for patients with pain, the presence of psychological symptoms of dependence, suggesting a lack of control over the use of the substance, may be better indicators of dependence (APA, 2000; Miotto et al., 1996; Portenoy, 1996). Dependence is suggested when the individual's use of the substance not only has become excessive, but has taken on a life of its own. The individual may experience craving of the substance and the person's activities become centered on acquiring more of the substance, using it (oftentimes to feel "normal"), and recovering from

misuse. The individual may resort to extreme measures to acquire the substance, even though such activities can incur significant legal and health consequences (e.g., prescription drug forgery, prostitution, drug trafficking). The addicted individual may persist in his or her use of the substance despite deleterious effects. For example, the person's capabilities at functioning socially, taking interest in normally pleasurable activities and interpersonal exchanges might suffer as a result of the attempt to acquire and use substances. Similarly, the person's basic self-care, as well as pursuit of adaptive academic and occupational endeavors may suffer as a result.

In such cases, patients may require formal detoxification from the agents to which they are addicted. Inpatient treatment may be required in those situations in which safe detoxification on an outpatient basis may be too uncomfortable or unsafe, e.g., in situations in which severe physical sequelae can arise from too abrupt a discontinuation of the substance, as would be the case for opiates, benzodiazepines, and barbiturates.

The patient with pain who simultaneously has ongoing alcohol or illicit substance abuse (or a prior history) can pose significant treatment challenges. Addiction to such agents can compromise functioning and full participation in the rehabilitation process. While effective pain management should never be withheld because of an abuse/addiction history, effective treatment may require use of an array of pain-reducing approaches, e.g., use of adjunctive agents, agents with low abuse potential, physical and psychological therapies, as well as participation in concurrent substance abuse treatment programs (Leo, 2003).

Inpatient detoxification may be indicated for alcohol and selected illicit substance dependence, especially those with significant withdrawal symptoms upon cessation of use. Outpatient treatment is likely to be required to facilitate maintaining health, reducing health risk behaviors, and maintaining abstinence from illicit substances. Psychological interventions, along with prudent psychopharmacologic interventions may be warranted especially when patients abuse substances as a means of controlling psychological distress, e.g., cannabis and/or benzodiazepine abuse to alleviate anxiety.

PAIN AND SUICIDE

The impact of painful conditions and psychiatric comorbidities can be so compromising that patients may despair. Suicide risk is increased among persons with medical illnesses (Druss & Pincus, 2000) and, therefore, warrants clinical attention and intervention. Medical disorders associated with increased risk of suicide include terminal illnesses (e.g., cancer and AIDS), heart disease, renal failure (especially for those on dialysis), CNS disorders, and chronic inflammatory conditions (Work Group, 2003).

Furthermore, the risk of suicide is increased among those persons with medical illnesses in which there is distress over disfigurement (Work Group, 2003), pain (Chochinov et al., 1995; Fishbain, 1999b; Fishbain et al., 1991), comorbid mood disorders (Work Group, 2003), substance abuse (Borges, Walters, & Kessler, 2000), severe functional impairments (Waern et al., 2002), and increased perceived levels of disability. Hopelessness on the part of the patient can be an additional significant predictor of suicide risk as well as the individual views his or her plight as unremitting and may believe that there is nothing to look forward to (Chochinov et al., 1998).

The medical clinician can be the first to expect, anticipate, and intervene for the suicidal patient. The clinician caring for the patient with pain should be attentive to the prospect that despair has seeped into the patient's existence. Clinicians may be reluctant to inquire into the possibility that their patients may be entertaining thoughts of suicide, fearing incorrectly that making such inquiries may be offensive to patients or may "plant" such thoughts into their head (Henderson & Ord, 1997). Inquiries should be framed in a matter-of-fact, nonjudgmental, concerned, and empathic manner. It is probably best to inquire frankly whether the patient is experiencing distress and harboring thoughts of suicide. Patients may actually find that such frank inquiry is relieving. If the patient is given an opportunity to verbalize their concerns, thoughts, feelings, and despair, the physician–patient relationship may be strengthened, particularly if the clinician is concerned and not particularly shocked by the admission of despair. Admission of thoughts of suicide should be taken seriously and never minimized or dismissed as manipulative ploys.

The clinician should, in turn, appropriately direct the patient to psychiatric treatment. It is incumbent upon the clinician to arrange for psychiatric referral or transfer to an emergency psychiatric facility to be certain that a comprehensive lethality assessment is conducted and to ensure that all reasonable measures are undertaken to maintain the patient's safety. Psychiatric hospitalization may be required in cases in which there is significant psychiatric comorbidity, imminent lethality risk, suicidal intent/plans, and when the patient's cooperation in mobilizing available resources to ensure their safety is not forthcoming (Work Group, 2003).

PSYCHOLOGICAL VARIABLES AFFECTING THE EXPERIENCE OF PAIN

Psychological variables, separate from psychiatric comorbidities, can have a profound impact on the experience of pain. Patients' beliefs and expectations regarding the pain experience and its ramifications can have a profound impact on their functioning and well-being.

The individual who believes that even if the pain is not totally eradicated, he or she may have the capacity to develop ways of dealing with it may be more inclined to develop a proactive approach to the treatment process. By contrast, patients with pain may harbor unreasonable expectations and beliefs about pain and its treatment. So often, such patients expect that their pain will be unremitting and that there is no hope for relief over the horizon. Hence, patients who harbor belief that regardless of what they do, "the pain seems to get worse" will be less inclined to be active participants in prescribed treatment and rehabilitation endeavors. Similarly, one cannot be expected to be optimistic or anticipate much in the way of pleasure in life if the person appraises that his or her life "is hardly worth living." Patients will be less inclined to engage in collaborative endeavors with treating sources if they believe that the "doctors don't take my pain seriously enough." It becomes extremely difficult to manage the pain of patients who harbor maladaptive beliefs and expectations. Indeed, maladaptive cognitions may lie at the very center of the pain problem.

The experience of chronic pain can be associated with a number of stressors (see Table 47.3). Patients' ability to cope with a stressor is contingent on their appraisal of the significance and severity of the stressors, their appraisal of their intrinsic repertoire of coping strategies (and the utility of those measures), the availability of social supports and their ability to make use of those supports. Distress may result if patients believe they lack the requisite abilities to deal with such stressors effectively, or when the severity of the stressors is overly magnified. The distress, in turn, can aggravate and exacerbate the experience of pain.

In reality, individuals often cannot control or avoid distressing life events. However, the patient can almost always exert some control over how much distress and life disruption those events produce. A number of psychotherapy approaches can be helpful in assisting the patient's ability to cope with the disorder and the ramifications of having a chronic disorder (Leo, 2003).

Psychological and psychiatric endeavors might well be invoked to address concurrent stressors, and beliefs can be instrumental in optimizing the patient's response to treatment. Psychotherapeutic measures would attempt to foster patient empowerment by addressing maladaptive and ineffective beliefs and by developing effective coping strategies and mobilizing social supports in such a way as to assist individuals assert control over their reactions to pain and its ramifications. These interventions might be beyond the scope of the sole pain practitioner, and referral for psychiatric and psychological consultation might prove to be a necessary adjunct to manage the patient's condition.

Psychotherapy can be quite individualized, contoured to the needs of the patient. Thus, for patients whose pain appears to be exacerbated by perceived stress, patient instruction on the use of a variety of relaxation techniques and hypnosis might prove helpful (Turner & Chapman, 1982a,b]. For those experiencing marked difficulties with conceptualizing their pain and ineffective coping, a variety of psychotherapeutic approaches, e.g., cognitive-behavioral therapy, might be of use (Turner & Chapman, 1982b). Other therapy approaches, e.g., interpersonal psychotherapy, might address the way in which patients relate to other social supports in their life. Individuals sustaining marked marital and family stress might benefit from couples/marital and family therapies. For those facing intense distress over loss of work and concomitant loss of self-efficacy, vocational rehabilitation may be essential to improve adaptive functioning (Leo, 2003).

PSYCHOLOGICAL ASSESSMENT

Consistent with comprehensive pain management approaches, it is useful to organize how we think about our patients with chronic pain in terms of biopsychosocial variables. While clinical interview is probably most useful, it can sometimes be helpful to employ standardized scales and assessment instruments to conceptualize patients in terms of psychological characteristics, personality traits, and social supports. Useful assessment instruments might include those listed in the Table 47.4. Consultation with

    Depletion of social support networks
    Strained relationships
    Little emotional reserve to pursue customary interests
    Decline in recreational interests
Legal
    Litigation regarding disability
    Workers' Compensation issues

TABLE 47.4
Psychometric Scales Used in Assessing Chronic Pain

Coping Strategies Questionnaire — Assesses coping strategies in one's repertoire to deal with chronic pain. May predict the level of activity, physical impairment, and psychological functioning associated with pain (Rosenstiel & Keefe, 1983).

Fear Avoidance Beliefs Questionnaire — Assesses beliefs characterized by danger, threat, or harm associated with pain. The degree to which patients assign threat to activities may limit their participation in, and lead to avoidance of, activities related to work (Waddell et al., 1993).

McGill Pain Questionnaire — Assesses the features of pain severity and intensity. Allows patients to qualify pain in emotional, cognitive/evaluative, and sensory terms (Melzack, 1975, 1987).

Minnesota Multiphasic Personality Inventory — Provides personality profiles and pathological assessment of patients with chronic pain (Hathaway et al., 1989).

Quality of Life Indices — Assess the impact of chronic pain states on various aspects of one's life, activity, recreation and leisure time activities, social interactions, work, and adaptive self-care (Ferrell, Wisdom, & Wenzl, 1989).

West Haven-Yale Multidimensional Pain Inventory — Assesses one's appraisals of pain, its impact on functioning, and perceived responses of others in response to pain (Kerns, Turk, & Rudy, 1985).

psychologists skilled in the administration, scoring, and interpretation of such instruments is warranted.

CONCLUSIONS

As clinical practice within the realm of pain management has evolved, it has become increasingly apparent that the effective treatment of patients with pain requires recognition of prevailing psychiatric issues. In addition to the physical discomfort associated with pain, patients likewise experience marked emotional and psychosocial distress. A number of biological, psychological, and social factors can have an impact on the experiences and life of the patient with chronic pain. Emotional factors, e.g., depression and anxiety, not only emerge as a consequence of pain but can, in addition, contribute to pain, exacerbating and maintaining it. Psychological factors can likewise interfere with treatment adherence and efficacy. The frustration caused by ongoing pain, the effects on functioning, and the impact on families and other relationships can contribute significantly to psychiatric morbidity. The comprehensive approach to the patients with pain requires assessment of each of these dimensions. Barriers may be ascertained which pose impediments to the recovery of the patient. A number of psychiatric disorders can coexist

with chronic pain disorders. The presence of such psychiatric comorbidities can add to the complexities of the presentation of the patient with pain, and warrant treatment as part of the comprehensive rehabilitation program offered to the patient.

A multidisciplinary approach to the management of patients with pain is advocated. Treatment of coexistent psychiatric disorders would require the cooperation and assistance of psychiatrists and other mental health professionals who can lend their knowledge and skills to such endeavors. In addition, a multimodal approach to the patient, involving somatic treatments and psychological interventions, would be required to manage the complexities encountered among the patients suffering from chronic pain disorders.

Psychotherapeutic Approaches in Pain Management

Kathleen Sitley Brown, PhD, and Lorie T. DeCarvalho, PhD

HISTORICAL VIEWS OF PAIN

It has been said that "pain upsets and destroys the nature of the person who feels it" (Aristotle, *Nicomachean Ethics*). Centuries have come and gone, and the message behind this statement still rings true for individuals who suffer from persistent pain. Philosophers, physicians, and psychologists alike have struggled with the issue of how to best deal with and treat people suffering from pain. Historically, one argument was given by Descartes (1596–1650), who ushered in a new paradigm of viewing the human experience with his argument that the mind or "soul" was separate from the physical body, and that the mind was a passive, dependent entity, incapable of directly affecting either physical or somatic processes (Gatchel, 1999). Damasio (1994) claimed that Descartes's ideas of such a separation between the mind and body "have shaped the peculiar way in which Western medicine approaches the study and treatment of diseases" (p. 251). Even in today's health care system, psychologically based problems or contributing factors are often disregarded, while the diseased body part is examined solely as the cause of pain and illness.

Kossman and Bullrich (1997) brought to light a new theory, initially proposed by von Bertalanffy in the 1960s, which stated that the study of general systems necessitated an understanding of the "whole" rather than the sum of parts. This gestalt-like theory led to a shift from former biomedical reductionism as science began to look at human functions in terms of the whole. And by the late 1980s, pain researchers realized that both organic pain *and*

psychogenic pain resulted in an experience of pain. This led to the *Biopsychosocial Model* of pain, which proposed that the assessment, diagnosis, and treatment of organically caused pain should incorporate both the physiological and psychological factors that contribute to patients' experiences with pain (Gatchel, 1999).

THE CHALLENGE OF PAIN

Chronic pain has been defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage" (Merskey & Bogduk, 1994). Indeed, individuals who suffer from chronic pain not only experience physical pain but they may also become disabled as a result of their condition(s). For example, chronic low back pain is the leading cause of physical disability in persons under the age of 45 in the United States, and after the age of 45, it is the third leading cause of disability (Mayer & Gatchel, 1998). Along with the physical manifestations of chronic pain and disability, these individuals also tend to experience the psychological effects of fear, anxiety, and depression. Of course, no two individuals respond the same way to a similar injury. Consequently, "one individual may view pain as disabling, whereas the other continues to function in spite of his or her pain and returns to a productive lifestyle" (Koestler & Doleys, 2002). But as practitioners treating these individuals, it is vital that we are mindful of their experience in its entirety, to incorporate the biopsychosocial perspective.

Cognitive, affective, and behavioral factors have all been shown to play essential roles in the perception and behavioral responses to chronic pain. Given this complex perceptual experience of chronic pain, treatment must address the reciprocal interactions between the physical consequences and psychological factors, as well as the social sequelae of chronic pain. Chronic pain also affects family functioning as their support of the person with pain often results in role changes, financial difficulties, changes in lifestyle, and emotional distress in family members (Turk, Flor, & Rudy, 1987). Therefore, treatment must address the psychophysiological processes, as well as the inter- and intrapersonal challenges posed by chronic pain.

In the perception of pain, cognitive appraisals of nociceptive stimuli based on prior learning history, the meaning of the context in which this stimuli is perceived, and the evaluation of resources for controlling pain all directly affect an individual's emotional state. Furthermore, emotional factors influence physiological functioning, appraisal processes, and behavioral responses. And, environmental reinforcement contingencies subsequently influence thoughts, feelings, and behavior.

In this chapter, we first review psychotherapeutic issues related to chronic pain that should be addressed (i.e., depression, suicidality, and post-traumatic stress disorder, or PTSD) and integrated into a comprehensive pain management treatment plan. This incorporates use of a model for PTSD and chronic pain (DeCarvalho, 2004), with specific application to clinical treatment of patients with chronic pain. We then discuss issues related to chronic pain and grief work, which we follow with a discussion of psychotherapeutic approaches for effective pain management. This includes sections on cognitive-behavioral therapy, behavior therapy/operant conditioning, stress inoculation therapy, self-directed treatments, adjunctive treatments, and relapse prevention for patients with chronic pain. Finally, we address barriers encountered in the practice of pain management and how to overcome them. As a note, biofeedback and hypnosis, which can be used as stand alone treatment approaches or integrated as adjuncts to psychotherapy, are discussed in other chapters and thus are not included in this chapter.

PSYCHOTHERAPEUTIC ISSUES RELATED TO CHRONIC PAIN

CHRONIC PAIN, DEPRESSION, AND SUICIDALITY

According to the *Diagnostic and Statistical Manual of Mental Disorders* (APA, 2000; DSM-IV-TR), symptoms of depression incorporate marked changes in mood, diminished interest or pleasure, and vegetative changes (e.g., weight loss or gain, insomnia or hypersomnia, fatigue, psychomotor agitation or retardation). Additionally, individuals who experience depression may have feelings of worthlessness, difficulty concentrating, and suicidal ideation, thoughts, or impulses (APA, 2000).

A large body of literature acknowledges that there is a high incidence of depressive symptoms in persons with chronic pain (Lindal, 1990; Trief, Carnricke, & Drudge, 1995; Turk, 1994). For example, Schuster and Smith (1994) assessed 101 patients with chronic pain and found that 47% of the patients exhibited significant depressive symptoms. They found that nearly 90% of the patients' depression was explained by symptoms of hopelessness, decreased interest, and sadness. Other researchers have indicated that within the United States, depression is the single most common psychiatric diagnosis in patients with chronic pain in general (Fishbain, 1986) and chronic low back pain specifically (Magni, 1987). Prevalence rates for depression as a comorbid disorder with some chronic pain conditions have been found to range from 10 to 100% (Romano & Turner, 1985). Most studies report prevalence rates between 30 and 60% (Magni, 1987). Although it is frequently assumed that patients with pain have a premorbid history of depression, Hendler (1989) found that although the incidence of depression in patients with chronic pain admitted to his clinic was 77%, 89% did not have a pre-morbid history of depression prior to the onset of pain.

It is well-known that patients with chronic pain who are depressed secondary to their conditions are more likely to physically function more poorly and demonstrate more significant levels of physical disability (Fields, 1987). Further, there is some research evidence that patients with chronic pain who scored higher on depressive symptomatology reported greater intensity of perceived pain, more pain behaviors, and pain tending to interfere with daily living more so than in patients experiencing fewer depressive symptoms (Haythornthwaite, Sieber, & Kerns, 1991). It is important to note that the generalizability of this study is questionable due to the sample demographics. Despite the methodological problems in the Haythornthwaite et al. (1991) study, their findings were remarkably similar to those of a more recent study by Burns et al. (1998), who found that feelings of helplessness decreased as pain severity decreased. This study demonstrated that depression significantly relates to levels of perceived pain.

Similarly, there is a clear relationship among personal control, learned helplessness, anxiety, and chronic pain disability (Abramson, Garber, & Seligman, 1980; DelVecchio-Good, Brodwin, Good, & Kleinman, 1992). For example, Lackner, Carosella, and Feurstein (1996) concluded that chronic pain disability and perceived levels of severity of pain correlated negatively with functional self-efficacy, or patients' confidence in their abilities to cope with their pain. Burns et al. (1998) found that pre- to post-treatment decreases in pain helplessness were related to improvement in pain severity, activity, and downtime. Thus, patients who experience greater disability and have reduced functional self-efficacy are likely to experience greater psychological

distress, which can be evidenced in the form of secondary depressive symptoms.

Overall, patients with chronic pain who use positive, active coping strategies tend to have lower levels of self-reported pain severity, depression, and functional disability while the opposite is true of those patients who use passive coping strategies (Brown & Nicassio, 1987; Brown, Nicassio, & Wallston, 1989; Keefe & Williams, 1992; Kores, Murphy, Rosenthal et al., 1990). As such, it may be said that patients' beliefs in themselves that they are able to take a proactive approach in the healing process, or self-efficacy, is key in helping patients with chronic pain to manage their condition. Those who perceive that they are unable to control their physical pain may use passive-avoidant coping strategies and tend to rely upon wishful thinking and avoidance to cope with their pain (Weickgenant, Slater, Patterson, Atkinson, Grant, & Garfin, 1993).

Of paramount importance is the acknowledgment that those suffering from uninterrupted, extreme pain and disability are highly vulnerable to suicidal ideation (Fuerst, 1993; Heller, Flohr, & Zegans, 1989; Ivey, Ivey, & Simek-Morgan, 1993; Jourard, 1971). These individuals may feel guilty and humiliated because they have suicidal ideation (Herman, 1992). Fishbain, Goldberg, Rosomoff, and Rosomoff (1991) found that males with chronic pain complete suicide at a rate two times higher than the general population, while those involved in workers' compensation litigation completed suicide at a rate three times higher than the general population. Females with chronic pain were found to complete suicide at a rate three times higher than the general population. A limitation of this study was that the ethnic composition of the sample was limited only to Caucasians. Further research is needed to determine whether such suicide rates are similar in other ethnic groups with chronic pain.

As clinicians, screening individuals for depression, as well as assessing for suicidal ideation and risk of danger to self or others, should be incorporated as a fundamental part of the treatment process for any person suffering from chronic pain. This is particularly true if the individual has a history of psychiatric illness, or if this is true of his or her family, as well as if the individual lacks adequate social support that can buffer the stress entailed in coping with ongoing, persistent severe pain and/or disability.

CHRONIC PAIN AND POST-TRAUMATIC STRESS DISORDER

Although PTSD has been recognized as "shell shock" and related to wars, especially World War II (Kizer, 1996), it may occur with *any* serious trauma that involves helplessness and potential loss of physical or mental integrity. In fact, the experience of chronic pain is a traumatic event involving serious injury and/or threat to one's physical integrity of self, and the person's response involves fear and helplessness. PTSD is categorically defined in the DSM-IV-TR (APA, 2000) as a disorder wherein both of the following are present:

1. The person experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or threat to the physical integrity of self or others, and

2. The person's response involved intense fear, helplessness, and horror.

According to the DSM-IV, the individual persistently reexperiences the trauma. This may take on different forms: intrusive images, thoughts, or perceptions; nightmares or night terrors; behaviors or feelings related to the event; psychological and/or physiological reactivity to internal or external cues resembling aspects of the traumatic event. As a response to the reexperiencing of the trauma, the individual reacts with (1) persistent avoidance (e.g., of thoughts, feelings, conversations, activities concerning the trauma) and (2) arousal (e.g., sleep difficulties, irritability or difficulty controlling anger, difficulties with concentration, hypervigilance, exaggerated startle response). Individuals experience clinically significant distress or impairment for at least 1 month. With delayed-onset PTSD, the presentation of symptoms is at least 6 months after the traumatic event took place (APA, 2000). To appreciate the relationship to and impact of PTSD on patients with chronic pain, we first examine the relationship for individuals in the general population.

In the general population, PTSD has been found to be one of the most common anxiety disorders, having a lifetime prevalence of 5 to 10% in the general population (Ballenger et al., 2000). The long-term prognosis or outcome of persons with PTSD can vary, depending on factors such as the individual's social support network; however, it has been determined that approximately 40% of persons do *not* experience a resolution of symptoms in the long term (McFarlane, 2000). The U.S. National Comorbidity Survey determined that the median duration of PTSD is approximately 3 years if the individual obtains treatment; yet this estimate neglects the fact that many individuals do *not* get treatment and could potentially experience more than one traumatic event in their lifetime (Kessler, Sonnega, Bromet, et al., 1995).

More recent studies indicate that the average duration of a PTSD episode is more than 7 years (Ballenger et al., 2000). Shalev (1996) concluded that there might be a progressive instability of the underlying neurobiological systems, which may lead to a continuation of the disorder. Ballenger et al. (2000) concluded that PTSD, along with depression, heads the list in terms of disability resulting in the individual, as well as in terms of the financial costs

to society. Persons with PTSD tend to have difficulties sustaining stable employment, have more relationship strife, and have more troubles with the law when compared with nonsufferers of PTSD (Shalev, 2000). PTSD has been associated with misuse of psychotropic medications, illicit drugs, and alcohol; and persons with PTSD also tend to engage in risky behaviors more frequently than nonsufferers (Hearst, Newman, & Hulley, 1986).

Yet another serious ramification of PTSD is its correlation with suicidality. More specifically, PTSD is more strongly associated with suicidal behaviors when compared with other anxiety disorders (Kessler, Borges, & Walters, 1999). In fact, it has been found that the rate of attempted suicide in persons with PTSD is approximately 19% (Hendin & Haas, 1991), which is comparable with the suicide attempt rate for persons experiencing major depressive disorder (Buda & Tsuang, 1981).

Consequently, the prevalence of PTSD has been found to be substantially elevated in patients with chronic pain when compared with the general population (15 to 35% vs. 2%, respectively) (Asmundson, Bonin, Frombach, & Norton, 2000). For example, diagnoses of PTSD in patients with chronic pain following motor vehicle accidents have been found in numerous studies (Blanchard et al., 1995; Chibnall & Duckro, 1994; Kuch, Swinson, & Kirby, 1985; Muse, 1986). Hickling and Blanchard (1992), in a study of patients being treated for chronic headache pain and pain resulting from motor vehicle accidents, found that 50% of the patients met criteria for PTSD. A more recent study showed that approximately 51% of patients with chronic low back pain assessed evidenced clinically significant levels of PTSD symptoms (DeCarvalho, 2004). Furthermore, another 24% of the patients evidenced a mild PTSD symptom severity level, reporting at least one to eight symptoms of PTSD (DeCarvalho, 2004). The findings resembled those of other investigators (DeCarvalho, 2001; Hickling & Blanchard, 1992). DeCarvalho (2004) also found that 77% of those patients with chronic low back pain who experienced a combination of trauma (back-related and non-back-related) reported clinically significant levels of PTSD symptoms. A very significant finding, however, was that pain alone appears to be a sufficient trauma to trigger clinically significant levels of PTSD symptoms for some patients (DeCarvalho, 2004), which supports the conclusions of Schreiber and Galai-Gat (1993); Buckley, Blanchard, and Hickling (1996); and Geisser, Roth, Bachman, and Eckert (1996).

As is true with depression, not every individual who suffers from chronic pain will develop PTSD. As such, it is important to attempt to determine certain possible predictive factors. By doing so, clinicians can better treat these individuals. DeCarvalho (2001, 2004) proposed a model for the predictors of PTSD in patients with chronic low back pain. While the model has not yet been researched with individuals with different forms of chronic pain, it is believed that this model may tentatively serve as a means of improving the assessment and treatment of persons with chronic pain. Essentially, DeCarvalho (2004) found that (1) the characteristics of the person, (2) history of antecedent trauma(s), (3) complicated physical involvement, (4) proactive measures, and (5) perceptions of pain are intricately woven together to predict PTSD symptom severity level. Because patients with chronic pain tend to be more difficult to treat, not only because of slow-going clinical improvements, but also because of the emotional component, it is strongly recommended that a very thorough history be taken for each patient. These aforementioned areas inherent in the model (DeCarvalho, 2004) may be used as a guide for assessing each patient's needs. The relevance of each of these areas to the treatment of chronic pain is now discussed.

PERSONAL CHARACTERISTICS

Pre-Trauma Vulnerability

The characteristics of the person would include such things as an individual's sex, age, family history of psychiatric or other illness, and personal history of psychiatric illness. This would also include personality style or traits, including tendencies to be neurotic, or to the other extreme, it would incorporate axis II or long-term personality disorders of some kind. Individuals who possess negative histories or personality makeups are essentially predisposed to other psychiatric or psychological problems in the future. Thus, pre-trauma vulnerability means that those individuals who have these person characteristics, as well as a history of trauma, are already psychologically more fragile and vulnerable should another traumatic event occur in the future. Pre-trauma vulnerability can ensue from several possible factors, including genetics, family history of mental illness, personality traits such as neuroticism, and previous traumatic experiences (McFarlane & Yehuda, 1996; Shalev, 1996). As clinicians, this means that we must address more than the individual's physical pain in treatment. We must inquire about personal history, particularly a history of trauma, as this will significantly affect treatment outcomes.

Age, Chronic Pain, and PTSD

Other personal characteristics that significantly predict PTSD symptom level are age and what has been labeled as perceived uncontrollability (DeCarvalho, 2004) over pain. We know that exposure to trauma appears to decrease with age, including certain traumatic events (i.e., physical and sexual assaults; Norris, 1992). However, it is known that aging tends to increase the prevalence of acute and chronic diseases, as well as disabilities (Kemp, 1985). In fact, disability has been commonly accepted as a normal

and prevalent characteristic of older age (Ben-Sira, 1991). Because elderly persons are likely to view disease and disability as a normal part of the aging process, they may actually dismiss warning signals (e.g., pain) (Kart, 1981). Further, it is possible that many elderly persons internalize societal expectations for degeneration and deactivation, which could lead to many elderly persons assuming that pain and disability are normal aging processes (Ben-Sira, 1991; Kovar, 1980).

In working with elderly patients who suffer from chronic pain, it is important to be aware that, because of societal expectations and individual perceptions about ageism, they may cope with their pain in one of two ways. Some older persons who have an *internal locus* of control tend to use less escape-avoidance, hostility, and self-blame as coping mechanisms when compared with younger persons (Blanchard-Fields & Irion, 1988). Conversely, older individuals who have an *external locus* of control in coping with their conditions tend to catastrophize more, thereby having a more difficult time in reducing their pain (Gibson & Helme, 2000). Those who perceive they have less control over their pain are more likely to report greater levels of pain and disability, and to develop PTSD (DeCarvalho, 2004). Thus, treatment goals should include helping patients to feel more in control and empowering them to own responsibility for their treatment.

ANTECEDENT TRAUMA

As discussed earlier, pre-trauma vulnerability strongly predicts individuals developing PTSD symptoms a second time; this is essentially because persons who have experienced trauma before must heal from it, and if another trauma occurs prior to "resolution" of this, it is more likely that these individuals feel more out of control and anxious. This means they experience a compounding effect of trauma upon trauma, and it predisposes them to PTSD. Patients who have a history of antecedent trauma(s) are more likely to manifest these experiences in the form of chronic pain.

Childhood trauma (physical, sexual, or psychological abuse) is one form of antecedent trauma that has been linked to somatic and behavioral manifestations in adulthood. Moreover, adult survivors of childhood trauma are predisposed to predictable physical and behavioral problems (Scaer, 2001). Examples of physical syndromes include pelvic, lower back, orofacial, and chronic bladder pain, as well as fibromyalgia, interstitial cystitis, nonremitting whiplash syndromes, and eating disorders. Scaer (2001) added that infants and young children who experienced abuse will have permanent neuronal patterns or procedural memories imprinted in their brains, which may result in long-term personality traits, behaviors, and coping styles for dealing with traumas (Grigsby & Hartlaub, 1994; Perry, Pollard, Blakely, Baker, & Vigilante, 1995). Similarly, Damasio

(1994) proposed that memories of emotions and sensations comprise somatic markers, which contribute to future behaviors when faced with trauma. Thus, in clinical practice, integrating psychodynamic, gestalt, interpersonal, and cognitive-behavioral therapies is invaluable in helping such patients heal from their traumatic experiences, as well as to reduce symptoms of pain. Neglecting to address antecedent trauma and focusing solely on the pain condition will hamper therapeutic gains, particularly as tension-related problems have both somatic and emotional underpinnings.

COMPLICATED PHYSICAL INVOLVEMENT

Patients who have more complicated presentations of chronic pain are generally harder to treat. As a form of chronic pain, chronic low back pain secondary to a herniated or ruptured disk(s) usually involves pain at the site of the injury, as well as referred pain, which involves the sciatic nerve root (Rosomoff & Rosomoff, 1991). Thus, patients experience a "double dose" of severe pain, which when combined with a longer duration, results in disability. Such disability may include (but is not limited to) difficulty ambulating or poor gait; paralysis; frequent urination or, in cases of extreme nerve impingement, incontinence; loss of reflex(s); sensory or proprioceptive losses; bilateral foot-drop; rigid and tight muscles; and loss of functional activity (Deyo, 1988). Patients with ruptured disk(s) are also more likely to undergo more back surgery(s).

The experience of surgery incurs fears of death, injury, postoperative pain, and helplessness. Studies with patients who have undergone breast cancer surgery have indicated that even 1 year after surgery, one third of the patients continued to have insomnia because of intrusive thoughts or images of their illness; one fifth of the patients had nightmares; 12% continued to meet criteria for PTSD; and over 50% had dissociative symptoms (Tjemsland, Soreide, & Malt, 1998). Therefore, Tjemsland et al.'s (1998) study reinforced the importance of addressing fears and experiences associated with surgeries and invasive procedures, as patients generally tend to have long-term symptoms of dissociation, nightmares, flashbacks, panic, and fear.

Previous studies in both the general population and with patients with chronic pain have indicated that perception of life threat and significant physical impairment were major predictors of the development of PTSD (Blanchard et al., 1995; Butler, Moffic, & Turkal, 1999; Helzer, Robins, & McEnvoi, 1987; Kilpatrick et al., 1989; Martini, Ryan, Nakayama, & Ramenofsky, 1990; Pitman, Orr, Forgue, De Jong, & Claiborn, 1989), as is the physical experience of severe, unrelenting pain (Geisser et al., 1996). Furthermore, nagging physical injuries may be constant reminders of the trauma, which would maintain or exacerbate PTSD (Buckley et al., 1996). In clinical practice, therefore, reducing patients' sense of helpless-

ness and lack of control is crucial. Using guided imagery and relaxation exercises such as diaphragmatic breathing and visualization are simple and quick, yet effective techniques that can help patients with chronic pain feel less threatened. In the long run, this may prevent them from developing anxiety disorders such as PTSD.

PROACTIVE MEASURES

It is important to find out what types of treatments patients are trying and using for their chronic pain condition, as well as how frequently they are engaging in these treatments. This will provide you, as the clinician, with an indication of how compliant the patient is and will be in treatment with you, as well as how proactive the patient is in taking necessary measures to feel better. The converse of this is that patients who try numerous treatments and are hopeful they will help may experience disappointment when the treatments do not work. Such disappointment tends to result in frustration, anger, and even depression as the individual begins to feel more and more helpless and out of control of the situation. In general, the more treatments a patient tries that fail, the greater the anxiety he or she will experience, which strongly contributes to greater levels of PTSD. By the same token, such patients who tend to be very proactive and who have more self-efficacy are more likely to try other treatments that are offered to them, provided they believe there is a glimmer of hope and that possibility that the treatment can help.

PAIN PERCEPTIONS

The physical experience of severe, unrelenting pain as a result of trauma relates to the development of PTSD symptoms (e.g., Geisser et al., 1996). Geisser et al. (1996) also found that PTSD symptoms were positively related to increased affective distress, self-report of pain, and functional disability among patients with chronic pain. In another significant study, Schreiber and Galai-Gat (1993) presented a case study of a patient with chronic pain stemming from the loss of an eye. Their case study suggested that uncontrolled and prolonged chronic pain may be a strong enough stressor to lead to the onset of PTSD. This valuable study also supported that accidents or traumatic injuries are not necessary prerequisites for the development of PTSD in patients with chronic pain. Of course, as a case study based on only one participant, results are not generalizable.

Another study found that nagging physical injuries in patients with chronic pain may be constant reminders of the trauma, which would maintain or exacerbate PTSD (Buckley et al., 1996). The authors made an important contribution to an understanding of the relationship between chronic pain and PTSD. Their findings suggest that the presence of an injury could, in itself, maintain or exacerbate PTSD.

Perceived loss of control is a central facet in the experience of trauma. Patients suffering from chronic pain who utilize an internal locus of control tend to believe that their actions and efforts contribute to reduced pain (Crisson & Keefe, 1988). Therefore, individuals with an *internal locus*, or a decreased sense of perceived uncontrollability, are more likely to be proactive in their efforts to minimize or reduce pain. On the other hand, patients with chronic pain who utilize an *external locus* of control tend to believe that their own personal efforts will not reduce their pain. They tend to rely on the efforts of powerful others (e.g., physicians, health care providers, friends, family), or luck to bring relief from their pain (Crisson & Keefe, 1988). Patients who have an external locus of control (chance locus) tend to catastrophize and divert their attention, and they typically report being in more pain (Gibson & Helme, 2000; Toomey, Mann, Abashian, & Thompson-Pope, 1991). These individuals tend to experience greater helplessness and are less able to effectively cope with their chronic pain conditions (Crisson & Keefe, 1988; Skevington, 1983).

We have discussed each of these areas of the model (DeCarvalho, 2004). The most important thing to understand is that each of these areas plays a role in how patients individually perceive and cope with their chronic pain conditions. Of course, individuals may have different chronic pain conditions. The most common type, as discussed throughout this chapter, is chronic low back pain. As one example, in its most severe forms, chronic low back pain may cause paralysis and numbness, loss of gross motor control, loss of bowel and bladder control, loss of reflexes in lower limbs, spasticity, and degeneration of nerves. Chronic pain in general most often results in disability, and with chronic pain disability comes a cognitive reevaluation and reintegration of one's belief systems, values, emotions, and feelings of self-worth (Miller, 1990).

Coping with a chronic pain condition and being told that one will need to "live with it" and "manage the pain" for the rest of one's life is certainly more easily said than done. Being faced with the news of impending health problems, ongoing severe pain, and disability is extremely difficult. Learning to live with chronic pain presumes that the patient accepts that the diagnosis and prognosis are accurate. However, research demonstrates that misdiagnosis of patients with chronic pain occurs 40 to 60% of the time (Hendler & Kozikowski, 1993; Hendler, Bergson & Morrison, 1996). Hendler and Kozikowski (1993) reexamined 60 patients consecutively admitted to their chronic pain clinic and found that approximately 66% were referred with diagnoses that were considered incomplete as they did not reflect the complexity of the underlying pathology. Of this group, half of these patients were found to have surgically correctable lesions. Considering the large number of missed and treatable diagnoses, the formulation of differential diagnoses must be based on

patient complaints, history, and physical examination rather than negative test results.

The process of acceptance of living with chronic pain is very much like that designated by Elizabeth Kubler-Ross (1969) for death and dying, wherein the person experiences feelings of shock/denial, anger, bargaining, depression, and acceptance. Such people have lost a part of themselves. They have lost their physical abilities, and they have lost the assurance that they can fully control whatever is going on in their lives. This process of grief work is now discussed.

Chronic Pain, Disability, and Grief Work

In being told that they will be living with chronic, painful, and potentially disabling conditions, individuals will initially experience shock or denial. They may attempt to deny that they are having such an experience; for example, patients who face dangerous and invasive surgical procedures may experience shock and deny that they are subject to the risks involved. And, as patients become more anxious from severe chronic pain, there may also be other factors that contribute to the disruption in their lives. Wheeler (1995) stated that fear of reinjury and panic may reinforce patients' anxieties, and complicate recovery. Patients with chronic pain and disability may experience deep uncertainty about the meaning of the events and circumstances that have occurred and how they are to deal with life from the present onward (Mishel & Braden, 1988). All these factors may result in a person either feeling numb inside or expressing to clinicians or others that they are really doing okay and will be getting better soon. This is an attempt to maintain control over the situation.

As the situation becomes worse and the pain and disability worsen, the individuals may attempt to try more treatments to relieve the pain. However, when their pain is not relieved, and their condition worsens, they are likely to start to feel anger (Miller, 1990). Because anger is strongly related to fear, some patients will express this in the form of anxiety (McCracken, 1993), deep-seated frustration, and/or decreased self-efficacy (Altmaier, 1993). These individuals may feel powerless and have a sense of uncontrollability in their situation (Carpenito, 1989). The more powerless an individual feels, the more likely he or she is to be angry.

Patients may express anger at themselves for getting injured in the first place, toward their loved ones for not being more helpful or supportive, against agencies such as the government or workers' compensation departments for not financially compensating them, and at their providers for not taking away the pain like they believe they should be able to. At this point, it is important to understand that when patients become angry and frustrated, it is a normal human response to pain. Being empathetic and gently confronting the patients may mean reminding the patients that you want to help them, but that they need to own a share of the work too. Generally, this is the most difficult point in the psychotherapy process, as it tends to involve the most resistance, and it can trigger a great deal of frustration and anxiety in the therapist. Coming to an understanding that this is a normal process that each patient, as a person, must go through to be able to make sense of his or her condition, can facilitate a smoother therapy process as well as a stronger therapeutic alliance with the patient.

As the anger turns more into fear, patients may begin bargaining in their healing process. While this process varies from person to person, this may involve blame and judgment. For example, some patients with chronic pain may reach a point where they attribute their pain to their behaviors or personal life decisions; for example, some individuals will blame their self-judged "bad behavior" for their pain, which they view as a punishment from God. Other chronic pain sufferers feel that their pain provides for their moral and spiritual atonement (Hawthorn & Redmond, 1998). When their pain gets to a point of unbearability, many patients with such beliefs will bargain with God or their Higher Power for respite, and in return, they promise to "be good" in the future (Kubler-Ross, 1969). By doing so, these individuals are, again, attempting to restore their sense of control over their condition. Referring the individual to a chaplain, pastor, or minister can be very therapeutic and should be done when possible if you are not trained to deal with such issues.

As they realize their efforts have failed, the individuals experience depression. Again, it is crucial to assess for any suicidal ideation, as persons with chronic pain are far more likely to attempt suicide than the general population. Kubler-Ross (1969) indicated that, eventually, patients who face severe illness, pain, and/or loss reach a point of acceptance. One common concern that pain practitioners have is that labeling a person as having a specific diagnosis of a chronic nature will strongly relate to the individual coping in maladaptive ways, which may lead to a state of chronicity (e.g., Abenhaim, Rossignol, & Gobeille, 1995). This phenomenon is commonly referred to as the "labeling effect." However, Fishbain (2003) disputes this position and states, "The patient with intractable pain needs to stop looking for a cure and thus stop doctor shopping. The patient needs to understand that they have a chronic condition which has no cure in most situations, but which can be managed" (p. 68).

Understandably, individuals who perceive that they cannot attain their goals in finding relief from their pain and who are unable to be flexible in accommodating negative stressors tend to have poorer psychological functioning (Brandtstadter & Renner, 1992). Thus, such individuals are also more likely to be depressed and to report greater levels of pain intensity and disability (Schmitz, Saile, & Nilges, 1996). Acceptance takes time, and this

may mean that the patients come to accept a particular aspect of their condition, but not others at that time. Acceptance can be an ongoing process for many individuals with chronic pain. As professionals working with these patients, the key to their healing lies in the acknowledgment that the process is different for everyone.

Any psychotherapeutic interventions on our part will be futile if we ignore the bigger picture, which is that each individual has a unique history and present experience. We need to respect, honor, and accommodate treatments that fit each individual based on where the individual is in life. In addition, it is fundamental that we are cognizant of the fact that chronic pain and disability tend to alter one's self-image and body image. By nature, human beings are considered to be fundamentally meaning-making creatures (Baumeister, 1991). As the implications of the pain condition unfold, individuals will begin to consider the meaning of the losses associated with their pain in the broader context of their ongoing lives. The subjective meanings associated with interpersonal loss are evident on a continuum, which extends from relatively mundane appraisals, to concrete evaluations of specific problems caused by the loss, to deeper and more encompassing questions about emotional well-being and identity, to the most profound existential concerns about the meaning of life (Bonanno & Kaltman, 1999). In respecting that each individual copes with chronic pain differently, we will now address specific psychotherapeutic approaches in the practice of pain management.

PSYCHOTHERAPEUTIC INTERVENTIONS IN PAIN MANAGEMENT

COGNITIVE BEHAVIORAL THERAPY

Overview of Cognitive Behavioral Therapy in Pain Management

Cognitive behavioral therapy (CBT) for pain management is based on a cognitive-behavioral model of pain (Turk, Meichenbaum, & Genest, 1983) and has become the common standard of psychosocial intervention for pain (Morley, Eccleston, & Williams, 1999). Pain is defined in this model as a complex experience that is influenced not only by its underlying psychophysiology, but also by the individual's cognitions, affect, and behavior (Keefe & Gil, 1986). CBT is designed to reduce emotional distress and covert self-statements concerning pain. By altering negative self-talk, which directly reduces anxiety and/or depression, indirect modification of pain perception and tolerance will occur and allow the patient to increase activity levels and decrease medication use.

Several cognitive-behavioral models have been developed in which fear and avoidance variables were postulated as critical mechanisms by which acute pain develops into chronic pain (Letham, Slade, Troup, & Bentley, 1983; Phillips, 1987; Waddell, Newton, Henderson, & Somerville, 1993). For example, Vlaeyen, Haazen, Schuerman, Kole-Snijders, and van Eek (1995a, 1995b) developed a cognitively oriented model in which pain catastrophizing and pain-related fear are central in the development of chronic pain. Pain catastrophizing promotes avoidance behavior and hypervigilance to bodily sensations, followed by disuse, depression, and disability. These factors then maintain the pain experience and reinforce fear reactions and avoidant behaviors (Asmundson, Norton, & Norton, 1999; Vlaeyan & Linton, 2000). Thorn, Boothby, and Sullivan (2002) developed a group treatment program specifically to reduce catastrophizing and promote adaptive coping. This program incorporates principles from stress management training (Meichenbaum, 1986), cognitive therapy for depression (Beck, 1995), communal coping methods (Coyne & Smith, 1991), and assertiveness training (Turk et al., 1983). By reducing catastrophizing and increasing adaptive coping, the patient's attention is diverted away from his or her pain and onto mastery of activities and achievement of tasks.

Application of CBT to Pain Management

In using CBT for pain management, there are three basic components involved in the treatment process. First, there must be a treatment rationale that helps patients understand that cognitions and behaviors can affect the pain experience (Holzman, Turk, & Kerns, 1986). This rationale must emphasize the role that patients can play in controlling their own pain. Psychoeducation is used to teach patients about the relationship between their thoughts, feelings, behaviors, and chronic pain. It is also the point at which a therapeutic alliance begins to build, and we explain the importance of a collaborative relationship with the patients. Thus, we emphasize to the patients that we will guide and support them, but that they will need to do the work in order to get better and find some relief from their pain. This part of the treatment also involves being very honest with patients and letting them know that while the treatment is very effective for most people, we are not trying to set up false hopes for them. It is at this point in treatment where we work with patients to derive attainable short- and long-term goals for management of their pain.

The second part of treatment involves coping-skills training to help patients manage their chronic pain. For instance, progressive relaxation and cue-controlled brief relaxation exercises are used to decrease tension, reduce emotional distress, and divert attention from pain. Pacing of activities and scheduling of pleasant events are used to help patients increase the levels and range of their activities. Training in distraction techniques such as pleasant imagery, counting methods, and use of a focal point can help patients learn to divert attention away from severe

pain episodes. Cognitive restructuring is used to help patients identify and challenge overly negative pain-related thoughts and to replace these thoughts with more adaptive, coping thoughts. Cognitive restructuring emphasizes alteration of the patient's irrational beliefs through Socratic dialogue and rational self-examination of cognitive responses. Thus, an individual learns to discriminate irrational self-defeating thoughts from rational alternatives. Through this process, patients begin to generate more rational cognitive responses surrounding their pain experience and their capacity to manage it more effectively. Cognitive strategies may also address past illness experiences, learned patterns, and schemas related to personal and family developmental issues (Looper & Kirmayer, 2002).

Finally, the third component involves the application and maintenance of learned coping skills. During this phase of treatment, we encourage patients to apply their coping skills to a progressively wider range of daily situations. Patients learn to use behavioral techniques in place of illness behaviors such as help seeking, avoidance, and disability (Looper & Kirmayer, 2002). Strategies may include the following: graduated increases in activity to promote a return to prior functioning levels, desensitization and exposure techniques to treat avoidance, and response prevention to diminish maladaptive responses to distressing thoughts and situations. Problem-solving methods enable individuals with pain to analyze and develop plans for dealing with pain flares and other challenging situations. Teaching patients to self-monitor and hold to behavioral contracts can prompt and reinforce patients in frequently practicing these various coping skills and strategies.

CBT for pain management is typically carried out in small group (four to eight patients) sessions that are held weekly for 8 to 10 weeks. Numerous studies have shown that CBT generally decreases pain, improves functioning, and decreases physical and psychosocial disability among patients with chronic pain (Bradley et al., 1987; James, Thorn, & Williams, 1993; Keefe et al, 1990; Kole-Snijders et al., 1999; Syrjala, Donaldson, Davis, Kipps, & Carr, 1995; Thorn & Williams, 1993; Turner & Clancy, 1986, 1988; Vlaeyan, Haazen, Schuerman, Kole-Snijders, & van Eek, 1995). Thus, evidence suggests that CBT is effective in treating both chronic pain conditions, such as back pain, and persistent disease-related pain conditions, such as arthritis and cancer. However, as it does not benefit everyone, individual differences play a role in treatment success or failure (Thorn et al., 2002).

Behavior Modification/Operant Conditioning

Overview of Behavior Modification in Pain Management

The learning theory model of chronic pain emphasizes the role and importance of environmental factors in chronic

pain states (Fordyce, 1976). The most widely used definition of chronic pain looks at pain in terms of behavior, that is, how the person behaves and communicates his or her pain to others. In some patients, pain behaviors occur as a result of environmental contingencies rather than from antecedent stimuli, such as tissue damage. Behaviors originally respondent in nature can become operant through learning. This is a result of pain behaviors receiving direct positive reinforcement, or being negatively reinforced because they lead to avoidance of aversive situations, as well as non-reinforcement of activity related to "well behavior." The operant conditioning approach to chronic pain management demonstrates that all voluntary behaviors are influenced by their contingent consequences and the surrounding environment in which they occur (Sanders, 2003).

Anxiety has been identified as a part of the motivational-affective dimension of pain as discussed by Melzack and Torgerson (1971) in their three-component model of pain. The motivational-affective component compels an organism in pain to act in a way that relieves the aversive stimulation. Physical withdrawal, rest, and immobility are innate survival skills in acute pain, but are maladaptive in chronic pain. Often individuals in pain anticipate future increases in pain intensity and thus avoid physical activities that have previously been associated with increased pain. Another effect is the tendency to be "on guard" by tensing certain skeletal muscles or using protective movements and postures (Hanson & Gerber, 1990). Consistent guarding and decreases in physical movements and activities usually result in a physical deactivation syndrome, which is associated with increased levels of chronic pain and disability.

The goal of this operant approach to pain management is not to directly modify or "cure" pain, but to modify the maladaptive pain behaviors by extinction and to reinforce "well behavior" by teaching patients to be more functional in their environment despite their pain experience. The patient's experience of pain decreases significantly as a result of change in pain behavior and/or reduced levels of muscle tension. In Sanders' (2003) review of 30 studies during the past 25 years using operant and other behaviorally based therapies with patients with pain, clinically significant improvement was shown in physical functioning, activity, reduced analgesics, and subjective pain intensity ratings in the application of operant conditioning therapy for patients with low back pain. However, he noted a lack of research on the efficacy of operant approaches in other chronic pain states; other developmental age groups, such as pediatric and geriatric patients; and other cultural populations.

Application of Operant Conditioning to Pain Management

In essence, in using behavior therapy in the form of operant conditioning, we use "reinforcement" (both a proce-

dure and a behavioral effect) to diminish ineffective coping strategies and to increase positive coping. The basic procedure is to follow a well-defined behavior with a consequence, which in turn leads to an increase in the frequency, strength, and duration of the behavior. For example, we can use positive reinforcement with patients by providing social attention with praise following active participation in physical therapy; this is likely to increase the probability of active participation in the next session. The reverse of reinforcement, extinction, may be used to reduce the frequency of an unwanted behavior.

In using extinction, we do a behavioral assessment to identify naturally occurring reinforcers that can be removed. We then remove those reinforcers to decrease the negative behaviors that patients are engaging in to "cope" with their chronic pain. For example, if pain behavior, as evidenced by grimacing or limping, co-occurs upon the solicitous attention of a partner, the partner is instructed to ignore and not attend to the person in pain when displaying such behaviors but to provide this attention only during socially appropriate, nonpain-related behavior. Over time, this will extinguish reinforcement of pain behavior as a means of communication in the relationship.

The implementation of rehearsal in behavioral treatment emphasizes the importance of practicing and consolidating those skills learned in sessions. Rehearsal techniques can include mental practice, role-playing, and role reversal (Holtzman & Turk, 1986). For example, individuals with chronic pain may role-play an employment interview with their therapist to answer questions about missed periods of work or a conversation with their spouse to negotiate changing household roles. To increase the likelihood of successful behavior change, we can assign homework to patients so that they can practice skills learned during treatment sessions (Turk et al., 1983). Homework assignments could use various modalities, such as written exercises, behavioral skills to practice in specific situations or with certain people, or mental practice of affirmative self-statements or images.

STRESS INOCULATION TRAINING

Overview of Stress Inoculation Training in Pain Management

Within the coping literature, the term *stress* has been defined by the transactional view of stress and coping conceived by Lazarus and Folkman (1984). This viewpoint addressed the efforts people make, regardless of whether those efforts are successful. Losses, threats, and other stressful demands, such as the pain itself, are appraised cognitively along with available coping resources. Based on this appraisal process, specific coping responses are used to focus either on the perceived problem or on the resulting emotional reactions. Because of the importance placed on appraisal processes, cognitive therapy to address maladaptive thinking patterns influencing the perception of pain is part of the standard of care.

More recently, the psychophysiological interconnection between the mind and body have been referred to as *allostatic load* rather than the historical term *stress* (Ray, 2004). Allostasis refers to the psychophysiological system of communication between the brain, endocrine system, and the immune system (McEwen, 2002). Allostatic load, or stress, occurs when there is an inadequate match between an individual's coping skills and the environmental demands that the individual believes these skills must confront. Patients with pain must learn the cyclical relationship in which stress increases pain and increased pain, in turn, is a stressor. Pain is just one stressor among many, and only one source of their suffering. Training on coping skills focuses on helping patients to separate pain from other sources of stress and that which they are unable to control.

Application of Stress Inoculation Training to Pain Management

Stress inoculation training (SIT) helps clients cope with stress by teaching them coping skills and then having them practice the skills while they are exposed to stress-evoking events (Meichenbaum & Turk, 1976). Stress inoculation therapy is commonly used for treating anxiety, anger, and pain. The treatment consists of three phases: conceptualization, coping skills acquisition, and application. Stress inoculation is a behavioral analogue of biological immunization. Thus, the coping skills clients learn can be considered "psychological antibodies," which increase resistance to potentially stress-evoking events.

In using SIT with patients, we teach them to view coping as a four-part process. We have summarized these as 4 Cs, and they are listed below.

1. *Consideration* of preparing for a pain episode
2. *Confronting* and handling the pain
3. *Coping* with feelings at critical moments
4. *Consistently* practicing reinforcement to increase effective pain management

SELF-DIRECTED TREATMENT

Overview of Self-Directed Treatment in Pain Management

Self-directed treatment broadens pain management to permit individual responsibility for as much of the treatment of pain and maintenance of health as is possible. Self-management training primarily focuses on changing thoughts (cognitions) and actions (behaviors), which in

turn changes negative emotions and pain sensations. Goals of self-management include the following: (1) improving the ability to divert attention away from pain sensations through activities and mental techniques, (2) improving overall physical conditioning, (3) improving pacing of daily activities, and (4) learning how to manage depression, anger, pain flares, and interpersonal conflict more effectively (Hanson & Gerber, 1990; Turk et al., 1983). The advantage to using a self-directed treatment approach lies in the greater specificity of therapy procedures, which enhances the uniformity of training and evaluation, client-centered control, and the probability of maintaining therapeutic effects after contact with the provider has ended.

Application of Self-Directed Treatment to Pain Management

Self-directed treatment goals are typically framed in the context of life-long learning as individuals learn healthy patterns of responding and continue to adjust their goals as interpersonal and environmental changes occur in their lives. This approach involves the following components:

1. *Physical*: Exercise regimen, use of proper body mechanics, appropriate rest, and use of analgesics when warranted, decreasing pain behaviors such as guarding and bracing
2. *Emotional*: Using positive self-statements, enhancing self-efficacy
3. *Cognitive-Behavioral*: Relaxation training, distraction techniques for pain flare-ups, reduction of maladaptive self-statements (i.e., catastrophizing, wishful thinking)

Note. Goals adapted and modified from Jensen et al. (1994), Loeser and Turk (2001), and Jensen, Nielson, and Kerns (2003).

Self-instructional training can be used in pain management. This approach focuses primarily on covert responses rather than hypothesized belief systems and thought processes (Meichenbaum, 1986). The patient gradually learns to use self-instructions and replace maladaptive self-statements with adaptive coping self-statements. In self-instructional training, individuals learn to instruct themselves to cope effectively with difficult situations. Self-instructions serve to prepare individuals to focus attention, guide behavior, provide encouragement, evaluate performance, and reduce anxiety. The five steps of self-instructional training are (1) cognitive modeling, (2) cognitive participant modeling, (3) overt self-instructions, (4) fading of overt self-instructions, and (5) covert self-instructions.

TREATMENTS FOR INSOMNIA RELATED TO CHRONIC PAIN

Overview of Treatments for Insomnia in Pain Management

Sleep disturbance has been associated with chronic pain across a variety of diagnostic groups, such as headaches, fibromyalgia, and Sjögren's syndrome (Burckhardt et al., 1997; Perlis et al., 1997; Tishler, Barak, Paran, & Yaron, 1997); rheumatoid arthritis (Stone, Broderick, Porter, & Kaell, 1997); osteoarthritis and back pain (Hyyppa & Kronholm, 1995; Ingernarsson, Sivik, & Nordholm, 1996). However, despite this association, the causal relationship between sleep disturbances and pain remains unknown. Multiple types of sleep disturbance have been identified across chronic pain populations and may include difficulty falling asleep, difficulty staying asleep, early awakening, and interrupted sleep. Lack of sleep has long been associated with daytime fatigue (Dinges et al., 1997). Depression may potentiate pain and sleep disturbances, although that relationship is neither consistent nor linear. Depression has been associated with frequent awakenings and decreased quality of sleep (Burckhardt et al., 1997).

A review of the merits of behavioral interventions in improving outcomes in the treatment of pain and insomnia demonstrated the efficacy of multiple behavioral treatments (National Institutes of Health, 1990). The degree of functional impairments and associated economic costs of the suffering and distress associated with these disorders led the panel to conclude, "Conventional medical and surgical approaches have failed — at considerable expense — to adequately address these problems" (p. 3).

Application of Treatments for Insomnia to Pain Management

Relaxation and behavioral approaches for the treatment of insomnia in patients with chronic pain include sleep hygiene (Turner, 1986), stimulus control therapy (Bootzin & Nicassio, 1978), and sleep restriction therapy (Spielman, Saskin, & Thorpy, 1987). When administered by experienced clinicians as part of a complete treatment program, behavioral interventions can produce reductions in sleep-related symptoms for up to 73% of patients with insomnia referred for treatment (Chambers & Alexander, 1991). Behavioral techniques primarily provide improvements in sleep latency and time awake after sleep onset.

Sleep restriction, stimulus control, and multimodal treatment were the three most effective treatments in reducing insomnia. In using the technique of stimulus control, we use cueing strategies to gradually reduce and eliminate stimuli that are likely to elicit undesirable behaviors; conversely, we increase stimuli that are likely to elicit desirable behaviors. For example, we may instruct the patient to fall asleep at specified times and places, while

excluding other activities, such as watching television, reading, or worrying. Inconsistencies in the assessment measures of insomnia and the lack of established criteria for what constitutes a therapeutic outcome reveal the need for the use of valid objective measures of insomnia, more meaningful outcome criteria relevant to a patient's quality of life, and empirically established guidelines for the selection of treatment techniques (Chambers, 1992).

ADJUNCTIVE TREATMENTS

Behavioral medicine focuses on altering behavior or physiology to enhance medical treatment. Relaxation training and biofeedback specifically address changing the physiological response of the sympathetic nervous system in response to pain stimuli.

An integrated adjunctive treatment approach may include use of biofeedback and various forms of relaxation training, which can incorporate the three major sources of data — physiological, self-report, and behavioral observations. Application of these treatments are not discussed, because it is discussed in a separate chapter of this book.

RELAPSE PREVENTION FOR CHRONIC PAIN

Overview of Relapse Prevention in Pain Management

Turk, Holzman, and Kerns (1987) modified the relapse prevention approach applied to addictive behaviors for use with chronic pain to help individuals learn to identify and successfully cope with factors that might trigger pain flares. Such an approach allows the patient to anticipate and plan for future events. It also provides the individual with the expectation that although minor setbacks may in fact occur, they do not signal complete failure. Setbacks are considered as means of implementing coping skills previously learned in a more effective manner. As the patient generalizes the use of learned coping skills across problem situations that arise in his or her experience with chronic pain, greater perceived self-efficacy will occur. Ultimately, this will directly affect the expectation that changes will be maintained.

Application of Treatments for Relapse Prevention to Pain Management

Maintaining and generalizing learned skills requires practice and graduated, stepwise increases in behavior across different situations. Similar to the treatment for phobias, based on exposure to fear-arousing stimuli, alternative coping behaviors must be substituted for the maladaptive avoidant tendencies typically used in patients experiencing pain.

Exposure and relapse prevention strategies for chronic pain include six steps, which we have summarized as the 3Es/3Rs method. Thus, patients with pain

can reduce the risk of relapse by applying the following to their everyday lives:

1. *Eliminating* habit-forming central nervous system medications
2. *Exposing* themselves gradually to previously avoided physical activities
3. *Exercising* to physically recondition and reduce postural guarding
4. *Relaxing* by using techniques such as diaphragmatic breathing, progressive muscle relaxation, visualization, guided imagery, meditation, yoga, and body self-awareness to decrease muscle tension
5. *Reinforcing* themselves in a positive manner for successful behaviors and interactions with others
6. *Rethinking* things by using cognitive-behavioral strategies during increased pain flares

Note. List adapted and modified from Hanson & Gerber (1990).

BARRIERS TO EFFECTIVE PAIN MANAGEMENT

ADHERENCE AND COMPLIANCE ISSUES

Poor adherence to treatment has historically been a major and costly problem. An estimated 50 to 55% of patients with chronic medical conditions fail to adequately adhere to their treatment regimens (Rapoff, 1999). Turk and Rudy (1991) note the negative effects of non-adherence in the chronic pain population include a greater number of medical emergencies, increased number and strength of prescriptions, worsening of disability and prognosis, increased likelihood of secondary complications, and suboptimal recovery following injury.

There is speculation, but little available documentation, that a substantial proportion of present-day health care costs could be significantly reduced by improving patient compliance. Clinicians and researchers may erroneously conclude that therapeutic trials are ineffective when they fail to recognize, identify, and control for compliance. Reviews of the literature have revealed no clear or consistent patterns in the association of demographic variables with adherence (Kaplan & Simon, 1990; Meichenbaum & Turk, 1987). Clay and Hopps (2003), in their review of the literature, found no studies that addressed the factors governing treatment refusals, premature terminations, or receipt of fewer treatment sessions than prescribed, even though these circumstances occur with regularity in pain management. They advocate for the treatment of choice, and its delivery must be customized to the lifestyle and personality of the patient.

When speaking of noncompliance, the focus is often on the individual and his or her characteristics. When

talking of adherence, the focus is on what people do. This shift of perspective led researchers away from the study of attributes or character to studies of behavioral cues, triggers, and consequences (Gatchel, 1999). The treatment of chronic pain is often perceived by health care professionals as complex, demanding, and challenging. Problematic family and work relationships, conflicts with health care providers, and ongoing battles with the disability compensation system are common co-occurrences. There has been extensive research to no avail to identify predictors of personality and psychosocial factors that predispose individuals to problems with chronic pain (Gatchel & Weisberg, 2000). In fact, these efforts have been challenged extensively (Gatchel, 1991; Turk & Salovey, 1984) given the lack of empirical support.

Hendler (1984) initially described a four-stage response to chronic pain that paralleled the stages of dying described by Kubler-Ross (1969). In the acute state (0 to 2 months), the individual expects to get well and is without psychological changes. During the second pain stage (2 to 6 months), the person begins to get anxious as a transient response to continued pain. When chronic pain persists beyond 6 months, depression ensues with the realization that the pain may be permanent. In the acceptance stage, which could take from 3 to 12 years from onset of pain, the individual becomes reconciled to the need to make accommodations for coping with chronic pain.

Gatchel (1991, 1999; Gatchel & Weisberg, 2000) later proposed a three-stage model of developmental changes that occur in an individual in response to pain. As pain or hurt is associated with harm, Stage 1 is associated with the emotional reactions as a consequence of the perception of pain, such as fear, anxiety, and worry. If the pain persists beyond a 2 to 4 month course, the time period when acute pain typically resolves, the individual progresses to Stage 2 in which a wider array of behavioral and psychological reactions occur. These reactions, such as depression or anger, depend on the preexisting psychological characteristics of the individual, as well as the environmental conditions, such as social or economic supports. The model presumes a general nonspecificity in terms of the relationship between personality, psychological problems, and pain rather than an inherent personality type associated with the development of chronic pain. The persistence of psychological and behavioral problems then leads to Stage 3, which results in the acceptance of the "sick role." This assumption of the "sick role" serves as a powerful reinforcer for disability. If compensation issues are present, these serve as further disincentives for becoming well. Compensation has been found to be a critical factor in the persistence of disabilities (Beals, 1984). Mayer and Gatchel (1988) also found that physical deconditioning, in which disuse and subsequent atrophy of the injured area result in physical incapacity, serves as an interaction vari-

able to reduce psychological well-being and self-esteem and thus maintain the pain cycle.

The prevalence of personality disorders is higher in patients with chronic pain (Gatchel, Garofolo, Ellis, & Holt, 1996; Livengood & Johnson, 1998; Weisberg & Keefe, 1997) than in the general population, although it is similar to rates found within the outpatient psychiatric population (Weisberg, Vittengl, Clark, Gatchel, & Gorin, 2000).

The diasthesis-stress model (Weisberg & Keefe, 1997) was postulated as an explanation for the emergence of personality disorders activated by the stress of chronic pain when no such disorder was found to be present on examinations of patients' premorbid functioning. The model has been applied to various chronic pain populations (Banks & Kerns, 1996; Dworkin & Banks, 1999; Flor & Turk, 1994; Turk & Flor, 1984; Weisberg & Keefe, 1997). The diasthesis is the underlying personality predisposition that is activated by the extreme stress of pain and its physical, psychological, and social consequences. Turk and Salovey (1984) suggest that low back pain develops when stress and sympathetic arousal become activated in an individual who has a predisposition to develop hyperactive back muscles, has inadequate coping resources, and experiences recurrent problems, such as family or work stressors. As the pain cycle begins, with pain as an additive factor to these already existing issues, muscle tension increases and the cycle is maintained. The relevance of this model to multidisciplinary treatment in general, and psychotherapy in particular, is the importance of shifting the focus from the personality deficit of the individual to the situational context in which the behaviors are being expressed and maintained (Weisberg et al., 2000).

Research indicates that it is futile to attempt to define a noncompliant personality; thus, the task remains to identify those individuals who are the least likely to adhere and focus on intervention efforts to improve their adherence rates. Physicians and health care providers tend to poorly predict which of their patients will comply, although they often assume that they can identify potentially noncompliant patients by their patient's educational level, income, gender, or personality. One survey indicated that 76% of physicians attributed non-adherence to one or more of these characteristics, but in fact the accuracy of predictions based on these variables is no better than chance (Meichenbaum & Turk, 1987). In general, there are no characteristics that consistently identify noncompliant patients, with one exception: Across all studies and all diseases, individuals who are experiencing depression or psychological distress tend to be less compliant with treatment (Chesney, 1997).

One of the most consistent findings of research on compliance is that there is a direct association between poor compliance and the extent to which an assigned regimen interferes with daily life, the complexity of drug regimens, the number of specific medications that are

prescribed, and poor communication between patient and provider (Dunbar-Jacob, Burke, & Puczynski, 1995). Clinicians can promote compliance by providing patients with tools that will help them achieve and maintain a high level of compliance, by devising dosing schedules that can be integrated into their patients' daily routines, and by encouraging compliance in every encounter with every patient (Chesney, 1997).

Rapoff (1999) has proposed a model of treatment adherence that specifically addressed the importance of treatment characteristics, such as the face validity, duration, and complexity of the treatment regimen; the deviation required from normal routine; adverse side effects of medication; technical skills required; and the self-awareness needed to implement treatment. Clay and Hopps (2003) focused on treatment accommodations for rehabilitation patients, which refers to the extent to which a specific treatment is adaptable to better fit into the unique and complex lifestyles and limitations of patients. Providers must focus on the values and desired outcome of the patient and the content of the treatment.

The purpose and goals of treatment must reflect the values and desired outcomes of the patient and family (Clay & Hopps, 2003). Pain rehabilitation providers generally establish treatment goals that include optimal medical outcomes (i.e., decreased pain intensity, and maximization of physical functioning and functional capacity). Our aim as clinician should be to encourage patients to make the goals as achievable as possible while still demanding some change.

Treatment Goal Setting to Improve Compliance/Adherence

It cannot be stressed enough how important goal setting is in the treatment process, particularly with patients with chronic pain. As stated earlier, building strong rapport with the patient and establishing a collaborative therapeutic alliance will serve not only to build trust in the patient, but also to increase the patient's motivation and sense of self-efficacy and mastery. Therefore, we recommend the following suggestions that may help increase adherence and compliance, and ultimately help the patients heal and manage their chronic pain more effectively.

Goals should therefore be

Specific: Well-defined goals must be written in terms of what clients will be doing rather than what they will not be doing or thinking. Goals should be broken down into the short and long terms and should be as specific and detailed as possible.

Personal: Goals should be written so that patients know they are in control of fulfilling and meeting those goals, irrespective of other people.

Additionally, goals should be described in the patient's language to ensure that we are working toward a goal that the patient wants, not what we want or what we think the patient should want.

Present-focused: Goals should be anchored in the here-and-now so that the patient can start the solution immediately.

Along with monitoring goal progress throughout treatment, it is also important to assess and monitor the patient's motivation for pain management, or readiness to change, as patients must engage in an active role to manage their pain. Readiness to change was first proposed by Prochaska, DiClemente, and Norcross (1992) who developed the transtheoretical model of behavior change to integrate existing models of psychotherapy into a single model of positive change. Five stages of change were delineated: precontemplation, contemplation, preparation, action, and maintenance. Individuals who change their behavior use different behavior change strategies to progress from one stage to the next.

Motivational interviewing (MI) is a therapeutic approach, based on Prochaska's transtheoretical model, to help clients address and resolve feelings of ambivalence about initiating positive behavioral changes. According to Miller and Rollnick (2002), there are three critical components of motivation: importance (value or incentives), confidence (self-efficacy), and readiness. Change is more likely to occur in a collaborative relationship in which each of these components is elicited from the patient. Despite its efficacy having been demonstrated in other patient populations, no study to date has yet directly tested the efficacy of MI-based treatments for enhancing the efficacy of chronic pain treatment.

Individuals living with chronic pain vary in their degree of readiness to adopt a self-management approach to their chronic pain. Kerns and Rosenberg (2000) have proposed that understanding a patient's stage of change might predict both engagement in self-management strategies and outcomes of these interventions. The measurement of pain stages of change has lent support to the relevance of the model in understanding the processes of engagement, adherence, and change during self-management treatments for chronic pain (Biller, Arnstein, Caudill, Federman, & Guberman, 2000; Dijkstra et al., 2001; Jensen, Nielson, & Kerns, 2003; Jensen, Nielson, Romano, Hill, & Turner, 2000; Keefe, Lefebvre, Kerns, Rosenberg, Beaupre, Prochaska et al., 2000; Nielson, Jensen & Kerns, 2003).

Jensen et al. (2003) developed a preliminary model of understanding motivation for chronic pain self-directed treatment and the implications for enhancing adherence to chronic pain treatment. They define motivation as the readiness to change pain, and postulate that patients will engage in specific pain self-management strategies as a function

of their readiness to use these strategies. Readiness is influenced by the individuals' beliefs both about the importance of and about their ability to engage in pain self-management behaviors. Nielson et al. (2003) have demonstrated that readiness to adopt a self-management approach to pain might be multidimensional in nature. Other researchers believe that the commitment to the learning and application of skills more accurately reflects a continuum of change rather than a stepwise movement through discrete changes (Bandura, 1997; Little & Girvin, 2002).

Interventions for compliance and health behavior change have included strong educational components and behavioral strategies for change and maintenance. For health behavior interventions, specific interventions for pain management, such as pacing activities and relaxation training, can benefit from the basic research and intervention developments within these respective content areas (Dubbert, 2002). Research based on an understanding of the factors involved in the persuasion, social influence, and social control must be directed at educational strategies to alter patients' values, expectations, and belief systems.

SUMMARY

Psychotherapeutic interventions in the management of chronic pain typically involve a cognitive-behavioral approach. The cognitive-behavioral model of chronic pain integrates the physical, psychological, and behavioral aspects of the chronic pain experience. Assessment should be an ongoing process throughout treatment. Interventions are oriented toward the assumption of patients' responsibility for self-management of pain and maintenance of their health. A comprehensive multimodal approach, as reviewed in Turk and Rudy (1994), should include education, skills acquisition, cognitive and behavioral rehearsal, homework, and generalization and maintenance. As clinicians, our primary objective is to assist patients in learning self-regulation and self-control skills, while shaping the patient to owning greater personal responsibility for lifestyle habit changes.

It is crucial that we, as clinicians, understand that treatment of chronic pain cannot operate in a vacuum. By integrating psychotherapeutic interventions with a multidisciplinary approach, not only will we help our patients to better manage their chronic pain, but in addition we will help facilitate their healing from other problems or painful life experiences that have resulted in emotional pain and turmoil. This, as a whole, is effective pain management.

Relaxation and Biofeedback Self-Management for Pain

Frank Andrasik, PhD

INTRODUCTION

Pain is a complex experience that typically requires a multifaceted, multidimensional, multidisciplinary approach. Relaxation and biofeedback are often components of treatment and, although this chapter focuses on these treatments as isolated techniques, rarely are they applied in this fashion. More typically they are combined with one another, various aspects of cognitive-behavior therapy (Gatchel, Robinson, Pulliam, & Maddrey, 2003; Thorn, 2004; Waters, Campbell, Keefe, & Carson, 2004), and ongoing medical care. Consequently, they are one of many options that patients and therapists consider and find of value.

Relaxation, biofeedback, and related self-management treatments (such as hypnotherapy; see Chapter 51 this volume by Burte) share common features that distinguish them from standard medical care. Self-management treatments place less emphasis on physical procedures applied by others; place more emphasis on patient involvement and personal responsibility; expand the scope of treatment to include emotional, mental, behavioral, and social factors that impact pain; and seek to enable patients to cope more effectively with pain and associated symptoms. Active involvement of patients can lead to an increased confidence in their ability to prevent and manage pain and promote new and different ways of dealing with pain, which can lead to less pain-related disability (French, Holroyd, Pinell, Malinoski, O'Donnell, & Hill, 2000). Additionally, patients who attribute therapy improvements to their own efforts demonstrate better long-term outcome than patients who attribute improvement to the interventions of health care providers (Spinhoven et al., 1992).

This chapter begins with a detailed look at varied generalized relaxation techniques, including biofeedback-assisted relaxation approaches. Next follows discussion of more focused or specific approaches to biofeedback and then various procedural matters. The chapter concludes with a brief review of the evidence base for the approaches discussed in this chapter.

RELAXATION THERAPIES

Several rationales justify the use of relaxation with patients experiencing pain. First, a reduction in general arousal leads to reduced central processing of peripheral sensory inputs. Another assumption derives from the pain–negative affect cycle (Fernandez, 2002). Pain often produces negative affective states (depression, anxiety, and fear), which in turn decrease pain tolerance and increase reports and complaints of pain. Achieving a more relaxed state can help to reverse these trends. A final consideration is based on the association of stress and pain, which Melzack (1999) has discussed in detail. Prolonged activation of the stress system increases cortisol levels, which is related to a number of physiological changes that can give rise to pain. Stress is also directly linked to the negative affective triad. Based on these considerations, a case can be made that most patients with pain could benefit from some form of general relaxation.

A number of procedures have been used to promote generalized relaxation. Chief among these are guided imagery, relaxed breathing, autogenic training, and progressive muscle relaxation training. Recent research with

functional magnetic resonance imaging (MRI) has shown that distraction, a common component of relaxation, leads to significant activation within the periaqueductal gray region, a site recognized for higher cortical control of pain (Tracey et al., 2002). Thus, these treatments may be exerting an impact on central mechanisms as well.

GUIDED IMAGERY

The first and simplest approach involves teaching a patient how to create a mental image ("picture in your mind's eyes") of a pleasant or relaxing scene, such as lying on a blanket at the beach while listening to the waves roll in and back out or walking through a pleasant meadow on a warm, sunny day. Patients are advised to avoid images that involve sexual content or vigorous physical activity (as these activities can increase rather than decrease arousal) and to include as many sensory modalities (auditory, olfactory, tactile, and even gustatory) and details as possible (Arena & Blanchard, 2002), as these are believed to deepen the experience. It is recommended that patients practice employing several different relaxing images, so that they can switch to another image if the selected one is not working at a given time. With practice, images can be recalled quickly and vividly and can be used effectively to provide mental escape when situations become seemingly overwhelming. A more detailed discussion of this topic may be found in Bresler (Chapter 52 in this volume).

RELAXED BREATHING

Regulating breathing is a particularly useful procedure because breathing can be readily brought under voluntary control, and it is an activity that is vital to survival. The notion of relaxed breathing is deceptively simple, so most patients need detailed instructions for correct use. Improper application can lead to blood gas imbalance and hyper- or hypoventilation. Also, patients whose initial respiration rate is high (greater than 30 breaths per minute) may feel quite strange as their breathing rate approaches the relaxed range. Such patients are instructed to pay no particular attention to this and are informed that these peculiar feelings will pass with time.

Diaphragmatic breathing is commonly used. It involves teaching the patient to draw air more deeply into the lungs by moving the diaphragm downward toward the umbilicus, thus causing a notable expansion of the abdomen upon inspiration. Gevirtz and Schwartz (2003) provide an excellent discussion of this topic, which includes a brief review of the physiology of breathing and provides instructions on how to teach patients to breathe slowly (to a target range of five to eight breaths per minute), deeply (to full lung capacity), and evenly (to facilitate approximately the same rate for exhaling and for inhaling), while concentrating on the associated physiological sensations.

Having the patient subvocalize a word associated with relaxation on each exhalation can help "cue" subsequent relaxation, just by recalling the word.

Three methods can be used to illustrate this technique. Patients can practice breathing while: (1) holding their arms straight overhead (which minimizes chest movement); (2) lying on a firm surface, placing a medium-weight book on the abdomen, and raising and lowering the text with each breath cycle; and (3) placing one hand on the chest and the other just below the rib cage, breathing in a manner that limits movement of the hand on the chest and maximizes movement of the hand on the abdomen.

When breathing is the sole or main focus, certain instruments may be useful to quantify and shape proper breathing. These include nasal airflow temperature gauge, strain gauge, electromyography (EMG) from accessory breathing muscles, capnometer and oximeter methods, spirometry, arterial blood oxyhemoglobin saturation, and the like. Gevirtz and Schwartz (2003) discuss other approaches for promoting more relaxed breathing as well, including paced respiration, breath meditation, breath mindfulness, rebreathing, pursed-lip breathing, and instrument-based approaches. These very portable procedures can be easily combined (and often are) with other relaxation techniques.

AUTOGENIC TRAINING

A third form of relaxation borrows from the well-developed body of literature on autogenic training, a meditation-type of relaxation that is made up of six components. Autogenic training has an extensive history and involves having patients passively concentrate on key words and phrases selected for their ability to promote desired somatic responses (Schultz & Luthe, 1969). Clinicians typically use two of autogenic training's six components. Patients are instructed to focus on feelings or sensations of *warmth* and *heaviness* in the extremities, as this is believed to facilitate increased blood flow to the extremities, which accounts for peripheral warming and a reduction in sympathetic nervous arousal. It is recommended that patients develop their own phrasing and subvocalize these phrases numerous times (50 to 100) during practice to maximize effects (Arena & Blanchard, 1996). Autogenic training is commonly added to thermal biofeedback (to be discussed later), leading to a technique termed "autogenic feedback" (Sargent, Green, & Walters, 1972)

PROGRESSIVE MUSCLE RELAXATION TRAINING

This form of relaxation involves active tensing and relaxing of groups of muscles as a way to facilitate overall relaxation. The following points are stressed when introducing this form of relaxation training: (1) relaxation training consists of systematic tensing and relaxing of

Note: From Andrasik, F. & Walch, S. 2003. In *Handbook of Psychology* (Vol. 9), A. M. Nezu, C. M. Nezu, & P. A. Geller (Eds.). New York: Wiley. Reprinted with permission.

major muscle groups; (2) tensing muscles even for a brief period results in their reflexively achieving a subsequent lower level of tension; (3) experiencing a broad range of muscle tension levels enables patients to better discriminate when muscle tension is building; (4) with improved discrimination abilities and newly acquired skills for rapidly relaxing muscles, this technique can be used to counteract tension buildup as it occurs throughout the day (termed "applied relaxation"); (5) achieving a deep state of relaxation is a learned skill and requires regular practice; and (6) the focus is initially on all major muscle groups, but groups are subsequently combined over time to permit rapid deployment.

The procedure described here is based on Andrasik (1986) and is summarized in Table 49.1. It begins by having the patient sequentially tense and relax 14 separate muscle groupings in the 18 steps indicated in Table 49.2. Prior to formal instruction, the patient is observed when completing a few practice tension–release cycles, to ensure that the tension generated is proper (neither incomplete nor overly zealous) and is confined to the target group (as this is important to developing discrimination skills). Muscles that are very painful or that have been strained or injured are omitted so as not to cause further problems. Target muscle groups are tensed for 5 to 7 seconds and then relaxed for 20 to 30 seconds, which constitutes a complete cycle. The patient is instructed to attend to the sensations associated with tension and relaxation during each cycle. If a patient prefers a different muscle sequence, it is acceptable to modify the sequence. Once modified, it is important that the patient adhere to the same order, as consistency and routine facilitate training effects. Patients may be periodically instructed to mentally scan select muscle groups that have been targeted

previously in order to identify any residual tension. If detected, another tension–release cycle may be completed. Various procedures, all involving therapist suggestions, may also be used to promote a deepened sense of relaxation (such as having the therapist count out loud backwards from 5 to 1 and instructing the patient that a deeper level of relaxation will be experienced with each successive count, picture oneself descending a staircase and becoming more relaxed as each floor is passed). These deepening strategies are similar to hypnotic techniques, but they are not typically labeled as such. Relaxed breathing and imagery are added early on, in the manner discussed previously. Once the patient has made adequate progress at tensing and relaxing the 14 major muscle groups, the therapist begins to combine various muscle groups in order to abbreviate the procedure first to eight total muscle groupings, and then to four groupings (see Table 49.3).

More specific training for muscle discrimination can be added for areas of difficulty. To demonstrate this aspect, a patient is asked to engage in a complete tension–release cycle involving the hand and arm, then to tense these muscles by only half as much. This is followed by a tension cycle involving only a quarter as much force and so on. Once the concept of differential tension is understood, the patient is instructed to apply differential muscle tensing to the muscles most associated with pain (another procedure for enhancing muscle discrimination abilities is presented later). Final techniques concern relaxation by recall and cue-controlled relaxation. To implement relaxation by recall, the patient is instructed first to recall the sensations associated with relaxation and then to attempt to reproduce these sensations without the aide of tension and release cycles. Actual tension–release

TABLE 49.2
The 14 Initial Muscle Groups and Procedures for Tensing in 18 Steps

 1. Right hand and lower arm (have client make fist, simultaneously tense lower arm)
 2. Left hand and lower arm
 3. Both hands and lower arms
 4. Right upper arm (have client bring his or her hand to the shoulder and tense biceps)
 5. Left upper arm
 6. Both upper arms
 7. Right lower leg and foot (have client point his or her toe while tensing the calf muscles)
 8. Left lower leg and foot
 9. Both lower legs and feet
10. Both thighs (have client press his or her knees and thighs tightly together)
11. Abdomen (have client draw abdominal muscles in tightly, as if bracing to receive a punch)
12. Chest (have client take a deep breath and hold it)
13. Shoulders and lower neck (have client "hunch" his or her shoulders or draw his or her shoulders up toward the ears)
14. Back of the neck (have the client press head backwards against headrest or chair)
15. Lips/mouth (have client press lips together tightly, but not so tight as to clench teeth; or have client place the tip of the tongue on the roof of the mouth behind upper front teeth)
16. Eyes (have client close the eyes tightly)
17. Lower forehead (have client frown and draw the eyebrows together)
18. Upper forehead (have client wrinkle the forehead area or raise the eyebrows)

Note: From "Headaches," by F. Andrasik & S. Walch, 2003. In *Handbook of Psychology* (Vol. 9), edited by A. M. Nezu, C. M. Nezu, & P. A. Geller, New York: Wiley. Reprinted with permission.

cycles are used only as needed to promote the desired somatic state. Practice outside of the office is necessary to maximize effects and patients are typically instructed to practice techniques taught them once or twice per day, and then on an as-needed basis for everyday coping. Pairing relaxing words or cues with the feelings of relaxation can help to evoke relaxation later on (cue-controlled relaxation). Audiotapes prepared commercially or by the therapist during an actual session with the patient facilitate home practice. See Andrasik (1986), Arena and Blanchard (1996), Bernstein and Borkovec (1973), Lichstein (1988), and Smith (1990) for further information about relaxation in general.

BIOFEEDBACK-ASSISTED RELAXATION

BIOFEEDBACK DEFINED

"Feedback" is a process in which the factors that produce a result are themselves modified, corrected, or strength-

TABLE 49.3
Abbreviated Muscle Groups

2. Chest
3. Neck
4. Face (with a particular focus on the eyes and forehead)

Note: From "Headaches," by F. Andrasik & S. Walch, 2003. In *Handbook of Psychology* (Vol. 9), edited by A. M. Nezu, C. M. Nezu, & P. A. Geller, New York: Wiley. Reprinted with permission.

ened by the result. "Bio" is commonly referred to as pertaining to self. Hence, biofeedback is a technique in which information about the self is used to modify, correct, or strengthen processes within the self. More specifically, biofeedback is a therapeutic or research technique that involves monitoring an individual's physiological processes or responses, such as muscular contraction or heart rate, and providing information about that physiological process back to the individual in a meaningful way so that he or she can modify the physiological process (Blanchard & Epstein, 1978). In therapeutic settings the goal is to help individuals alter their physiology to a healthier standard. We all use biofeedback every day. Looking into a mirror to guide how makeup is applied or how our hair is combed are examples of elementary uses of biofeedback.

Feedback is most often presented in auditory or visual modalities, in either binary or continuous proportional fashion. Binary feedback uses a signal that comes on or goes off at a specified value and is used when the therapist is having the patient strive for a specific target level (a shaping procedure). Many applications involve obtaining the lowest possible level of arousal, and these use continuous feedback to produce ever-increasing degrees of relaxation (e.g., a tone is provided that decreases in pitch or volume as relaxation occurs). On occasion, combinations of both are used. The information that is presented to the individual has reinforcing or rewarding qualities when the desired response is produced. Typically the information is presented to the individual in real time, so that the individual can immediately see the results of his or her actions. The individual will eventually cultivate a

greater awareness of his or her physiological processes that are ordinarily beyond conscious control and will eventually develop greater voluntary control over the processes. Voluntary control is developed initially through trial and error, then by successively getting closer and closer to the desired training goal and repeated practice (Andrasik & Lords, 2004).

When recording physiology, care must be taken to ensure that areas for sensor placements are prepared adequately and that the sensors are placed on the proper locations. Electrode sites may need to be cleaned and lightly abraded (although advances in instrumentation are making this less necessary), and a conductive gel applied to facilitate conductance and reduce measurement artifact in certain instances. More detailed discussion of physiology, electrical theory, and bases of the primary responses used in biofeedback may be found in Peek (2003) and various chapters within Andreassi (2000); Cacioppo, Tassinary, and Bernston (2000); and Stern, Ray, and Quigley (2001). Various theories have been used to account for biofeedback, ranging from operant learning to cognitive and expectancy models (Schwartz & Schwartz, 2003).

The goal of biofeedback, in its most common application, is quite complementary to relaxation and other self-management approaches. The distinguishing characteristic is that biofeedback uses instruments that record information about a person's body as a way of gauging targets for treatment and evaluating progress. Biofeedback can give concrete evidence that relaxation is actually occurring. Think of it as *instrument-aided* relaxation. Feedback is a critical link and an additional distinguishing feature of this approach. Imagine how difficult it would be to learn to play tennis if you were blindfolded and were not told when a ball would be served your way. If you should happen to hit the ball, you would have little idea where it went. Removing the blindfold establishes a feedback loop that allows learning to take place more quickly (Andrasik & Lords, 2004).

THREE BASIC APPROACHES

Any response modality indicative of heightened arousal theoretically can serve as a target for promoting relaxation, although three are used most commonly — muscle tension (EMG), skin conductance (or sweat gland activity), and peripheral temperature. These modalities, termed the "workhorses" of the biofeedback general practitioner (Andrasik, 2000, 2004), are easily collected, quantified, and interpreted and are discussed below. Other responses, such as heart rate, respiration, blood volume, and electroencephalogram, can be useful, but these will not be addressed further (see Andrasik, 2000; Andrasik & Lords, 2004; Cacioppo et al., 2000; Flor, 2001; Stern et al., 2001; and Othmer & Othmer, Chapter 50 of this volume, for discussion).

EMG-Assisted Relaxation

The rationale for employing muscle tension (and skin conductance, too; see next section) feedback to facilitate relaxation is straightforward. The basis of the EMG signal is the small electrochemical changes that occur when a muscle contracts. By placing a series of electrodes along the muscle fibers, the muscle action potentials associated with the ion exchange across the membrane of the muscles can be detected and processed (when single motor units are the focus of treatment, as in the case of muscle rehabilitation, fine wire electrodes that penetrate the skin surface are used). EMG monitoring from surface sites is accomplished by the use of two active electrodes, separated by one ground electrode, to set up two separate circuits to detect electrical activity that leaks up to the skin surface. With this arrangement, the resultant signal is the difference between the two circuits (with the amount subtracted out considered to be noise).

When EMG is used for generalized relaxation, sensors are typically placed on the forehead region (one active sensor about 1 inch above the pupil of each eye, with the ground or reference sensor placed above the bridge of the nose), or along the neck or trapezius (shoulder) muscles. The frontal placement, which employs large-diameter sensors, is sensitive to muscle tension from adjacent areas, possibly down to the upper rib cage (Basmajian, 1976). Reducing forehead muscle tension can affect other adjacent untrained muscles, promoting a state of "cultivated low arousal." This does not automatically occur (Surwit & Keefe, 1978), so clinicians may need to train patients from several sites in the course of general relaxation treatment (or combine biofeedback with other approaches).

Surface EMG has a power spectrum ranging from 20 to 10,000 Hz. Some of the commercially available biofeedback machines sample a very limited amount of this range. For example, some machines filter out EMG occurring below 100 Hz and/or above a certain value (sometimes as low as 200 Hz). This misses much of the EMG power spectrum and results in lower readings overall. Clinicians need to be aware of the "band pass" of their equipment and to realize that readings obtained from one machine may not be comparable with those obtained on another machine where different settings may be employed. Some of the other factors affecting measurement quantity include sensor type and size, sensor placement on the muscle, distance between sensors, and patient adiposity (as fat acts as an insulator and dampens the electrical signal).

EMG activity can be summarized and presented in various ways. The EMG signal is an alternating response with a very high frequency. These characteristics make it difficult or nearly impossible for subjects to discriminate the small changes in EMG activity that must be detected for learning to occur. Consequently the raw signal is

hardly ever used. EMG signals are rectified, smoothed, and averaged over time periods to provide useful feedback, with the values expressed as microvolts. The microvolt information is provided back to the person via some type of computer presentation that is pleasing and understandable to the patient.

Skin Conductance-Assisted Relaxation

Electrical activity of the skin or sweating has long been assumed to be a good measure of arousal. In fact, in the late 1800s Romain Virouroux included measures of skin resistance to facilitate understanding when working with cases of hysterical anesthesias. Electrodermal activity became popular and was thought of as a way to read the mind when used by Carl Jung in the early 1900s in word-association experiments (Neumann & Blanton, 1970; Peek, 2003).

Two separate portions of the central nervous system are believed to be responsible for control of electrodermal activity (Boucsein, 1992). Sensors are typically placed on body surface areas that are most densely populated with "eccrine" sweat glands (such as the palm of the hand or the fingers), as these respond primarily to psychological stimulation and are innervated by the sympathetic branch of the autonomic nervous system (Stern et al., 2001). Sweat contains electrically conductive salts, and sweaty skin is more conductive to electricity than dry skin. A skin conductance biofeedback device applies a very small electrical voltage to the skin (so small it is undetectable to the person). Conductance measures (the reciprocal of resistance; measured in microohms or microsiemens), as opposed to resistance measures, are preferred in clinical application because the former measures have a linear relationship to the number of sweat glands that are activated. This permits a straightforward explanation to patients (as arousal increases, so does skin conductance; focusing on decreasing skin conductance helps to lower arousal and to achieve a state of relaxation).

Skin-Temperature-Assisted Relaxation

It is less obvious why skin temperature has been targeted for general relaxation. This is because the first clinical application resulted from a serendipitous finding by clinical researchers at the Menninger Clinic. During a standard laboratory evaluation it was noticed that spontaneous termination of a migraine was accompanied by flushing in the hands and a rapid, sizable rise in surface hand temperature (Sargent et al., 1972). This led Sargent et al. to pilot-test as a treatment a procedure wherein migraineurs were given feedback to raise their hand temperatures as a way to regulate stress and headache activity. Treatment was augmented by components of autogenic training (Schultz & Luthe, 1969), leading to a procedure

they termed "autogenic feedback." Noting that constriction of peripheral blood flow is under control of the sympathetic branch of the nervous system, these researchers reasoned that decreases in sympathetic outflow lead to increased vasodilation, blood flow, and a resultant rise in peripheral temperature (due to the warmth of the blood). Thus, temperature feedback may best be thought of at the moment as yet another way to affect the sympathetic nervous system and facilitate general relaxation.

Temperature is monitored by highly sensitive probes, called thermistors, whose resistance changes in a lawful, linear manner as a function of temperature change. They are typically composed of a semiconductor, although thermocouples, composed of two different metals in juxtaposition, are used occasionally. It is important to note that the laboratory, clinic, and outdoor temperature and humidity influence heat buildup if sensors are not attached properly, and wind/air conditioning currents within the room can influence the accuracy of skin-temperature measurements.

SPECIFIC BIOFEEDBACK APPROACHES

"Specific" approaches begin by identifying precisely the physiological dysfunction or response system underlying the pain condition, using a psychophysiological assessment (or "psychophysiological stress profile") (Andrasik & Flor, 2003; Arena & Schwartz, 2003; Flor, 2001), before launching into a course of biofeedback. Psychophysiological assessment is designed to identify the physiological dysfunction or response modalities assumed to be relevant to the pain condition and to do so under varied stimulus conditions, psychological and physical, that mimic work and rest (reclining, bending, stooping, lifting, working a keyboard, simulated stressors, etc.) in order to guide treatment efforts and gauge progress (Andrasik, Thorn, & Flor, in press). This assessment may or may not precede biofeedback-assisted relaxation approaches.

Flor (2001) points out the various functions, utility, and advantages of psychophysiological data collection: (1) providing evidence for the role of psychological factors in maladaptive physiological functioning; (2) justifying pursuit of biofeedback therapy; (3) facilitating tailoring treatments to patients; (4) making it possible to document efficacy, generalization, and transfer of treatment; (5) helping to identify predictors of treatment response; and (6) serving as a source of motivation (e.g., as patients realize they are able to influence bodily processes by their own thoughts, emotions, and actions, their feelings of helplessness decrease and they become more open to psychological approaches).

This data collection involves the following phases or periods:

Adaptation allows patients to become familiar with the therapist, setting, and recording procedure; minimizes

pre-session effects (rushing to the appointment, temperature and humidity differences between the office or laboratory and outdoors); and permits habituation of the orienting response and response stability to occur. Meeting the therapist for the first time, coming into a novel environment, and being attached to unfamiliar equipment may result in temporary increases in arousal for the patient. Without a proper adaptation, the therapist or experimenter may mistake a habituation effect for a training effect. Adaptation refers to the client becoming comfortable and returning to a "normal" level of functioning. Patients are instructed merely to sit quietly during this period.

Although the importance of having an adequate adaptation period is widely acknowledged, little research has been conducted to help identify key parameters of adaptation, the amount of time needed to achieve stability, or how best to define *stability*. Most but not all individuals will adapt within 15 minutes (some may not adapt for the entire appointment; Lichstein, Sallis, Hill, & Young, 1981; Taub, 1977; Taub & Emurian, 1976; Taub & School, 1978). Practitioners may not always be able to wait until stability is observed for key responses of interest (defined as minimal to no fluctuation within a specified period of time). They need to remain mindful of how initial levels may affect subsequent training.

Baseline serves as the basis of comparison for subsequent assessment phases and as the basis for gauging progress within and across future treatment sessions. In clinical practice, a baseline of from 1 to 5 minutes will provide a reasonable representation of the patient's current physiological state.

When the goal of biofeedback is generalized relaxation, therapists may collect a **second baseline** during which the patient is instructed something like the following: "I would now like to see what happens when you try to relax as deeply as you can. Use whatever means you believe will be helpful. Please let me know when you are as relaxed as possible." This serves as a test of preexisting abilities to relax and can be used as a comparison for judging future training effects.

It once was thought that elevated resting levels of muscle tension might be a unique characteristic of patients experiencing chronic pain. A review of 60 psychophysiological investigations including patients with headache, back, and temporomandibular joint disorder (TMD) found minimal support for this (Flor & Turk, 1989).

Reactivity assesses responses to simulated stressors that are personally relevant or conditions that approximate real-world events that are associated with pain onset or exacerbation. There are no standard empirically validated approaches. Some examples of commonly used stimulus conditions are (1) negative imagery, wherein a patient concentrates on a personally relevant unpleasant situation (the details of which are obtained during an intake interview); (2) cold exposure (e.g., for Raynaud's) or cold

pressor test (as a general physical stressor); (3) movement, such as sitting, rising, bending, stooping, or walking; (4) load bearing, such as lifting or carrying an object; and (5) operation of a keyboard or other work device. Although baseline differences for EMG have not been found to reliably characterize pain disorders, symptom-specific responses to stimuli have been found for certain pain conditions on a more consistent basis (see Flor, 2001, for a review).

In assessing reactivity in muscles, some researchers have turned their attention to the psychophysiological model of Travell and Simons (1983) who postulate that a large percentage of chronic muscle pain results from trigger points. Hubbard (1996) has expanded upon their view using the following line of reasoning: (1) muscle tension and pain are sympathetically mediated hyperactivity of the muscle stretch receptors, or the muscle spindles; (2) muscle spindles, which are scattered throughout the muscle belly (hundreds within the trapezius muscle), are encapsulated organs that contain their own muscle fibers; (3) although traditionally viewed as a stretch sensor, the muscle spindle is recognized now to be a pain and pressure sensor and an organ that can be activated by sympathetic stimulation; and (4) thus, the pain associated with trigger points arises in the spindle capsule.

Support for this model comes from studies where careful needle (indwelling) electrode placements have detected high levels of EMG activity in the trigger point itself, but data collected from adjacent nontender sites just 1 cm away are relatively silent (Hubbard & Berkoff, 1993). Further, when exposed to a stressful stimulus, EMG activity increases at the trigger point but not at the adjacent site (McNulty, Gevirtz, Hubbard, & Berkoff, 1994). This work provides further evidence of the link between behavioral and emotional factors and mechanisms of muscle pain. As a result of this basic research, Gevirtz, Hubbard, and Harpin (1996) have developed a comprehensive treatment program that uses EMG biofeedback to facilitate muscle tension awareness in sessions and in daily life activities, to identify stressors triggering increased EMG activity, and to assist patients in finding improved ways to cope with tension producing situations.

Recovery from stress assesses how and when a patient's physiology returns to a value close to that observed prior to stimulus presentation (often responses do not fully return to their starting values).

Figure 49.1 (from Flor, 2001) provides a sample psychophysiological profile. EMG was recorded bilaterally from three sites (masseter, frontal, and trapezius muscles), during baseline, imaginal neutral, stress, and pain situations, and during extended mathematical problems (another mental stressor) and extended movement. Heart rate and skin conductance were also monitored. The following was gained from this evaluation. EMG resting values were markedly elevated and asymmetrical. EMG
FIGURE 49.1 EMG profile of Mr. F. (From Flor, H. 2001.) *Handbook of Pain Assessment* (2nd ed., pp. 76–96). D. C. Turk & R. Melzack (Eds.). New York: Guilford. Reprinted with permission.)

values increased in response to imagery, particularly so for the pain episodes, and they were markedly exacerbated by movement. Heart rate and skin conductance were found to be unresponsive. Treatment focused on tension reduction in relevant muscles and alteration of responding during simulations of aversive situations (e.g., therapist displayed "aggressive verbalization" toward the patient).

The above components constitute the basic approach to psychophysiological assessment. One additional component can be very useful.

Muscle discrimination assesses a person's ability to perceive bodily states accurately. Flor and colleagues (Flor, Fürst, & Birbaumer, 1999; Flor, Schugens, & Birbaumer, 1992) have shown that patients with chronic pain are unable to perceive muscle tension levels accurately both in the affected and nonaffected muscles and that, when exposed to tasks requiring production of muscle tension, these patients overestimate physical symptoms, rate the task as more aversive, and report greater pain. These findings point to a heightened sensitivity.

Muscle discrimination abilities can easily be assessed in a clinical setting (Flor, 2001). This involves (1) presenting the patient with a bar of varying height on a monitor, (2) instructing the patient to tense a muscle to the level reflected in the height of the bar, which is varied from low to high, (3) correlating the obtained EMG readings with the actual heights of the bars, and (4) defining as "good" discrimination abilities correlation coefficients ≥0.80 and "bad" or poor discrimination abilities as correlation coefficients ≤ 0.50.

SELECT EXAMPLES OF SPECIFIC APPLICATIONS AND SPECIFIC SENSOR PLACEMENTS

Arena (cited within Arena & Blanchard, 2002) describes a somewhat straightforward approach to a more individ-

ualized biofeedback treatment for chronic low back pain. Treatment begins with EMG biofeedback-assisted relaxation, initially from the frontal or forehead area, which is then followed by feedback of the trapezius muscles, all performed with the patient sitting in a comfortable chair or recliner. Once the basic strategies are acquired, positions are changed to facilitate generalization of training effects. The patient practices in a comfortable office chair (with arms supported), then moves to an office chair without arm support, and then to a standing position. This phase of training continues for 12 to 16 sessions.

If improvement is insufficient and the patient has not had a prior course of general relaxation training, then this may be pursued. If this is unwarranted or has been unsuccessful, then an abbreviated psychophysiological assessment, based on the logic of biomechanical theory, is conducted to analyze the problem further. EMG sensors are placed bilaterally on the paraspinals (L4–L5) and the biceps femoris (back of the thigh). Recordings are made in at least two positions: sitting with back supported in a recliner and standing with arms by the side. These sites were selected because they provided greater information than other sites (such as quadriceps femoris or gastrocnemius) in prior examinations. References for these, and other EMG placement sites, may be found in Basmajian and DeLuca (1985) and Lippold (1967).

The resulting data reveal one of three patterns of abnormality: (1) unusually low muscle tension levels (which Arena states most typically occurs when nerve damage and muscle atrophy are present), (2) unusually high muscle tension levels (which Arena states is the most common finding), and (3) left–right asymmetry, wherein one side has normal muscle and the other side is either abnormally high or low. Treatment centers on returning EMG values to normal levels. Arena notes that much can be learned by examining gait and posture and correcting faulty positions as well. Sella (2003a, 2003b, and elsewhere in this volume) has commented on these postural aspects as well.

The approach that Arena describes is appealing because of its simplicity. The difficulty is in determining normal versus abnormal values. Experience with a considerable number of patients is necessary for this. Some researchers are approaching this problem in a more systematic manner and developing normative data banks for multiple muscle sites to help identify aberrant values, as these may be suggestive of bracing or favoring of a position or posture and, thus, targets for EMG treatment (Cram, 1990, and Sella, Chapter 45 this volume).

In this approach, multiple bilateral recordings need to be made in fairly rapid succession. To make this feasible, Cram uses two hand-held "post" electrodes to obtain brief (around 2 seconds per site) sequential bilateral recordings while the patient is sitting and standing (rather than having to apply multiple leads or apply and reapply the same set

of leads). Although seemingly straightforward, this approach is actually complex because a number of factors can influence the results (angle and force of sensor application; amount of adipose tissue present, as fat acts as an insulator and dampens the signal; and the exactness of sensor placement).

Studies used to support claims for efficacy of EMG biofeedback for recurrent headache (and summarized in the concluding section) have monitored muscle activity almost exclusively from the forehead area, despite patients reporting other sites as central to their pain (such as occipital, temporal, neck, and shoulders). Support exists for feedback from the upper trapezius muscles (Arena, Bruno, Hannah, & Meador, 1995), and an interesting and creative novel approach, termed the Frontal-Posterior Neck placement, is presented by Nevins and Schwartz (1985). This placement seeks to provide an indirect measure of activity in the occipitalis and temporalis areas, as they are frequent sites of headache activity for certain tension-type patients but sites that are not easily accessed (covered with hair). This is accomplished by placing one active electrode on the frontal area and the remaining active electrode on the posterior neck on the same side. The summated electrical activity between these sites closely approximates that which occurs in the occipital and temporalis areas (when direct comparisons have been made). This approach has been found useful for discriminating patients with headache from patients without headache and headache from headache-free periods in patients with headache (Hudzynski & Lawrence, 1988, 1990). For TMD, in addition to frontal sites, biofeedback is provided from masseter and temporalis muscles (Crider & Glaros, 1999; Glass, Glaros, & McGlynn, 1993; Glaros & Lausten, 2003).

Finally, work undertaken by Sherman and colleagues (Sherman, 1997) has helped to identify the most appropriate biofeedback treatment for patients experiencing phantom limb pain. Pain described as burning, throbbing, and tingling was associated with decreased temperature in the stump, while pain described as cramping was preceded by and associated with EMG changes. Targeting biofeedback accordingly leads to the greatest outcome.

SELECT TREATMENT CONSIDERATIONS

Individuals presenting for biofeedback and relaxation are often confused about the nature of their disorder and are anxious, fearful, depressed, discouraged, and uncertain about their chances for improvement. Brief instruction about factors underlying the condition, pointing out variables that potentially may be controlled by the patient, is often helpful in counteracting the patient's initial feelings of helplessness and in mobilizing interest in treatment. This is followed by a description of treatment and what will be required (frequency and number of sessions, home practice, etc.), and any ancillary treatment that may be used. The explanation of biofeedback is best understood when accompanied by a live demonstration, which points out the steps involved in measurement and provision of feedback. Education remains an integral part of treatment, as patients continue to discover more about causes and newfound ways to react.

Self-management involves learning skills and this requires regular practice and eventually incorporating learned skills into day-to-day activities. In biofeedback, some patients become successful simply by concentrating on the feedback stimulus and becoming aware of corresponding sensations. Others engage in various mental games or attempt to empty their minds completely and think of nothing (Arena & Blanchard, 2002). In early sessions, patients are encouraged to experiment with various techniques, but to remain with a given technique long enough to give it an ample trial period.

The biofeedback therapist is best viewed as a "coach," someone who has special skills the patient does not yet have, but who can impart these skills by properly timed guidance. This involves (1) sharing observations for discussion ("I noticed that your EMG signal suddenly increased. It seemed you might have been clenching your teeth then. How about dropping your lower jaw and moving it just a bit forward? I wonder if anything particular might have been on your mind then?"); (2) determining when breaks and encouragement might be needed (early attempts to lower EMG or skin conductance or to raise hand temperature often are met with the opposite effect and this situation is paradoxically worsened as patients try harder and harder; these occurrences can be of great therapeutic value as they help to demonstrate the relationship between thoughts and physiological functioning and illustrate to the patient how present means of coping are actually "backfiring"; explaining how and why this is happening helps to counteract frustration and get the patient back on track); (3) helping patients to articulate and consolidate learning; and (4) augmenting biofeedback with other self-management procedures as appropriate. With experience, the therapist learns when the patient needs uninterrupted time to practice biofeedback and when support and assistance would be valuable (and refrains from being overly active and intrusive; Borgeat, Hade, Larouche, & Bedwani, 1980).

A typical biofeedback treatment session involves the following components: (1) sensor attachment and time for adaptation, (2) initial progress review, (3) resting baseline, (4) "self-control" baseline (defined as the patient's ability to regulate the target response in the desired direction once training has begun but in the absence of feedback [Blanchard & Epstein, 1978], which provides an index of the ability to perform the biofeedback skills outside of the treatment setting), (5) 20 to 30 minutes of actual feedback (continuous or interrupted by breaks), (6) final resting or self-control baseline (to assess extent of learning within

the session), and (7) final progress review, homework assignment, etc.

Each session should end by reviewing the strategies explored and appraising their effectiveness. Once the patient has shown some abilities to regulate target physiological levels in the clinic, practice outside of the office is encouraged. Initially this practice is performed in a setting maximally conducive to achieving a relaxed state or concentrating on the task at hand. Subsequently, patients are instructed to practice during everyday, but low stress/low pain activities (when driving, shopping, standing in line, during a coffee break, etc.). The final goal is to employ learned self-management skills to counteract the buildup of stress and physiological arousal. Skills have to be highly developed to be successful at this step.

Thus, the goals of self-management are for the patient to be able to discriminate when the target response is in need of control, effect the necessary change in the absence of feedback, apply the learned skills in the real world, and continue use of these skills over the long term. Therapists need, then, to be concerned with generalization and maintenance of learned skills. Lynn and Freedman (1979) have identified a number of procedures for helping to make biofeedback training effects more durable, for example, overlearning the response; incorporating booster treatments; fading or gradually removing feedback during treatment; training under stimulating or stressful conditions, such as during noise and distractions, while engaged in a physical or mental task; employing multiple therapists, which is possible in group practices; varying the physical setting; providing patients portable biofeedback for use in real-life situations; and augmenting biofeedback with other physiological interventions and with cognitive and behavioral procedures (see Bresler, Chapter 52, and Burte, Chapter 51, this volume; Thorn, 2004; Waters et al., 2004).

There are no firm criteria for deciding when to terminate biofeedback. In research investigations of biofeedback as a general relaxation technique, patients are commonly provided a set number of treatments, typically ranging from 8 to 12. Research conducted with patients with headache has shown that a much-abbreviated form of treatment can be effective, when accompanied by detailed manuals and relaxation tapes that patients study and use at home (Haddock et al., 1997). In practice, the number of sessions is determined according to clinical response, as gauged by degree of symptom relief and/or adequacy of control of the target response. Skilled therapists come to sense when treatment has reached the point of diminishing returns or marginal utility (i.e., response reaches a plateau and further effort does not alter matters much). Some have argued for using a physiological training criterion as a deciding factor; e.g., ability to reduce and keep EMG levels below a certain value for a specified time, ability to raise hand temperature above a certain

value within a specified time period. This intuitive notion has great clinical appeal, but we are not yet at a point where it is possible to advocate for a specific approach.

Although relaxation and biofeedback treatments most commonly lead to positive outcomes, a small number of patients can experience initial negative outcomes (muscle cramps, disturbing sensory, cognitive or emotional reactions) and/or other problems that affect adherence and practice. A small portion of clients may experience what has been termed "relaxation-induced anxiety," defined as a sudden increase in anxiety during deep relaxation that can range from mild to moderate intensity and that can approach the level of a minor panic attack (Heide & Borkovec, 1983). It is important for the therapist to remain calm, reassure the patient that the episode will pass, and when possible, have the patient sit up for a few minutes or even walk about the office when this happens. With patients who are believed to be at risk for relaxation-induced anxiety, it may be helpful to instruct them to focus more on the somatic aspects as opposed to the cognitive aspects of training (Arena & Blanchard, 2002). Schwartz, Schwartz, and Monastra (2003) provide detailed discussions of these potential problems, as well as solutions for addressing them.

Biofeedback as an "Indirect" Approach

Belar and Kibrick (1986) point out how biofeedback can be considered as an "indirect" approach for certain patients. Their use of this term is based more on clinical than empirical reasons. Here the approach is used as a means for facilitating psychosomatic therapy. Consider the example of the patient with pain who steadfastly holds to a purely somatic view and refuses to accept the notion that other factors (emotional, behavioral, and environmental) may be precipitating, perpetuating, or exacerbating pain and somatic symptoms. With this type of patient, a referral for biofeedback is likely to be less threatening (it is construed as a "physical" treatment for a "physical" problem) and to at least open the door for help. As "physiological insight" is acquired, such patients may begin to see the broader picture, i.e., the interplay of physical and psychological factors. In fact, it is not all that uncommon for a patient with pain, who denies psychological factors upon entry to therapy, to make a request like the following after just a few sessions of biofeedback: "Doc, how about turning off the biofeedback equipment today. I want to talk about a few things." From this point on, session time is divided between biofeedback and psychotherapy.

Biofeedback: Therapists, Credentialing, and Resources

The increasing popularity of biofeedback has led to a significant increase in the number of professionals provid-

ing this service to the public. Biofeedback clinicians can be found in a variety of settings: mental health centers, universities, medical schools, hospitals, rehabilitation clinics, and private practice. These clinicians hold degrees in psychology, social work, mental health, medicine, physical therapy, occupational therapy, nursing, and related disciplines. Their training may have been formal, such as at one of the few professional training programs in the country, or as informal as a self-directed literature review. As the issue of reimbursement for biofeedback services becomes increasingly important, professionals are moving toward more formal training and credentialing in the area. Insurance companies and other reimbursement agencies are beginning to require credentialing in biofeedback, in line with their expectation for other modes of treatment. Although credentials are not always required to deliver biofeedback, the extended training and knowledge that is acquired through the credentialing process can only add to a practitioner's competence.

Because anyone can purchase biofeedback equipment and provide treatment, it is important that biofeedback providers be properly trained and credentialed. The applications of biofeedback are diverse and there are many types of training programs. The Biofeedback Certification Institute of America (BCIA) provides accreditation of educational programs that are not based at universities, and this institute also provides certification for basic or general biofeedback and for one specialized use, that concerning EEG biofeedback (or neurotherapy). Both certifications require professional training and an internship period where the applicant works under the supervision of a certified member. Following the internship period, the applicant must then take a written examination and a practical examination. If the applicant is successful, he or she must then participate in ongoing continuing certification to maintain certified status (which is renewed every 4 years).

The Association for Applied Psychophysiology Biofeedback (www.aapb.org), the Society for Neuronal Regulation (www.snr-jnt.org), and the Biofeedback Foundation of Europe (BFE; www.bfe.org) sponsor various training programs at their annual conferences and at other times as well. The BFE has available on its Web site treatment protocols for various conditions developed by experienced clinicians/researchers.

When selecting a biofeedback therapist, consider the following: Is the provider credentialed? Has the provider received extended training (attendance at workshops or professional training in biofeedback)? Does the provider engage in academic pursuits involving biofeedback (present or teach courses on the topic)? Is the person licensed or certified in his or her specific field? Is the provider familiar with the diagnosis you are seeking to have treated? A list of certified providers may be found at the BCIA Web site (www.bcia.org).

EVIDENCE BASE

The aforementioned procedures have been extensively researched in the literature, with this literature evaluated both by efficacy or task force panels conducting evidence-based reviews and by scientists conducting quantitative or meta-analytic reviews. The chapter closes by providing a brief summary of the extant literature.

The most extensive empirical support for relaxation and biofeedback pertains to treatment of headache. Evidence-based reviews have been performed by various task forces within the Association for Applied Psychophysiology and Biofeedback (Andrasik & Blanchard, 1987; Blanchard & Andrasik, 1987; Yucha & Gilbert, 2004), the Task Force on Promotion and Dissemination of Psychological Procedures (1995), the U.S. Headache Consortium (composed of the American Academy of Family Physicians, American Academy of Neurology, American Headache Society, American College of Emergency Physicians, American College of Physicians–American Society of Internal Medicine, American Osteopathic Association, and National Headache Foundation; Campbell, Penzien, & Wall, 2000), the NIH Technology Assessment Panel on Integration of Behavioral and Relaxation Approaches into the Treatment of Chronic Pain and Insomnia (1996), among others for adult patients. Similar reviews have been conducted for children and adolescents (Holden et al., 1999). Further, meta-analytic reviews have been performed for both adults (Blanchard & Andrasik, 1987; Blanchard et al., 1980; Bogaards & ter Kuile, 1994; Haddock et al., 1997; Holroyd & Penzien, 1986; Goslin et al., 1999; McCrory et al., 2001) and children (Eccleston et al., 2002, 2004; Hermann & Blanchard, 2002; Hermann et al., 1995; Sarafino & Goehring, 2000). All show strong support for relaxation, biofeedback, and related approaches (cognitive behavior therapy). Some research suggests that biofeedback may offer an advantage over relaxation with certain patients (Blanchard et al., 1982). Finally, a meta-analytic comparison revealed similar outcomes for relaxation and biofeedback when compared with various standard prophylactic medications (Holroyd & Penzien, 1990).

Biofeedback-based treatments for TMD have also been the subject of a meta-analysis (Crider & Glaros, 1999). This work primarily involves EMG biofeedback from the following sites: masseter, temporalis, frontal, or intraoral locations. This analysis revealed a mean improvement rate of 68.6% for biofeedback treatments compared with 34.7% for various control conditions. Effect size scores for pain measures were 1.04 and 0.47 and for actual examination results were 1.33 and 0.26 for biofeedback and controls, respectively. Effects noted at the end of treatment were either maintained or improved during follow-up evaluations, some of which extended over 2 years.

Finally, biofeedback and related procedures do have value in isolation when treating patients with chronic pain (Arena & Blanchard, 2001; Flor & Birbaumer, 1994), but effects are maximized when combined with other inventions, as is the practice in most comprehensive treatment centers (Flor et al., 1992; Gatchel et al., 2003; Morley et al., 1999).

Efficacy of Neurofeedback for Pain Management

Siegfried Othmer, PhD, and Susan Othmer, BA, BCIAC

INTRODUCTION

It has been known for some time that self-regulation strategies can alter the perception of pain. The evidence for this is strongest in certain very specific areas such as application to migraines (see Andrasik, Chapter 49 of this volume), tension headaches (Middaugh & Pawlick, 2002), and myofascial pain (Meyers, White, & Heft, 2002). Other applications of traditional autonomic biofeedback have been to arthritis pain, fibromyalgia, temporomandibular disorders, tinnitus, vulvodynia, complex regional pain syndrome, and other kinds of chronic pain (Yucha & Gilbert, 2004). In recent years, we have seen the reemergence of electroencephalography (EEG)-based biofeedback in application to a variety of psychopathologies and neurological disorders. In the context of this work, clinical benefit for certain pain syndromes was also observed. In some instances, this is simply corroborative of what had already been established with peripheral biofeedback. In others, it represents new departures.

The evidentiary basis in the literature for these new findings is still sparse. This is for many of the obvious reasons. Pain syndromes do not present clean targets for research. They are heterogeneous in clinical presentation and often obscure in terms of etiology. They are rarely seen in isolation from other clinical syndromes and/or psychiatric involvement. Self-regulation strategies, in turn, are almost never used as a stand-alone treatment. Chronic pain is rarely addressed with a single clinical approach, particularly in the complex cases where neurofeedback might be most helpful. This fact, plus the strong emotional involvement with pain, renders the demonstration of specific efficacy of neurofeedback problematic. Moreover, self-regulation strategies have traditionally been regarded as part of the discipline of psychology and, hence, have been published largely in psychology journals, most specifically biofeedback journals, with little cross-pollination occurring with medical disciplines (Masterpasqua & Healey, 2003). Further, behavioral interventions have not been favored in the current funding environment. They also present many methodological challenges to placebo-controlled evaluations that are typically mandated in the modern era. Sham training has even been ruled unethical by institutional review boards (IRBs). Finally, there is little motivation for neurofeedback research in the private sector, because nothing patentable is likely to be forthcoming. The process is straightforward and already solidly established within the public domain.

On the other hand, clinicians who have employed self-regulation techniques for pain management have been amply rewarded. Because the utilization of peripheral biofeedback for pain management is already well established, peripheral measures have remained the default choice. Efficacy of neurofeedback for pain control was therefore only discovered fortuitously, reported anecdotally, and studied nonsystematically over the years. In line with increasing interest in brain function and growth in the neurosciences, neurofeedback has recently eclipsed conventional biofeedback in terms of clinical interest, but with respect to cumulative published research, neurofeedback remains far behind. A sober appraisal finds much commonality between the disciplines as well as areas of unique

strengths. We can only hope to bring order to this untidy state of affairs by means of an overarching model.

For present purposes, we intend to construct our argument that neurofeedback represents an alternative mechanization of an overall strategy for improved self-regulation. For purposes of such argument, traditional biofeedback and neurofeedback can be seen as making fundamentally the same case, and the evidence for each is mutually supportive of a single proposition, namely, the responsiveness of pain syndromes to a general self-regulation strategy. Choice between various feedback modalities would then be a matter of relative efficiency rather than of relative efficacy. For other applications, such as neuropathic pain, episodic pain such as migraine, and chronic pain, neurofeedback appears to offer some unique clinical opportunities. Something very specific is being accomplished, and that cannot be understood entirely based on the more comprehensive models.

In sum, then, we build on the surprisingly robust body of research in peripheral biofeedback for headache, plus the strands of evidence that have been forthcoming on neurofeedback specifically, to make the case for a key role of self-regulation in comprehensive pain management strategies. From that vantage point, the case can be made for the specific and perhaps unique role that can be played by neurofeedback for such conditions as neuropathic pain, migraines, and chronic pain in general.

The case for self-regulation-based remedies is compatible with modern conceptions of pain as a homeostatically regulated and emotionally modulated sensory system (Craig, 2002). These centrally mediated, homeostatic mechanisms can become disregulated, and pain itself over time can contribute to further dysregulation through positive feedback. It is easiest to think of self-regulation strategies as targeting dysregulation itself, rather than the pain response directly, in the general case. This makes it reasonable to invoke self-regulatory strategies that on the surface have no obvious direct involvement with pain pathways. Similarly, strategies may be invoked that target emotional regulation rather than pain, with a favorable consequence for pain then being a second-order effect of improved emotional stability.

The principal utility of peripheral biofeedback in pain management has been the calming of high arousal and of hyperexcitability, with beneficial fallout for reactivity to pain and for excessive focusing on the pain experience. With neurofeedback, a more comprehensive approach to arousal dysregulation appears to be possible, so that in addition to the vulnerabilities of high-arousal states one is also able to address the consequences of depressive tendencies and low-arousal conditions. These include lowered pain threshold and adverse impacts on sleep that militate against recovery. Hence, neurofeedback appears to confer improved bilateral control of arousal, both on the high-arousal and low-arousal domains. It should there-

fore be seen as enhancing the regulation of arousal generally (Othmer, Othmer, & Kaiser, 1999).

As central arousal regulation is trained through neurofeedback, it is found that autonomic arousal is better managed as well. In this respect, neurofeedback and biofeedback strongly overlap. In addition, however, nervous system stability is enhanced, which has beneficial fallout for episodic pain syndromes such as migraines. The kindling of a migraine becomes progressively less likely as training proceeds. Benefits are also observed for fibromyalgia pain and for episodic pain events such as trigeminal neuralgia. It is in the stabilization of brain function that particular advantage may exist for neurofeedback, with favorable implications for a number of pain syndromes.

In its role for pain management, neurofeedback must be regarded at the systems level as impinging on primary regulatory functions such as arousal regulation, in which capacity it has varied, diffuse, and multiple effects. Because it impinges at such a basic level on brain function, neurofeedback can be thought of as targeting neuroregulation itself, with the arousal dimension primary. Additionally, however, one aspect of neuroregulation is active management of sensitivity to pain. Here the pain response is considered as a regulatory system in its own right, with its own internal feedback pathways. There are indications that neurofeedback can have a specific effect on the regulatory set points of nociception as well as more general effects on modulatory influences on that system. Hence, neurofeedback can be expected to help not only with centrally mediated pain, but also with nociceptive pain and neuropathic pain.

Finally, neurofeedback offers help for chronic pain that is not fully recoverable because organic injury to the pathways of nociception has already occurred. In these cases, neurofeedback can still favorably affect the pain experience. In this application, one is addressing (in addition to central modulatory mechanisms) the psychological and subjective dimension of the pain response with a technique that is experiential rather than directly ameliorative. The rationale for this approach is the observation that there is an intimate connection between the chronic pain experience and a history of prior psychological or physical trauma. The correspondence is so high that one would not be far wrong to start therapy with the working hypothesis that any case of chronic pain most likely involves trauma as a priming event, irrespective of whether the individual is aware of a specific trauma history.

A particular kind of neurofeedback can be used as an induction technique into regressed, low-arousal states that facilitate the recall and benign processing of traumatic material. Once such processing has occurred, the individual may be in a position to acquire mastery over his or her pain that would not have been possible otherwise. Whereas the primary driver for this aspect of neurofeedback is the experiential, psychological realm, there is also

an EEG training aspect involved. The experience of deep states supports and fortifies the individual's gradual movement out of hyperexcitable states. The training helps to abolish excessive fear responses and, on the positive side, promotes a more secure and stable sense of self. Of most immediate interest is that this training allows the patient to shed victim status with respect to pain, which is quite possibly a signal factor in the successful treatment of chronic pain.

In summary, then, neurofeedback can impinge favorably on the pain experience indirectly through arousal regulation, as well as through enhanced central nervous system and autonomic nervous system stability and improved homeostatic control. These can affect reactivity to pain and reduce vulnerability to episodic pain events. Neurofeedback may also be able to affect pain regulation directly by influencing the pain threshold. Moreover, it can prepare the individual to relieve the psychological factors that sustain the chronic pain experience in an unremitting state. This addresses the degree of suffering experienced because of unremediated pain.

In the following discussion, we focus on a number of pain syndromes and attempt to document the impact that neurofeedback can have even at its current state of novelty and relative immaturity. Brevity compels us to ignore a great deal of clinical detail that has been diligently amassed in this field. We apologize in advance, in that we are single-mindedly focused on the particular contribution that might be made by self-regulation approaches, based on a dysregulation model that establishes connections above the level of such clinical details (Othmer, Othmer, & Kaiser, 1999). It is implicitly understood that self-regulation strategies must find their place alongside a variety of other interventions and work synergistically. It is not the purpose of this chapter to establish that proper balance, nor even to illuminate all of the issues involved, and certainly not to seek an exalted or unique role for the proposed methods.

WHAT IS NEUROFEEDBACK?

Neurofeedback is biofeedback with the EEG used as the physiological variable being measured. Typically, it is some aspect of the amplitude and frequency distribution of the EEG that is placed in feedback configuration with an external feedback loop that involves auditory, visual, or tactile cues to the individual sourcing the EEG. Historically it has been the most prominent features of the EEG spectral distribution that have received the most attention. In the human, waking EEG is the alpha rhythm, which for present purposes can be considered the resting rhythm of the visual system. Also subject to training has been the sensorimotor rhythm, observable most prominently as the sleep spindle in Stage II sleep, which can be considered the idling rhythm of the motor system. Sterman has

recently reviewed this work in application to the control of seizures (Sterman, 2000).

Training an individual to enhance either of these amplitudes typically takes that person toward a lower state of arousal for the duration of the experience. More significantly, however, extended training improves the person's autonomous capacity to regulate arousal appropriately, if that capacity had been in any way deficient. It has become apparent that the EEG reflects the state of central arousal in both the frequency and amplitude properties of the EEG generally (Othmer et al., 1999). Empirically it has been found that the brain responds in terms of arousal regulation in both a general and a specific fashion when reinforcement occurs at any of a variety of EEG frequencies and cortical sites. The response can be thought of in terms of the activation or deactivation of specific brain networks. Thus, arousal dysregulation can now be targeted with a delineated strategy of reinforcements that take into account what is known about localization of function, hemispheric laterality of functional organization, and the particular dysregulation that the patient brings to the task. The entire EEG spectral range has become a target of training in neuro-regulation; similarly, the entire cortex has been targeted by one or another strategy of functional re-normalization.

The EEG also reveals aspects of dysregulation that are of clinical interest. In recognition of the inherent complexity of EEG morphology, an operational solution has emerged in which the EEG is treated self-referentially, and any excursions far beyond "typical" behavior for an individual are deemed to reflect states of dysregulation. Given our still limited understanding of the myriad underlying proximal mechanisms that connect these electrochemical patterns with overt behavior and function, extreme deviation from norms is equated with deviance, i.e., dysregulation. When such excursions are used in a negative feedback configuration over an extended period, a more stable distribution of brain states can be brought about. Clinical phenomenology associated with such dysregulations will then be observed to drop away.

Three main strategies of remediation have emerged in the field. The first targets known physiological mechanisms such as the alpha and sensorimotor rhythm. This was historically the first approach and is referred to as mechanisms-based training. It still dominates the field, and benefits from the most robust literature support. The second strategy attempts to normalize steady-state EEG deviations as discerned by comparison with normative databases. This is referred to as QEEG-based training. As it is very strongly data-driven, this approach has flourished particularly in the medical applications such as traumatic brain injury, stroke, dementia, and seizure disorder. Finally, an approach based on brain function as a nonlinear dynamical system has emerged, in which the targets are dynamically established through a multivariate assessment

of the quality of self-regulation manifested in the EEG at any moment. This is referred to as NLD-based training. There has now been considerable cross-fertilization between these disparate approaches, and the distinctions among them will be obscured in what follows. We refer the reader to other resources for more detailed discussion. The entire issue of *Clinical Encephalography*, 31(1), January 2000, is devoted to neurofeedback and serves as a comprehensive reference (see also Othmer, 2002a, b).

In its most common implementations, EEG neurofeedback has emerged as a dual strategy in which there is both a narrow targeting of specific frequency activity and a broad targeting of what has come to be called dysregulation. The narrow range of target frequencies is reinforced in amplitude, in the hope of establishing the individual in a particular state, namely, one of calm focus. Once that state is achieved, the person is reinforced for maintaining that state. Hence, the exercise may be seen as training the individual in the maintenance of continuity of states. The second aspect of the training involves a comprehensive appraisal of the EEG throughout the frequency domain to discern, and then to discourage through negative reinforcement, excursions into disregulated states.

The two aspects of EEG neurofeedback are generally referred to as reward-based training and inhibit-based training, respectively. By means of reward, the person effectively exercises certain brain rhythms that are important in the regulation of state. These rhythms are always observable and can always be appealed to, irrespective of any dysfunction. Through the feedback pathway, the brain is gently led out of its prevailing state (of arousal, vigilance, attention, emotional set point, etc.). Because the brain actively manages its own states, it will react to this perturbation by way of countering it and restoring the state that it had intended for itself. A kind of push–pull situation is set up in which the brain is provoked to change state through the feedback mechanism, and the brain both yields to this intervention in first instance and then resists it. The brain will not allow its state to be changed arbitrarily. The continuing exercise of this push–pull operation eventuates in improved regulatory control of arousal, and commonly also in the gradual movement toward more functional states.

The information density involved in this feedback process is very high because the EEG is so highly dynamic. When the EEG is surveyed with a narrow-band filter to focus on the part of the spectrum of immediate clinical interest, we tend to observe wavelets of some 300 ms in duration. Evidently, the neuronal ensembles under observation organize themselves transiently to subserve some aspect of brain function, and then that organization dissipates, followed by the formation of another ensemble. Hence, there is a very prominent ebb and flow of EEG amplitudes in any subband even on the 1-s timescale. This makes for potentially highly dynamic, information-rich

feedback to the brain, which is then coached to enhance these amplitudes in the moment. The feedback signal to the brain is updated at normal computer monitor frame rates of 30 to 90/s. Discrete rewards for meeting goals may be given as rapidly as two times per second. Hence, the reinforcement schedule amounts to many thousands of cues in the analog domain, along with a thousand or more discrete (binary) cues in a typical half-hour session. Additionally, the information may be presented simultaneously through visual, auditory, and tactile cues for a still more reinforcing ambience.

This kind of work was originally conceptualized in terms of conventional operant conditioning. However, conventional operant conditioning typically refers to discrete rewards for discrete behavioral contingencies, and in its current implementation, we have moved essentially to a continuous data stream and more toward analog representations. Although discrete reinforcements still play a significant role, they do not index discrete events in most cases but rather signal a state in which all goals of training are being simultaneously met. Because such goals are generously set in order to motivate the client, the nearly continuous stream of discrete rewards becomes the expectation. The disappearance of the reward becomes the uncommon event that draws attention. An analogy can be drawn here to the oddball paradigm in continuous performance tests. In view of such changes, the classical operant conditioning model no doubt needs to be modified or augmented to accommodate these new methods.

An example of a highly disregulated EEG is shown in Figure 50.1. The full-bandwidth EEG shown in the top trace (with 0.5 to 30 Hz bandwidth), and clinically relevant limited-bandwidth traces derived from the raw signal are shown in the remaining three traces. The wavelets referred to above can be readily seen in the band-limited traces.

Insofar as its organization of synaptic information processing is concerned, the human brain is clearly organized exquisitely toward pattern recognition. When such explicit information is provided to the brain about its own function, the brain appears to be able to readily "recognize itself" in the information being presented. We have come to understand the reward-based training based on such pattern recognition. The brain can often respond rather quickly (i.e., within a timeframe of seconds to minutes) in a frequency-specific and cortically localized manner to the proffered signal. The initial consequence is a shift in state of arousal. This shift can then be appraised by the clinician as to its appropriateness to the clinical objective. Is the person moving toward a calmer, more alert state? Is pain subsiding? Is drowsiness increasing or decreasing? Is agitation and anxiety subsiding? Over the longer term, improved self-regulation of arousal and other state variables ensues. Because the patient is often highly labile, the clinician must assure that the training takes place within the envelope of stability of the patient's nervous
FIGURE 50.1 Raw and filtered EEG signals as utilized in EEG neurofeedback. The exemplar shows a highly disregulated EEG. The raw waveform is elevated in amplitude, itself a signature of dysregulation. It also shows epochs of rhythmic EEG dominated by frequencies falling into the theta band. This is a key signature of dysregulation, and it shows up prominently in the second trace, the theta band filtered signal. The reward band (15 to 18 Hz) shown in the third trace reveals the characteristic brief wavelets mentioned in the text. Note the change in average amplitude over the 14-s timescale of the plot, a signature of instability. The same is even more evident in the high-frequency filtered data, where the change in average amplitude is even more abrupt. Note also the sharp, high-amplitude burst in the high-frequency plot, which is also a signature of instability. All of these features are incorporated into multidimensional feedback to cue the brain toward better regulation.

system at that moment, and the magnitude of the challenge has to be adjusted to suit the capacities of the patient.

The inhibit-based training, by contrast, is opportunistic in character. One detects the brain in a trajectory toward dysregulation, and then inhibits any reward as long as this state of dysregulation persists. This repetitive, gentle negative reinforcement eventually moves the brain toward better internal regulation. In contrast to the reward-based training, which is very specific and directive in nature, the inhibits are nonspecific with regard to remedy. The brain simply has to figure out how to respond to the challenge. An advantage of the inhibit-based training is that it can be performed with almost no clinical discernment involved with respect to the nexus of EEG extrema and specific clinical phenomenology. Inhibit-based training is the embodiment of the principle that dysregulation itself is the target of the training. However, refinements are possible here in terms of the subtlety with which incipient dysregulation may be detected. At worst, even normal excursions in the EEG are called out for inhibition (that is, if the threshold for inhibition were to be set inappropriately). For that reason, the training is carried out under baseline conditions of no overt challenge to the patient, whose only duty is to witness the feedback and to rejoice in his or her success in achieving the rewards that the instrument metes out. Under such baseline conditions, episodic excursions in the EEG should be more unambiguously indicative of dysfunction than would be the case under challenge conditions.

In the final application of neurofeedback, namely, to the remediation of psychological trauma, the feedback technique is deployed in a manner that gently encourages movement toward states dominated by low-frequency activity, in the range of 12 Hz or less. The individual is thus moved toward states of low arousal, and toward internal engagement, shutting off the outside world. Under such benign circumstances, traumatic material has increased likelihood of reaching consciousness, where the material becomes available for resolution or for subsequent processing in a therapeutic setting.

The first utilization of neurofeedback can be considered as primarily impinging on physiological mechanisms: the improved regulation of central and autonomic arousal. The second utilization is intended predominantly to facilitate psychodynamic interventions. Indeed, it appears important to address both physiological and psychological aspects of pain (Singer et al., 2004; Wager et al., 2004) with an aim of reducing it. In practice, a combination of the conventional neurofeedback and the low-frequency inductions are deployed in cases of treatment-resistant chronic pain. The first, or conventional, approach is commonly referred to as SMR/beta training, because of the historical circumstance that the primary training initially took place at the sensorimotor strip, and targeted the sensorimotor rhythm (hence SMR). The sensorimotor rhythm is the 12 to 15 Hz subset of the broader beta band that extends from the top of the alpha band out to gamma (nominally 35 Hz). The second of these techniques is commonly referred to as alpha–theta training because the alpha and theta bands are jointly or alternately reinforced in that procedure. The alpha band is nominally 8 to 12 Hz, and the theta band typically 4 to 7 Hz (although in our mechanization we have adopted the variation of 5 to 8 Hz).

In view of the larger range in terms of both reward frequencies and electrode placement that now characterizes the "SMR/beta" training, the term has become anachronistic, and we now prefer to call this simply "eyes-open" training. For parallelism, then, the lower-frequency training may be referred to as eyes-closed training.

HOW IS NEUROFEEDBACK DONE?

A variety of strategies has emerged in the clinical world to effect both kinds of neurofeedback training. These approaches, or protocols, differ primarily in the relative emphasis given to the single-frequency enhancement and the broadband inhibition strategy, as well as in the kind of decision making that enters into placement of electrodes and targeting strategy. The robustness of the technique becomes apparent when it is considered that a variety of different techniques can all yield positive clinical outcomes. The fact that there is no uniqueness to the remedy also speaks to the issue that what is sought is improved regulation, not a specific set point of function. The term *homeostasis* has been gradually eased out of common usage in the field of biofeedback, as we are recognizing that we do not so much seek a particular brain state as much as we seek the capacity for improved regulation. The focus has shifted from static set points to the dynamics of brain function. Homeostasis is not a point in state space, but rather a trajectory, and a very dynamic one at that.

In the most common implementation of neurofeedback, including our own, the primary emphasis remains on the reward signal. The particular reward frequency that leaves the patient or client in a calm and focused state turns out to be highly individual. It is determined by iterative trial and frequent communication with the patient as to mental, physical, and emotional state. In sensitive individuals, discernment of change in state of arousal can often be achieved within just a few minutes. Patients with pain, however, may be so involved with their pain that they cannot report well on subtle changes. They may have lost some degree of discrimination. In that event, we work session to session to optimize the reward frequency for best outcome. To this end, we inquire as to quality of sleep and other factors. (Peripheral physiology can be helpful in this appraisal as well. Autonomic measures such as finger temperature and galvanic skin response are sensitive to state shifts that are beneath the level of awareness of the untutored patient.) In this application, however, the autonomic measures are made available to the clinician rather than to the patient, as they would be in conventional biofeedback (Schwartz & Andrasik, 2003).

In our reinforcement of the target frequency, there need be no concern about whether we are targeting a particular deficit in the EEG. It is best to think of this in terms of an exercise of the mechanisms by which the brain manages its activation–relaxation dynamics. Such an exercise could presumably be conducted at a number of EEG frequencies. However, it is also necessary to maintain the individual in a good state of functioning throughout the exercise. This constraint makes it necessary to assure precise targeting of the reward frequency. This is most particularly true in patients who are highly reactive, patients with pain foremost among them.

The inhibit strategy can either target the whole range of EEG frequencies at once, as we commonly do, or it can selectively target those bands where the dysregulation is most likely to manifest. The difference in training strategies falls out in terms of relative training efficiency, but not in terms of basic efficacy. Dysregulation simply needs to be systematically detected, and that can be done in a variety of ways using any number of variables by which the EEG may be characterized. One now increasingly takes the perspective of nonlinear dynamical systems theory to argue that normal EEG behavior is of bounded variation. Any extreme excursions in any EEG variable are deemed signatures of dysregulation, particularly in the benign baseline state in which the training takes place. The particulars need not even be understood in order for this strategy to be successful, although our understanding of the EEG is advancing rapidly.

Sessions are conducted with nominally 30 min on the instrument. Reinforcement schedules are set to maximize motivation of the client throughout the process — not too difficult to prevent frustration, and not too easy to forestall boredom. Hence, reinforcement thresholds are set according to psychological criteria more than psychophysiological or neurological ones. A discrete criterion is needed, but the specific choice involves some arbitrariness. Sessions can be conducted at rates from 1 to 10 per week, essentially up to the tolerance of the individual. Learning rates appear to scale with session time over that entire range.

Assessment to guide neurofeedback training is done comprehensively. This follows from the fact that the immediate objective of the training is improved self-regulation of central states and the autonomic nervous system. Pain is just one index of such function. The quality of sleep must be assessed, as well as daytime functioning in terms of arousal level, affect, energy level, and executive function. Other factors that may be brought to bear are cognitive function (e.g., Egner & Gruzelier, 2001; Vernon et al. 2003) and the variation in any other symptoms that the patient may have reported or to which the patient is known to be vulnerable.

PAIN FROM THE PERSPECTIVE OF THE SELF-REGULATION TECHNOLOGIES

In the following, various pain syndromes are discussed in terms of the general categories that have been identified:

(1) pain that is significantly connected to arousal level and to nervous system hyperexcitability, (2) episodic pain associated with central nervous system instability, (3) pain that is exacerbated by prior traumatic experience, and (4) specific pain categories such as neuropathic pain. This is admittedly an unusual partitioning, but it fits with the remedy that is being brought to bear. From the standpoint of neurofeedback, the genetic endowment and any organic factors exacerbating the pain response are simply givens that are oblique to our concerns. What matters is how regulation of physiological state can be recruited to diminish or even abolish the ongoing pain experience, to diminish severity of episodic pain and reduce incidence of events, and to remediate the trauma response and the general emotional vulnerability that sustains and infuses the pain experience.

The case of migraines is discussed first because of the foundation of evidentiary support available from research in traditional biofeedback. Migraines are most representative of the class of episodic pain phenomena grounded in central nervous system instabilities. The case of migraines illustrates what is perhaps the greatest contribution of neurofeedback, namely, a general strategy for the stabilization of cortical/subcortical regulatory networks. This example is also featured first because it represents one of the few categories of debilitating pain in which essentially complete resolution is a prospect for the large majority of cases.

APPLICATION TO MIGRAINE HEADACHE: CEREBRAL INSTABILITY

The diagnostic category that has benefited from the most solid research support in biofeedback is migraine and what has been called tension headache. This application area is covered in another part of this volume with respect to autonomic or peripheral biofeedback and, therefore, is not treated here. The collective import of numerous studies on migraine is that peripheral biofeedback matches medication efficacy in the short term and exceeds it in the long-term. Moreover, the two modalities can have additive benefits. The solidity of the evidence notwithstanding, there has not been a groundswell toward the adoption of biofeedback for migraines over the years.

This might be primarily because neither the culture of medicine nor the constraints of the reimbursement environment favor the adoption of a time-consuming training strategy. However, there are at least three additional reasons relating to the shortcomings of traditional biofeedback. First, biofeedback is not generally relied upon to abort ongoing migraines. If despite biofeedback training a migraine eventuates, little can be done in terms of traditional biofeedback to help in the moment. Therefore, biofeedback is not an emergency treatment. (However,

biofeedback countermeasures taken during the prodrome may be helpful prophylactically.) Second, biofeedback approaches tend not to be successful with hormonally mediated migraines, a large subset because migraines tend to afflict females predominantly and to occur preferentially either at ovulation or in the late luteal phase. Finally, there appears to be quite commonly the need for ongoing physiological self-regulation practice. Few chronic migraineurs "graduate" from biofeedback with any finality.

These three critical shortcomings of traditional biofeedback appear to be largely resolved with new developments in neurofeedback. First, with emerging EEG training strategies there is now a high likelihood of aborting an ongoing migraine or at least of setting it upon a largely irreversible course toward resolution some time after the session is completed. With current practice, some 50% of migraines can be aborted within a 30-min session, and 80% of the remainder will be redirected from their normal trajectory toward resolution over the succeeding few hours. Second, there appears to be no residual distinction in terms of efficacy between hormonally mediated and other migraines. Third, migraines may resolve so completely, even in long-term case histories of medically intractable migraines, that no further intervention is required, at least over typical periods of post-treatment follow-up care.

These findings are now merely observational, but they have gained empirical confirmation over more than a decade of clinical work. Jointly they appear to make the case that EEG neurofeedback offers something unique in migraine management that happens to address all of the principal shortcomings of the standard autonomic self-regulation approach. On the other hand, there have been complementary developments in conventional thermal biofeedback as well, which bear on this question.

Carmen (2004) reports startling results for a technique of thermal reinforcement of cortical activity prefrontally. This finding emerged fortuitously out of an attempt to recover from the terminal stage of migraines by use of thermal down training of cortical vascular activity. Migraines are commonly attended, after all, by elevations in thermal emissions from the scalp surface. It was found that thermal down training was relatively ineffective in the intended role of aborting migraines, but not, however, thermal up training. With a simple scheme of rewarding the person for increasing output in the thermal band of 12 to 14 μm using an infrared sensor, recovery from an ongoing migraine could be routinely achieved. Similarly, the long-term outcomes of such training were more satisfactory. In addition, there was no longer any talk of hormonally mediated migraines being refractory to treatment.

Thus, it appears that a "conventional" biofeedback technique was, in fact, capable of matching the results of neurofeedback in nearly every respect. While both of these techniques are unambiguously superior in outcome to the

standard biofeedback that has been the subject of so much published research, the relative advantage of the two emerging techniques can be established only by formal comparative studies. In the meantime, claims of exceptionalism for neurofeedback with respect to migraine have to be set aside as well.

Interestingly, Carmen makes the case that this kind of thermal training should be considered a neurofeedback technique, rather than fitting within traditional thermal biofeedback. The reasoning goes as follows: Traditional temperature training of hands or feet finds its rationale in the normalization of autonomic — in particular, sympathetic — arousal. This is clearly not the case with thermal training of cortical activity. It is well known by now that neuronal activity (including glial cell activity) is the source of heat in the brain, and that the vasculature is the thermal sink on which we critically depend. An increase in thermal emissions from cortex could arise either from greater cortical neuronal activation or from reduction in heat removal. Given the traditional preoccupation with vascular phenomena in migraines as well as the direct tie-in with heat removal, Carmen calls his technique hemoencephalography (HEG), and by virtue of detection of infrared cortical emissions, more specifically pIR HEG (for passive infrared). His paper reporting on 100 cases of migraine has been recently published (Carmen, 2004).

The startling finding was that if one counted only those subjects who came for at least six sessions of training, men in the study were successful in 100% of the cases in significantly reducing their migraines. Women were successful at a 92% level. The overall success rate was 95%. One may conjecture that in women there tend to be more severe comorbidities and, in particular, more trauma histories that may not have been disclosed to the (male) practitioner. Carmen also reports that migraine-like (i.e., episodic) phenomena may continue to be observed after the completion of training, but these events may not involve pain at all.

We are confronted with the emerging reality that unprecedented results can be achieved in migraine management using two techniques that have essentially nothing in common methodologically. Moreover, when one delves into the details with respect to both techniques, the results appear to depend on very particular circumstances. For example, the most favorable outcomes in pIR HEG seem to require training at Fpz vis-à-vis Fp1 or Fp2 (in the Standard International 10–20 System), for example. The EEG training proceeds most efficiently, on the other hand, by training at temporal sites, T3–T4 in bipolar placement (vs. C3–C4, F3–F4, T5–T6, or P3–P4, for example). Even if a migraineur requires training at Fp1–Fp2 for one issue or another, when it is a matter of obtaining migraine relief it appears preferable to repair back to T3–T4. Carmen is developing a rationale that involves frontal lobe

training to underpin this technique. That same model could not serve to explain the neurofeedback results.

It is possible, of course, that the particularity follows from the unique features of each kind of training, rather than from any properties of the migraine mechanism itself. In that event, one may argue that both techniques simply cue the brain toward restoration of the normal state of self-regulation. The fact that neither T3–T4 EEG training nor pIR HEG is targeting a known deficit supports this more general view. The great disparity in techniques, combined with high similarity in clinical outcome, further supports the case for the general self-regulation model. In this view, any physiological variable that either manifests the dysregulation directly or simply ties into the disregulated networks could serve equally well in principle. However, the training of any such variable may also have other effects that are not strictly related to the migraine mechanism, yet need to be taken into account. The training not only serves to stabilize the brain over the long term, but as an immediate consequence also profoundly alters the person's state. In migraineurs who are very sensitive to such changes in state, the training parameters end up being very circumscribed. Thus, training with pIR HEG at Fp1 or Fp2 could, in principle, be equally efficacious from the standpoint of migraines, but also have implications for anxiety, depression, and affective regulation that may be an issue in the same subject. Indeed, this appears to be the case. Moreover, with regard to neurofeedback at T3–T4, a small shift in reinforcement frequency can serve to induce a migraine, or exacerbate migraine pain, as effectively as the "correct" frequency is able to expunge it.

At this point in our understanding, and in cognizance of the Zeitgeist respecting the emergence of integrative medicine, we would be inclined to promulgate the more inclusive view that both EEG and HEG neurofeedback cue the brain toward a more regulated state, each in its own way. The details are important clinically and tactically but are of lesser import in the basic mechanism sense. Both lines of evidence then give independent and complementary support to the same proposition, namely, that migraine susceptibility yields systematically and consistently to a targeted self-regulation strategy.

At the current state of maturity of EEG training procedures, the expectation is that migraine pain should significantly subside or abate entirely within a 30-min training session in the vast majority of cases. In-session changes in levels of pain are also found to be a reliable guide to the optimum training frequency. For obvious reasons, it is preferable to conduct the training when the person is not thus afflicted. However, if the person is able, then there is no reason not to attempt training even with a migraine. Visual hypersensitivity under those circumstances may require resorting to auditory training under eyes-closed conditions or to tactile means of reinforcement.

If migraines occur very frequently, a reduction in both incidence and severity should typically be observable within six sessions, whether these occur via pIR HEG or EEG neurofeedback. Migraine incidence should be eliminated in the vast majority of cases within 20 to 40 sessions. If migraines recur over time, some additional booster sessions may be scheduled. If migraines are observed as comorbidity to other conditions such as fibromyalgia, complex regional pain syndrome, or irritable bowel disease, more extended training is commonly necessary. That is discussed further below.

Efficacy of neurofeedback and biofeedback for migraines needs to be understood. However, the technique itself does not give us much of a handle because it engages with the cerebrum at such a high level. A presumptive deficit in self-organization must exist that renders the brains of migraineurs susceptible to occasional excursions into migraine. The neurofeedback apparently rebalances the excitatory/inhibitory network relations to the point where such an excursion becomes much less likely. The observation that ongoing migraines can also be systematically disrupted by the same technique is intriguing, and most satisfying, but it is not required to support the first claim and may quite possibly require additional explanation.

The complexity of cortical networks is such that the brain satisfies the condition of a nonlinear dynamical system (Llinas, Ribary, Jeanmonod, Kronberg, & Mitra, 1999) and, as such, has to satisfy a variety of stability criteria. If for the sake of argument we refrain from drawing on other hypotheses for insights into the migraine generator, i.e., we confine the discussion to the realm of control theory, then it is possible to say that the problem is one of marginal function with respect to requisite stability criteria. The problem is instability itself. The problem of instability, moreover, now has an operational remedy. The brain can be trained toward greater stability of function, even in the absence of any other intervention. The target of the intervention is the identified instability. Such instability in this case is the property of distributed networks. It cannot simply be assigned to the presumptive migraine generator.

The hypothesis finds support in the extraordinary success rate of this intervention. The essentially equivalent clinical success achieved with pIR HEG supports the hypothesis as well. It is a secondary issue of whether we target the bioelectrical activity of the brain or the thermodynamic measures because the target in each case is the source of the instability in the dysregulation of cortical/subcortical networks. Any variable that reveals such dysregulation to us is a potential target for a strategy of functional renormalization.

One other argument that can be made for the instability model of migraine is that the arousal model does not fit. Migraine susceptibility does not map into high arousal states, for example, as the phenomenon of rebound migraines attests. On the other hand, rapid change in arousal level can trigger the instability, and this includes, in particular, rapid decrease in arousal level. By virtue of their clinical preoccupation with high-arousal states, biofeedback therapists have historically been misled into thinking that parasympathetic dominance was inherently a zone of stability. This has delayed coming to terms with instabilities in the parasympathetic subsystem such as migraine and asthma attacks. Instability can be found anywhere on the arousal curve and anywhere on the sympathetic/parasympathetic continuum.

Another argument is that seizures respond to the same protocol that has been found optimal for migraine. So does bipolar disorder. These three conditions have little in common. They cover a wide variety of possible triggers of unstable state shifts. Yet they all respond to the same intervention. This is not unprecedented, as all three conditions are treated with anticonvulsants. These pharmacological agents target neuronal (i.e., cell membrane) hyperexcitability generally. By analogy, one may think of neurofeedback as changing network excitability through bioelectrical rather than neurochemical means. Just as anticonvulsants do not specifically and differentially target the seizure focus or the migraine generator, but rather the stability of neuronal networks, so does neurofeedback.

There is, in fact, one published study on neurofeedback for migraines that is relevant to the issue of the instability model. In this technique, slow cortical potentials in the EEG are trained transiently in order to shift neuronal populations at that location toward hyperpolarization, i.e., toward reduced excitability, under voluntary control. Evidently, there is a residual effect from this exercise that leaves cortical networks less excitable. This technique has also had a long research history and is known primarily for its use in brain-based communication for locked-in syndrome, as well as for the control of medically refractory seizures. With this technique, a 50% reduction in migraine incidence could be achieved (Kropp, Siniatchkin, & Gerber, 2002). This evidence can serve as independent validation of the efficacy of the neurofeedback intervention. In addition, its use for both seizure control and migraine supports the more inclusive instability model. In terms of clinically significant results, however, this technique has clearly been eclipsed by the new techniques devised with frequency-based training.

FIBROMYALGIA AND REFLEX SYMPATHETIC DYSTROPHY: HYPEREXCITABILITY

It was pointed out above that outcomes are not nearly so straightforward when migraines are seen in the context of other pain syndromes such as fibromyalgia and reflex sympathetic dystrophy (RSD). This is closer to the clinical reality when dealing with chronic pain, in that we rarely

have the luxury of addressing one symptom per patient. The essential difference here is that in these comorbidities one encounters a high degree of cortical hyperexcitability across the board. This feature may be seen in the context of over-arousal, but it is not to be identified with it. It is not a unitary phenomenon. There are various ways in which such hyperexcitability can be expressed. Just as with the instability model above, this particular formulation is chosen because neurofeedback appears to moderate hyperexcitability in the general case. One can think of arousal as a more global variable, whereas hyperexcitability can arise from inadequate inhibition at the level of a particular neuronal network and, thus, can characterize specific systems such as visual or auditory processing.

Hyperexcitability is an issue in migraines as well, for example, visual hypersensitivity. Moreover, instability in turn is an issue in fibromyalgia and RSD. It is a question of which model has the greater explanatory power in each case. Hyperexcitability can be developmental in origin, but more likely is the result of specific physical injury and/or psychological trauma. A deficit in inhibitory control develops that allows neuronal pools to be too responsive to weak inputs, to respond too broadly to inputs (e.g., enlarged sensory receptive fields), and to respond too strongly to inputs that should be handled benignly. These circuits could even activate in the absence of any provocation whatsoever, or they can recruit other cortical regions into what we call a dysregulation cascade.

The essential nonlinearity of the organization of synaptic activity comes to the fore particularly when the system goes into dysregulation. A bowling analogy comes to mind, which leads us to the concept of a dysregulation cascade. On the short timescale of minutes, hours, to days, one can often observe patients slip into states of more profound dysregulation, and one can observe the same on long time scales of months to years. The dysregulation of one system gradually disregulates another. The nonlinearity of this process explains the paradox that whenever one intervenes successfully with one aspect of such dysregulation, the entire physiology appears to benefit. Thus, one may target sleep dysregulation, depression, or the pain response itself, and obtain a certain amount of relief for pain. In addition, once we move the person into the right direction physiologically, the nonlinearity is our ally. Symptom improvement should be greater than the change we produce in constituent variables, or in a particular subsystem. Put simply, even a little progress can do much good.

We have found it necessary to accept a certain lack of tidiness when it comes to chronic pain and to realize that however re-regulation is brought about, we are having an impact on dysregulation itself and, in particular, on the dysregulation cascade, its nonlinearities, and mutual couplings. The consequences do not fall out narrowly for one symptom or another but rather to the whole bouquet of symptomatology, including, in addition to pain, the quality of sleep, the anxiety/depression domain, energy level, perceived level of cognitive function, as well as emotional tone and equilibrium.

FIBROMYALGIA

There have been two published studies that bear on the application of neurofeedback to fibromyalgia. The first of these, by Donaldson and colleagues (Donaldson, Sella, & Mueller, 1998) employs a mix of techniques that includes both peripheral biofeedback and EEG biofeedback modalities. Even with regard to the neurofeedback component, the study deviates from convention. It employs a relatively novel technique in which extremely small electromagnetic fields, modulated at EEG frequencies, are delivered to the scalp to alter the EEG. First, such stimulation can be used to disrupt the brain's residence in pathological states. Second, the brain apparently detects even such low-level disturbance and attempts to compensate for it to maintain its desired function. Such a reaction exercises the regulatory circuits, with the longer-term consequence of improved regulatory function.

The second study, by Xavier Caro, evaluates one of the standard neurofeedback protocols for fibromyalgia when used in conjunction with a comprehensive medical treatment (Caro & Winter, 2001). Amazingly, Caro finds that patients maintain the intensive training schedule with surprising regularity. Such unusual compliance with a time-intensive regimen is itself an argument for the neurofeedback contribution to recovery. In a comparison study of 15 patients with long-term fibromyalgia who received at least 40 sessions of neurofeedback (average of 58 sessions; range of 40 to 98) and a group of 63 patients who had been involved in long-term follow-up, Caro found significant improvement in physician-assessed tenderness, self-reported pain, and fatigue ($p < 0.006$). Visual attention measures also improved (although not auditory ones), as indexed by a continuous performance test ($p < 0.008$).

Somatic symptoms had not changed significantly in the historical controls over a median of 6.4 years of longitudinal observation. Quantitative EEG measurements were also used in his clinic to document progress with the training. The experimental group of 15 was drawn from 42 subjects who had entered into the study. Of these, 19 received at least 40 sessions of EEG training. Of these, 4 were excluded from the analysis because of conflicting medical or psychological problems. Forty sessions were thought to be a reasonable cutoff to judge the effect of the training, but it turns out that a number of patients did not reach the 40-session milestone because their symptoms remediated sooner. Others dropped out for lack of insurance company support.

Caro's work involved the use of one of the standard neurofeedback protocols that was commonplace at the

time and had much literature support in application to attention-deficit hyperactivity disorder (ADHD). The technique involved reinforcement of the SMR band (12 to 15 Hz) with simultaneous inhibition of excessive amplitudes in the 4 to 7 Hz and 22 to 30 Hz bands, with placement at Cz, the vertex of the International 10/20 System (Jasper, 1958). This particular protocol had been devised for working with ADHD (Nash, 2000). Could this same technique help with the attentional and cognitive deficits of fibromyalgia? Also, "In our experience many FMS symptoms correlate with one another, i.e., when one symptom worsens or improves, other symptoms tend to worsen or improve simultaneously" (Caro & Winter, 2001). This empirical finding supports the dysregulation model for fibromyalgia. Indeed, a correlation was observed between the improvement in attentional measures and the pain assessments.

Over time, with the growth of the field of neurofeedback, there has also been an increased diversity of protocols. In our own work, the evolution has taken us to the point where a variety of techniques are used to address different aspects of the clinical presentation. Substantial reduction or even elimination of fibromyalgia pain is now possible in the vast majority of cases within 20 to 40 sessions of neurofeedback. Improvement in the quality of sleep is likely to be reported. There should be improvements in energy level when fatigue is an issue. Moreover, improved cognitive function is often reported anecdotally, even if that cannot always be documented.

Although assessments are necessarily subjective when it comes to pain and self-perceived energy level, it should be possible to quantify the improvement in cognitive function. Paradoxically it has not often been possible to verify the cognitive deficits of which patients complain. One possible explanation is that we are dealing with patients who have historically been high performers, and who are suddenly reduced to performance that still lies within the normal range of function, but is experienced as a deficit. Another explanation may lie in the fact that typical assessment tools tend to cover the range of more profound cognitive deficits, and suffer from ceiling effects when applied to those who are more functional. It is also possible that these patients can briefly rally to meet a cognitive challenge in a testing environment, without necessarily being in a position to sustain such a level of mental efficacy.

Over time, it may be necessary to undergo an occasional neurofeedback session in order to maintain gains. The vulnerability to symptoms manifestly persists, and the vicissitudes of life often plunge the patient with fibromyalgia back into symptoms. This is in contrast to migraines, where training may reach a definable end point. It may be considered paradoxical that instability conditions such as migraine can respond more completely and more comprehensively to neurofeedback than conditions grounded in hyperexcitability. This may be understood in the following way. The brain of a migraineur may be considered quasi-stable against migraine formation. It may not take much in terms of brain training to confer sufficient stability to the brain so that migraine formation does not propagate from the presumptive migraine generator. Hyperexcitability, on the other hand, may be a more fundamental, general, or intrinsic property of a particular brain, whether by virtue of developmental history, learned behavior, or organically acquired dysfunction. It may take longer to normalize.

In fibromyalgia cases, we may find certain characteristic EEG anomalies that constrain our operational space. Often, for example, excess alpha amplitudes are observed in the waking EEG, and alpha intrusion in sleep is sometimes observed. In consequence of this, a lack of restorative sleep is often reported. EEG training can serve to normalize the EEG in such cases, and sleep behavior may normalize as well. The underlying vulnerability may remain, however. If one later initiates alpha–theta training in order to access prior traumas, the alpha signature of dysregulation may resurface. As with other conditions of chronic pain, a high likelihood prevails of a trauma history among those with severe and intractable cases of fibromyalgia. If these cannot be accessed via alpha–theta training, then other techniques, such as eye movement desensitization and reprocessing or hypnotherapy, may need to be brought to bear.

REFLEX SYMPATHETIC DYSTROPHY

Reflex sympathetic dystrophy or complex regional pain syndrome is one of the most challenging conditions confronted in the neurofeedback practice. We are not aware of any published report, and the following is simply a reflection on our clinical work with this condition. The extent of symptom relief that can be achieved appears correlated with the length of time that the person has been symptomatic. What may start out as a largely functional deficit may progressively become a more intractable organic condition. In application to RSD, we expect neurofeedback to be only moderately ameliorative in severe cases. Patients report improvement in sleep, in energy level, in the ability to undertake life tasks, and perhaps in the level of pain. However, sleep improvements may be transient, in some cases lasting only one to three nights after a neurofeedback session. In these cases, it is advantageous for the person to conduct training sessions at home between visits to the clinic.

In RSD, we may be engaged through neurofeedback in an ongoing campaign of symptom suppression. A variety of techniques may be used in that effort, including, in particular, peripheral biofeedback and possibly cortical electrical stimulation (CES). No matter what array of techniques is employed, the patient will usually identify some unique benefit with the neurofeedback, even if that benefit

TABLE 50.1
Self-Reported Symptom Severity before and after Neurofeedback in RSD

Pre–Post Comparison Variable	n-Value	p-Value
Average pain level for five sites	19	0.001
Headaches	17	0.000
Muscle tension	12	0.000
Muscle spasms	13	0.046
Anxiety–agitation	13	0.002
Feeling more rested	7	0.007
Falling asleep	7	0.021
Staying asleep	7	0.033
Depression	15	0.017
Mental clarity	12	0.000
Ability to cope with the pain	15	0.000
Perceived energy level	12	0.018
Feeling of well-being	16	0.001

is only transient in nature. For cases such as this, we may find it beneficial to move to "always on" neurofeedback using ambulatory monitoring of the EEG and auditory feedback, in order that the patient may continuously optimize his or her state, and in order to be able to take advantage of the most propitious times to train the brain.

The objective first is to reduce the high arousal level in which the person is living. Second is to help normalize autonomic arousal. Third, the objective is to improve sleep architecture. Fourth is to address the anxiety–depression continuum. Specific training is undertaken to bring about a sense of body calmness. In each of these aspects of training, the level of pain is used as one index of progress. Training generally has to be maintained over the long term, and for that purpose transition to home training, with continual clinical supervision, is facilitated.

Although no published data on neurofeedback for RSD are available, we have been furnished preliminary statistical data on a clinical study being undertaken with standard protocols (Tracy-Smith, personal communication). Areas of concern where significant improvement was observed with the neurofeedback are listed in Table 50.1. Some additional variables where the improvement was not significant included the following: swelling at RSD sites, discoloration at RSD sites, utilization of spinal cord stimulator, tics, cold or burning skin, light sensitivity, sound sensitivity, memory function, language skills, feeling centered, and relaxation. All assessments were by self-appraisal using a 10-point scale.

It is noteworthy that there were significant improvements in the depression category, in mental clarity, in sleep criteria, in muscle tension, and in the feeling of well-being. Improvements in these disparate variables tend to support the dysregulation model. Finally, it may be seen as ironic that the nonlisted category of "relaxation"

showed no significant change. Actually, this highlights that the objective of relaxation training is not relaxation in the colloquial sense, but rather control. Success in that enterprise may not necessarily be accompanied by the subjective feeling of relaxation.

TRIGEMINAL NEURALGIA

Only a single published report is available on the use of neurofeedback for trigeminal neuralgia, and in this case a combination of neurofeedback and peripheral biofeedback was used (Sime, 2004). The response to the biofeedback was often immediate, however, which supported the clinician's view that each of the features of the protocol contributed to the ultimate resolution of the symptoms. The case concerned a person who was poorly regulated on medical management, and the next planned intervention was the severing of the trigeminal nerve. Some 10 sessions of electromyography (EMG) biofeedback were conducted over a period of 9 months, plus 29 sessions of neurofeedback. Left-hemisphere training appeared best for sleep issues, and interhemispheric training at T3–T4, identical to what is used with migraines, was best for the pain episodes.

The patient experienced a substantial reduction in pain and bruxism as well as improved sleep quality. Symptom reduction varied with the specifics of the protocols used in neurofeedback and later, in follow-up symptom reduction, fluctuated with life stresses. Counseling on stress management was provided in addition to the biofeedback. The success of the treatment was such that surgery could be avoided, and even medication could be discontinued, except for an occasional resort to Ultram. There was some continuing need for self-regulation practice, and the patient returned once for maintenance neurofeedback over the subsequent year.

A number of cases have been seen in clinical settings over the years. Generally, it has emerged that the same techniques are useful for this condition as have been evolved for the remediation of migraines and seizures. Hence, an enhancement of cortical stability appears to serve also to thwart painful episodes of tic douloureux.

MYOFASCIAL PAIN

Insofar as the self-regulation technologies are concerned, myofascial pain has been firmly in the domain of peripheral biofeedback. It was presumed that elevated muscle tension was implicated in the pain mechanism, and EMG training was brought to bear in consequence. For many years, this was considered the standard biofeedback treatment of the condition. More recently, it has been established that the presumptive excess of muscle tension could not be universally identified in this condition.

Rather, it was found that the problem could be traced to an inappropriate set point of the muscle spindles. These set points are sympathetically mediated, so any biofeedback impinging on sympathetic nervous system regulation should have beneficial fallout for myofascial pain, not only EMG training.

At the same time, it was found that a different biofeedback modality, namely, heart rate variability training, gave superior relief clinically (Lehrer, 2003). In this modality, paced breathing is used to drive blood pressure regulation and heart rate over a wider dynamic range. In a well-regulated system, heart rate varies in approximate synchronization with the breath, a phenomenon known as respiratory sinus arrhythmia. The baroreflex system that modulates blood pressure fluctuates at the same frequency, but at a different phase. At a sufficiently slow breathing rate, nominally 6/min, the system achieves resonance, with the forcing function of the breath "pumping" the baroreflex system and the oscillations in heart rate to larger cyclical excursions. This process can be thought of as exercising the relevant autonomic regulatory loops. These are enervated both sympathetically and parasympathetically, so that both arms of the autonomic nervous system are trained in a dance of mutual regulation.

It is important to observe that the target here is pure self-regulation. There is no bias in favor of a particular set point of function. There is no direct nexus to myofascial pain. Yet this is observed to be the strongest available remedy in the arsenal of self-regulation technologies. There is a comforting similarity in the language now being applied to heart rate variability training and to neurofeedback by its respective practitioners. Both are challenging regulatory systems somewhat nonprescriptively, simply allowing them to renormalize or reequilibrate. Given this new understanding of the mechanism of relief of myofascial pain, it should be equally appropriate to apply neurofeedback to the task.

Only one publication is available that speaks to the point. Ibric (1996) reports on the response of nine patients diagnosed with myofascial pain. The data are compromised by the fact that each of the patients had at least one additional diagnosis among the following: depression, sleep disorder, anxiety, diabetes, and attention-deficit disorder. The EEG biofeedback training was also provided in the context of other therapies, including other biofeedback. Significant pain reduction could usually be achieved within a neurofeedback session, to the accompaniment of measurable EEG change. Results on one patient are reproduced in Figure 50.2, with pain levels going from 10/10 (maximal rating) at the outset to 1 to 2/10 (minimal rating) by the end of the session, accompanied by substantial (albeit transient) normalization of the EEG. In this particular patient, there was transient recovery from ptosis during the session as well. The patient reported that she had not experienced equivalent relief from relaxation training or any other therapy. No data were provided on long-term outcome.
FIGURE 50.2 Comparison of two EEG plots in the same patient, one taken at the beginning of a neurofeedback session, and one taken near the end. Observe the profound change in EEG amplitudes produced within the session. The change correlates with reported symptom improvement. The initial amplitudes are elevated with respect to norms, so that a reduction in amplitude is to be expected. Significantly, all the bands are elevated in amplitude in the first plot, a feature often seen in severe patterns of dysregulation. As in Figure 50.1, the raw waveform is depicted at the top within each panel, with 4–7 Hz, 15–18 Hz, and 22–30 Hz bands, respectively, below.

TRAUMATIC BRAIN INJURY

There are certain similarities in the history of the medical treatment of minor traumatic brain injury to that of pain. Many of the sequelae involve subjective judgments. Many lack an identifiable organic foundation for which objective evidence can be adduced. There is often very poor prognosis for the most severe cases. Largely, one relies on whatever resources for self-recovery may exist. One defaults to the tincture of time. It took a long time for pain to become recognized as a disease process in its own right. Similarly, it has taken the emergence of functional imaging to reveal the full dimensions of the disease process in minor traumatic brain injury. Meanwhile, a tradition of denial carried the day in the medical management of pain, and accusations of malingering became commonplace in traumatic brain injury. Physician perceptions of malingering in patients with chronic pain, for example, ranged up to 75% (Fishbain et al., 1999).

Both of these find their resolution in the recognition that we must look to the domain of functional illness — of dysregulation — for explanations of the panoply of typical symptoms reported in traumatic brain injury. Such dysregulations need leave no trace in standard tests of structural injury. They may be observable in functional imagery. Prominent in head injury symptoms are various pain syndromes, in particular head pain. Dysregulation of arousal, of sleep, of vigilance, of cognitive function, of emotional stability, of attention and other aspects of executive function, of appetite — these go a long way toward explaining the dysfunctions reported as the consequence of even minor head injuries. The dysregulation of pain mechanisms fits this pattern.

Given the relative dearth of medical remedies for even apparently minor insults such as whiplash and postconcussion syndrome, victims have sought recourse to legal redress. It is instructive to look at how the legal community, largely in service to the insurance industry, has responded. A defense is usually mounted by finding evidence that the symptoms existed at some level prior to the traumatic event. This does not surprise. Minor traumatic brain injury is best seen as a signal event in a cumulative dysregulation cascade, in this case one that covers the entire lifespan of the victim. There may well have been priming events in the person's life that placed him or her at the threshold of significant dysregulation upon further physical insults to the central nervous system. In the extreme, these are referred to as "eggshell" cases.

What interests us at this moment is that this entire trajectory into dysfunction is to be understood largely in the domain of functional illness — of the disordering of central regulatory networks. Pain in traumatic brain injury fits this model as well. Thus, it makes little sense to discuss pain in traumatic brain injury as a distinct entity. Rather, traumatic brain injury presents perhaps the most cogent demonstration of the dysregulation model of functional illness: the sudden appearance of a wide variety of disparate symptoms as the result of a singular event. Once that model is understood, then pain fits readily within its framework as an exemplar.

It is in application to traumatic brain injury that neurofeedback distinguishes itself even from peripheral biofeedback and other general psychophysiological remedies. Unfortunately, very little of this promising work has reached the literature. In one study recently published, Walker reported on the recovery through neurofeedback of some 17 people who had been totally disabled by their traumatic experience. All were more than 2 years posttrauma, by which time self-recovery processes have reached a plateau. The average recovery with neurofeedback was >80% by self-report. Pain was the most prominent symptom and recovered substantially, but the pain data were not broken out. Significantly, more than 60% of the subjects were back at work within months of beginning neurofeedback (those who had been employed prior to their injury), whereas the expectation when they initiated neurofeedback was that none of these people was capable of further recovery (Walker, Gilbert, & Weber, 2002).

Walker had previously made available to us data on a prior cohort of traumatic brain injury subjects that had been treated with a single protocol, one that has historically been used for seizure management. The data were virtually identical in terms of self-report of progress and average number of sessions (just over 30) to that obtained with the more refined protocols. This tends to support the view that most of the symptoms refer to general dysregulation accessible to generic protocols.

The import of the above for pain management in general is that traumatic brain injury of sufficient magnitude to be clinically relevant is often entirely overlooked. Emergency room treatments are not oriented toward the long-term consequences, with the result that patients are discharged under the impression that all is well, when in fact the worst is yet to come. It is in practice very difficult to extract reports from patients with respect to such events in their personal histories. In our intake interview, we ask the question about head injury in six different ways before we take no for an answer. Additionally, birth trauma is often shrouded in ambiguity, particularly with adopted children.

Based on such scrupulous attention to traumatic brain injury, we have come to regard it as a kind of stealth disease — like pain itself — commonplace among us but too frequently disregarded. Both play a role in the dysregulation cascade, with the likelihood that attention will be paid only after the best opportunity for remediation is already past. Pain treatment specialists may want to inquire more diligently into traumatizing events in the patient's history, or else simply to test the hypothesis that pain may be remediable with neurofeedback by recommending a trial.

EMOTIONAL TRAUMA

The intimate association of emotional trauma with chronic pain syndromes has been known for some time. This association was statistically robust even when the focus was almost entirely on what may be called event-related trauma, or post-traumatic stress disorder. By analogy to physical injury, such event-related trauma exposes in clearest relief the sudden thrust into dysregulation. Emotional trauma is therefore to be seen as another singular event in the dysregulation cascade. Because this cuts so close to the "self," it is perhaps no surprise that emotional trauma can have consequences that are just as significant as those of physical trauma. In fact, there is a surprising overlap in symptoms attributable to both kinds of trauma: the dysregulation of arousal, of sleep, of attentional and memory capacities, of emotional stability, of executive function, etc. On the one hand, this unitary quality helps to make the case for the general dysregulation model. On the other, it can be argued that emotional trauma must be part of physical trauma as well. The sudden loss of function and of mental capacities is a blow to self-hood, to the basis of one's self-regard, and a threat to all of one's social ties. In addition, at the level of brain function, it can be argued that just as physical trauma can disregulate attentional networks, emotional trauma can disturb the networks that govern emotional stability.

Ross has put the case for general dysregulation in trauma victims most succinctly (Ross, 2000). If we were to adopt the assumptions of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and regard all of the diagnostic categories of mental disorders as representing discrete, independent entities, then it is trivial to calculate the joint probability of finding, say, 10 such diagnostic categories to be represented in one individual. If each of these categories had a population incidence of 10%, we would still expect fewer than one person on Earth to satisfy criteria for 10 conditions. Yet such findings are plentiful among those with a trauma history. Quite clearly, the different classifications cannot be seen as independent.

Among mental disorders, diagnostic entities are manifestly coupled. There is likely, then, to be a fundamental explanatory principle that underlies many of them, or at least a much smaller set of basic mechanisms than the more than 400 disorders represented within the DSM. Moreover, trauma can be seen as inducing dysregulation generally. If the trauma occurs to a vulnerable individual, e.g., one that has had a history of traumatically priming events, then the particular trauma at issue may be the signal event that catastrophically initiates the dysregulation cascade, leading to a gradual and cumulative progression of symptomatology. Pain dysregulation simply fits this pattern and, with respect to central mechanisms of pain modulation, may not be understandable apart from this more inclusive model. For example, Fishbain reports

that the likelihood of more than one Axis I diagnosis in chronic pain is 60% (Fishbain, Goldberg, Meagher, Steele, & Rosomoff, 1986). Add to that the 35% of patients with chronic pain exhibiting one such diagnosis, and it is apparent that chronic pain is highly correlated with psychiatric disorders, and that they cannot be understood independently of each other.

To this point, the focus has been on event-related trauma because it makes the most persuasive case for the dysregulation model in general and for the dysregulation cascade in particular. In recent years, growing insights into child development have revealed that other trauma mechanisms can possibly contribute to the same syndromes. It is now known that mere neglect can be as damaging to the mental health of a growing infant as overt abuse (Schore, 1999). There is also the trauma of grief and the trauma of shame. Even life with one's disabled child can predispose a parent to the kindling of the dysregulation cascade.

We are mindful of the hazard of trivializing the concept of trauma by invoking it so broadly. That would be counterproductive to our intentions. We seek simply to put forward a new organizing principle for our conceptualizations: traumatizing events or steady-state conditions with traumatizing potential have as their primary physiological consequence the disruption of key regulatory modalities. We should not fall once again into the trap of asking whether the particular provocation — the ostensibly traumatic event — could really have been sufficient to explain the clinical phenomenology that now confronts us. A traumatic event is one to which the patient responded with a classical trauma response, quite irrespective of the magnitude of the triggering event. Depending on where this event falls in a person's particular status with respect to the dysregulation cascade, an even minor trauma can be one's undoing. This is the same dilemma that we confronted with apparently minor cases of whiplash, and with apparently minor provocations in chronic pain cases, not to mention cases with no identified antecedent.

If dysregulation is the primary consequence of trauma, then the clinical target should be the state or condition of dysregulation itself, rather than any particular symptom. Putting this kind of construction on these clinical presentations would not be very meaningful if we did not also have a remedy at hand in the form of neurofeedback, peripheral biofeedback, and related psychophysiological techniques. This remedy constitutes the final argument in support of the dysregulation model. In the first instance, it is remarkable that most of the clinical objectives can be met with a very small number of protocols. This speaks to parsimony of underlying mechanisms. Second, there appears to be no obvious or consistent target of the neurofeedback, no universal EEG deviation that characterizes the disorders. It appears that neurofeedback targets dysregulation itself. The mere exercise of the regulatory loops effects improved regulation.

The neurofeedback approach to trauma consists of two parts. The first consists of challenge training under eyes-open conditions in which the brain is active and engaged. The intent here is to enhance stability of state and to move homeostatic set points to more appropriate levels with regard to central arousal, autonomic arousal, vigilance, attention, and pain. The second consists of reinforcement of low-frequency states under eyes-closed conditions. This phase places the individual in a state more conducive to the psychological resolution of trauma. It is important to make clear at this point just what it means to "resolve" psychological trauma. After all, the reference is presumably to a historical event. Neurofeedback does not produce amnesia.

The clinical pattern issues from the fact that the traumatic experience is registered in memory in its totality, including the entire set of physiological responses. Subsequent spontaneous recall therefore recruits the physiological responding as well. Whereas this process of association can clearly happen in single-shot learning, cumulative traumas reinforce this "whole-body" memory. Early traumas (i.e., threats to the integrity and viability of the self) establish a kind of template or scaffolding with respect to which subsequent traumas are processed and recorded. Each trauma, then, reawakens and reinforces what went before. The body memory is simply carried forward essentially intact, and is reinforced by events that call to mind the original traumas. We postulate that the traumatic experience serves as a kind of wick that perpetually nourishes the state of dysregulation of the patient. It is as if the person in some sense remains in a trauma status. The state of living with unprocessed trauma allies pain to suffering in a mutually reinforcing, progressive descent into abject misery.

The clinical objective is therefore to separate the event memory from the pattern of adverse physiological responding and thus to allow the event to take its appropriate place in historical or declarative memory. Historically this has been done through sequences of reexperiencing the event in the attempt to gradually desensitize the individual. The hazard is further traumatization. Neurofeedback represents a fresh alternative that avoids these hazards first by working at low arousal, where a sudden excursion into hyperreactivity, hypervigilance, and hyperarousal is less likely. Second, the process is self-pacing. Third, the process is nonverbal. Finally, any abreaction that may nevertheless occur tends to abort the process.

Physiologically the neurofeedback takes the person toward states of more whole-brain EEG synchrony. Such states of synchrony prevail when the brain is least challenged and least engaged. Hence they promote states of calmness and internal stillness, states that the traumatized person is unable to reach unaided. Additionally, these states replicate conditions that may have prevailed during early life stages, when the EEG was less mature. Such low-frequency EEGs facilitate recall of traumatic material,

and they may particularly favor the recall of traumatic material that was laid down during such EEG states, i.e., during the early years of life, and even preverbally.

The promotion of both alpha-band activity and theta-band activity in this eyes-closed training may facilitate not only the recall but also the visual processing of the traumatic material even while the person is in the regressed and protected state. It may also be significant that this involves no verbal processing of the material. Deep trauma seems to be encoded preferentially in the right hemisphere, whose "language" is through visualization and through feeling states (Baker & Kim, 2004). It is apparent that there is some difference in the quality of consciousness during alpha-dominant and theta-dominant states. The visualization is more dreamlike and linearly progressive in alpha-dominated states, whereas it is more hypnagogic, episodic, and disjointed in theta-dominant states. It may well be that traumatic material is accessed in the theta state and then processed in the alpha-dominant state. In any event, excursion into high arousal, hypervigilance, or other visceral responding is disfacilitated in this state, and any reexposure to the traumatic material is experienced as benign.

Once the traumas have been rendered innocuous, the person can gradually achieve improved autonomic regulation and progress toward the normalization of the pain response. Whereas the low-frequency training is an important if not essential step, the actual symptom relief comes with the higher-frequency eyes-open training. The eyes-open training is also required to stabilize the brain at the outset to the point where the low-frequency work can even be undertaken. Moreover, in some cases of seizure disorder or of traumatic brain injury the low-frequency work may be contraindicated. The trauma work may instead have to be done with hypnotherapy, which does not involve reinforcement of states of high synchrony at low EEG frequencies.

The whole sequence of steps suggested to address the problem of intractable chronic pain has not yet been subjected to formal study. Rather, the above understandings emerge from clinical work. The first claim, that chronic pain is ineluctably bound up with prior traumatic experience, can be challenged on the contemporary theory that traumatic memories can be introduced into the therapeutic setting by an overly zealous therapist. This hazard does not exist in the neurofeedback setting, however, where the process is largely nonverbal. Nor is the therapist likely to make things worse, because no sooner is the traumatic memory recovered than it is already on the pathway to resolution.

A further objection is that traumatic memories are not reliable. This objection is also not relevant in the present context. We are not in a court of law where this might matter. The only relevant question is whether the particular memory is still "radioactive" for the patient now. Rightly or wrongly, the trauma is the patient's reality, and the only question of clinical import is whether recall recruits inap-

propriate physiological responding. It does not have to have historical truth on its side. In fact, the therapeutic approach is based on the knowledge that memory is alterable. The objective is to alter the memory of the event that resides in the body–mind. Remedy lies in a benign re-experiencing and re-scripting process that is largely under the direction of the patient.

Then there is the question of whether trauma desensitization can in fact be achieved with the low-frequency training. In support of this proposition, we draw upon a controlled study by Peniston, working with post-traumatic stress disorder in Vietnam veterans with this approach (Peniston & Kulkosky, 1989, 1991). After neurofeedback, done in conjunction with conventional treatment for alcoholism in the VA (Veterans' Administration), these individuals no longer met diagnostic criteria for post-traumatic stress disorder, whereas all the controls (who received only the conventional treatment) stayed true to pattern.

The proposed low-frequency training also bears a similarity to the technique called eye movement desensitization and reprocessing (EMDR). This technique also involves inducing low-frequency modulation of states. It is used to aid in the processing of traumas. Whereas in EMDR the therapist directs the action and determines both the reinforcement frequency and the pacing of the process, neurofeedback merely invites participation in the process. This absence of external forcing and constraint may be one of the key virtues accounting for its clinical efficacy on the one hand, and for the absence of significant abreactive experiences on the other.

A REPRESENTATIVE CASE HISTORY

The following is a clinical case history from the practice of Richard Soutar, one that illustrates the issues that have been raised in this chapter.

The client was a 45-year-old male who had been diagnosed first with multiple sclerosis (MS) by a neurologist and later with fibromyalgia by a rheumatologist. The tender points tended to be in his lower rather than upper body. The client had been on Paxil for 10 years, as well as Zoloft for sleep. He had also been taking hydrocodone for some time for pain. He reported that he had been to "every pain specialist in the area," and that he had consulted many alternative health practitioners as well.

At the time of his brain map at intake, he was moderately depressed but still functioned effectively at his work in spite of the severe episodes of pain. The pain was usually severe in the morning and dissipated as the day progressed. It was accompanied by numbness, tingling, weakness, and fatigue. Sometimes he required a cane to walk. His symptoms were aggravated by sudden changes in weather.

The most outstanding feature on his brain map was significantly elevated 12 to 14 Hz amplitudes as well as mildly elevated 23 and 24 Hz amplitudes in the posterior

region. There was also significant global beta hypercoherence between key regions of the anterior (F7, F8) and posterior region (O1, O2). We often see elevations of 12 to 14 Hz in the posterior regions with somatic symptoms. The beta hypercoherence and elevated posterior beta are commonly present in anxiety conditions.

We began by training 12 to 14 Hz amplitudes down at Pz as indicated by his map. The patient had difficulty gaining control over beta suppression and showed few symptom changes. At the fifth session, the target of training was moved to the location between O1 and O2 (Oz) and two trials of alpha (8 to 10 Hz) up training were introduced into each session. The patient demonstrated better control of alpha, and the beta came down during this training. The client began to experience relief from pain for 2 days after each session. By the 12th session, he had experienced a week without pain. By the 16th session, it was more than 2 weeks without pain. By the 19th session, he was reporting unusual levels of energy, reduced irritability, and improved mood. By the 29th session, he was pain-free and remained so until his brain map on session 40. At this point, he was on a very low dose of Paxil and would be off it completely by the 45th session. By the 50th session, he was off his Zoloft and we began to wean him off the neurofeedback treatments. He comes in periodically for a booster session.

Pre–post subjective rating scales indicate clear relief globally from both mental and physical suffering. The comparison of self-rating at sessions 5 and 29 are shown in Figure 50.3. The upper tier shows categories where the rating is expected to increase with successful intervention, and the lower tier shows categories where the score is expected to decrease.

Pre–post maps show almost complete normalization of the hypercoherence as well as reduction of beta amplitudes below significance levels in all posterior areas except P3 and P4. The coherence data are shown in Figure 50.4a and b.

First, the improvements across the board tend to support the dysregulation model. Second, it is observed that the most significant quantitative electroencephalography (QEEG) deviations, and the most numerous, consisted of coherence anomalies. This indicates deficits in cortical–cortical communication relationships. Finally, it is observed that the successful training did not directly target the observed deviations. In particular, when suppression of the excess 13-Hz amplitude was first tried, it was found to be relatively ineffectual. Yet a different challenge at a slightly different frequency was found to resolve nearly all of the anomalies. Perhaps surprisingly, single-site training was even effective in normalizing the two-site coherence anomalies. This again supports the dysregulation model. An appropriate challenge, empirically derived, effects broad and nonspecific functional renormalization that will be generally reflected in a tendency toward normalization of EEG parameters.

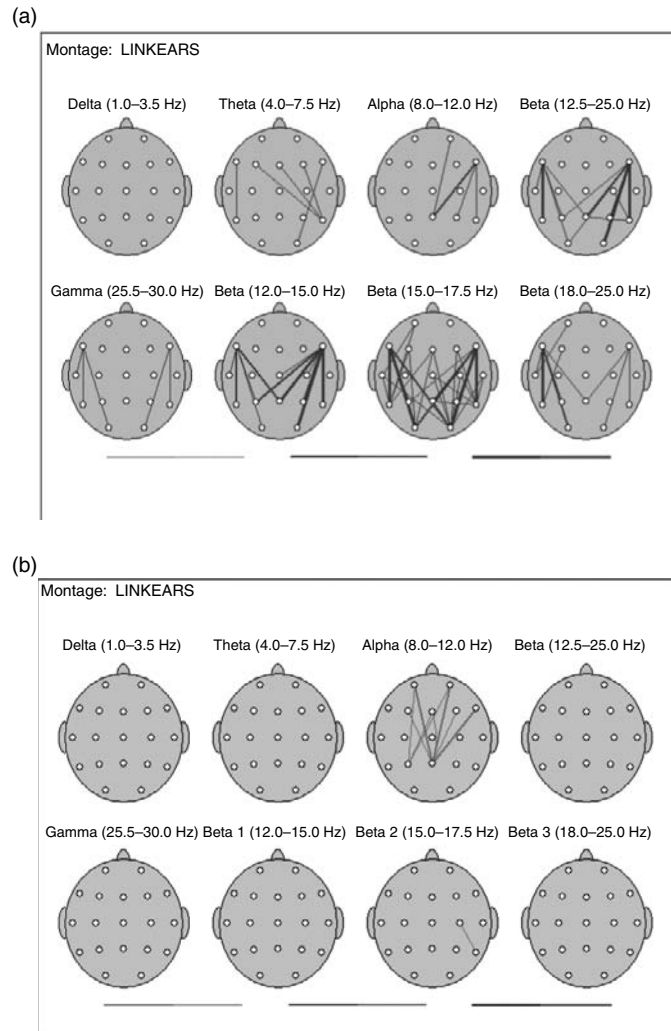
Session 5 vs. 29
FIGURE 50.3 Progress from session 5 to 29 by self-assessment. Data are shown in two blocks, with the upper tier referring to categories where an increase in score is expected, and the lower tier referring to adverse criteria where a decrease in score is expected.


FIGURE 50.4 (a) Initial coherence data, expressed in Z-scores (units of a standard deviation). Only deviations greater than a nominal $Z = 2$ are shown. (b) Coherence data after 29 sessions of neurofeedback. Observe that most coherence anomalies have resolved.

EEG CHARACTERISTICS OF DYSREGULATION

The above case was distinctive in that it was characterized by numerous coherence anomalies in the absence of many other deviations. More typically, deviations will be found across the board: in terms of spectral amplitudes or spectral power measures, in relative power, in amplitude asymmetries across the hemispheric fissure, as well as in coherence and/or spectral comodulation. All these measures refer to the stationary properties of the EEG. The most significant feature of dysregulation may in fact be the transient behavior, in the observation of elevated variability. Such transients are typically quite apparent on visual inspection of clinical EEGs, but they may also be sufficiently sparse as to leave no obvious impression on the stationary measures. The latter should therefore not be taken as an index to the severity of the dysregulation independent of other assessments, in particular of the EEG waveform morphology. For a realistic appraisal, it may even be necessary to evaluate the EEG dynamics under challenge, much as neurologists evaluate the EEG under conditions of hyperventilation or sleep deprivation. Even at this late date in the evolution of our tools for EEG quantitative analysis, there is still no substitute for looking at the EEG.

Some pain conditions have been shown to be correlated with specific deviations in the EEG. Thus, fibromyalgia is often characterized by intrusion of alpha dominance in non-REM sleep (Roizenblatt, Moldofsky et al., 2001). Both tonic and phasic alpha activity have been identified in fibromyalgia, with the phasic type (seen in half of all such patients) showing the greatest correlation with symptoms. Some 30% of patients with fibromyalgia do not show these alpha elevations, however, and some normal individuals show alpha elevations in absence of symptoms. Therefore, this particular EEG feature has limited predictive power diagnostically. (It is, however, a consideration with respect to how the patient is trained.) The existence of a single, obvious EEG feature may actually distract from what may be more meaningful ultimately, namely, the more general state of dysregulation manifested in the EEG upon more comprehensive quantitative analysis and inspection of EEG morphology.

Roizenblatt may have already hinted at a greater complexity of EEG morphology by pointing out that the phasic alpha activity in fibromyalgia occurs simultaneously with delta activity. This may be the more significant observation, as we see in the following.

A PHYSIOLOGICAL MODEL

Given the emergence of a general pattern of dysregulation in the EEG in chronic pain conditions, there is a need for equally general physiological models. In this we are handicapped by the belated recognition in the neurosciences of the frequency basis of organization of neuronal assemblies (Buzsaki & Draguhn, 2004). The core principles in a possible model are intimated in the following. Synaptic transport is contingent on the organization of simultaneity of action potentials over large regions of cortex on a timescale of milliseconds, and the persistence of states imposes the condition of periodicity on such processes. Synaptic transport further serves as a nexus of explicit processing of information and implicit modulation by homeostatic mechanisms. By such processes, the brain achieves a transient "binding" of neuronal assemblies into functional entities. The defining signature of such binding is temporal simultaneity of action potentials, i.e., time does binding. The Hebbian principle that "what fires together wires together" may extend also to the ensemble level, under the rubric that "what fires together functions together" (Gray, Koenig, Engel, & Singer, 1989).

The resulting ensembles must be bounded in frequency and space. That is to say, the binding problem brings together the boundary problem and the extinction problem — in effect the unbinding problem. How is the ensemble managed so that it does not recruit larger resources than necessary (amplitude deviations, spatial spread), couple too tightly or too poorly to other cortical regions (hemispheric asymmetries, coherence and phase anomalies), couple inappropriately the high and low EEG frequencies (dysrhythmias), or fail to extinguish upon completion of the task at hand (amplitude and/or coherence deviations)?

One may ground functional dysregulation, as referred to in this chapter, to an inadequacy in the organization of ensemble dynamics as suggested above. To understand this further, the architecture by which brain timing is organized at the ensemble level must be taken into account. It is most economical to propose that timing is the result of distributed network relations, i.e., that every element in the neuronal network in fact contributes to the overall unfolding of temporal relationships. Nevertheless, a hierarchy of control can be identified, and evolutionary arguments brought to bear on the proposition that commitments made early in our evolutionary history have been largely conserved.

One must therefore look to the earliest structures, the brainstem and the diencephalon, for the top of the hierarchy. Among these, only the thalamus has the topographical complexity to permit full description of the phenomenology of interest. Hence, it may be no surprise that the first candidate to emerge for a comprehensive neurological model for psychopathologies arises out of the study of thalamocortical networks over the past several decades. The model has been termed "thalamocortical dysrhythmia," and it is based on the observation of a profound distinction in bispectral couplings in the EEG between psychiatric patients and normal subjects. In the first presentation of this model, Rodolfo Llinas (Llinas et al.,

1999) found identical patterns of dysrhythmia in a patient with chronic pain as in a patient suffering from Parkinson's disease, one suffering major depression, and one suffering tinnitus. Only because the data were so dramatic in their contrast between pathology and normalcy would one have the courage to draw such generalized conclusions from such a meager database of only four disparate cases representing four different diagnostic categories.

It now seems obvious in retrospect that in addition to organizing spatial relationships between different cortical sites at any given EEG frequency, the brain must also organize the coupling or interaction of different frequencies at any one cortical site. Crudely speaking, the higher-frequency activity is more associated with processing "text," and the lower frequencies are involved more in organizing "context." Their interrelationship is crucial. Such frequency-to-frequency coupling has not surfaced much previously because bispectral analysis is not commonplace in clinical practice. For present purposes, the model of thalamocortical dysrhythmia is not yet being proposed as a definitive explanation applicable to all the chronic pain conditions discussed in this chapter. It is simply recruited as an exemplar of a generalized model in which EEG phenomenology is a point of departure to understand much of psychopathology in terms of disorders of dysregulation. Other such comprehensive models are needed for a full understanding of dysregulation in the bioelectrical domain: spatial correlations need to be modeled, and there needs to be an understanding of brain function under challenge. Only after "normal" brain function is successfully modeled can we hope to understand what happens under the constraint of organic injury or of acquired dysfunction.

Fortunately, the deficiencies in our fundamental understanding of bioelectrical mechanisms need not stand in the way of the clinical exploitation of the technique of neurofeedback, which can be accomplished through empirically derived and clinically validated techniques of functional renormalization. The history of medical science is full of examples in which the practice preceded our understanding.

SUMMARY

Self-regulation approaches in general, and neurofeedback in particular, should play a key role in the management of chronic pain. A model is suggested in which pain is recognized as a homeostatically regulated, affectively modulated sensory system, and that the excursion into chronic pain should be regarded from the perspective of a more inclusive dysregulation model. Such dysregulation manifests in the bioelectrical organization of neuronal networks and is observable in both the dynamic and stationary properties of the EEG. Neurofeedback is a self-regulation strategy that broadly targets the dysregulation of

central states through reinforcement of certain favored EEG behavior and the discouragement of disfavored activity. Pain relief is then obtained as a secondary consequence of improved self-regulation status. The key role of the emotions in pain perception is recognized. Chronic pain cannot be considered independently of the psychodynamic milieu in general and of trauma status in particular.

A neurofeedback strategy has been devised to address affect regulation in general and the trauma response specifically, to prepare the ground for resolution of pain syndromes with conventional neurofeedback techniques. Research data have been brought to bear on this discussion to the extent that such published data exist. However, the evidentiary support for the model presented is still fragmentary, and embarrassingly out of scale with the considerable promise of neurofeedback. Clinical data are good enough, however, to establish both EEG neurofeedback and pIR HEG neurofeedback as a categorical remedy for migraine pain. This observation alone is sufficient to commend neurofeedback to the attention of the pain community.

Hypnotherapeutic Advances in Pain Management

Jan M. Burte, PhD, MS Psychopharm, DAAPM

Hypnosis as a form of pain management has shown increasing favor within the past decade. This may be attributable to numerous factors including the increase of solid research demonstrating its efficaciousness with various forms of pain and the experiences of practitioners and patients utilizing it.

In situations where pharmacotherapy is limited by other factors and in situations of intractable pain, it has been shown to be an excellent adjunct to standard care. Research has helped to define its limitations (i.e., high vs. low susceptible subjects), its biophysiological and neurophysiological basis, and its interaction with the sensory and emotional pain receptor sites in the brain. The diversity of conditions to which it is currently being applied continues to expand with varied degrees of clinical success. In this brief chapter, I hope to provide an overview of hypnotic application based on recent peer-reviewed research and textual materials.

HISTORY

There is little doubt that the induction of hypnoidal states utilizing chanting and breathing exercises dates back to earliest history. Meditation and hypnosis have been frequently compared regarding their impact on concentration, altered states, and suggestibility (Holroyd, 2003). The earliest clinical records of hypnosis are attributed to John Elliotson (1792–1869), an English surgeon, who used hypnosis for pain management in his practice and James A. Esdaile (1808–1859), who performed more than 300 operations using hypnosis as analgesia while practic-

ing in India (Bassman & Wester, 1992). One such operation reportedly entailed the removal of a 103-lb tumor (Jackson, 1999). Although hypnosis and trance represent an age-old treatment for a variety of conditions including pain, hypnosis has been embraced as a legitimate therapy consequent to continuing research only over the past 50 years (Hrezo, 1998).

Hypnosis as a form of pain management fell in and out of favor from the early 1940s until the 1960s when Milton H. Erickson demonstrated its utility with acute and chronic pain control (Erickson, 1966, 1986). The application of hypnosis within the medical and pain setting has continued to develop from the work of Hilgard and Hilgard (1975), Hilgard and LeBaron (1982), Barber and Adrian (1982), and Melzack and Wall (1965, 1983).

Zohaurek (1985) points out two historical misconceptions of pain that have affected the role of hypnosis in treating pain.

Pain was considered to be only a symptom of an underlying disease or trauma. Therefore, research and treatment focused on the etiological cause and ignored the pain, assuming it would disappear when the cause was addressed. Historically, pain reporting was by necessity heavily relied upon as part of the initial diagnostic procedure, where severity, location, and nature of the pain often assisted in proper diagnosis. Although pain reporting maintains a significant role in diagnosis, the advent of additional diagnostic procedures (i.e., computerized axial tomography [CAT] and magnetic resonance imaging [MRI] scans), goes beyond pain reports and reduces their unique significance. The reliance on pain reports was

especially true in certain acute pain situations although not as much in chronic pain situations where a diagnosis had been reached (Bonica, 1990). It was postulated that hypnosis could mask the symptoms of pain and might interfere with obtaining a proper diagnosis and treatment (i.e., using hypnosis to mask pain associated with appendicitis could result in delaying care until the appendix has ruptured).

Fordyce (1976) and Sternbach (1978) point out that historically pain was seen as evolving from either a physical or a psychological origin rather than from both. Pain was perceived to have either a "real/organic" basis or a "functional/imaginary" basis. Current thinking might view the impact of pain as an etiological factor. As a result of its bidirectional psychoneuroimmunological role (on the psychological, endocrinological, and immunological systems), pain may contribute to the maintenance of illness or enhance the progression or metastasis of certain illnesses (Paige & Ben-Eliyahu, 1997).

Since 1958, hypnosis has been recognized by the American Medical Association as a legitimate form of medical treatment when administered by an appropriately trained practitioner (Simon & James, 1999). Fortunately, with the resurgence of integrative, mind/body, psychoneuroimmunological approaches, current thought and research have begun to view hypnosis as a potentially significant modality in the treatment of pain and illness.

CURRENT CONCEPTIONS OF PAIN

In this chapter, I focus on the hypnotherapeutic advances in pain management and discuss the applicability of hypnosis in the treatment of specific illnesses. Due in part to its historical misportrayal in the popular media, patients referred for hypnosis often ask, "But does it really work?" Contemporary popular media portray hypnosis as an effective means of pain control (Foderaro, 1996). Currently, sufficient experimental and clinical research exists to allow clinicians to respond affirmatively to the question. However, certain caveats, discussed later, still exist. An extensive review analysis of recent published research by Hawkins (2001) concludes that there is sufficient evidence of good quality in favor of views that hypnosis is an effective modality in the treatment of pain.

What then is medical or clinical hypnosis and what are the contemporary views of both practitioners and the public, especially within the realm of pain management? One recent survey indicates, "most people have a positive view of the therapeutic benefits with a vast majority of respondents believing that it reduces the time that is usually required to uncover causes of a person's problems, and that hypnotized persons can undergo dental and medical procedures without pain" (Johnson & Hauck, 1999).

Retrospectively, it is important to recognize that "pain," until the 20th century, was considered an untreat-able consequence of illness or injury. Indeed, Chaves and Dworkin (1997) astutely point out that hypnoanalgesia did not fully emerge until the 19th century, due largely in part to the societal belief that pain relief and reduced suffering were not a primary goal in treatment. Prior to effective clinical techniques for pain management, pain was an accepted aspect of life. One might wonder whether the introduction of pharmacological forms of pain relief such as analgesia and anesthesia altered patients' perceptions of the importance of pain relief and ultimately their thresholds for pain.

If pain can act as a mediator in trance production with patients experiencing pain, then did our progenitors and do perhaps third world cultures that had/have limited access to various forms of pain relief intuitively rely on hypnosis and self-hypnosis to alter their pain thresholds? For these individuals, pain, whether from childbirth, dental procedures, illness, or injury, was anticipated.

Today, the application of hypnotic analgesia in acute and chronic pain treatment has grown substantially. Both patients and clinicians are demonstrating increased knowledge and experience with hypnosis. In many cases, patients bring clinical experiences with hypnosis for related or unrelated issues to the treating physician (Lynch, 1999), thereby opening a door to increased complementary approaches to standard interventions. Where this may be significantly prevalent is in the non-pharmacological strategies employed in managing cancer pain. As Zaza, Sellick, Willan, Reyno, and Browman (1999) point out, while pharmacological treatments are appropriately the central component of cancer pain management, the under-utilization of effective non-pharmacological strategies may contribute to the problems of pain and suffering among cancer patients. In a study of 214 health professions, Zaza et al. (1999) found that the healthcare professionals recommended "imagery" exercises 54% of the time and meditation 43% of the time. They expressed interest in learning more about hypnosis and other non-pharmacological strategies, suggesting its under-utilization as a complementary or adjunctive treatment to standard care. In a critical review of the literature, Sellick and Zaza (1998) found that in randomized controlled studies of hypnosis in managing cancer pain, substantial evidence exists for its effectiveness when non-pharmacoligcal pain management approaches are being sought. Given the side effects frequently seen with many pain medications including sedations, gastrointestinal problems, and tolerance issues, it is not surprising to find patients seeking adjunctive means to reduce their reliance on analgesic.

BASIC CONSTRUCTS OF HYPNOSIS

This concept, then, of unifying both the confidence of the practitioner and the trust and belief of the patient, may represent the components necessary to obtain efficacious

pain relief. Barber (1998) aptly delineates a two-component model explaining why hypnosis may work for pain management. He suggests that in the first component the "clinician communicates specific ideas that strengthen the patient's ability to derive therapeutic support and to develop a sense of openness to the unexplored possibilities of pain relief within the security of a nurturing therapeutic relationship." In so doing, the patient is led to relax in the clinician's confidence in hypnosis. In the second component, "the clinician employs posthypnotic suggestions that capitalize on the patient's particular pain experiences which simultaneously ameliorate the pain experience and which, in small repetitive increments, tend to maintain persistent pain relief over increasing periods of time." This second component offers the patient a sense of voluntary learned control over his or her pain, thereby reducing anxiety and learned helplessness.

A somewhat more constructionistic view is offered by Chapman and Nakamura (1998), who suggest that hypnosis alters the learned pain experience (pain schemata) by interacting with feedback processes that prime the associations and memories tied to the pain, thereby shaping the formation of pain expectations and processes and ultimately reducing the experience of pain.

Holroyd (2003) notes that for highly suggestible subjects it may be that hypnosis alters the experience of suffering and not as much the experience of sensory pain. He contrasts the effects of hypnosis to meditation, pointing out the added effects of hypnosis and the different neurocognitive components of each. Of primary importance is that it is the superior attentional abilities of these areas of the brain, which are found only in highly susceptible individuals, that enables them to experience significant hypnoanalgesic effects.

NEUROCOGNITIVE COMPONENTS

As mentioned previously, hypnosis has fallen in and out of favor over the years due in part to arguments concerning the lack of hard scientific data to support its efficacy or pathophysiology. With increasing frequency, studies are demonstrating the impact of hypnosis on pain from the perspective of changes occurring in the brain itself. Rainville et al. (1997) demonstrated that positron emission tomography (PET) revealed significant changes in pain-evoked activity within the anterior cingulate cortex consistent with the encoding of perceived unpleasantness, thereby linking frontal lobe limbic activity with pain susceptible to hypnotic suggestion.

In an examination of exposure to noxious stimuli presented to subjects, Faymonville et al. (2000) found that hypnosis could reduce the intensity and unpleasantness of the exposure. By examining cerebral blood flow of subjects both with and without hypnotic intervention, they concluded that hypnotic modulation of pain appears to be mediated by the anterior cingulate cortex.

Rainville and colleagues (1999a) in their examination of cerebral blood flow using PET scans found that the hypnotic experience may result in increased occipital regional cerebral blood flow (RCBF) and delta activity as measured by electroencephalography (EEG) by altering the consciousness associated with decreased arousal via facilitation of visual imagery. Frontal increases in RCBF may be associated with verbal mediation of suggestions, working memory, and top-down processes involved in reinterpreting the perceptual experience of the noxious stimuli. They concluded that specific patterns of cerebral activation appear to be associated with the hypnotic state.

Other researchers have demonstrated the effectiveness of hypnotic analgesia on raising pain thresholds by examining the nociceptive flexion reflex and EEG patterns (Danziger et al., 1998). The actual mechanism on a neurophysiological basis has become an area of more recent research. Crawford et al. (1998) suggest that hypnotic analgesia is a function of the activity of the supervisory, attention control system involving the anterior frontal cortex, which then works with the cortical and subcortical processes in the allocation of thalamocortical activities. In addition, the anticipation of pain causes different adaptive behaviors, emotional states, attentional focus, and perceptual changes that affect the activity of the brain in the areas of the rostral anterior cingulated cortex, posterior cerebellum, ventromedial prefrontal cortex, mid cingulated cortex, and hippocampus (Ploghaus et al., 2003).

Crawford et al. (1998a) report that recent research "supports the proposal that hypnotic analgesia is an active inhibitory process involving several brain systems mediating attentional and nociceptive processes" (p. 22). More specifically, it appears that it is the anterior frontal (prefrontal) cortex that responds to pain. Pain has two components. The first is the physical sensory experience and the other, the emotional distress component. Through a process of "active disattention" individuals learned to disregard incoming pain/sensory signals during hypnoanalgesia (Crawford et al., 1998a).

Gruzelier (1998) notes that the significant role of the anterior cingulate cortex in managing sensory input in conjunction with the frontolimbic inhibitory processes allowing patients to suspend reality testing and critical evaluation. From the perspective of the emotional context of pain, research suggests that hypnosis resulted in inhibition of the amygdala and activation of the hippocampus. In addition, hypnosis appears to have an electrophysiological profile of its own, which shares electrophysiological features with lowered vigilance but other features with increased attention (Lehman, Faber, Isotani, & Wohlgemuth, 2001).

For the individual seeking an in-depth understanding of the interrelationship of hypnoanalgesia and brain activ-

ity the recent work of Crawford and coauthors (1998a, b) provides an excellent overview of the subject. For the role of social, environmental, and situational variable in pain interpretation and integration through neural activation of the cortical and subcortical systems, Chudler and Dong (1995) offer a discussion on the topic.

Raz and Shapiro (2002) notes that hypnotic analgesia is regarded as an active process requiring inhibitory effort. In contrast, Wagstaff (2000) in responding to the work of Gruzelier (2002) and others suggest it may be relevant to focus on the "various psychological activities and physiological processes involved in responding to a varied range of suggestions, hypnotic and otherwise, rather than attempting to identify an atypical brain state that we can specifically associate with hypnosis" (p. 161).

For those in the pain field this is especially relevant in being able to better treat the broadest range of patients available (low to high susceptible). Research continues to better delineate and specify the neurophysiological basis of sensory pain perception and emotional context. Hypnosis appears to trigger activation, "active disattention" to pain signals, and congruent emotional content at sites within the brain that are associated with pain perception. Hypnosis consequently may play a role in reducing both pain and suffering as well as function as a research instrument in defining how the brain neurophysiologically and cognitively processes the emotional and sensory pain experiences. Of interest is that with hypnosis pain reception centers in the brain can be activated with no external peripheral sensory input.

PAIN CONTROL

However, the real question for clinicians is: Can learning to develop hypnoanalgesia to noxious stimuli in a laboratory (an acute short-term artificial environment) be generalized to a patient's ability to control real nocioceptive acute or chronic pain? Crawford et al. (1998) found that patients with chronic back pain could be trained to use hypnotic analgesia on a noxious stimulus and then generalize the hypnotic analgesia to their back pain. They suggest that hypnotic analgesia is an active process that requires an inhibitory effort dissociated from conscious awareness where the anterior frontal cortex participates in a topographically specific inhibitory feedback circuit that cooperates in the allocation of the thalamocortical activities. They further point out that the subjects could successfully transfer the experimental pain reduction to reduction of their own chronic pain and, in so doing, experience increased well-being and increased sleep quality.

Using a modulated form of pain management, patients can learn the hypnotic skill of pain control or the raising of their pain thresholds. They can then be taught to generalize this skill to pain situations that are more a function of their illness or injuries.

Hypnotic analgesia has also been shown to reduce subjective pain perceptions and the nociceptive flexion reflex in highly hypnotizable subjects (Sandrini et al., 2000). This raises yet another question. If pain can be unlearned via hypnoanalgesia, does it imply that at least to some degree it is a psychoneurologically learned behavior? The concept of the existence of a "neural signature of pain" that acts as a progenitor of subsequent pain experiences is offered by Melzack & Wall (1983). If this is so, we should teach patients how to communicate more positively when in acute pain stages before they develop chronic pain. Meta-analyses of 18 studies revealed a moderate-to-large hypnoanalgesia effect supporting the efficacy of hypnotic technique for pain management in both clinical and experimental pain settings (Montgomery et al., 2000).

HYPNOTIC SUSCEPTIBILITY

When we speak of patients with pain and hypnosis, another important question is raised. Does hypnosis work equally well for all patients? The literature seems to suggest that numerous variables must be considered in drawing any conclusions. Issues of patients' hypnotic susceptibility, chronic vs. acute pain, and the origin and etiology of the pain are relevant factors. The term *hypnosis* as it is described in the pain literature represents a broad concept ranging from indirect suggestion to direct suggestion, Ericksonian, traditional, New Hypnosis, self-hypnosis, and hypnosis via face to face interactions versus audio and videotaped teaching modules (Araoz, 2001; Laidlaw & Willet, 2002). However, one common denominator, which appears prevalent within the literature, is that the type of hypnosis used is less important than the hypnotizability of the subject. The variance observed in determining the efficacy of hypnosis may be partially washed out by a lack of proper selection of subjects. As such, just as in pharmacotherapy where one medication may not fit all, hypnosis may prove to be more effective for some individuals than for others.

In the realm of hypnosis, the question of the importance of hypnotic susceptibility and trance depth has long been debated (Frankel et al., 1979; Hilgard & Hilgard, 1979; Perry et al., 1979), especially with regard to pain (Hilgard & LeBaron, 1982). Recent studies that have examined the importance of hypnotic susceptibility of patients experiencing pain (as opposed to patients not experiencing pain) appear to indicate that when dealing with acute pain issues, hypnotic susceptibility is very important. Sandrini et al. (2000) examined subjects rated as both high or low susceptibles on the Harvard Group Scale of Hypnotic Susceptibility (Shor & Orne, 1963) and the Stanford Hypnotic Susceptibility Scale (Weitzenhoffer & Hilgard, 1959). Using a noxious stimulus, they concluded, "the susceptibility of the subject is critical in hyp-

notically induced analgesia." Similarly, high hypnotic but not low hypnotic subjects demonstrated significant reductions in pain intensity and reduced nociceptive receptive reflexes during hypnotic analgesia (Holroyd, 2003; Zachariae et al., 1998).

Increased hypnotizability was also found to positively affect sensory and pain thresholds during dissociated imagery and focused analgesia as measured by skin conductance responses, somatosensory event-related potentials, and pain perceptions (De Pascalis et al., 1999). The ability to modulate pain was greater when subjects demonstrated higher hypnotic suggestibility (Rainville et al., 1999b). Controlled associative ability (Agagun et al., 1998) and the ability to use internal (guided imagery) and external distractors (word memory and pursuit of motor tasks) were found to be effective only in high susceptibility subjects fulfilling analgesic suggestions (Farthing et al., 1997).

Is the low suggestibility patient subjugated to not being able to use hypnosis or is suggestibility trainable? In a brief training experience, Milling et al. (1999), using the Carlton Skill Training Program, found that training failed to increase overall suggestibility scores or to enhance the effects of a suggestion for pain reduction. However, pain reduction was more highly correlated with post-traumatic levels of suggestibility than with pretreatment suggestibility.

Many authors have thought that hypnotizability is a skill that is enhanced with practice but occurring at a rate set by the patient. It has been further suggested that "hypnosis may be best conceived as a set of skills to be deployed by the individual rather than as a state" (Alden & Heap, 1998). Others have suggested that hypnotic susceptibility may not be a factor in treatment. In a study of hypnotic susceptibility and the treatment of irritable bowel syndrome, hypnotic susceptibility to suggestion was not a factor in the positive effect found for hypnosis (Galovski & Blanchard, 1998). Utilizing the Hypnotic Induction Profile as part of the hypnotic experience, clinicians can within 5 to 10 minutes assess a patient's hypnotic response capabilities and provide the patient with an initial firsthand experience (skill acquisition trial) of what hypnosis is like (Spiegel & Spiegel, 1987). Any patient, but especially patients with pain, may spontaneously shift to an altered state of awareness increasing their suggestibility merely as a function of their motivation to develop rapid rapport and trust in the clinician in an effort to escape the pain (Araoz, 1985).

A simple but effective means of incorporating the patient's willingness to accept suggestion is presented by Eimer (2000) who, at the end of an induction concludes, "As you go deeper and deeper into relaxation and hypnosis, the door way to your unconscious opens and, with your permission, I have the opportunity to talk directly to your unconscious and give it the information it needs to help you make the changes you want to make" (p. 20).

CLINICAL APPLICATIONS

BURNS

A review of the literature points to an increasingly broadening range of applications of hypnosis in treating medical conditions with associated pain. One area where hypnosis has been used for both acute pain and healing is with burn victims. Hypnosis has been shown to reduce pain even in situations where opioids fail to bring relief (Ohrbach et al., 1998). Treatment and dressing changes can be an extremely painful part of burn care. Wright and Drummond (2000) found that rapid induction analgesia was effective in reducing pain and anxiety associated with dressing changes, and Ewin (1986) found that hypnosis positively reduced pain in adults during debridement. Similar indications were also found with pediatric patients (Foertsch et al., 1998). Indeed, burn victims may demonstrate enhanced receptivity to hypnotic suggestion secondary to issues of motivation, dissociation, and regression (Patterson et al., 1997), especially within the subset of burn patients who report high levels of baseline pain (Patterson & Ptacek, 1997).

SURGERY

Another area where hypnosis has been extensively utilized is in the arena of surgical intervention. Hypnoanesthesia, the use of hypnotic suggestion rather than general anesthesia to mediate pain during surgical intervention, has been successfully employed for endocrine cervical surgery (Defochereux et al., 1999; Meurisse et al., 1999b). Hypnosedation (hypnosis in combination with conscious intravenous sedation and local anesthesia) has been employed as an alternative to traditional anesthetic techniques (Faymonville et al., 1999; Meurisse et al., 1999).

Hypnosis has also been shown to provide proprioceptive pain and anxiety relief, reduced Alfenta and Midazolam requirements, and increased patient satisfaction and surgical conditions when compared with other surgical stress strategies in patients receiving conscious sedation (Faymonville et al., 1997).

Audiotaped hypnotic instructions produced reduced anxiety (Ghoneim et al., 2000) while preoperative hypnosis resulted in a reduction of consumption of analgesics (Engvist & Fischer, 1997) in third molar surgeries.

Self-hypnosis has been employed as an anesthesia for liposuction surgery (Botta, 1999) and for postoperative levels of pain control and relaxation in coronary artery bypass surgery (Ashton et al., 1997) and arteriotomies (Austan et al., 1997). It is attributed to reduced reported pain and anxiety and improved hemodynamic stability

during invasive medical interventions such as percutaneous vascular and renal procedures (Lang et al., 2000). In particular, hand surgery that requires painful rapid remobilization of the hand is especially benefited by hypnosis. Hypnosis reduces perceived pain intensity allowing patients to be more compliant and able to withstand physical rehabilitative interventions (Mauer et al., 1999), as well as increased rates of anatomical and functional healing (Ginandes & Rosenthal, 1999).

Hypnosis has demonstrated its utility in the surgical setting resulting in decreased anesthetic utilization, more hemodynamic stability, and decreased recovery time (Lang et al., 2000). Using numerous outcome measures it was observed that postsurgical wound healing was significantly greater in patients who had received eight adjunctive hypnosis sessions targeting wound healing versus adjunctive supportive attention session or usual care. At 1- and 7-week follow-up the hypnosis group was significantly more healed than the usual care group. The hypnosis group also reported lower levels of postsurgical pain and higher scores on quality of life measures (Ginandes et al., 2003).

Hypnosis also has demonstrated its efficacy with children dealing with the pain and anxiety associated with invasive medical procedures (Hilgard & LeBaron, 1984), including bone marrow aspiration (Liossi & Hatira, 1999), resulting in lower levels of reported pain, reduced anxiety, and shorter hospital stays (Lambert, 1996; Smith & Barabasz, 1996). Distraction and imagery techniques have been shown to be highly effective in reducing pain in painful procedures (Broome et al., 1992). Scripts and metaphors for children with painful conditions are readily available to the pediatric pain practitioner (Mills & Crowley, 1986; Wester & O'Grady, 1991).

Cancer

Another significant area where hypnosis has continued to demonstrate its utility is cancer intervention. Numerous books and articles on the use of imagery and healing (Gaynor, 1994; Siegel, 1998) have discussed the psychoneuroimmunological benefits of hypnosis.

Pain, illness, injury, trauma, and loss are significant precipitants of a stress response, which may lead to a reduction in the efficacy of the functioning of the immune system. Hypnosis has been frequently demonstrated to reduce the psychological and physiological impact of stress on these systems. Hypnosis has demonstrated its utility in reducing physical and emotional stress reactions and in improving the functioning of these individuals and improving the quality of their lives (Shea, 2003).

Furthering this concept to examine the effects of unconscious motivations and metaphors, Araoz (2001) suggests that patients with pain should explore via hypnosis the somatopsychic connections that contribute to the maintenance of their pain, suffering, and negativistic experience of life.

Williamson (2002) reports that a single hypnosis session, which released suppressed anger and a revivification of a previous successful experience with acupuncture, resulted in a significant reduction in reported intractable pain. John Sarno (1998) recently continued his concept of repressed rage and intolerable emotional conflicts as contributing to reduced blood flow and autonomic system imbalance as significant factors in most back pain. Self-hypnosis has been shown to be effective in reducing the effects of stress on the immune system resulting in reduced expression of disorders associated with immunosuppression (e.g., virulent genital herpes recurrences significantly reduced, with increased cytotoxicity of natural killer cells for the virus; Gruzelier, 2002).

Chronic pain often results in lowered self-esteem, hopelessness, and despondency and decreased sense of control over pain and may be benefited by hypnosis (Turk & Holzman, 1986). Hunter (1996) furthers the concept through a metaphor of a dance that patients with chronic pain must develop "a relationship with their pain." In so doing, she emphasized that pain can be better tolerated and self-confidence improved via techniques such as hypnosis and stress management.

Liossi and White (2001) evaluated terminally ill patients with chronic pain. Using the Rotterdam Symptom Check List (DeHaes et al., 1996), a quality of life measure, she concluded that a 4-week hypnosis intervention resulted in reported enhancement of quality of life for patients with far advanced cancer. Reduced suffering was attributed to diminished pain and cognitive changes in the levels of anxiety and depression. Patients who wished to be active participants in their pain management are especially well suited for hypnosis as a means of pain control (Loitman, 2000).

Laidlaw and Willet (2002) note that terminal illness often results in strong feelings of sadness and anxiety, which can lower self-esteem, impair relationships, and lead to feelings of helplessness and despair and may result in a poor response to treatment. In what they refer to as a pilot study using a brief 10-minute audiotape intervention, they report a trend toward positive changes in patient functioning and reduced anxiety in patients with cancer.

For many years hypnosis has also been shown to provide specific pain relief and reduced suffering for patients with cancer (Hilgard & Hilgard, 1975; Hilgard & LeBaron, 1984; Sacerdote, 1966), and more recently, by employing physical relaxation coupled with imagery that provides a substitute focus of attention for painful situations (Spiegel & Moore, 1997). Patients demonstrate an increased awareness of the willingness to employ hypnosis adjunctively to their standard medical care, resulting in new programs that incorporate hypnosis into their treatment protocols (Lynch, 1999). As recently as 1996, the

NIH Technology Assessment Panel presented its conclusion in the *Journal of the American Medical Association* that strong evidence exists for the use of hypnosis in alleviating pain associated with cancer.

IRRITABLE BOWEL SYNDROME

The use of hypnosis has been shown in controlled trial cases to be highly effective (Whorwell et al., 1984) and may well be the treatment of choice for refractory patients with irritable bowel syndrome (IBS) (Zimmerman, 2003). Zimmerman presents a hypnotic metaphor of a river that is used to evoke both a smooth coordinated flow through the normal digestive tract and a normal flow in the management of the patient's emotions.

Using hypnotic suggestion for an induced emotional state, Houghton et al. (2002) brought an awareness of the role of emotions in the motility of the gastrointestinal tract and IBS. With seven biweekly sessions and audiotapes for practice at home, Palsson et al. (2002) demonstrated the effectiveness of hypnosis. The authors concluded that hypnosis improves IBS symptoms through reductions in psychological distress and somatization.

Vidavic-Vukic (1999) notes that IBS is a frequently observed painful disorder, but its etiology and pathogenesis are still unknown. However, it is clear that individual perceptions may play an important role in its pathogenesis. Vidavic-Vukic points out that in recent years hypnotherapy has been shown to be successful in the treatment of IBS, resulting in either reduction or complete disappearance of pain and flatulence or a normalization of bowel habits. Similar results with a hypnotic treatment where the focus of intervention was "gut directed" and "symptom driven" found that abdominal pain, constipation, and flatulence improved while anxiety scores decreased (Galovski & Blanchard, 1998).

McGrath (1998), based on the studies of P. J. Whorwell and those of O. S. Palsson, presents hypnosis as a significant component in the treatment of IBS with success rates approaching 80% reported in the literature. The focus of hypnosis for IBS should be on the gut-directed and associated symptomology. In a review article, Camilleri (1999) points out that in addition to various medicinal interventions and fiber intake, hypnosis may play an important role in relief of pain in patients with IBS. Notwithstanding recent medical and pharmacological advances, the treatment of IBS can be adjunctively enhanced with the addition of hypnosis.

ACUTE PAIN

Hypnosis also has been shown to be effective in acute pain care settings such as emergency room settings with burn pain, pediatric procedures, psychiatric presentations, and obstetric situations (Peebles-Klieger, 2000; Zahourek,

1985). Iserson (1999) describes a simple method of hypnosis used in pediatric fracture reduction on four cases of angulated forearm fractures employing distraction techniques when no other form of analgesia was available. Interestingly, fracture healing also may be enhanced using hypnosis. Faster edge healing, improved ankle mobility, greater function mobility to descend stairs, lower use of analgesic, and trends toward lower self-reported pain were found in patients who received hypnotic intervention in addition to standard orthopedic emergency room care (Ginandes & Rosenthal, 1999).

Hypnotically induced glove anesthesia with transference to the pain site for acute pain relief is a commonly used technique. This is accomplished by using suggestions of creating a numbing sensation in the hand. Patients may be asked to imagine their hands in a bucket of anesthetic gel or a glove or other such images. This numbing or pleasant sensation is then transferred to the pain site with a pleasant increase in numbness. An excellent example of this technique is offered by Basserman and Wester (1984). Other techniques include distraction techniques and dissociative techniques (Burte, 1999; Eastwood et al., 1998). In all cases, a trusting rapport with the clinician appears to be a critical factor in achieving the desired goals. In addition, as has been noted earlier, pain may act as a mediator toward an altered state of increased suggestibility to pain alleviation.

Patients with acute pain may willingly and rapidly transfer their pain to the hypnotherapist or anyone willing to accept the pain. Patients should be reassured that proper medical care is forthcoming and they can let go of their pain. As Schafer (1996) points out, perhaps as many as half the patients in an emergency room may be in spontaneous trance. An alternative approach is to focus on the imagery the patient spontaneously reports associated with the pain. Psychosemantics and somatopsychic queues are observed when utilizing the patient's perceptions, internal representations, and understandings of the pain to alter the cognitive, emotional, and sensory experience (Burte & Araoz, 1994).

Using the New Hypnosis Model developed by Daniel Araoz (1985), patients are helped to achieve an altered state of internally directed experiencing of their symptomology. By focusing on the way they interpret and communicate their pain through any or all of their five senses, patients are led to a reinterpretation and understanding of their ability to modulate their pain. How patients integrate pain sensations will affect their pain thresholds. Positive suggestions to pain altered the amount of time that patients could keep their hands immersed in ice water (Staats et al., 1998).

For example, in the case of a man with recently fractured ribs, he may be asked to experience or visualize the ribs as they appear to him. He is then asked to visualize ways to soothe, protect, or heal the ribs (e.g., an anesthetic

band wrapped around the chest, relaxing, protecting, and healing the area of injury), while communicating calming, relaxing, and possibly "in control of the situation" thoughts. At times, visualizing being in a safe or pleasant situation helps induce a hypnoidal form of relaxation or mild dissociation. Although creating relaxation has often been seen as an important element in inducing trance for the patient experiencing pain, it may be a secondary goal with the imaging or individualized experience of the pain as the primary pathway to the hypnotic state. In this regard hypnosis can be viewed as a state of focused internally directed learning experiences (FIDLE).

Acute pediatric pain represents a somewhat different issue in that children often lack clinical insight regarding their condition, an understanding of the etiology, potential longevity, or plausible interventions available for ameliorating their pain, concepts that help adults cope with acute pain more effectively. Patients provided appropriate preoperative information demonstrate less acute pain (Stevensen, 1995). Hypnosis may represent a complementary treatment in conjunction with other forms of intervention such as pharmacological pain management (Rusy & Weisman, 2000). By providing cognitive and behavioral schemata via modalities easily accessed by children (e.g., imagery, fantasy), the pediatric patient with acute pain can be empowered similarly to the way adults use reason to empower coping ability with pain. Pediatric pain management has been augmented by the utilization of hypnotic intervention in a broad array of conditions. Whereas there are numerous scales available to help young and preverbal children rate their pain (Wong & Baker, 1988), they may have drawbacks, which reduce their accuracy (Lehmann et al., 1990).

An area where hypnosis has proved helpful with children is in reducing acute procedural pain (Howard, 2003). Hart & Hart (1998) notes that hypnosis is the most frequently used intervention for acute procedure pain and distress in pediatric patients with cancer. The utilization of hypnosis in pediatric pain control is well presented in Hilgard and LeBaron's (1982) work and is now found throughout the pediatric pain literature. Chronic pediatric pain was suggested to result in long-term emotional distress and may contribute to physical and emotional disability in later life (Campo et al., 2001; Hotopf et al., 1998; Howard, 2003).

Neuropathic pain appears to benefit from the adjunctive application of hypnosis to standard pharmacological and physical treatment. Often cognitive and hypnotherapeutic interventions can help children better understand and create a sense of mastery over their pain. In so doing, an increased sense of control can lead to reduced anxiety and potentially improved immunological functioning. Gastrointestinal disorders such as IBS may show an equal benefit from hypnotherapy in both pediatric and adult populations. A combined acupuncture/hypnosis intervention was successfully employed in treating chronic pediatric pain. Improvement was found in both pain levels and emotional well-being (Zeltzer et al., 2002).

From a biophysical perspective, it may be relevant to recognize that much of the adult literature concerning hypnotic procedures for treating acute pain may apply equally for adults and children. As we develop greater understanding of the central nervous system and physiological mechanisms of hypnotic analgesia, its applicability should be relevantly generalizable to the pediatric population. Hypnosis has demonstrated a reliable and significant impact on both acute procedural pain and chronic pain conditions (Patterson & Jensen, 2003).

A procedure common to many pediatric patients with acute and chronic pain as well as patients without pain is the painful experience of venipuncture and intravenous insertion. Fear, anxiety, and conditional responding to procedures associated with venipuncture and intravenous insertions often result in elevated levels of pain and anticipatory pain. Hypnosis and distraction techniques can help children to reinterpret painful experiences and reduce negative associations with pain (Carlson et al., 2000).

In a recent article on the use of imagination and hypnosis in the treatment of children with pain and anxiety, LeBaron (2003) presents a strong case for the effectiveness of hypnosis utilizing vignettes illustrating its implementation. He points out that through hypnosis, fantasies and wishes and desires can be vivified and that in so doing, it may "create enough renewed excitement and interest that the child experiences an increase in energy and motivation and a new connection with their family."

Anbar (2001) found that children with recurrent abdominal pain in the absence of an identifiable physiological cause respond following a single hypnotic session. One cannot discuss pediatric pain without referring to where it all begins. Hypnosis and self-hypnosis have proved effective in reducing pain and fear associated with induced pain in labor during childbirth (albeit we are talking about the mother's pain and not the child's) (Jackson, 2003; Ketterhagen et al., 2002; Mongan, 1998).

Hypnosis may be a means of reducing both pain and pain-related distress (Chen et al., 2000). For example, Adam, a young patient with cancer was treated using hypnosis for pain. First, he was taught glove anesthesia, which he applied to areas where he was to have finger sticks, Broviac changes, and later bone marrow aspirations. He was taught to visualize himself as a cartoon superhero named He-Man. He was taught how to enter a trance state. A signal was then used to initiate rapid induction. By lifting his crutch and later his finger into the air and reciting the words, "By the power of Grey Skull, I am He-Man," Adam was magically (hypnotically) transformed into He-Man, the strongest man in the universe. At such times, he could withstand increased levels of pain and invasive procedures.

Recurrent pediatric headaches appear to show a positive response to hypnotic intervention when relaxation and/or thermal feedback techniques are employed (Holden et al., 1999). The use of autogenic training (hand warming) with imagery has also been useful in reducing or eliminating pediatric migraines when done early in the migraine episode at the first signs of visual aura or muscular discomfort.

GERIATRICS

Lamberg (1998) reported on the new guidelines on managing chronic pain in older persons. At the other end of the lifespan within the over-65-year-old population and geriatric population, pain is reported in 45 to 80% of individuals. The most common treatment for pain in older persons is analgesic drugs. She states that the American geriatric panel included hypnosis among these coping skills. "Non pharmacological interventions used in combination with appropriate drug regimes often improve overall pain management."

CHRONIC PAIN

Crawford et al. (1998), in drawing attention to the transition of the patient with acute pain to the patient with chronic pain, note that by utilizing hypnosis, patients could alter acute pain experiences. They further suggest that learned hypnotic analgesia resulted in reported chronic pain reductions, increased psychological well-being, and increased sleep quality. The "neuro signature of pain" can influence subsequent pain experiences (Melzack & Wall, 1983). Specific pain-reduction hypnotic skills may indeed be essential in developing lasting pain relief, especially in situations where chronic pain based on medical conditions (e.g., cancer tumors, herniated discs) is anticipated. In this context, hypnotic pain control may be conceived as a set of skills rather than a state (Alden & Heap, 1998).

Patients with chronic pain clearly represent a population different from patients with acute pain. The most common form of chronic pain, other than from illness, is chronic low back pain, accounting for $50 billion to $100 billion a year in lost wages and medical care (Burte et al., 1994). Unlike acute pain, chronic pain may result in significant changes in individuals, personalities, and clinical presentations as evidenced by performance on Minnesota Multiphasic Personality Inventory (MMPI) profiles (Strassberg et al., 1992), as well as on specific pain measures such as the Posttraumatic Personality Profile (P3) and the behavioral assessment of pain (BAP).

Clinically, we commonly find that patients with chronic pain demonstrate elevated levels of feelings of hopelessness, helplessness, and despair. They often report ongoing struggles with depression, somatic preoccupations, and obsessive concerns with fatal illness. When chronic pain becomes a central issue in the individual's life, it may function as a coping mechanism altering the patient's capacities, both psychopathophysiologically and etiologically (Kuhn, 1984).

In addition to its direct impact on pain alleviation, hypnosis can play a key role with the depression and hopelessness the patient with chronic pain experiences. Metaphors and hypnotic scripts can address both the pain and psychological distress (Havens & Walters, 1989). Margaret Jack (1999) cites the case of a patient with chronic pain syndrome (CPS) for whom hypnosis played a critical role in her emotional recovery with some additional pain relief. Individuals who are diagnosed with CPS are often overwhelmed by the impact of their pain. For patients with CPS, the pain often takes on an all-encompassing life of its own, dictating the patient's quality of life both psychologically and physically. Issues of learned behaviors, conditioned avoidances, and conscious and unconscious secondary gains often complicate the alleviation of the pain patients with CPS experience.

Hypnotherapy represents a complementary component in a multidisciplinary approach that should first acknowledge that the patient with CPS is not primarily a psychiatric patient but rather a composite of both psychological and physical distress. Melzack (1990) points out the advantages of a multidisciplinary approach, inclusive of narcotics, for rescuing people in chronic pain. As Hitchcock (1998) points out, there are significant myths and misconceptions about the patient with chronic pain that the pain practitioner must address in formulating a treatment plan. She further points out that in many ways the patient is a valuable contributor to the understanding of his or her own condition. As such, hypnosis may assist patients in that understanding via uncovering techniques and experiential insights into various aspects of their pain.

In addition to low back pain, many other conditions can result in CPS. Patients experiencing temporomandibular disorders who underwent hypnotic intervention demonstrated significant decreases in pain severity and frequency, which were maintained for at least 6 months after treatment (Simon & Lewis, 2000). Ray and Page (2002) demonstrated how even a single session of hypnotherapy brought about reductions in subjectively reported pain in patients with chronic pain.

Hypnosis has helped adolescent teens and adults with cystic fibrosis (CF) develop improved attitudes about health and a sense of independence and decreased anxiety (Belsky & Kahanna, 1994; Olness & Kohen, 1996). Using a technique introduced by Bressler (1990), Anbar (2000) taught patients with CF to seek an inner advisor while in self-hypnosis to uncover information pertaining to their physical or psychological symptoms. In so doing, they

achieved greater levels of physical comfort and reduced anxiety levels.

Hypnotic intervention resulted in improvement in symptoms resulting from multiple sclerosis (Sutcher, 1997); fibromyalgia syndrome, especially when used as part of a multidisciplinary treatment (Berman & Swyers, 1999); procedures associated with dermatological disorders (Shenefelt, 2003); and phantom limb pain (Muraoka et al., 1996; Sthalekar, 1993). Using a hypnotically induced "virtual mirror" to allow patients to create hypnotic movement in imagery, Oakley and Halligan (2002) were able to modify long-standing intractable phantom limb pain. Tinnitus has been described as what pain would sound like if it made a sound (McSpaden, 1993). The cognitive distress that often overwhelms these patients has been treated hypnotically with some success (Burte, 1993; Harosymczuk, 2002). The list of illnesses, disease conditions, and injury-induced pain conditions for which hypnosis has historically been utilized and for which its application may apply is beyond the scope of one chapter. A review of the literature suggests that its clinical application is continually expanding.

PSYCHOGENIC AND PSYCHOSOMATIC PAIN

Another arena in which hypnosis may play a significant role in pain management and suffering is with patients experiencing psychogenic and psychosomatic pain. Using the affect bridge initially described by Watkins (1971) and listening to the patient's somatopsychic language (Araoz, 1985; Burte et al., 1994), patients can gain insight into the range and variety of symptoms they are experiencing. The psychosemantics the patient uses in describing his or her life situations or pain offers insight into the non-organic etiology of the conditions. Cues and stimuli associated with past trauma may maintain the patient's symptoms, whereas reassociating those symptoms to positive images may result in symptom reduction or alleviation (Burte, 1993).

With the psychosomatic patient with no known organic etiological basis for the pain, the exploration of the negative self-hypnotic (NSH) statements associated with the condition will lend insight into the symptom output. Patients' expectations of pain may result in the need for the therapist to "dehypnotize" patients out of their expectation of pain (i.e., painful childbirth). In a study by Whalley and Oakley (2003), psychogenic pain was hypnotically induced in highly hypnotic subjects, reinforcing the cognitive element in pain perception. This is especially relevant with patients experiencing sexual dysfunction associated with pain (Araoz, 1998; Burte & Araoz, 1994).

Techniques and case histories are presented in the above-noted works, but the essence of the hypnotherapy is to have the patient, by experiencing these NSH statements in trance, identify the bridges between his or her psychic conflicts (semantic input) and the pain or dysfunctional symptoms (somatic output).

DENTAL PAIN

As stated earlier, learned emotional responses and anticipation of pain (anxiety) are very common. One area where this is seen is with dental patients. Whether the result of childhood trauma associated with painful procedures or the result of painful procedures in adulthood or issues of loss of control, many individuals demonstrate anxiety and fear reactions to dental care resulting in avoidance of proper or timely treatment. Hypnosis can prove to be an effective intervention in reducing anticipatory anxiety.

In addition, hypnosis can reduce anxiety during procedures and be used hypnoanalgesically within the dental setting. Dyas (2001) compared 40 subjects (20 per group), who received intravenous drug administration of Midazolam and Fentanyl for mandibular third molar surgical removal either with or without hypnosis. He found that heart rate (an indicator of stress and anxiety), electrocardiographic, and pulse oximeter recordings were better for patients who received hypnosedation. Further, the hypnosedative group required less intravenous sedation, their heart rate increase was significantly lower, and their recovery time was significantly shorter.

Hypnosis effectively allowed for reduced intravenous doses in dental treatments (Lu & Lu, 1996). Hypnosis in general dentistry has been shown to be an effective intervention for pain management, increasing rate of healing, reducing analgesic medication, and reducing anxiety and phobia (Hammond, 1990).

CONCLUSION

In conclusion, the field of hypnosis for pain management is diverse. Its range encompasses hypnoanalgesia, treatment of acute and chronic pain, pre- and postsurgical intervention, distress and suffering, neurophysiological intervention, and psychosomatic pain, to mention but a few areas. It continues to grow as an accepted modality in pain management and has been endorsed as an effective adjunctive treatment by many professional societies and organizations for intervention with all age populations from pediatric to geriatric. It has shown its utility with intractable conditions such as cancer pain and has been used for pain with terminal illness. Hypnosis has been suggested to be effective in enhancing immune functioning via stress reduction and increased cognitive coping.

For the health care provider seeking a broader range of knowledge about hypnosis, there is a plethora of information available. Works such as the *Handbook of Hypnotic Suggestions and Metaphors* (Hammond, 1990) offer an overview of hypnotic intervention, whereas for the pain

practitioner, the work of Elmer and Freeman (1998) focuses on hypnotic interventions more relevant to the cognitive and sensory aspects of pain (Munafo, 1998). Rossi (1993) presents a good introduction into the field of psychobiology of mind, body connectedness, and healing. Fredericks (2002) provides an excellent text on surgery and anesthesia, an overview of which is presented by Rogerson (2002). For practitioners seeking applications to clinical cases, Frank and Mooney's (2002) work on hypnosis and counseling in the treatment of chronic illness is an excellent resource.

As cited earlier, hypnosis with pharmacotherapy has been shown to be more effective than either alone and should not be overlooked by professionals seeking to help manage patients' pain.

Clinical Applications of Interactive Guided Imagery℠ for Diagnosing and Treating Chronic Pain

David E. Bresler, PhD, LAc

INTRODUCTION

Chronic pain has become the Western world's most expensive, disabling, and common disorder. An estimated 45 million Americans suffer from some form of chronic headache, which costs the U.S. economy $50 billion directly and indirectly (National Headache Foundation, 2003). Arthritis afflicts nearly 50 million Americans and accounts for 36 million outpatient visits and 750,000 hospitalizations annually (Centers for Disease Control, 2004).

Back pain generates nearly 12.5 million office visits per year and has disabled 7 million Americans (Cherry & Woodwell, 2002). Add facial and dental pain, neuralgia, cancer pain, chronic neck and shoulder pain, fibromyalgia, and other common pain syndromes, and it's easy to understand why pain is estimated to cost the nation's economy $100 billion per year (American Pain Society, 2000; Marcus, 1996). The cost in human suffering is incalculable.

The focus of this chapter is on the uses of a particular form of mental imagery, called Interactive Guided Imagery℠, to diagnose and treat chronic pain, increase pain tolerance, and reduce amplification and the emotional toll of pain, and its ability, in short, to alleviate suffering.

Of all the modalities and techniques studied and developed during the past 30 years of treating patients with chronic pain and other chronic illnesses, I have found Interactive Guided Imagery℠ to be highly effective in increasing compliance, relieving symptoms, enhancing tolerance, reducing feelings of hopelessness and help-lessness, promoting healing, and increasing functional abilities in our patients, while carrying few, if any, significant risks.

WHAT IS INTERACTIVE GUIDED IMAGERY℠?

Mental images, formed long before we learn to understand and use words, lie at the core of who we think we are, what we believe we can do, what we think the world is like, what we feel we deserve, and even how motivated we are to take care of ourselves. They also strongly influence our beliefs and attitudes about how and why we fall ill, what will help us get better, and whether any medical and/or psychological interventions will be effective.

Images also have profound physiological consequences that powerfully influence the healing systems of the body, including the immune, endocrine, and nervous systems. Images can affect the cardiovascular, respiratory, and gastrointestinal systems, and probably all other bodily systems, as well. For example, does not a vivid scary (or erotic) thought cause powerful changes to occur in many of these systems?

Positive images can stimulate and support the healing systems of the body, and the remarkable healings that have been documented following religious or faith-based healing ceremonies, while often difficult to explain, may be related to the positive healing images that they evoke. Scientists have coined a term that they use to describe the

impact of positive expectant faith on health and healing — it is called the "placebo effect."

Research on the omnipresent placebo effect, the standard to which we compare all other modalities and interventions (and find relatively few more powerful), has provided some of the strongest evidence for the power of the imagination and positive expectant faith in healing. It is well documented that from 30 to 55% of all patients given inactive placebos respond as well or better than those given active treatments or agents (Frank, 1974).

Although we do not completely understand the mechanisms involved, *it is clear that people can derive not only symptomatic relief, but actual physiologic healing in response to treatments that work primarily through beliefs and attitudes about an imagined reality.*

Thus, learning how to better mobilize and amplify this "mind/body" phenomenon in a purposeful, conscious way is an important, if not critical, area of investigation for modern medicine and psychology. Marty Rossman, co-founder of the Academy for Guided Imagery, often remarks that there should be a new discipline in medicine called "placebology" to train health care professionals how to mobilize and enhance the placebo effect in the service of healing.

In addition to its potential for stimulating and accelerating physical healing, imagery provides a powerful window of insight into unconscious processes, rapidly and graphically revealing underlying unconscious psychological dynamics that may support either health or illness. To the trained imagery clinician, this "window" is an invaluable tool for quickly identifying unique opportunities for positive change, subtle manifestations of resistance to change, and ways to work effectively with both.

Guided imagery is a term used to describe a wide range of techniques from simple visualization and direct imagery-based suggestion, through metaphor and story-telling, to unscripted free association and fantasizing. Guided imagery is most commonly used to help teach psychophysiologic relaxation, to relieve symptoms, to stimulate healing responses in the body, and to enhance tolerance to procedures and treatments.

Most people do imagery all the time, primarily by worrying, for what we worry about usually is not going on anywhere except in our imagination. We regret the past, recalling moments when we should have acted differently, and then we drag them into our imagination in the present time to be "ruminated," analyzed, reviewed, re-scripted, and/or grieved.

Alternatively, we fear the future as we think about all the possible negative things that could happen, but all those things are happening only in our imagination. In a sense, we poison the present by attending to (and growing) our past worries and future fears. Remember, all images can have profound physiological consequences. It has

been said, "Yesterday is history. Tomorrow is a mystery. Today is a gift. That's why it's called the present."

Fortunately, more and more people are realizing that they can use this same mind/body connection to facilitate healing and to self-treat a variety of chronic pain problems, including back pain, headaches, arthralgia, neuralgia, myalgia, and even secondary pain-related problems, such as anxiety, depression, insomnia, and relationship issues.

According to a nationwide survey by the National Center for Complementary and Alternative Medicine (NCCAM), up to 25% of Americans use mind/body techniques for health (including deep breathing, relaxation, meditation, hypnosis, and guided imagery). If you add prayer, it is up to 68% (Centers for Disease Control and Prevention, 2002).

Interactive Guided Imagery[sm] (IGI) is a service-marked term used by the Academy for Guided Imagery to represent its highly interactive, nonjudgmental, content-free style of guiding imagery, which is particularly effective for enhancing patient self-management and self-care, and for evoking greater patient autonomy.

This autonomy is often critical to achieving long-term success, for people living with chronic pain can become highly dependent on health care providers, family members, and others. Unfortunately, this can reinforce the sense of helplessness, hopelessness, and worthlessness (i.e., depression), which is already problematic.

Rather than processing patients through a standardized program or protocol that may or may not be appropriate to meet their unique needs, IGI helps people in pain to draw upon their own inner resources to explore the meaning of their pain symptoms, to relieve symptoms and support healing, to choose the most appropriate interventions, to identify and deal with their resistance to change and issues that sabotage compliance, and to find creative solutions to challenges that they previously thought were insoluble.

IGI is particularly useful in our current health care climate, where briefer yet more effective, efficient, and empowering mind/body approaches to health care are becoming highly valued by patients, providers, and insurers alike. Before explaining the principles and practices of IGI, let us briefly examine some of the unique aspects of chronic pain that illuminate the unique value of using mind/body approaches such as IGI to achieve long-term success.

CHRONIC PAIN DEMANDS TREATMENT DIFFERENT FROM ACUTE PAIN

Modern technology has created a huge variety of pharmaceutical products and interventional techniques for acute or self-limiting pain. These agents are usually highly effective and patients who undergo operative or other acute invasive procedures are generally spared all but the slightest degree of pre- or postsurgical discomfort. Like-

wise, for patients with acute sprains, strains, menstrual cramps, or headaches, a variety of effective medications are available over the counter.

Yet, the approaches that have proved to be so successful in the management of acute pain are often ineffective or even counterintentional for controlling *chronic* or long-term pain. Although acute pain usually gets better by itself, and pain medications can provide greater comfort as the body heals, *chronic pain typically becomes worse with time*. Its victims are referred endlessly from doctor to doctor, for even if temporary relief can be obtained, the pain inevitably returns for most people with chronic pain diagnoses.

For example, when opiate-based analgesic medications are used over a prolonged period of time, pharmacologic tolerance can develop and effectiveness becomes progressively reduced. As tolerance develops, patients often increase their dosages with the idea that "if a little is good, a lot will be even better." Unfortunately, higher dosages only produce greater side effects, and tolerance continues to develop. In addition, many of the most effective analgesic agents also carry a high risk of dependency.

As a result, it is common to find patients with chronic pain taking large amounts of medications that they say are not really helping to ease their pain. These medications may also be producing significant side effects, some of which could be contributing to the pain experience. When patients or their doctors attempt to reduce these medications, withdrawal symptoms can make pain even less tolerable, and the patients return in desperation to their former regimens, feeling as though they have been total failures and are doomed to be hopeless victims of pain and suffering.

When medications or other medical interventions fail, patients are often told, "Nothing more can be done. You'll have to learn to live with it." This statement has two iatrogenic implications. First, it destroys one of the most significant healing assets that chronic pain (or other chronic illness) sufferers possess — namely, hope or positive expectant faith. Second, it conveys the subtle message that if you "have to learn to live with it," the only time you *won't* have it is when you are no longer alive. This may add to the significant suicidal ideation experienced by many people already severely depressed from being in chronic pain.

The way we communicate with patients in pain and the images that our communications evoke can have an important, if not critical, influence on the outcome of any interventions we recommend or provide. As I discuss below, negative communications may actually retard the body's intrinsic healing abilities, while more positive, imagery-based suggestions may enable patients to unlock the door to the most potent and varied pharmacy yet discovered — the one in our own brain.

WHAT IS PAIN?

As I have discussed in detail elsewhere (Bresler & Trubo, 2002), one of the greatest challenges in researching and treating chronic pain is to resolve the inherent ambiguity in the terms and concepts we use to describe it. For example, I find it helpful to distinguish between a painful *sensation* (mental awareness of an unpleasant physical stimulus) and the pain *experience* (the total subjective, cognitive, and emotional experience of pain). Furthermore, it is important to recognize that *there is not necessarily any direct relationship between the sensation and experience of pain*.

This is seen in several studies that reported that soldiers seriously wounded in battle complained of only mild discomfort compared with civilians with similar injuries, for they were elated to learn that the war was over for them and that they were to be sent home. In contrast, patients with phantom limb pain often report agonizing discomfort even though the entire stump has been anesthetized.

In our language, we often talk about pain as if it were a tangible, *invasive thing*, much like a splinter is an *invasive thing* — that is, an object or substance from outside that infiltrates or penetrates the body. Thus, if you accidentally strike your thumb with a hammer, you might say you that you "feel pain in the thumb which is radiating to your hand."

Such a notion is very inaccurate, for there is no pain "in" your thumb, any more than there is pleasure "in" your mouth when you eat something that tastes good. You probably would not say, "Umm. My mouth is full of pleasure which is radiating to my stomach."

When you injure your thumb, you stimulate local neural receptors that send a barrage of electrochemical messages up through the nerves in your hand and arm to your spinal cord and brain. *Whether or not we become aware of a potentially painful stimulus depends upon the way the stimulus information is interpreted by the nervous system.*

If the nervous system decides that the messages from the thumb are urgent and require immediate action, it creates an experience of pain that is identified with the thumb so that you will give it proper attention. If it decides that the messages are unimportant, the messages may be ignored altogether until they become important (e.g., when your thumb swells).

For example, as you read this, your shoes may be stimulating neural receptors in your toes and feet, and if so, these are generating electrical and neurochemical messages that ascend the neuraxis to your brain. There, probably in the thalamic nuclei, your brain interprets those messages as being unimportant, and thus, information about your shoes is usually not communicated to higher centers. You may have had no awareness whatsoever that your shoes were pressing against your toes and feet unless your attention was called to them, as I just did.

The same is true if you are wearing a watch, jewelry, or any tight clothing. If your brain can choose to ignore unimportant information generated from neural receptors in your feet, can it not choose to ignore information from a neuralgia or pain-related injury if it interprets that information as being no longer important? What if your brain could interpret a painful stimulus as being pleasurable? For example, if you have ever scratched an itch hard, you know that it is often difficult to determine if it hurts or really feels good. All of this reminds us that the main pain receptor is between our ears, and that is where pain usually resides.

Like many *perceptions*, pain is well known to be influenced by learning and early developmental predispositions. For example, animals raised in a pain-free environment showed insensitivity to noxious stimuli in later life. Social, cultural, and ethnic differences in the experience of pain also are well documented. Vivid examples are the horrific initiation rituals of many primitive tribes. These would be considered nothing short of torture if practiced by members of Western cultures.

Aristotle was the first to suggest "pain is an *emotion*," as pervasive as anger, terror, or joy. The emotional component of pain is inexorably bound to other aspects of the pain experience, for anxiety and agitation are the natural consequence of a painful sensation that tells higher cognitive centers "something is wrong." If the "something" can be clearly identified and appropriate corrective action can be taken, the (acute) pain experience is usually terminated as the body heals.

However, for most patients with chronic pain, the "something" is vague, unknown, or untreatable, and fear of continued pain for an indefinite future produces even greater stress and anxiety. On a physiologic level, this anxiety causes sympathetic hyperactivity, as manifested by increased heart rate, blood pressure, respiration, palmar sweating, and muscle tension.

In patients with musculoskeletal pain, this increased muscle tension often augments the sensation of pain, which further increases stress and anxiety, which, in turn, produces even greater muscular tension and more pain. The amplifying relationship among stress and anxiety, muscle tension, and pain is well known to clinicians, for treatment of one frequently provides relief of the others as well. This relationship is also one of the reasons that chronic pain symptoms can be temporarily alleviated by providing stress management training or antianxiety agents, physical therapy or muscle relaxants, or pain medications.

However, over time, exhaustion of sympathetic hyperactivity is inevitable, and more vegetative signs and symptoms soon emerge, such as feelings of helplessness, hopelessness, worthlessness, and despair, sleep and appetite disturbances, irritability, decreased interests, low libido, erosion of personal relationships with family and friends, as well as increased somatization of complaints.

Thus, acute pain and anxiety become chronic pain and depression.

It is well known that the most notable emotional change in patients with chronic pain is the development of depression, the "crash" that occurs after a long period of unrelenting stress. This depression may be overt or masked to both patient and health practitioner alike. In a sense, depression can be thought of as "emotional pain," and when its symptoms are effectively treated, the chronic pain experience is often relieved, as well. This is why antidepressant agents can be helpful in the management of chronic pain.

It is important to emphasize the psychophysiological basis of chronic pain, for it is a complex subjective experience that involves physical, perceptual, cognitive, emotional, and spiritual factors. When a patient with low back pain complains that "my back hurts," his or her pain experience also may involve anxiety or depression (producing insomnia, loss of appetite, and decreased sexual desire); drug dependence or addiction; separation from work, family and friends; loss of avocational interests and hobbies; numerous secondary gains; and a host of other problems. These may remain indelibly associated with the experience of back pain, even after the entire spine has been chemically anesthetized.

Thus, it is easy to see why no simple pill or shot is the cure-all for chronic pain. The most common error made by clinicians is to primarily evaluate and treat the physical symptoms associated with the problem, for they assume that the objective of therapy is to *treat pain in people*.

To me, however, the objective of therapy is to treat *people in pain*, which takes a much broader perspective. From this point of view, it is unnecessary to wonder if a patient has "real" versus "unreal" pain, "organic" versus "psychologic" pain, or "legitimate" versus "hysterical" pain. Pain is an intensely subjective and personal experience, and even if no physical explanation for it can be found, *all pain is real*. According to the scientific method, the absence of data does not disprove a hypothesis, and simply because we cannot find the source of pain does not mean that it is not real.

PAIN VERSUS SUFFERING

In our Western culture, pain is usually considered an enemy to be fought and overcome, and as a result, our first approach is usually to search for a "pain killer." This overlooks and ignores the survival value of pain, which can be a warning signal, a protector, a potential teacher, a guide, a motivator, or even an incentive for change.

While some believe that chronic pain is a symptom that has lost its meaning and become "an illness in itself," I believe that this is the result of our health care system's tendency to medicalize and externalize symptoms rather

than to examine their meaning in a more holistic context, as discussed below.

Whatever the cause, if an individual cannot tolerate or cope effectively with pain, he or she *suffers*, which is manifested as an inability to sleep, eat, work, function, or fully enjoy life. Life, in the most personal, meaningful sense, stops. As we discuss below, I believe that suffering is primarily an epiphenomenon of one's attitude and beliefs, and that it is *possible to have pain, and yet not suffer,* depending on how we relate to the pain we experience.

In the more traditional psychological literature, a distinction is often made between pain sensitivity and pain tolerance. To illustrate the clinical importance of pain tolerance, when teaching fellows and residents at UCLA, I found it helpful to compare x-ray films of two patients, both of who complained of knee pain.

The first patient was a professional football player who had undergone six prior knee surgeries. While reviewing his films, I wondered how this individual could walk, much less continue to play football. However, he reported only minor pain or discomfort, took no pain medications (because they made him "feel less ferocious"), and only desired treatment that would increase the strength, stability, and range of motion in his knees.

The second patient was injured on-the-job and had filed extensive workers' compensation litigation. Although his knee x-rays appeared to be completely normal, he suffered greatly and was unable to climb stairs, drive a car, or sleep for more than 2 to 3 hours at a time. He was totally disabled, despondent and depressed, and completely dependent on his family, four medical doctors, and seven different pain medications.

The first patient had significant pathology but high tolerance and barely complained of pain. The second had minimal, if any, pathology, but little tolerance to the pain he experienced and lots of suffering.

In the clinical situation, we often confront limitations in our ability to reverse severe physical pathology (e.g., degeneration of cartilage in a joint). However, our ability to help patients reduce their suffering by enhancing their tolerance of pain appears to have no upper limit. Thus, practitioners who help patients embrace a more positive belief or attitude about pain can often successfully help reduce their suffering and enhance tolerance, even when "nothing more (medically) can be done."

There is evidence that positive imagery and the placebo effect can stimulate the production of endorphins, naturally occurring pain-relieving substances in the central nervous system. I have long believed that endorphins have nothing to do with pain, and everything to do with suffering. For example, when a patient is given an injection of morphine (which mimics the effects of endorphins), he or she will often state that "it still hurts, but it doesn't bother me." This represents enhanced pain tolerance, not a reduced pain sensation, which is why morphine is considered to be an analgesic (that enhances pain tolerance), not an anesthetic (that blocks all sensation)

The extent to which a patient's suffering can be reduced through psychophysiological approaches such as IGI depends on many complex variables including the patient's belief systems and attitudes, early life experiences, the degree of physical pathology, and perhaps most importantly, the *meaning* of pain in the context of the patient's life.

THE MEANING OF PAIN

Since the dawn of creation, pain has provided critically important information concerning our relationship to our inner and outer environments. Pain strongly conveys the message that "something is wrong," and it encourages the body to take action to prevent further injury. From an evolutionary point of view, it is one of the most powerful ways to ensure the survival of an organism in a dangerous world.

While most authorities acknowledge these positive aspects of acute pain, many believe that chronic pain is a "biological mistake" or "obsolete symptom" that serves "no useful purpose." To correct this "mistake," they recommend strong medications or surgical interventions in an attempt to obliterate the sensation of pain.

It is interesting to note that the exact technique utilized will depend more on the type of specialist consulted than on the patient's unique needs. For example, an internist may prescribe medication; an orthopedist, physical therapy or surgery; a psychologist, family psychotherapy; an acupuncturist, needles or herbs; a chiropractor, manipulation; and so forth. Abraham Maslow used to say, "When you are holding a hammer, you tend to look for nails."

In my opinion, the best long-term interests of the patient usually are not well served when the major goal of therapy is to mask or suppress the symptoms of pain without first attempting to understand its underlying meaning. To do so is like responding to a ringing fire alarm by cutting its wires to stop the annoying clamor, rather than by leaving the burning building.

I invite patients to consider the notion that like the oil light in a car, their nervous system may be generating the experience of chronic pain *for a reason.* I invite them to explore the possibility that their chronic pain is not a disease or "mistake" but a symptom generated through the wisdom of the body.

I then teach them about the extraordinary healing, regeneration, repair, and regulatory systems that are at work in their body, and remind them that *symptoms are the way that the body tries to heal itself or prevent further injury.* Like the oil light and the fire alarm, once the message is heard and appropriate action is taken, symptoms usually will decrease and ultimately disappear, for they are no longer needed or important.

Western medical practitioners consider a fever to be a pathologic symptom that is best treated by prescribing antipyretic medications that will reduce it. Oriental practitioners do not treat a fever at all, unless it becomes so high as to be imminently dangerous. They consider a fever to be a healthy symptom that represents the body's attempt to raise its core temperature to destroy an invading microorganism.

Unfortunately, much of contemporary Western medicine is focused on reducing or suppressing symptoms. For example, if a patient has high blood pressure, antihypertensives are prescribed to reduce it. If a patient is unable to sleep, medications are given for sedation at night. If a patient has excessive anxiety, antianxiety agents are often utilized. However, should not a health care practitioner first determine *why* that particular patient has hypertension, sleep disorders, or anxiety neurosis? What is the message that these symptoms are trying to convey? Exploring the meaning of symptoms in a nonjudgmental way can be the key to finding answers to many intractable health challenges, including chronic pain.

Pain is a message that alerts us to danger. Through the primitive, survival-oriented wisdom of the nervous system, it motivates us to correct the situation by changing and adapting to the shifting demands of the world in which we live. Through pain, we are warned about *all* of the dangers we face, and if we continue to ignore them, our nervous system will often increase the intensity of pain in an attempt to get our attention and/or to elicit some change.

Perhaps this is why many patients with chronic pain receive only temporary relief after symptomatic treatment. Although symptoms can be suppressed for a short period by drugs or surgical interventions, if their meaning remains unacknowledged and the nervous system believes that something important is still not being attended to, it will cause pain to increase, break through, and continue to return until the message is heard and appropriate corrective action is taken.

PRINCIPLES OF INTERACTIVE GUIDED IMAGERY^{SM}

GIVE ATTENTION TO WHAT YOU WANT TO GROW

Although no one really knows what "consciousness" is, I believe that it is critically related to the process of *attention*, for we only experience what we personally attend to. There is an old saying "whatever you give your attention to grows," whether it be your garden, your children, your worries and fears, or your pain.

Over the years, most of us learn to give our attention to the conscious, verbal part of our mind that narrates a linear, logical, rational, analytic monologue describing its perspective of the world, and how we *think* about it. It is the "little voice inside your head" that talks all the time,

the "person" who most of us think we are. Because we have given it so much attention and reinforcement (e.g., reading, writing, and arithmetic are highly rewarded in our culture), it is a very strong presence in our lives.

However, who we really are is much more than simply what we "think." We are also the richness of our intuitions, emotions, feelings, memories, drives, fantasies, goals, appetites, aspirations, expectations, ambitions, values, passions, beliefs, perceptions, and sensations. Any or all of these aspects of self may require and even demand attention, finding ways to compete by intruding on everyday consciousness through physical, cognitive, emotional, or even behavioral symptoms, if need be.

Rather than suffer the results from neglecting these parts of ourselves, we can focus attention on them in a relaxed state of mind and invite images that seek attention to "come to mind." By properly dialoguing interactively with these images, we can reconnect with important and powerful inner resources that are deeply dedicated to protecting us, healing us, and improving the quality of our lives.

IMAGERY IS THE PRIMARY ENCODING LANGUAGE OF THE BODY'S HEALING SYSTEMS

Imagery can be thought of as one of the brain's higher-order information processing and encoding systems or "languages." The language we are most familiar with is the verbal one spoken by the "little voice in our head." It uses *sequential information processing* that provides a linear, analytic, and conscious verbal perspective of the world. It makes linear associations and connections, and most health professionals are highly educated and rewarded for their abilities in using this mode of information processing, e.g., associating specific symptoms with specific illnesses.

Images, on the other hand, are the language of the emotions, which use *simultaneous information processing*. This provides an instantaneous, holistic, synthetic perspective that includes vital input and information from the unconscious mind. As is said, "a picture is worth a thousand words," and imagery can reveal to us how seemingly disparate areas of our lives are intimately related. A brief clinical example can help to bring the importance of this relational quality to life.

> A 52-year-old cardiologist named John was suffering from excruciating low back pain following treatment for rectal cancer. Although surgery and radiation therapy apparently had eradicated the cancer, he described the pain that remained as unbearable. Because the area had been so heavily irradiated, neither repeated nerve blocks nor further surgery could be used to help relieve his terrible discomfort, and he had long ago developed tolerance to his pain medications.

When John first came in, he already had narrowed down his personal alternatives to three: (1) successful treatment, (2) voluntary commitment to a mental institution, or (3) suicide. John was convinced that under no circumstances could he continue to live with pain and, at the same time, maintain his sanity.

In reviewing his medical records, I noticed that during a psychiatric workup, John had described his pain as "a dog chewing on my spine." This image was so vivid that I suggested we make contact with the dog, using guided imagery. With his training in traditional medicine, he thought the idea was silly, but he was willing to give it a try.

In John's case, our initial goal was to encourage the dog to stop chewing on his spine. Over the next few sessions, the dog began to reveal critically important information. According to the dog (named Skippy), John never had wanted to be a physician — his own career choice was architecture — but he had been pressured into medical school by his mother. Consequently, he felt resentment not only toward his mother, but also toward his patients and colleagues. Skippy suggested that this hostility had in turn contributed to the development of his cancer and to the subsequent pain problem as well.

During one session, Skippy told John, "You're a damn good doctor. It may not be the career you wanted, but it is time you recognized how good you are at what you do. When you stop being so resentful and start accepting yourself, I'll stop chewing on your spine." These insights were accompanied by an immediate alleviation of the pain, and in only a few weeks' time, John became a new person, and his pain progressively subsided.

This type of experience demonstrates how powerfully the imagery process can reveal meaning in a supposedly "meaningless" symptom, and illuminate the path to healing. While IGI does not always lead so dramatically to relief, it usually leads to better self-understanding and enhanced coping skills for dealing with a chronic illness or condition.

IMAGERY HAS POWERFUL PHYSIOLOGICAL CONSEQUENCES

As mentioned previously, numerous research studies have shown that imagery can affect almost all major physiologic control systems of the body, including respiration, heart rate, blood pressure, metabolic rates in cells, gastrointestinal mobility and secretion, sexual function, and even immune responsiveness (Sheikh & Kunzendorf, 1984).

Imagery is essentially a way of thinking that uses sensory attributes, and in the absence of competing sensory cues, the body tends to respond to imagery as it would to a genuine external experience. For example, take a moment to imagine that you have a big, fresh, juicy, yellow lemon in your hand. Experience what it might feel like to hold it. Imagine it in your mind's eye until you sense its heaviness and fresh tartness. Now, imagine taking a knife and slicing into the lemon. Carefully cut out a thick, juicy section. Now, if you're willing, imagine taking a deep bite of the lemon slice, feeling how sour the lemon juice tastes, saturating every taste bud of your tongue so fully that your lips pucker, and your tongue begins to curl.

If you are able to imagine this vividly in your mind's eye, the image probably caused some salivation, for the autonomic nervous system easily understands the language of imagery and responds as if it is real. While the image of the lemon may be imaginary, the salivation is real.

Here is the crux of the matter: *If imagining a lemon makes you salivate, what happens if you imagine that you are a hopeless, helpless victim of chronic pain?* Does it not tell your nervous system to give up? Is it not likely to create neural and biochemical signals that indicate you are getting worse rather than actively healing? From another perspective, if you believed you were able to resolve various life problems, improve communications and relationships, and learn how to modulate pain, would this not create a healthier and more functional physiology in the body?

IMAGERY IS THE LANGUAGE OF THE EMOTIONS

Imagery is a powerful tool in the healing arts also because of its close relationship to the emotions. Imagery is the expressive language of the arts — poetry, drama, painting, sculpture, music, and dance — and it reflects various aspects of the emotional self. Emotions reveal what is personally important to us, and they can be either potent motivators that promote healing or barriers to changing dangerous lifestyle habits.

Emotions motivate us to action and they produce characteristic physiologic changes in the body, including varying patterns of muscle tension, blood flow, respiration, metabolism, and neurologically and immunologically reactive peptide secretions. Modern research in psychoneuroimmunology points to the emotions as the key modulators of neuroactive peptides secreted by the brain, gut, and immune systems (Pert & Chopra, 1997).

Our emotions represent communications about basic survival that originate from our primitive, reptilian-like limbic system. There are four primary emotions: sad, mad, glad, and frightened. In short, fear is about *flight*. Frightening feelings let you know that the object you fear may be dangerous or stronger than you, and this motivates you to get away from it so you don't lose something of value (e.g., your possessions, your health, or even your life).

Anger, on the other hand, is about *fight*. It is a message implying that something has been taken from you (e.g., your possessions, safety, pride, self-esteem), and it motivates you to fight to get it back so you do not lose even more.

Grief motivates us to detach and move away. It lets us know that the object of our grief has been lost and that we most likely will not get it back. Joy, on the other hand, is about *attachment*, and it motivates us to move closer to the things that make us feel good.

PATIENT AUTONOMY IS MOST EFFECTIVELY SUPPORTED BY USING A TWO-WAY INTERACTIVE GUIDING STYLE

One key to the extraordinary clinical effectiveness of Interactive Guided Imagery^sm is the unique interactive communications component that it incorporates. By working interactively instead of simply reading an imagery script, the Interactive Imagery Guide^sm ensures that the experience has personal meaning for the client, and that it proceeds at a pace determined by the client's actual needs and abilities rather than the guide's "best guess estimate."

For example, an Interactive Imagery Guide might ask, "Of all the different problems, symptoms, and challenges now going on in your life, allow an image to form that represents the single most important and critical issue for us to work on now, and then describe it to me." The guide can then facilitate a dialogue between the client and the image to find out what the image wants, needs, and has to offer.

Because the content, direction, and pace of the imagery experience are set by the client, not by the guide, it is the client who actually (unconsciously) guides the process to the resources most needed to support healing, change, and positive therapeutic results.

PATIENT AUTONOMY IS MOST ENCOURAGED BY USING CONTENT-FREE LANGUAGE AND NONJUDGMENTAL GUIDING

Whenever possible, the Interactive Imagery Guide uses nonjudgmental, content-free language that encourages clients to tap their own inner resources to find solutions for solving their own problems. I often like to say, "while the guide provides the setting, it's the client that provides the jewel."

At a time when there is so much concern about "false memory syndrome" (Pope, 1996), this type of content-free guiding also ensures that the client's experience is not unduly contaminated or influenced by the suggestions of the guide.

PATIENT AUTONOMY IS MOST ENCOURAGED BY SPECIFIC QUALITIES AND SKILLS UTILIZED BY THE GUIDE

There are important personal qualities that the well-trained Interactive Imagery Guide brings to the therapeutic experience, including a nonjudgmental attitude, patience, and trust in clients' own abilities to identify healing resources and to find solutions to their problems. The guides provide vital support as clients explore their inner world and inner issues, and emphasize the notion that clients have within them more healing resources than they had previously imagined. This approach leads to minimal transference, greater client self-confidence, increased opportunities for effective self-care, an enhanced sense of self-efficacy, and the rapid development of greater patient autonomy.

PROVIDER–PATIENT/CLIENT INTERACTIONS

DIAGNOSTIC AND ASSESSMENT PROCEDURES AND TECHNIQUES

The Interactive Imagery Guide must first decide whether there are any contraindications to introducing imagery to the patient, such as a medical or surgical condition requiring emergency treatment, or a mental illness precluding its use. Having decided that imagery may offer some benefit, a history is taken regarding the client's prior experience with imagery, visualization, hypnosis, relaxation, meditation, biofeedback, or related approaches. This allows the guide to utilize prior positive experiences or to address relevant issues in the case of negative experiences.

If the client has no prior experience with relaxation or imagery, the guide usually begins with a brief relaxation technique. The client is invited to imagine being in a beautiful, safe, and peaceful place and, then, to describe what he or she sees, hears, smells, feels, or experiences there. The guide may ask, "What's the weather like there?" or "What time of day is it there?" Such questions encourage the client to more vividly imagery the "Personal Place" in order to answer them.

The guide may suggest that the client choose a personal place with specific qualities that could be uniquely helpful. For example, fearful clients might be encouraged to imagine themselves protected in a "sanctuary," a "powerful place," or a "place where you are completely safe and free from any harm." A client who feels too exhausted to deal with a situation might be encouraged to imagine a place of "great energy and vitality" or "a place of rest, renewal, and nourishment."

Imagining a visit to a quiet, safe personal place is one of the quickest ways to teach people in pain how to relax, and it powerfully illustrates the profound effects a simple imagery experience can have. Occasionally, clients have difficulty imagining such a place or become more anxious as they close their eyes and begin to relax. If their anxiety does not respond to reassurance that they are completely in control, and to gentle encouragement that it might be helpful to see what comes next, this can simply reflect inexperienced clients' insecurity that they won't do it correctly, or it may be a signal that relaxing their vigil may be psychologically dangerous to them.

Such relaxation-induced anxiety can be a marker for early trauma, as is the experience of having an imaginary

safe place suddenly turn dangerous or foreboding. When early trauma is identified and found to be producing strong resistance to inner exploration, it is essential that the guide be appropriately trained to handle such situations in order to prevent the occurrence of traumatic insight or regression panic.

Once relaxation is introduced and a personal place is established, clients may be guided in one of several directions, depending upon their unique needs, as determined by the guide. Clients might be invited to turn their attention to specific symptoms, then to allow images to form for them, and then to invite healing imagery to come to mind. The client may be invited to dialogue with an image representing a specific symptom in order to find out why it is there, what it wants, needs, has to offer, and importantly, under what circumstances it is willing to leave.

Clients may also be invited to meet with an imaginary, kind, wise "Inner Advisor" who can provide previously inaccessible information about their issues or illness, as well as loving support and encouragement.

In this relaxed state, clients can invite images to form for almost anything they want to know more about, and by dialoguing with these images, they can expand their awareness of previously unknown connections and identify new options that can promote greater healing.

Typically, clients are initially seen one to three times to explore their history, status, and the potential benefits of working with guided imagery. The guide must consider whether the client will be able to use imagery most effectively as part of an individual counseling or therapy relationship, in a group or class, or as a self-care technique. Self-help books, CDs, and tapes are an inexpensive option for many clients who are capable of using imagery techniques on their own.

In practice, most well-trained guides recommend the imagery methods and techniques that suit a given client's situation and needs the best, considering the unique nature of the issue, the client's innate coping responses and worldview, and the amount of time, energy, and funds the client is willing or able to invest in the process.

In the course of only a few imagery sessions, most clients will have solved their problem, found a successful way to work it out by themselves, identified issues that require additional work, or found that the method or practitioner is not suitable for them or their situation.

DESCRIPTION OF COMMONLY USED TREATMENT TECHNIQUES

The list of techniques used in IGI is quite extensive, and this approach has been applied to problems ranging from severe depression, chronic pain, post-traumatic stress, and relationship conflicts, to enhanced creativity and the search for meaning and life purpose. However, some of the most basic techniques include the following.

1. Conditioned Relaxation

This powerful relaxation technique is based on Pavlovian classical conditioning techniques and utilizes imagery-linked breathing and body awareness techniques that train the client to relax automatically by taking a special "signal breath." Instead of tensing when pain starts to flare, patients become conditioned to relax and imagine gently moving any painful symptoms out of their body.

2. Symptom Suppression Techniques

Symptomatic imagery techniques reduce the physical symptoms of pain without concern for their cause. They are a useful alternative to analgesic or anesthetic medications, and they are particularly helpful when discomfort is so intense that the patient cannot concentrate enough to use other guided-imagery approaches.

Symptom suppression techniques include a wide variety of methods, such as "glove anesthesia," a two-step imagery exercise in which patients are first taught to imagine developing feelings of numbness in the hand, as if it were being placed into an imaginary anesthetic glove. Next, they learn to transfer these feelings of numbness to any part of the body that hurts, simply by placing the "anesthetized" hand upon it.

Glove anesthesia often helps to "take the edge off" the pain sensation, thus permitting patients to explore other aspects of the pain experience more fully. In addition, glove anesthesia provides a dramatic illustration of the power of self-control. When patients realize that they can produce feelings of numbness in their hands at will, they recognize that they may be able to control their discomfort, too. This is profoundly therapeutic for pain sufferers who previously felt totally helpless and unable to affect their discomfort in any way.

3. Symptom Substitution Techniques

Symptom substitution techniques invite the nervous system to move the discomfort to a new area of the body where it will be less disruptive. For example, patients can learn to experience their headaches in their little finger instead of their head. This technique does not require the nervous system to suppress or stop the experience of pain, or to cover up the message it is trying to communicate. Rather, it moves the symptom to a less traumatized area so that patients can work more effectively to identify what the pain message is really trying to communicate.

4. Interactive Imagery Dialogue

This interactive technique can be used with an image that represents anything the client or therapist wants to know more about, and in many ways, it is the ultimate insight-oriented technique. It can be used to explore an image of

a symptom (whether physical, emotional, or behavioral); an image that represents resistance that arises anywhere in the process; an image for an inner resource that can help the client deal with the current problem; or an image of the solution.

When using Interactive Imagery, the point is not to analyze the images, but to communicate with them as if they are alive, which of course, they are. This is not to say that they have an existence apart from the client, but rather that the images represent living complexes of thoughts, beliefs, attitudes, expectations, memories, feelings, body sensations, and values that at different times can function as distinct and relatively autonomous aspects of the personality. These constellations have been referred to as "subpersonalities" by Assagioli (1971), or "ego states" by Watkins and Watkins (1979).

Conflicts are often generated by subpersonalities that appear to have completely opposite beliefs, attitudes, and motivations. This is seen most clearly in issues related to habit control such a smoking, where people are of "two minds" about it. One part of them desperately wants to quit, while another part is determined to maintain the habit. The same is usually true when dealing with drug dependence, eating disorders, and other habits.

IGI is uniquely suited to mediate this conflict and to bring the parts closer together. By dialoguing with each of the parts, and finding out what they are willing to give up in order to get what they really want, unique solutions often arise. It is like conducting marriage counseling inside the skin.

5. The Inner Advisor

After learning to relax in their personal place, clients are frequently invited to dialogue with an imaginary figure that is designed to be both wise and loving, or as characterized in analytic terms, an "Ego Ideal." This figure is called an "Inner Advisor," and it is sometimes referred to as an "Inner Guide," "Inner Healer," "Inner Wisdom," "Inner Helper," "Inner Physician," "Higher Self," or any other term that is meaningful and comfortable for the client.

By dialoguing with their Inner Advisor, clients often receive creative and imaginative suggestions for how to alleviate their primary and secondary pain symptoms. Even more significantly, they can also often find answers to puzzling questions related to the etiology of their pain, as well as ideas for raising their pain tolerance.

6. Evocative Imagery

This state-dependent technique helps clients to shift moods and affective states at will, thus making new behaviors and insights more accessible to consciousness. Through the structured use of memory, fantasy, and sensory recruitment, clients are encouraged to identify a per-

sonal quality or qualities that would serve them especially well in their current situation. For instance, clients may feel they need "calmness" or "peace of mind" in order to deal more effectively with pain.

The guide then invites the client to relax and recall a time when peace of mind was actually experienced. Using sensory recruitment and present tense recall, clients are encouraged to imagine they are there again now, feeling that peace of mind. Once this peaceful feeling state has been well established and amplified, patients are invited to let the past images go, and to return to the present, bringing back with them the feelings of peace of mind. As they become aware of their pain problem while strongly in touch with this feeling, they are usually able to tolerate it far more effectively.

Evocative imagery was researched by Dr. Sheldon Cohen (personal communication) at Carnegie-Mellon University and found to be highly effective in shifting affective states. Research aimed at assessing the effects of those altered affective states on subsequent behavior, problem solving, and self-efficacy remains to be done, and this approach offers a fertile field for future psychological and behavioral research.

7. Grounding: Moving From Insight to Action

Grounding is the process by which the insights evoked using imagery are turned into actions, and where the increased awareness and motivation that result are focused into a specific plan for attitudinal, emotional, and/or behavioral change.

This process of adding the will to the imagination involves clarification of insights, brainstorming, choosing the best option, affirmations, action planning, imagery rehearsal, and constant reformulation of the plan until it actually succeeds. It is often the "missing link" in insight-oriented therapies, for it connects the new awareness to a specific action plan. It is where the "rubber meets the road," and imagery can be used to enhance this process by providing creative options for action and by using imagery rehearsal to troubleshoot and anticipate obstacles to success.

Treatment Evaluation

The time spent preparing the client before entering into a formal guided imagery exploration is called the "foresight" part of the process. Along with evaluating the appropriateness of using imagery with the client, the guide works with the client to establish the desired goals and objectives for their work together.

As with any medical or psychological situation, goals can be defined in physical, emotional, or behavioral terms, and a reasonable trial period for exploration is agreed upon. Typically, patients are asked to participate in three

exploratory sessions and then to decide whether this approach seems useful to them; whether they can best employ it as self-care in a brief, time-limited period of work (10 to 15 sessions); or whether it looks as if longer-term work will be needed.

At the end of each formal imagery experience (called "insight'), the goals of the work are reviewed and progress assessed (this phase is called "hindsight"). After this evaluation, an agreement is made to continue for another period of time, to define a period of time in which the client will do "ownwork" and then return to report progress, to terminate treatment, and/or to refer to another practitioner.

CONTRAINDICATIONS AND PRECAUTIONS

1. Do not substitute imagery for necessary medical or surgical interventions.

The primary danger in using imagery to augment healing in medical situations is when it is used in lieu of appropriate medical diagnosis and/or treatment. I have emphasized the necessity of an accurate diagnosis prior to using any psychophysiologic approach, so that the client is also aware of the medical options for treatment.

At times, patients may decide that they do not like the risks associated with the accepted medical treatments available and will then choose to use guided imagery or other mind/body approaches as their first-line treatment alternative. Although there are some situations in which this may make sense, each situation must be evaluated individually to ascertain patients' abilities to judge wisely for themselves and to make such important choices on their own.

2. Do not use imagery inappropriately with patients with unstable or poorly managed psychopathology.

There are several diagnostic categories of mental illness where the practitioner must use extreme care when utilizing exploratory imagery techniques. In particular, patients who are psychotic or who are on the verge of psychotic breaks, patients with dissociative identity disorders, and patients with borderline personality disorders must be treated with extreme caution, and only by well-trained and experienced imagery guides.

While these diagnoses do not represent absolute contraindications for imagery work, they require treating health professionals to have appropriate training and expertise in these areas. While many clients with these diagnoses may benefit from certain types of imagery (usually directed imagery focusing on centering, calmness, self-control, safety, etc.), great caution should be taken when using potentially disorganizing exploratory imagery techniques.

In proper therapeutic hands, guided imagery techniques may be one of the most effective ways available to work with clients who are survivors of traumatic abuse and who tend to experience pathological dissociation. However, such treating practitioners must be extremely well trained and experienced both in working with survivors of abuse and in working with exploratory IGI approaches.

3. Do not confuse responsibility with blame.

The fact that an illness can be helped through mental means does not necessarily mean it was caused by mental means. When using exploratory techniques such as the Imagery Dialogue with Symptoms or Working with an Inner Advisor, there is a tendency to confuse the ability to learn from illness with blame for causing the illness. What I usually tell clients is, "We may never know to what extent you or your unconscious is responsible for this pain problem, and that's really not the most important question. While it may not be clear to what extent you are responsible for your problem, it's absolutely clear that you are responsible for how you *deal* with your pain problem, and that's what we need to address."

This issue needs to be handled with skill and sensitivity, and while the practitioner may not be able to prevent certain clients from self-blaming (this may be an important issue to address with them), they can remind clients that using positive images to stimulate healing does not necessarily mean that it was their negative images that *caused* their problem in the first place.

4. Do not underestimate the power of the client's inner resources.

Imagery is a potent form of communication and suggestion. Whenever possible, we advocate using the patient's own imagery and an interactive guiding style with the conviction that clients have within them a great deal of information, experience, knowledge, and problem-solving resources that they are not yet using most effectively.

While there are certainly places and situations where an imagery guide may need to provide suggestions or even starting images, these are relatively rare when using IGI, and they risk robbing clients of the opportunity to learn an important way to help themselves. This can also create or sustain a sense of dependency on the expertise of the guide, rather than attention to the inner abilities that have always been available to help them to help themselves.

SCOPE OF PRACTICE FOR INTERACTIVE GUIDED IMAGERY℠

This has been an important and problematic area for the Academy for Guided Imagery. When initially considering

the criteria for formal certification in IGI, certification eligibility was restricted to professionals licensed to provide counseling services in their states of residence.

However, it was quickly determined that many states have no such licensing for therapists, and people with highly varying levels of training and experience were providing counseling, psychotherapy, hypnosis, and guided imagery. As a result, the academy evaluates each candidate on an individual basis, assessing the candidates for both competence and ethical standards as they are observed in clinical supervision as part of their IGI certification training.

Health professionals must ethically practice within the scope of their licensure, education, experience, and competence. Within these guidelines, certification in IGI can significantly help health professionals to become more effective at what they already do. Using guided imagery or IGI does not turn a physician into a psychotherapist, or a psychotherapist into a physician. Instead, it gives each a greater range of skillfulness in working with issues that involve both mind and body, and with issues involving emotions and behavioral change.

Certified IGI practitioners must discriminate between psychotherapy and psychoeducation, and between enhancing healing responses and practicing medicine. To maintain their certification status, they must also ethically practice within their scope of licensure, training, experience, and competence.

TRAINING, CERTIFICATION, AND ISSUES OF COMPETENCE

Many health professionals already utilize guided imagery in their work, although they may have learned how to guide someone only by reading a non-interactive script. The quality of training and competence of practitioners using this approach is highly variable. Because there is always the potential for doing harm when these techniques are used inappropriately or without adequate skills, standards of practice and quality control is an issue of critical importance.

The Academy for Guided Imagery has established specific standards of competence and ethical behavior that must be met before certification in Interactive Guided Imagery℠ is awarded. Quality assurance is based largely on direct observation of clinical work in small group and individual supervision sessions during the training program. During 52 hours of direct supervision, several different faculty members carefully observe the candidates and provide specific feedback to help them enhance their guiding skills.

Except for the academy's Professional Certification Training Program, there are no other such standards of quality assurance established for imagery practitioners.

REIMBURSEMENT STATUS

Imagery practitioners usually bill and are reimbursed for their guided imagery work in the same way they are for other professional services they render. Sessions are usually billed as psychotherapy, counseling, stress reduction training, or medical hypnosis. When applied for medical purposes, medical practitioners may ethically bill for medical services, although insurance companies may challenge this if services are lengthy and repetitive. There are currently no separate billing codes for guided imagery or IGI.

PROSPECTS FOR THE FUTURE

When you look closely at nearly every form of human therapeutic interaction and communication, imagery is usually centrally involved, primarily because it is a fundamental language of the body's healing systems. As this is better recognized, we are hopeful that health professionals will learn more about the best ways to utilize this potent form of thinking to support optimal health and healing.

Feedback from the thousands of health professionals who have taken the academy's training program in IGI confirms that it is a rapid route to insight, growth, and change. One constant piece of feedback received is that learning to use imagery interactively has improved the listening, communicating, and therapeutic skills of the academy's graduates, whether they are mental health professionals, physicians, or nurses.

Competence in effectively yet respectfully guiding the imagery process should be a fundamental part of every health professional's education and training, and the Academy for Guided Imagery is working toward that goal by co-sponsoring many of its professional training programs with well-established schools of medicine, nursing, and psychology, and with other professional medical and psychological associations.

In addition to professional training and certification in Interactive Guided Imagery℠, the academy's Imagery Store is a valuable resource for self-help books, CDs, tapes, and reliable information on imagery (Academy for Guided Imagery, www.interactiveimagery.com). The academy is also participating in research studies exploring the uses of imagery in pain control, surgical preparation and recovery, and cancer chemotherapy, and it recently established the nonprofit Imagination Foundation to support further research in these and other areas. The Imagination Foundation (www.imaginationfoundation.org) is currently soliciting both funds and research proposals investigating various applications of imagery in healing.

Humans have always used their imagination to solve problems that threatened their survival. These times demand more than ever that we now learn to use this powerful information processing and problem-solving

mechanism to help heal ourselves, our families, our communities, and our planet. A sustainable future depends in part on our ability to imagine it in both personal and global terms, and we are committed to supporting the healing potential of this much underutilized resource — the human imagination.

Nonsteroidal Anti-Inflammatory Drugs

Grace M. Kuo, PharmD

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) are used frequently to treat mild to moderate pain and have been shown to be most effective in treating pain related to muscle ache, headache, dysmenorrhea, toothache, osteoarthritis, and rheumatoid arthritis. Natural products, such as willow bark, that contain salicylates have been used for pain relief for more than 3,500 years (Vane, 2000; Warner & Mitchell, 2002). Many NSAIDs used today (e.g., aspirin, ibuprofen, naproxen) are available as over-the-counter products. An estimated 100 million prescriptions for NSAIDs are written by clinicians in the United States each year, and the use of over-the-counter NSAIDs may be as much as seven times higher (Jouzeau et al., 1997). Currently, more than 30 million Americans use prescription or over-the-counter NSAIDs regularly (Singh, 2000).

MECHANISMS OF ACTION: PAIN RELIEF FROM NSAIDS

The pain associated with inflammation results from the production of prostanoids in the inflamed body tissues that sensitize nerve endings and lead to the sensation of pain (Gordon et al., 2002). Pain reduction is achieved through the inhibition of prostaglandin synthesis, specifically, of cyclooxygenase (COX). COX is the key enzyme for the conversion of arachidonic acid into prostaglandins. Two main isoforms of the COX enzyme have been discovered — COX-1 and COX-2 — which are structurally similar and produce the same prostaglandins. COX-1 is a constitutive isoenzyme that has a protective function and is continuously produced in tissues throughout the body (e.g., gastric mucosa, platelets, kidneys) (Vane & Botting,

1997). COX-2 is predominantly an inducible isoenzyme that is produced by stimuli such as inflammation, although it also has a constitutive property in the brain, kidneys, synovium, and female reproductive tract (Hawkey, 1999). A third isoform, COX-3, is expressed constitutively, particularly in the cerebral cortex and the heart (Bazan & Flower, 2002).

NSAIDs inhibit COX by interfering with the conversion of arachidonic acid into prostaglandins (Vane & Botting, 1997). Traditional NSAIDs are a mixture of COX-1 and COX-2 inhibitors, such as salicylates (e.g., aspirin) and nonsalicylate anti-inflammatory agents (e.g., acetaminophen, etodolac, ibuprofen, naproxen, sulindac). Although salicylates have been used to treat pain for millennia, their mechanism of action was not known until 1971, when Nobel laureate John Vane discovered the mechanism by which aspirin and other traditional NSAIDs exert their therapeutic effects (Vane & Botting, 2003). Aspirin undergoes acetylation, a process that leads to the inhibition of COX, which, in turn, prevents the formation of prostaglandins. Traditional NSAIDs are nonselective in their mechanism of action, have different inhibitory effects on the COX-1 and COX-2 isoenzymes, and cause different complications (e.g., gastrointestinal and renal) (Cryer & Feldman, 1998). For example, etodolac and meloxicam inhibit COX-2 strongly and COX-1 weakly. This difference in inhibition explains why etodolac and meloxicam have fewer gastrointestinal side effects while exerting potent anti-inflammatory effects (Bazan & Flower, 2002).

In the late 1980s, Dan Simmons discovered a second, distinct COX gene from which the newer NSAIDs have been derived (Vane & Botting, 2003). These newer NSAIDs (e.g., celecoxib, rofecoxib, valdecoxib) are primarily COX-2 inhibitors (Dionne, 2003). Although COX-

2 inhibitors (e.g., celecoxib) do not affect platelet aggregation as much as nonselective NSAIDs, they can produce renal complications that are similar to those encountered with traditional NSAIDs. Both celecoxib and rofecoxib were approved by the U.S. Food and Drug Administration (FDA) in 1999; however, rofecoxib was withdrawn from the market by its manufacturer in 2004 because of concerns about an increased incidence in adverse cardiovascular effects. Celecoxib is currently approved by the FDA for the treatment of osteoarthritis, adult rheumatoid arthritis, familial adenomatous colorectal polyps, acute pain, and primary dysmenorrhea. Second-generation COX-2 inhibitors (e.g., valdecoxib, parecoxib, etoricoxib, lumiracoxib) that have different selectivity for COX-1 and COX-2 and different pharmacokinetic properties are currently being developed (Capone et al., 2003; Stichtenoth & Frolich, 2003). Valdecoxib has greater biochemical selectivity for COX-1 *in vitro* than does celecoxib and may be clinically important for improving gastrointestinal safety; valdecoxib was approved by the FDA in 2001 for the treatment of the signs and symptoms of osteoarthritis and adult rheumatoid arthritis and for the treatment of primary dysmenorrhea. In April 2005, the Food and Drug Administration requested sales of valdecoxib be suspended in the United States due to concerns related to cardiovascular risk and rare serious skin reactions. Parecoxib is a prodrug of valdecoxib and is the only injectable COX-2 inhibitor that is available; however, the FDA disapproved its manufacturer's new drug application in 2001 because of concerns related to its adverse effect profile. Etoricoxib has a slightly greater selectivity of COX-2 *in vitro* than does refecoxib and may also clinically improve gastrointestinal safety. As it is the only acidic COX-2 inhibitor, lumiracoxib is the most selective COX-2 inhibitor *in vitro*. The Food and Drug Administration has not yet approved the use of etoricoxib and lumiracoxib.

Acetaminophen is a weak inhibitor of COX-1 and COX-2, lacking strong anti-inflammatory effects. The mechanism of its analgesic effect was a mystery until the recent discovery of the COX-3 enzyme (Simmons et al., 1999). COX-3 is derived from the COX-1 gene with alternative splicing of the COX-1 messenger RNA (Bazan & Flower, 2002). It is suggested that acetaminophen selectively inhibits COX-3 (Chandrasekharan et al., 2002; Swierkosz et al., 2002), thereby exerting its analgesic effect by dulling the pain sensory system. In addition to the COX-3 enzyme, Simmons et al. (1999) identified two partial COX-1 (PCOX-1) proteins derived from the COX-1 gene. Although the PCOX-1 proteins are abundant in the brain, their mechanism of action and functions are not clearly known at this time (Simmons et al., 1999). The discovery of COX-3 and the PCOX-1 proteins is significant because it will contribute to the continual search for potential drugs that can target these isoenzymes.

THERAPEUTIC USES

NSAIDs are commonly used to relieve mild to moderate pain (e.g., myalgia, dysmenorrhea, dental pain, arthritis). Evidence-based therapeutic uses of NSAIDs for commonly encountered pain are summarized below, with the focus on COX-2 inhibitors.

LOW BACK PAIN

The prevalence of low back pain varies from 7.6 to 37% in different U.S. populations (Borenstein, 1997). Back pain is the most common reason for claiming workers' compensation. The prevalence of back pain among industrial workers is 4.6%, projecting to an estimated 101.8 million lost workdays per year (Guo et al., 1999). The rationale for using NSAIDs to treat low back pain is based on their analgesic property, as well as their anti-inflammatory action. In a Cochrane meta-analysis, van Tulder et al. (2000) concluded from the data of 51 clinical trials ($N = 6,057$) that NSAIDs were effective for short-term relief of pain in patients with acute low back pain. The pooled relative risk for global improvement was 1.24 (95% CI 1.10, 1.41). Additional qualitative analysis showed conflicting evidence that NSAIDs were more effective than acetaminophen, and the evidence for various types of NSAIDs being equally effective for acute low back pain was strong (van Tulder et al., 2000).

DYSMENORRHEA

Dysmenorrhea is a common complaint that affects as many as 50% of women; 10% of affected women report being incapacitated for up to 3 days during each menstrual cycle (Dawood, 1999). Women who have dysmenorrhea have higher levels of prostaglandin than women who do not have it (Pickles, 1979). For this reason, NSAIDs are thought to bring pain relief to women with menstrual cramps. In a Cochrane meta-analysis, Marjoribanks, Proctor, & Farquhar (2003) compared the effectiveness and safety of traditional NSAIDs with placebo and paracetamol and of different NSAIDs in relieving pain related to primary dysmenorrhea. The review included 63 randomized controlled trials ($N = 4,066$); 19 of the studies had a parallel design and 44 had a crossover design. Overall, NSAIDs were found to be significantly more effective than placebo (OR 7.91, 95% CI 5.65, 11.09) in relieving menstrual pain, but they were also found to be significantly more likely to be associated with adverse effects—combined gastrointestinal adverse effects (e.g., nausea, vomiting) and neurological adverse effects (e.g., headaches, fatigue). There was little evidence showing any significant difference between traditional NSAIDs and paracetamol or among the various NSAIDs.

Selective COX-2 inhibitors (e.g., celecoxib and valdecoxib) have been shown to be as effective as traditional

NSAIDs (e.g., naproxen) in the management of dysmen-orrhea (Chavez & DeKorte, 2003; Fenton, Keating, & Wagstaff, 2004; Malmstrom et al., 2003; Ruoff & Lema, 2003).

ACUTE PAIN

The analgesic effects and safety profiles of the various NSAIDs used to treat acute pain (e.g., postoperative pain) have been evaluated by Cochrane reviewers. In 72 random-ized single-dose trials that together included 3,253 patients in an aspirin group and 3,297 patients in a placebo group, aspirin was shown to be significantly more beneficial than placebo in its relief of acute pain (Edwards et al., 2000). The numbers needed to treat (NNTs) to achieve at least 50% relief of pain were found to be 4.4 (95% CI 4.0, 4.9) with the 600/650-mg dose, 4.0 (95% CI 3.2, 5.4) with the 1,000-mg dose, and 2.4 (95% CI 1.9, 3.2) with the 1,200-mg dose (Edwards et al., 2000). In addition, the side effects of drowsiness and gastric irritation were also shown to be significantly greater in the aspirin group than in the placebo group (Edwards et al., 2000). In 47 clinical studies that together included 2,561 patients in an acetaminophen group and 1,625 patients in a placebo group, the NNTs for at least 50% relief of pain over 4 to 6 hours were found to be 3.8 (95% CI 2.2, 13.1) with the 325-mg dose, 3.5 (95% CI 2.7, 4.8) with the 500-mg dose, 4.6 (95% CI 3.9, 5.5) with the 600/650-mg dose, 3.8 (95% CI 3.4, 4.4) with the 975/1,000-mg dose, and 3.7 (95% CI 2.3, 9.5) with the 1,500-mg dose (Barden et al., 2004b). Adverse effects were generally mild and transient, and the reported adverse effects between the 975/1,000-mg dose and placebo were not statistically significant (Barden et al., 2004).

In 32 trials comparing ibuprofen and placebo (3,591 total patients), the NNTs for at least 50% relief of acute pain were 3.3 (95% CI 2.8, 4.0) with the 200-mg dose, 2.7 (95% CI 2.5, 3.0) with the 400-mg dose, and 2.4 (95% CI 1.9, 3.3) with the 600-mg dose (Collins et al., 2000). In seven trials that included 581 patients treated with diclofenac and 364 patients treated with placebo, the NNTs for at least 50% relief of acute pain were 2.8 (95% CI 2.1, 4.3) with the 25-mg dose, 2.3 (95% CI 2.0, 2.7) with the 50-mg dose, and 1.9 (95% CI 1.6, 2.2) with the 100-mg dose (Barden et al., 2004a). The side-effect pro-files of the 50-mg diclofenac and placebo groups were not statistically different (Barden et al., 2004).

In two trials that compared 200-mg celecoxib with placebo (418 total subjects), the NNT for at least 50% relief of acute pain was found to be 4.5 (95% CI 3.3, 7.2) with the 200-mg dose (Barden et al., 2003a). Celecoxib has also been shown to display efficacy comparable with naproxen in relieving pain associated with acute shoulder tendonitis/bursitis and acute ankle sprain (Petrella et al., 2004; Petri et al., 2004). Preliminary findings from two trials have demonstrated that 40-mg valdecoxib has a

quicker onset of action and has a longer time-to-rescue than does 50-mg rofecoxib (Christensen & Cawkwell, 2004; Fenton et al., 2004). In a quantitative systematic review conducted by Barden et al. (2003b), the NNTs for at least 50% relief of acute postoperative pain were found to be 1.7 (95% CI 1,4, 2.0) with the 20-mg dose of val-decoxib, 1.6 (95% CI 1.4, 1.8) with the 40-mg dose of valdecoxib, 3.0 (95% CI 2.3, 4.1) with the 20-mg dose of parecoxib, and 2.3 (95% CI 2.0, 2.6) with the 40-mg dose of parecoxib.

OSTEOARTHRITIS

More than 20 million Americans have osteoarthritis (National Institute of Arthritis and Musculoskeletal and Skin Diseases, 2004). NSAIDs do not prevent or slow the progression of the disease; they are used only to help relieve pain associated with osteoarthritis. The efficacy of NSAIDs in the treatment of osteoarthritis has been widely studied. A search for NSAIDs and osteoarthritis using the Cochrane Database (EBM [evidence-based medicine] Reviews) yielded 36 meta-analyses and systematic reviews. In a meta-analysis, Towheed et al. (2003) evalu-ated the effects of NSAIDs on pain reduction, patient global assessments, and improvements in functional sta-tus. The objectives of the review were to assess the efficacy and safety of (1) acetaminophen versus placebo and (2) acetaminophen versus other NSAIDs (including ibupro-fen, arthrotec, celecoxib, naproxen, and rofecoxib) in the treatment of patients with osteoarthritis. Six randomized controlled trials ($N = 1,689$) were included in the review; one trial compared acetaminophen with placebo and five trials compared acetaminophen with other NSAIDs. In the trial comparing acetaminophen with placebo ($n = 25$), acetaminophen was found to be more significant in reduc-ing pain while at rest (RR 8.0, 95% CI 2.08, 30.73) and while in motion (RR 3.75, 95% CI 1.48, 9.52) and in improving patient global assessment (RR 18.0, 95% CI 2.66, 121.64). Differences in the safety profiles of these two groups were not statistically significant. In the trials comparing acetaminophen and various other NSAIDs, the other NSAIDs were found to be more effective than ace-taminophen in reducing pain while at rest (effect sizes were 0.32, 95% CI 0.08, 0.56 and 0.34, 95% CI 0.10, 0.58), but all of them were similar in improving functional status and in the safety profile. Patients taking NSAIDs were more likely to experience a gastrointestinal adverse event (RR 2.24, 95% CI 1.23, 4.08).

A second search of the English-language medical lit-erature in PubMed on NSAIDs using the search terms "osteoarthritis and celecoxib efficacy," "osteoarthritis and rofecoxib efficacy," and "osteoarthritis and valdecoxib efficacy" and limiting the search to reports on human adults (≥19 years) enrolled in clinical trials yielded 12, 17, and 4 journal articles, respectively, for each set of

TABLE 53.1
Selected Clinical Trials Using NSAIDs for Osteoarthritis (OA) Treatment (sorted by recent publication year)

Study	Year	Study Design[a]	N	OA	Treatment	Duration (Months)	Outcome Measures[b]	Results
Gibofsky et al.	2003	R, DB, PC, MC	475	Knee	Celecoxib 200 mg/day; rofecoxib 25 mg/day; placebo	1.5	1. VAS 2. Total domain score on WOMAC	1. Similar efficacy between celecoxib and rofecoxib 2. Celecoxib and rofecoxib were superior to the placebo ($p < 0.02$)
Geba et al.	2002	R, P, DB	382	Knee	Rofecoxib 12.5 or 25 mg/day; celecoxib 200 mg/day; acetaminophen 4,000 mg/day	1.5	1. Pain on VAS by WOMAC 2. Global response to therapy	1. Patients in the acetaminophen group discontinued treatment early due to lack of efficacy (31% vs. 18% to 19% of patients in other treatment groups) 2. Efficacy showed greatest response to rofecoxib 25 mg/day, followed by rofecoxib 12.5 mg/day, celecoxib, and acetaminophen
Kivitz et al.	2002	R, DB, PC, MC	1,016	Knee	Valdecoxib 5, 10, or 20 mg once daily; naproxen 500 mg BID; placebo	3.0	1. PaGAA, PhGAA, VAS, WOMAC 2. Upper GI ulceration from endoscopy	1. Valdecoxib 10 mg and 20 mg once daily (but not 5 mg once daily) were similar to naproxen; all three dosages were superior to placebo for the PaGAA, PhGAA, VAS, and WOMAC osteoarthritis indices ($p < 0.05$) 2. The incidence of ulcers was significantly higher in the naproxen group than in the 5- and 10-mg valdecoxib groups, but not in the 20-mg valdecoxib group; all three valdecoxib doses were comparable with placebo
Makarowski et al.	2002	R, DB, MC	467	Hip	Valdecoxib 5, 10 mg once daily; naproxen 500 mg BID; placebo	3.0	1. PaGAA, PhGAA, WOMAC 2. Incidence of adverse events	1. Valdecoxib was clinically and statistically superior to placebo for PaGAA, PhGAA, WOMAC ($p \leq 0.05$) 2. Valdecoxib 10 mg was similar to naproxen in terms of efficacy and superior to valdecoxib 5 mg 3. Valdecoxib 5 and 10 mg were similar in tolerability when compared with placebo and had a lower incidence of GI-related adverse effects when compared with naproxen
Tindall et al.	2002	OL, MC	2,327	Knee Hip	Celecoxib 200 mg/day to 400 mg/day	12.0	1. Radiographs in subsets of patients	1. Significant hip joint-space narrowing ($p = 0.029$); the observed increase in narrowing was small, was observed prior to celecoxib exposure, and was not dose related
Kivitz et al.	2001	R, PC, MC	1,061	Hip	Celecoxib 100, 200 or 400 mg/day; naproxen 1,000 mg/day; placebo	3.0	1. Standard measures of efficacy	1. Celecoxib (all doses) and naproxen were superior to the placebo 2. Celecoxib 200 mg/day, 400 mg/day, and naproxen were similar in pain relief and improvement in functional capacity
McKenna et al.	2001	DB, PC, MC	600	Knee	Celecoxib 100 mg BID; diclofenac 50 mg TID; placebo	1.5	1. Index joint pain by VAS, WOMAC index 2. Tolerability and safety profile	1. VAS and WOMAC index showed superior efficacy for both celecoxib and diclofenac but not for the placebo 2. No differences in efficacy between celecoxib and diclofenac 3. More diclofenac patients reported GI side effects, elevations in mean hepatic transaminases and serum creatinine, and reductions in hemoglobin concentration

Study	Year	Design	N	Site	Treatment	Duration	Outcomes	Results
Truitt et al.	2001	R, PC	341	OA	Rofecoxib 12.5 or 25 mg/day; nabumetone 1,500 mg/day; placebo	1.5	PaGAA WOMAC IGADS	1. Rofecoxib and nabumetone were superior to the placebo (p < 0.001) 2. Renal safety was similar for rofecoxib and nabumetone; no GI ulcers occurred
Williams et al.	2001	DB, PC, P, MC	718	Knee	Celecoxib 100 mg BID or 200 mg once daily; placebo	1.5	1. PaGAA, PhGAA, VAS 2. Lequesne Osteoarthritis Severity Index	1. Both celecoxib groups were superior to the placebo group in all measures of efficacy (p < 0.05) 2. No significant differences in efficacy or adverse events were shown between the celecoxib groups
Cannon et al.	2000	R, DB, C	784	Knee Hip	Rofecoxib 12.5 or 25 mg once daily; diclofenac 50 mg TID; placebo	12.0	1. VAS, WOMAC 2. PaGAA 3. PhGAA	1. Clinical efficacy of rofecoxib and diclofenac was similar 2. All treatments were well tolerated.
Day et al.	2000	R, DB	809	Knee Hip	Rofecoxib 12.5 or 25 mg once daily; ibuprofen 800 mg TID; placebo	1.5	1. WOMAC 2. PaGAA, IGADS	1. Both rofecoxib and ibuprofen were superior to the placebo (p < 0.001) 2. All treatments were well tolerated
Saag et al.	2000	R, DB, P, PC	736 693	Knee Hip	Rofecoxib 12.5 or 25 mg once daily; ibuprofen 800 mg TID; placebo Rofecoxib 12.5 or 25 mg once daily; diclofenac 50 mg TID; placebo	1.5 12.0	1. VAS, WOMAC 2. PaGAA, IGADS, PhGAA 3. Study joint tenderness	1. Rofecoxib and ibuprofen were similar in clinical efficacy 2. Both rofecoxib and ibuprofen were superior to the placebo at 6 weeks 3. Both rofecoxib and diclofenac showed similar efficacy over 1 year 4. All treatments were well tolerated
Bensen et al.	1999	R. DB, PC, MC	1,003	Knee	Celecoxib 50, 100, or 200 mg BID; naproxen 500 mg BID; placebo	3.0	1. Standard measures of efficacy	1. All celecoxib doses were efficacious when compared with the placebo, although the celecoxib 50 mg BID dose had only minimal efficacy 2. Celecoxib 100 mg and 200 mg BID were similarly efficacious, and the efficacy was comparable with naproxen 500 mg BID 3. All doses of celecoxib and naproxen were well tolerated
Ehrich et al.	1999	DB, P, R, MC	219	Knee	Rofecoxib 25 or 125 mg once daily; placebo	1.5	1. WOMAC	1. Clinical improvement was similar in the rofecoxib 25-mg and 125-mg groups
Zhao et al.	1999	R, DB, P	1,004	Knee	Celecoxib 50, 100, or 200 mg BID; naproxen 500 mg BID; placebo	3.0	1. Functional status by WOMAC index 2. Pain scores	1. Celecoxib and naproxen were superior to the placebo 2. The celecoxib 100 mg BID group had significantly better improvement in pain scores than did the placebo and naproxen groups

[a] C, controlled; DB, double-blind; MC, multicenter; OL, open-label; P, parallel; PC, placebo control; R, randomized.

search terms. The clinical efficacy of COX-2 inhibitors is superior to the placebo and is similar to traditional NSAIDs in the treatment of osteoarthritis. Table 53.1 summarizes information from selected articles pertaining to the efficacy of COX-2 inhibitors in the management of osteoarthritic pain (Bensen et al., 1999; Cannon et al., 2000; Day et al., 2000; Ehrich et al., 1999; Geba et al., 2002; Gibofsky et al., 2003; Kivitz et al., 2001, 2002; Makarowski et al., 2002; McKenna et al., 2001; Saag et al., 2000; Tindall et al., 2002; Truitt et al., 2001; Williams et al., 2001; Zhao et al., 1999).

RHEUMATOID ARTHRITIS

Rheumatoid arthritis affects 2.1 million Americans and costs the U.S. economy nearly $125 billion per year in medical care and indirect costs. It is a disease that causes inflammation of the membranous lining of the joints, producing symptoms of pain, stiffness, and swelling (Arthritis Foundation, 2004). NSAIDs are frequently used to decrease inflammation, as well as to control associated symptoms.

In a systematic review, Wienecke and Gltzsche (2004) found that the comparison between NSAIDs and acetaminophen in the treatment of rheumatoid arthritis was inconclusive because of insufficient information with regard to study methods, blinding methods, and collection of data on adverse effects. Nevertheless, NSAIDs were preferred as the treatment of choice by patients and study investigators.

In a systematic review that included five randomized controlled trials ($N = 4,465$), Garner et al. (2002a) found that celecoxib was as efficacious as other NSAIDs, such as naproxen, diclofenac, and ibuprofen, in treating pain related to rheumatoid arthritis. In the same review, celecoxib was also found to be superior to the placebo (51% celecoxib 200 mg twice daily and 52% celecoxib 400 mg twice daily vs. 29% placebo) in achieving the 20 improvement criteria of the American College of Rheumatology (ACR).

In a second systematic review that included two clinical trials, Garner et al. (2002b). found the efficacy of 25-mg and 50-mg rofecoxib to be similar and both forms of rofecoxib to be more efficacious than placebo in reducing pain associated with rheumatoid arthritis, as measured by the number of ACR improvement criteria achieved. Although the safety profiles of rofecoxib and placebo were similar, the difference in the efficaciousness of rofecoxib and placebo was statistically significant (RR 1.39, 95% CI 1.07, 1.80 with rofecoxib 25 mg and RR 1.55 CI: 1.20, 1.99 with rofecoxib 50 mg). In the same review, Garner et al. (2002b) also found that the efficacy of rofecoxib at a dose of 50 mg/day was similar to that of naproxen at a dose of 500 mg twice daily. Rofecoxib produced fewer gastrointestinal adverse events than naproxen did (RR 0.46, 95% CI 0.34, 0.63) but was associated with a higher rate of cardiovascular adverse events (RR 2.36, 95% CI

1.38, 4.02 with any cardiovascular event and RR 4.48, 95% CI 1.52, 13.23 with nonfatal myocardial infarction).

UNLABELED USES

NSAIDs have several unlabeled uses, including the treatment of Alzheimer's disease and various types of cancer. Epidemiological studies found that patients taking NSAIDs had a 50% lower risk of developing Alzheimer's disease than those who were not (Turini & DuBois, 2002). NSAIDs may delay the onset and slow the progression of Alzeimer's disease by suppressing the inflammatory processes in the brain and by decreasing the production of beta-amyloid peptides (Blasko & Grubeck-Loebenstein, 2003; Giovannini et al., 2003; McGeer & McGeer, 2002; Michaelis, 2003; Pasinetti, 2002; Turini & DuBois, 2002; Zandi, Breitner, & Anthony, 2002). Several epidemiological studies found that NSAID users had a 40 to 50% decrease in the relative risk of having colon cancer (Turini & DuBois, 2002), possibly due to the role of NSAIDs in regulating COX-2 expression in tumorigenesis (Chan, 2003; Ferrandez, Prescott, & Burt, 2003; Kawai, Tsujii, & Tsuji, 2002; Ricchi et al., 2003; Yamamoto & Viale, 2003). Overexpression of COX has also been found in other epithelial tumors, such as those of the breast (Howe & Dannenberg, 2003; Singh-Ranger & Mokbel, 2002) lung (Natale, 2003; Saha, Pyo, & Choy, 2003), and cervix (Dannenberg & Howe, 2003).

USUAL DOSES

Table 53.2 lists the therapeutic uses of common NSAIDs, including acetylsalicylic acid, acetaminophen, celecoxib, diclofenac, etodolac, ibuprofen, indomethacin, ketoprofen, ketorolac, nabumetone, naproxen, sulindac, and valdecoxib, for pain management. Specifically, the indications approved by the FDA are listed with the corresponding doses. The cytochrome P450 enzymes are listed as a reference source for assessing potential interactions with drugs that are substrates, inhibitors, or inducers of these enzymes. Therapeutic monitoring related to hepatic and renal dosage adjustment recommendations are included, as well as the pregnancy categories recommended by the FDA.

CONTRAINDICATIONS

NSAIDs are generally contraindicated in persons who have hypersensitivities to NSAIDs and to salicylates. Celecoxib and valdecoxib have sulfonamide groups that confer selectivity and, consequently, are contraindicated in persons who are allergic to sulfonamide-related compounds.

PHARMACOKINETICS

In general, COX-1 inhibitors bind with isoenzymes competitively and reversibly, whereas COX-2 inhibitors bind

TABLE 53.2
Therapeutic Uses of Selective NSAIDs for Pain Management

Generic Name	Brand Name	FDA-Approved Indications	Common Doses[a]	Mechanism of Action	Drug Interaction	Therapeutic Monitoring
Acetaminophen	Tylenol	Mild pain, dysmenorrhea, OA	*Adults and children ≥ 12 years:* 325–650 mg PO/PR q 4–6 h, PRN; do not exceed 1 g/dose or 4 g/day *Children < 12 years and infants:* 10–15 mg/kg PO/PR q 4–6 h; do not exceed 5 doses in 24 hours *Neonates:* 10–15 mg/kg PO/PR q 6–8 h PRN; do not exceed 75 mg/kg/day	COX-3	Substrate (minor) of CYP1A2, 2A6, 2C8/9, 2D6, 2E1, 3A4 Inhibits CYP3A4 (weak) Interactions: ↑ hepatotoxicity with CYP2E1 and CYP1A2 inducers (e.g., carbamazepine, rifampin, barbiturate, isoniazid)	*Hepatic:* use with extreme caution *Renal:* analgesic of choice for episodic pain in patients with underlying renal disease, but chronic use should be discouraged. Cl$_{cr}$ 10–50 ml/min: administer q 6 h; Cl$_{cr}$ <10 ml/min: administer q 8 h; moderately dialyzable (20% to 50%) Pregnancy category C[b]
Acetylsalicylic acid	Bayer aspirin; Ecotrin	Mild to moderate pain, dysmenorrhea, OA, RA	*Adults and Adolescents:* 325–650 mg PO/PR q 4 h, PRN; do not exceed 4 g/day *Pediatrics:* 10–15 mg/kg PO/PR q 4–6 h, PRN; do not exceed 4 g/day	COX-1 and COX-2	Substrate of CYP2C8/9 (minor) Interactions: ↑ bleeding ↑ nephrotoxicity	Salicylate toxicity when the total salicylate level is usually >300–350 μg/ml *Hepatic:* at increased risk of salicylate-related adverse reaction *Renal:* avoid in patients with severe renal dysfunction, CrCl < 10 ml/min; dialyzable (50 to 100%) Pregnancy category C[b]
Celecoxib	Celebrex	Moderate to severe acute pain, dysmenorrhea, OA, RA	*Pain and dysmenorrhea:* 200 mg PO BID PRN *OA:* 100 mg PO BID or 200 mg PO QD *RA:* 100–200 mg PO BID; do not exceed 800 mg/day (adults) or 400 mg/day (elderly adults); lower doses for patients weighing < 50 kg	COX-2	Substrate of CYP P450 2C9 Inhibits CYP P450 2D6 (weak) Interactions: ↑ bleeding in the elderly	*Hepatic:* reduce dose by 50% and not recommended in patients with severe hepatic impairment *Renal:* no adjustment recommendation *Contraindications:* sensitivities to sulfonamide Pregnancy category C[b]
Diclofenac	Voltaren	Mild to moderate pain, dysmenorrhea, OA, RA	50 mg PO TID; do not exceed 150 mg/day	COX-1 and COX-2	Substrate (minor) of CYP1A2, 2B6, 2C8/9, 2C19, 2D6, 3A4 Inhibits CYP1A2 (moderate), 2C8/9 (weak), 2E1 (weak), 3A4 (strong) Interactions: ↑ bleeding	*Hepatic:* no adjustment recommendation *Renal:* close monitoring *Contraindications:* hematological disease or bone marrow suppression Pregnancy category B[b]
Etodolac	Lodine	Mild to moderate pain, OA, RA	*Pain:* 200–400 mg PO q 6–8 h, up to 1,000 mg/day as needed; do not exceed 1,200 mg/day *OA and RA:* 300 mg PO BID–TID, or 400–500 mg PO BID	COX-1 and COX-2	Interactions: ↑ bleeding	*Hepatic:* dosage adjustment in cases of severe liver disease or failure *Renal:* no adjustment needed Pregnancy category C[b]

TABLE 53.2 (Continued)
Therapeutic Uses of Selective NSAIDs for Pain Management

Generic Name	Brand Name	FDA-Approved Indications	Common Doses[a]	Mechanism of Action	Drug Interaction	Therapeutic Monitoring
Ibuprofen	Advil, Motrin	Mild to moderate pain, dysmenorrhea, OA, RA	Pain and dysmenorrheal: Adults and adolescents: 400 mg PO q 4–6h PRN; self-treatment: 200 mg q 4–6 h PRN; do not exceed 1,200 mg/day and/or 10 days OA and RA: 400–800 mg PO TID–QID; do not exceed 3,200 mg/day	COX-1 and COX-2	Substrate of CYP P450 CYP2C8/9, 2C19 Inhibits CYP2C8/9 (strong) Interactions: ↑ bleeding	Hepatic: avoid use in severe liver disease or failure Renal: no adjustment recommendation Pregnancy category B[b]
Indomethacin	Indocin	Moderate to severe pain, OA, RA	Pain: 75 mg (sustained-release)/day PO QD–BID; usually 7 to 14 days OA and RA: 25 mg PO BID–TID; may increase dose by 25 mg/day PO every 7 days up to 150–200 mg/day; reduce dosage by 25% in the elderly	COX-1 and COX-2	Substrate of CYP2C8/9, 2C19 Inhibits CYP P450 2C8/9 (strong), 2C19 (weak) Interactions: ↑ bleeding	Hepatic: dosage adjustment in hepatic dysfunction Renal: no adjustment recommendation Pregnancy category B[b]
Ketoprofen	Orudis	Mild to moderate pain, dysmenorrhea, OA, RA	Pain: 25–50 mg PO q 6–8 h PRN; self-treatment: 12.5 mg PO q4–6h PRN, do not exceed 75 mg/day OA and RA: 50 mg PO TID to 75 mg PO QID	COX-1 and COX-2	Inhibits CYP2C8/9 (weak) Interactions: ↑ bleeding ↑ nephrotoxicity	Hepatic: dosage adjustment in liver dysfunction or when albumin < 3.5 g/dl; daily dose not to exceed 100 mg Renal: dosage adjustments according to renal function CrCl<25 ml/min: 25–50 mg PO BID CrCl ≥ 25 and < 90 ml/min: 25–50 mg PO TID Pregnancy category B[b]
Ketorolac	Toradol	Moderate pain	60 mg IM or 30 mg IV × 1; then 30 mg IM/IV q 6 h.; do not exceed 5 consecutive days Oral dose: 20 mg PO × 1 after IV/IM dose, then 10 mg PO q 4–6 h; do not exceed 5 consecutive days	COX-1 and COX-2	Interactions: ↑ bleeding ↑ nephrotoxicity	Hepatic: use with caution Renal: reduce dose by 50% if CrCl < 30 ml/min; avoid use in patients with severe renal impairment Contraindications: breast-feeding, bleeding disorders, dehydration, renal failure, epidural or intrathecal administration, prophylactic use before or during surgery, labor Pregnancy category C[b]
Nabumetone	Relafen	OA, RA	Initially, 1,000 mg PO once daily or 500 mg PO BID; adjust dose according to patient response; do not exceed 2,000 mg/day	COX-1 and COX-2	Interactions: ↑ bleeding ↑ nephrotoxicity	Hepatic: dosage reduction may be needed Renal: discontinue if renal function worsens (CrCl < 30 ml/min) Pregnancy category C[b]

				COX selectivity	Interactions	Hepatic/Renal/Pregnancy
Naproxen	Aleve, Naprosyn	Mild to moderate pain, OA, RA	*Pain:* 250 mg PO q 6–8 h PRN (do not exceed 1,000 mg/day); self-treatment: 220 mg PO q 8–12 h (do not exceed 660 mg/day PO or 440 mg in any 8–12 hour period) *OA and RA:* 250–500 mg PO twice daily	COX-1 and COX-2	Substrate (minor) of CYP1A2, 2C8/9 Interactions: ↑ bleeding ↑ nephrotoxicity	*Hepatic:* 50% dosage reduction in hepatic impairment *Renal:* dosage reduction may be needed if CrCl < 20 ml/min Pregnancy category B[b]
Rofecoxib	Vioxx	Voluntarily withdrawn by Merck & Co. on September 30, 2004	N/A	COX-2	Substrate of CYP2C8/9 (minor) Inhibits CYP1A2 (strong) Induces CYP3A4 (weak) Interactions: ↑ bleeding	*Hepatic:* not recommended in hepatic insufficiency *Renal:* avoid use in severe renal impairment Pregnancy category C[b]
Sulindac	Clinoril	OA, RA	150 mg PO twice daily; do not exceed 400 mg/day	COX-1 and COX-2	Interactions: ↑ bleeding ↑ nephrotoxicity	*Hepatic:* dosage reduction needed in hepatic impairment *Renal:* dosage reduction may be needed Pregnancy category B[b]
Valdecoxib	Bextra	Dysmenorrhea, OA, RA	*Dysmenorrhea:* 20 mg PO BID PRN *OA, RA:* 10 mg PO once daily	COX-2	Substrate (minor) of CYP2C8/9, 3A4 Inhibits CYP2C8/9, 2C19 (weak) Interactions: ↑ nephrotoxicity	*Hepatic:* avoid in severe hepatic impairment *Renal:* avoid in severe renal impairment Pregnancy category C[b]

Note: CYP = cytochrome isoenzymes; OA = osteoarthritis; RA = rheumatoid arthritis. Based on Harrison's online database. [a] Common doses are dosages based on the adult population (< 65 years old and ≥ 50 kg) unless otherwise indicated.

[b] FDA Pregnancy Categories (regardless of the designated pregnancy category or presumed safety, no drug should be administered during pregnancy unless it is clearly needed and potential benefits outweigh potential hazards to the fetus). A = Adequate studies in pregnant women have not demonstrated a risk to the fetus in the first trimester of pregnancy and there is no evidence of risk in later trimesters. B = Animal studies have not demonstrated a risk to the fetus but there are no adequate studies in pregnant women, or animal studies have shown an adverse effect, but adequate studies in pregnant women have not demonstrated a risk to the fetus during the first trimester of pregnancy and there is no evidence of risk in later trimesters. C = Animal studies have shown an adverse effect on the fetus but there are no adequate studies in humans; the benefits from the use of the drug in pregnant women may be acceptable despite its potential risks, or there are no animal reproduction studies and no adequate studies in humans. D = There is evidence of human fetal risk, but the potential benefits from the use of the drug in pregnant women may be acceptable despite its potential risks. X = Studies in animals or humans demonstrate fetal abnormalities or adverse reaction reports indicate evidence of fetal risk. The risk of use in a pregnant woman clearly outweighs any possible benefit.

with isoenzymes tightly, dissociate slowly, and form irreversible binding that is time dependent (Hawkey, 1999). Traditional NSAIDs, such as salicylates, are acidic; newer COX-2 agents, such as celecoxib and rofecoxib, are non-acidic (Brune & Neubert, 2001). Celecoxib binds tightly to plasma proteins and has an elimination half-life of 11 hours; changes in the pharmacokinetics of celecoxib have been reported in elderly individuals and differences in the disposition of the drug have been found among various racial groups (Davies et al., 2000). The pharmacokinetic profile of rofecoxib is complex and nonlinear, with an elimination half-life that ranges from 9 to 17.5 hours after multiple dosing (Depre et al., 2000). Rofecoxib binds tightly to plasma protein and is eliminated predominantly by the liver; its termination half-life is about 17 hours at a steady state (Ahuja, Singh, & Singh, 2003). Valdecoxib also binds tightly (98%) to plasma protein; its steady-state plasma concentrations can be achieved on the fourth day, and its oral bioavailability is 83% with rapid absorption and maximal plasma concentrations in 3 hours (Alsalameh et al., 2003). Valdecoxib is metabolized extensively in the liver and has an elimination half-life of approximately 8 to 11 hours (Alsalameh et al., 2003).

The COX-2 inhibitors differ from each other in biochemical selectivity. *In vitro,* valdecoxib (COX-1/COX-2 ratio: 60) has greater biochemical selectivity than does celecoxib (COX-1/COX-2 ratio: 30) and may lead to improved gastrointestinal safety. Etoricoxib (COX-1/COX-2 ratio: 344) exhibits slightly greater biochemical selectivity than does rofecoxib (COX-1/COX-2 ratio: 272) and may have a gastrointestinal safety profile similar to that of valdecoxib. Lumiracoxib is the most biochemically selective COX-2 inhibitor *in vitro* (COX-1/COX-2 ratio: 400); as it is the only acidic COX-2 inhibitor, a high concentration of the drug may be found in inflamed body tissues (Capone et al., 2003).

ADVERSE EFFECTS

More than 100,000 hospitalizations, at an estimated cost of $20,000 per event, are associated with NSAID use each year. Some 16,000 deaths are attributed to NSAID use yearly among NSAID users who have osteoarthritis or rheumatoid arthritis (Singh, 2000; Wolfe, Lichtenstein, & Singh, 1999). Some common adverse effects are listed below.

GASTROINTESTINAL EFFECTS

NSAIDs that inhibit both COX-1 and thromboxane synthetase increase the risk of bleeding. Aspirin, in particular, acetylates platelets irreversibly and interferes with coagulation. NSAID-induced gastritis is common, with an estimated 30 to 40% of NSAID users having gastrointestinal side effects (Garcia Rodriguez, 1997). In one study, the relative risk of gastrointestinal complications in 4,164 patients seen at eight Arthritis, Rheumatism, and Aging Medical Information System centers was three to four times greater with NSAID use (Singh, 2000). Aspirin can cause severe gastric irritation and erosion of the gastric mucosa. Unlike nonselective NSAIDs, COX-2 inhibitors do not inhibit COX-1-dependent platelet aggregation and, therefore, are associated with a lower risk of bleeding.

In the Celecoxib Long-term Arthritis Safety Study (CLASS), Silverstein at al. (2000) found that fewer patients treated with celecoxib than patients treated with NSAIDs experienced chronic gastrointestinal blood loss and gastrointestinal intolerance. The Vioxx® GI Outcomes Research (VIGOR) Trial also found a gastrointestinal protective effect from rofecoxib compared with traditional NSAIDs (Bombardier et al., 2000). In general, COX-2 inhibitors are associated with a significant reduction in gastric irritation; they have been shown to be more cost-effective than NSAIDs in reducing gastrointestinal side effects while continuing to be efficacious in relieving pain (Lee et al., 2003).

CARDIOVASCULAR EFFECTS

Through inhibition of prostaglandin synthesis, NSAIDs may have a deleterious cardiovascular effect (FitzGerald, 2002). Heerdink et al. (1998) followed a cohort of 10,519 patients older than 55 years and found an overall increased risk of hospitalization for congestive heart failure in those taking diuretics and NSAIDs in combination than in those taking diuretics only (crude relative risk 2.2, 95% CI 1.7, 2.9). In patients with established cardiovascular disease, NSAIDs may interfere with the cardioprotective effects of aspirin (MacDonald & Wei, 2003). In the 6-month CLASS trial, the incidence of cardiovascular events associated with celecoxib and NSAIDs, irrespective of aspirin use, was similar (Silverstein et al., 2000). In the SUCCESS VI Study, Whelton et al. (2001) found that celecoxib was associated with less edema and fewer changes in blood pressure than was rofecoxib. In the VIGOR study, the incidence of myocardial infarction (MI) was lower in the naproxen group (0.1% in the naproxen group vs. 0.4% in the rofecoxib group; relative risk 0.2, 95% CI 0.1, 0.7) (Bombardier et al., 2000). Even though the overall mortality rate in both groups was similar, the incidence of MI in the rofecoxib group increased by a factor of five when compared with the naproxen group (Fitzgerald, 2004). Likewise, the Adenomatous Polyp Prevention on Vioxx (APPROVe) trial that enrolled 2600 patients also showed a significant increase by a factor of 3.9 (45 of the 3,041 patients in the rofecoxib group vs. 25 of the 3,315 patients in the placebo group; relative risk 2.0, 95% CI 1.2, 3.2) in the incidence of thromboembolic adverse events (MI and stroke) associated with long-term (>18 months) use of rofecoxib. Based on the finding of an excess risk of MI

and strokes in the APPROVe trial, Merck & Co., Inc., announced voluntary worldwide withdrawal of rofecoxib (Vioxx) on September 30, 2004 (Topol, 2004).

It is possible that the entire class of COX-2 inhibitors has the potential to produce adverse cardiovascular effects (Fitzgerald, 2004). For example, in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET), more cardiovascular events (nonfatal and silent MI, stroke, or cardiovascular death) were found to have occurred in the lumiracoxib group than in the naproxen/ibuprofen group (0.65% vs. 0.55%; hazard ratio 1.14, 95% CI 0.78, 1.66) after 1 year; however, the difference was not statistically significant (Farkouh et al., 2004). COX-2 is believed to affect the cardiovascular system by (1) selectively inhibiting prostaglandin I_2 over thromboxane A_2 in the eisocanoid pathway, which disrupts the normal homeostatic balance and promotes thrombosis, and (2) by inhibiting prostaglandins E_2 and I_2 in the kidney, thus causing blood pressure elevation and sodium and water retention (Krum et al., 2004; Mukherjee & Topol, 2003). Both the European Medicines Agency and the U.S. FDA are conducting safety reviews of COX-2 inhibitors to assess whether all drugs in this class adversely effect the cardiovascular system. Meanwhile, it is suggested that patients who have cardiovascular disease or who are at risk for it should avoid taking COX-2 inhibitors (Fitzgerald, 2004).

HEPATIC EFFECTS

Traditional NSAIDs are metabolized predominantly in the liver. In a review of 14 controlled clinical trials, Maddrey and colleagues (2000) found that the overall incidence of hepatic adverse events related to celecoxib use was similar to that related to placebo use and was significantly lower than that related to the use of a combination of celecoxib and other NSAIDs. Nevertheless, the steady-state area under the plasma-concentration time curve (AUC) of celecoxib is increased in patients with mild to moderate hepatic impairment (Davies et al., 2000); for this reason, a dosage reduction of 50% is recommended for patients who have hepatic dysfunction. Furthermore, celecoxib and valdecoxib are not recommended for patients who have severe hepatic impairment.

RENAL EFFECTS

NSAIDs reduce renal function and increase both sodium and water retention because they block the production of renal prostaglandins by regulating renal blood flow, glomerular filtration, and the release of rennin (Palacioz, 2001). A post hoc analysis of the safety of celecoxib with data from more than 50 clinical trials ($N > 13,000$) showed that the overall incidence of renal adverse events related to celecoxib use was similar to that related to the use of other NSAIDs but was higher than that related to placebo use

(Whelton, 2000). The adverse drug reactions report issued by the World Health Organization/Uppsala Monitoring Center showed that rofecoxib use resulted in more renal complications than occurred with the use of celecoxib or nonselective NSAIDs (Zhao et al., 2001). Pooled safety data from the etoricoxib clinical development program showed that the renal effects of etoricoxib were similar to those of naproxen and ibuprofen (Curtis et al., 2004).

EFFECTS ON PREGNANCY

Because NSAIDs inhibit prostaglandin synthesis, NSAID use during pregnancy may prolong gestation and labor and increase anemia and peripartum blood loss (Shaver, 2001). Use of NSAIDs during pregnancy may be associated with an increased risk of miscarriage. In a population-based cohort study of 1,055 pregnant women, Li, Liu, & Odouli (2003) found that NSAID users had an 80% greater risk of miscarriage (adjusted hazard ratio 1.8, 95% CI 1.0, 3.2); the association was stronger if they used NSAIDs around conception (35%) and if they used NSAIDs for longer than a week (52%). This trend was similar for aspirin users but not for acetaminophen users. Women attempting to become pregnant should be advised not to use NSAIDs because animal studies have shown that these drugs could block embryo implantation (Shaver, 2001).

NSAID use by pregnant women poses potential adverse effects on the fetus, including premature closure of the ductus arteriosus, kidney dysfunction, pulmonary hypertension, and increased risk of intracranial hemorrhage. The adverse effects are thought to be less common if NSAID use is discontinued at least 6 to 9 weeks before delivery (Shaver, 2001). NSAIDs usually meet the criteria in the FDA Pregnancy Category C, but most NSAIDs meet the criteria in Pregnancy Category D during the third trimester.

DRUG INTERACTIONS

The adverse effects most commonly associated with the use of NSAIDs include an increased risk for bleeding with concomitant use of anticoagulants, corticosteroids, or ginkgo biloba and an increased risk of nephrotoxicity with concomitant use of aminoglycosides or cyclosporin. NSAIDs impair the metabolic effects of anti-hypertensive medications. Celecoxib does not appear to interact with angiotensin-converting enzyme inhibitors, beta-blockers, calcium channel blockers, diuretics, ketoconazole, methotrexate, or warfarin (Davies et al., 2000; Karim et al., 1999, 2000; Whelton et al., 2000); however, clinically significant interactions of celecoxib with fluconazole and lithium have been reported (Davies et al., 2000). Because celecoxib is a substrate of CYP2C9, it may potentially interact with either CYP2C9 inhibitors (e.g., fluvastatin,

fluconozole) or inducers (e.g., rifampin). Valdecoxib is predominantly metabolized by the hepatic cytochrome P450 isoenzymes 3A4 and 2C9; the plasma concentration of valdecoxib has been shown to increase by 38% when coadministered with the CYP3A4 inhibitor ketoconazole and by 62% when coadministered with the CYP2C9/3A4 inhibitor fluconazole (Alsalameh et al., 2003). Coadministration of valdecoxib with warfarin was found to produce a small but statistically significant increase in the International Normalized Ratio (Alsalameh et al., 2003).

CLINICAL GUIDELINES AND EDUCATIONAL CAMPAIGN

Clinical guidelines for pain management have been endorsed by several medical organizations. Guidelines for the management of osteoarthritis and rheumatoid arthritis from the American College of Rheumatology (ACR) are available via http://www.rheumatology.org. For the management of osteoarthritis, the ACR recommends that NSAID users exploit nonpharmacologic adjunctive treatments (e.g., patient education, physical therapy, muscle-strengthening exercise) for more effective pain relief. For mild to moderate joint pain, the ACR states that acetaminophen and COX-2 inhibitors are as efficacious as traditional NSAIDs. The ACR also recommends that NSAIDs be used with caution in patients with risk factors for upper gastrointestinal adverse events — patients who are older than 65 years, with comorbid medical conditions or with smoking and alcohol consumption, who are taking oral glucocorticoids or anticoagulants, or who have a history of peptic ulcer disease or upper gastrointestinal bleeding. For the management of rheumatoid arthritis, the ACR recommends that salicylates, nonsalicylate NSAIDs, or COX-2 inhibitors be used in combination with disease-modifying antirheumatic drugs. NSAIDs are used to reduce joint pain and swelling but do not alter the progression of rheumatoid arthritis or prevent joint destruction. In terms of clinical efficacy, the ACR states that COX-2 inhibitors are no more effective than traditional NSAIDs, although COX-2 inhibitors have a significantly lower risk of serious gastrointestinal side-effects. The ACR does not recommend the routine use of H_2 blockers to prevent NSAID-induced gastropathy. However, the ACR does recommend concomitant use of low-dose aspirin with highly selective COX-2 inhibitors because there is evidence that COX-2 inhibitors are associated with a higher rate of thrombotic events and myocardial infarctions than are traditional NSAIDs.

To prevent NSAID-induced ulcers, the American College of Gastroenterology (ACG) recommends that patients at high risk for bleeding be considered for prophylaxis with misoprostol (e.g., 100 to 200 µg by mouth four times a day with meals) or proton pump inhibitors; to treat patients with NSAID-induced ulcers, the ACG recommends discontinuation of NSAIDs and treatment with any approved therapy for ulcer disease (Lanza, 1998).

In their guidelines for the management of persistent pain in older persons, the American Geriatrics Society (http://www.americangeriatrics.org) recommends that COX-2 inhibitors or nonacetylated salicylates be used to treat patients who require long-term daily analgesia. Both the American Chronic Pain Association (http://www. theacpa.org) and the American Pain Foundation (http:// www.painfoundation.org/) provide good educational resources for health care professionals and consumers. In addition, the Department of Defense Veterans Health Administration has useful clinical practice guidelines for the management of low back pain or sciatica in the primary care setting (http://www.oqp.med.va.gov/ cpg/LBP/ LBP_Base.htm). The Agency for Healthcare Research and Quality has compiled clinical guidelines on acute low back problems in adults and has indicated that acetaminophen is the safest effective therapy and that muscle relaxants are no more effective than NSAIDs (Agency of Healthcare Research and Quality, 2004).

Two educational campaigns have been launched recently to educate health care professionals and consumers about the adverse effects of NSAIDs (e.g., gastrointestinal bleeding). The first is the Risk Education to Decrease Ulcer Complications and Their Effects from NSAIDs (REDUCE) Campaign developed collaboratively by the American Gastroenterological Association and the American Pharmacists Association to educate physicians, pharmacists, and consumers about the risks caused by prescription and over-the-counter NSAIDs. The Roper Starch Worldwide Survey revealed that nearly 75% of the estimated 30 million Americans who regularly use NSAIDs were unaware or unconcerned about serious adverse effects (e.g., gastrointestinal bleeding) that may be associated with the use of these medications. The educational programs of the REDUCE Campaign include public service announcements and other educational materials. Additional information can be found at www. 2REDUCE.org.

On January 22, 2004, the FDA launched a national education campaign to provide advice on the safe use of over-the-counter pain relief products. Concerns the FDA raised about the prolonged used of over-the-counter pain relief products include the potential hepatoxicity associated with acetaminophen and the gastrointestinal bleeding and renal toxicity associated with other NSAIDs. Through this campaign, the FDA aims to increase the public's awareness and to minimize potential risks associated with NSAIDs. Additional information can be found via the MedWatch Web-link http://www.fda.gov/medwatch/ SAFETY/2004/safety04.htm#otc or http://www.fda.gov/ cder/drug/analgesics/default.htm.

THERAPEUTIC MONITORING

Monitoring of NSAID-related toxicities includes assessments at baseline and during therapy and continual follow-up. Before NSAID therapy is initiated, patients should have a complete blood cell count and kidney and liver function tests. During therapy, the following signs and symptoms of NSAID-related complications should be monitored: dark stool, dyspepsia, nausea and vomiting, abdominal pain, edema, and shortness of breath. Continual follow-up should include an annual complete blood cell count and kidney and liver functions tests (American College of Rheumatology, 2002).

Opioids Used in Primary Care for the Management of Pain: A Pharmacologic, Pharmacotherapeutic, and Pharmacodynamic Overview

Robert L. Barkin, MBA, PharmD, FCP, DAAPM, Arcangelo M. Iusco, MD, and Stacie J. Barkin, MEd, MA, PsyD

INTRODUCTION

Opioid analgesics are drugs that bind to opioid receptors and share properties of the naturally occurring endogenous opioids. The term *narcotic* is derived from the Greek word narkotikos, meaning to numb or deaden (narcotic can refer to non-opioids as well as opioids and is not a pharmacologic term, but does appear in legislative, judicial, and government documents). This chapter provides an overview of the pharmacology, pharmacokinetics, and pharmacodynamics of this diverse group of analgesics (American Academy of Pain Medicine and American Pain Society, 1997; Ashburn & Ready, 2001; Ashburn & Staats, 1999; Ballantyne et al., 1993; Barkin & Barkin, 2001; Barkin, Barkin, & Barkin, 2005; Barkin, Fawcett, & Barkin, 2002; Bartleson, 2002; Carr & Goudas, 1999; Carr et al., 2002; de Leo-Casasola & Lema, 1996; DeRuiter, 2000; Edwards & Breed, 1990; Foley, 2003; Resnik et al., 2001; Zenz, Strumpf, & Tryba, 1992).

MECHANISMS OF ACTION

Opioids are primarily employed for their ability to reduce the perception of pain. Their analgesic activity is mediated by opioid receptors in the central nervous system (CNS).

Opioids act as agonists at stereospecific endogenous opioid receptors, which are found at both presynaptic and postsynaptic central and peripheral nervous system sites. Four major categories of opioid receptors are known; three provide analgesia mu (μ), kappa (κ), delta (δ). The sigma (σ) receptor has biologic effects, but is no longer considered to be an opioid receptor. Opioid drugs bind to the same receptors as endogenous opioid peptides (enkephalins, endorphins, and dynorphins). These three families of opioid peptides differ in their protein precursors, anatomic distributions, and receptor affinities. Both the endogenous agonists and opioid analgesics alter the central release of neurotransmitters. The actions of the opioid analgesics now available can be defined by their activity at three specific opiate receptor types: mu, kappa, and delta. Some opioids also have mechanism as partial agonists and mixed agonist antagonist (Barkin et al., 2005) (Table 54.1 and Table 54.2).

OPIOID RECEPTORS

Opioids are classified as agonists, partial agonists, mixed agonist–antagonists, and antagonists (naloxone) (Table 54.1). Only drugs with agonist effects provide analgesia.

Mu receptors (Barkin et al., 2002; Zenz et al., 1992) mediate analgesia, euphoria, respiratory and physical

TABLE 54.1
Overview of Opioid Receptors

Receptor	Proposed Location	Proposed Events
Mu$_1$ (μ_1)	Supraspinal, peripheral analgesia, spinal cord, nucleus raphe magnus, locus ceruleus, cerebral cortex (lamina IV), thalamus, periaqueductal gray, periventricular gray, substantial gelatinosa	Analgesia
Mu$_2$ (μ_2)	Spinal analgesia, spinal trigeminal nucleus, gastrointestinal tract, Limbic area, reticular activating system (RAS), striatum medulla, medullar raphe nuclei	Sedation, vomiting, urinary retention, respiratory depression, euphoria, miosis, physical dependence, delayed gastrointestinal motility
Kappa (κ)	K$_1$ spinal cord K$_3$ supraspinal	Spinal analgesia, dyspnea, psychomimetic effects, respiratory depression, miosis, diuresis, sedation, physical dependence, euphoria, dysphoria

Delta (δ)	δ_1 spinal
	  supraspinal
	δ_2 frontal cortex
	  limbic area
	  olfactory tubercle
	  spinal
		Analgesia, spinal analgesia

TABLE 54.2
Chemical Classification of Opioid Medications

Chemical Class for Opioid Agonists	Opioid Agonist	Opioid Agonist–Antagonist and Partial Agonist
Phenanthrenes	Codeine	Buprenorphine (partial agonist)
	Hydrocodone	Butorphanol (agonist/antagonist/mixed)
	Hydromorphone	Nalbuphine (mixed agonist/antagonist)
	Levorphanol	Pentazocine (mixed agonist/antagonist)
	Morphine	
	Oxycodone	
	Oxymorphone	
Phenylpiperidines	Alfentanil	
	Fentanyl	
	Meperidine	
	Sufentanil	
Diphenylheptanes	Levomethadyl	
	Methadone	
	Propoxyphene	
Anilidopiperidines	Remifentanil	

depression, miosis, and reduced gastrointestinal (GI) motility. These receptors have been further subtyped as mu-1 and mu-2 receptors, and there may be affinity and pharmacologic differences between two. For example, mu-1 receptors may mediate high-affinity supraspinal analgesia, whereas mu-2 receptors have been implicated in opioid side effects, such as respiratory depression, euphoria, and GI motility (see Table 54.1). Enkephalins are the endogenous ligands for these receptors and morphine is the prototypic exogenous ligand.

Delta receptors (δ) mediate spinal and supraspinal analgesia and potentiate the action of μ agonists. These receptors have been subtyped delta 1 and delta 2 and are implicated in terms of analgesia, location, function.

Kappa receptors (κ) mediate spinal analgesia, sedation, miosis, and dysphoria. Dynorphins are endogenous ligands at these receptors and morphine functions as the exogenous ligand. These receptors have been further subtyped as kappa 1, which mediates supraspinal analgesia, and kappa 2 whose function is not known (see Table 54.1).

Sigma receptors (σ), which are not considered opioid receptors (although opioid agonists may bind to sigma receptors), have been implicated in psychotomimetic and dysphoric side effects. They possibly cause dilation of the pupils (American Academy, 1997; Barkin & Fawcett, 2000; Barkin et al., 1998, 2002, 2005; Bartleson, 2002; Bonica, 1990; DeRuiter, 2000).

Opioid-receptor activation inhibits the presynaptic release and postsynaptic response to excitatory neurotransmitters (e.g., substance P) from nociceptive neurons. The cellular mechanism for this neuromodulation may involve alterations in potassium and calcium ion conductance leading to an influx of potassium and resultant hyperpolarization, which limits calcium intracellular entry. Furthermore, coupling of opioid receptors to G proteins results in decreased formation of intracellular cyclic adenosine monophosphate (cAMP), leading to a decrease in calcium channel phosphorylation and consequent diminished calcium entry. Opioid action on G proteins, which is independent of cAMP formation, directly diminishes calcium channel opening and enhances the opening of potassium channels. This sequence of events blocks substance P release, resulting in blockade of nociceptive transmission. Transmission of pain impulses can be interrupted at the level of the dorsal horn of the spinal cord with intrathecal or epidural administration of opioids. Modulation of a descending inhibitory pathway from the periaqueductal gray through the nucleus raphe magnus to the dorsal horn of the spinal cord may also play a role in opioid analgesia. These CNS areas are involved with pain perception, impulse integration, and pain response. Although opioids exert their greatest effect within the central nervous system, opioid receptors have also been isolated from somatic and sympathetic peripheral nerves. Effects on organ systems are listed in Table 54.1 (Barkin et al., 1998, 2002; Ellenhorn, 1997; McEvoy, 2004; Reves, 2002; Sabbe & Yaksh, 1990; Wickersham, 2003). Drug formulations of various opioid analgesics are arranged by chemical class in Table 54.2.

EFFECTS OF OPIOIDS ON SPECIFIC ORGAN SYSTEMS

CARDIOVASCULAR

Generally, opioids do not seriously affect cardiovascular (CV) function. However, high doses of certain opioids are associated with a vagus-mediated bradycardia. With the exception of meperidine, opioids do not depress contractility. However, blood pressure often falls as a result of bradycardia and decreased sympathetic activity. Also, opioids may evoke histamine release that can lead to decreases in arterial blood pressure and systemic vascular resistance. Areas in the brainstem that integrate CV responses and homeostasis include nucleus solitaris, dor-

sal vagal nucleus, nucleus ambiguous, and parabrachial nucleus (Barkin et al., 1998, 2005; Bonica, 1990; Cherny et al., 2001; Ellenhorn, 1997; McEvoy, 2004; Ready et al., 1995; Reisine & Pasternak, 1996; Reves, 2002; Rogers, 1991; Wickersham, 2003).

CENTRAL NERVOUS SYSTEM

In general, following a dose–response relationship, opioids decrease cerebral oxygen consumption cerebral blood flow and intracranial pressure. Stimulation of the medullary area postrema chemoreceptor trigger zone is responsible for the high incidence of nausea and vomiting. Physical dependence is a significant problem associated with chronic administration. Opioids do not reliably produce amnesia. Other effects on the CNS include euphoria, drowsiness, apathy, mental confusion, and mood alterations (Barkin & Barkin, 2001;. Barkin et al., 1998, 2005; Bonica, 1990; Cherny et al., 2001; Ellenhorn, 1997; McEvoy, 2004; Reisine & Pasternak, 1996; Reves, 2002; Wickersham, 2003).

RESPIRATORY

Opioids, by a dose–response relationship depress ventilation through brainstem respiratory centers, particularly respiratory rate and depth of respiration (minute ventilation) in patients at risk, especially with comorbidity. $PaCO_2$ (arterial partial pressure of carbon monoxide) increases and the response to a CO_2 challenge is blunted. This results in a shift of the CO_2 response curve down and to the right. These effects are mediated in the brainstem at the respiratory center. The hypoxic drive is decreased, and the apneic threshold (highest $PaCO_2$ at which a patient remains apneic) is increased. These effects are not usually clinically significant at typical therapeutic doses in otherwise healthy patients. Opioids, such as morphine, may induce histamine release causing bronchospasm in susceptible patients. Also, opioids cause a depression of the cough reflex center in the medulla creating antitussive activity (Barkin & Barkin, 2001; Barkin et al., 2005; Bonica, 1990; Cherny et al., 2001; McEvoy, 2004; Reisine & Pasternak, 1996; Reves, 2002; Sabbe & Yaksh, 1990; Wickersham, 2003).

GASTROINTESTINAL

Opioids slow gastric emptying time by decreasing peristalsis. The effect may be mediated by CNS mechanisms, as well as local organ effects. This may lead to constipation and esophageal reflux (lowers esophageal sphincter activity producing sphincter relaxation). In the biliary tract, the sphincter of Oddi constricts, leading to epigastric distress or biliary colic and increased biliary duct pressure and increased sphincter of Oddi tone in a dose-dependent manner (Barkin et al., 2002, 2005; Ellenhorn, 1997; McE-

voy, 2004; Reisine & Pasternak, 1996; Wickersham, 2003; Zenz et al., 1992).

PHARMACOKINETICS AND PHARMACODYNAMICS

Patients exhibit interpatient/intrapatient variation in dose responses to opioids (see CV, CNS, respiration, GI discussion). A single opioid may not be appropriate for every patient; which to use is a multifactoral decision that includes considering the types of pain (eudynia or maldynia), pharmacokinetics, pharmacogenetics, and pharmacodynamics in a specific patient. The cytochrome P450 (CYP450) system is partially responsible for the metabolism of opioids, especially CYP450 2D6 and 3A4. An overview of this material is presented with each specific opioid and is reviewed in several references (Barkin & Barkin, 2001; Barkin et al., 2002, 2005; Barkin, Schwer, & Barkin, 1999; Cepeda et al., 2001; Davis & Walsh, 2001; DeRuiter, 2000; Gear et al., 1999; Hansten & Horn, 2004; McCarberg & Barkin, 2001; Raffa et al., 1992; Rogers, Nafziger, & Bertino, 2002; Tatro, 2004). See abbreviations list for an explanation of the abbreviations used in the specific opioid listings.

CODEINE (PHENANTHRENE)

Weak analgesic mu (μ) and to a much lesser extent K$_1$, K$_3$, by its active metabolite morphine

responsible for codeine analgesic effect; alone very weak mu affinity.

Duration of action: 4 to 6 h

Absorption: Rapid, and adequate oral

PPB%: 7% (plasma protein binding)

T 1/2 β: 3 h (codeine, 1.5 h; but increased up to 18.7 h with hemodialysis)

Metabolism: Prodrug: 10% to morphine by CYP2D6 and 3A3/4 dependent: followed by conjugation, 1% hydrocodone

Vd: 3.5 L/kg

Time to peak plasma level: 30 to 60 min all routes

Subject to genetic polymorphism (unable to metabolize) CYP 2D6 is absent in >10% of population

Onset: SC 15 to 30 min, duration analgesia 4 to 6 h, Peak analgesia 1 to 1.5 h

Onset analgesia PO: 30 to 60 min (peak PO analgesia 1 to 1.5 h)

Elimination: Unchanged, norcodeine, morphine, conjugated morphine, hydrocodone

Cl$_{cr}$ 10 to 50 ml/min: Administer ≤75% of dose utilized

Cl$_{cr}$ ≤ 10 ml/min: Administer ≤50% of dose utilized

Hepatic insufficiency: Dose adjustment

Renal dysfunction: Narcosis sedation may occur

Caution: Sulfite content

PG: C (D if chronic use or high doses at term), crosses placenta, in breast milk

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002, 2005; Carr et al., 1995; deGroot & Conemans, 1986; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Lubenow, Ivankovich, & Barkin, 2005; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

DIHYDROCODEINE (PHENANTHRENE)

Mu and kappa agonist

Onset: ≤30 min

Duration: 4 to 6 h

Bioavailability (F): (21% range 12 to 34%) due to first pass

T 1/2 β: 3.3 to 4.5 h (similar in normal and renally impaired patients)

Similar to codeine in most respects pharmacokinetically, pharmacologically, and pharmacotherapeutically; a CYP450 2D6 substrate

Time to peak plasma levels: 1.6 to 1.8 h (greater in renally impaired)

AUC: Greater in renally impaired (area under the curve – plasma concentration time curve)

Prodrug: Morphine

PG: B: (D if chronic use or high doses at term) no information on lactation available

Metabolite: morphine salt

Renal dysfunction/impairment: Narcosis sedation may occur

Renal failure: Reduced systemic clearance or increased bioavailability

References: American Pain Society, 2003; Carr et al., 1995; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Lubenow et al., 2005; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

PENTAZOCINE

Partial agonist–antagonist

Mixed kappa 1 and kappa 3, sigma agonist, partial mu agonist/antagonist (supra spinal level); partial mu antagonist may precipitate abstinence in opiate dependence

F: About 20%, ↑ 60 to 70% in cirrhosis

PPB%: 60 to 70%

T 1/2 β: 2 to 3 h, ↑ with ↓ hepatic function

Metabolism: First pass hepatic metabolism 80%, Phase I/II pathways; CYP450 2D6 substrate

Side effects/ADRs: Euphoria, psych. (see below), weakness, miosis

C/I: Myocardial ischemia

Note: ↓ analgesic ceiling due to partial K agonist

CNS psychomimetic effects: Disorientation, confusion, dysphoria, hallucinations, delusions, seizure, CNS depression

Onset: PO, IM, SC: ≤15 to 30 min, IV ≤2 to 3 min

Parenteral dosage form may contain sulfites

Note: Smokers may require a 40 to 50% greater dose due to hepatic induction, another reason to avoid this opioid

Duration: PO: 4 to 5 h; parenteral: 2 to 3 h

Vd: 4.4 to 7.8 L/kg

Cl$_{cr}$ 10 to 50 ml/min: ≤75% of dose

Cl$_{cr}$ ≤ 10 ml/min: ≤50% of dose

Note: Infrequent use is recommended

PG: B (D if used chronically or high dose at term) crosses placenta

References: Abramowitz, 2000; Alexander & Spence, 1974; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; Challoner, McCaroon, & Newton, 1990; De Bard & Jagger, 1982; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Hanunen et al., 1993; Kaiko et al., 1982; Lubenow et al., 2005; McEvoy, 2004; Mokhlesi et al., 2003; Reed & Schnoll, 1994; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2003

FENTANYL (PHENYLPIPERIDINE)

Mu agonist, lesser kappa agonist

Peak plasma level: ≤30 min IM

PPB%: 84 (range 80 to 86), basic drug binds to α_1 AGP (acid glycoprotein)

Peak analgesia: 3 to 5 min

IV analgesia: Onset ≤ 3 to 5 min

Analgesia duration: 30 to 60 min

T 1/2 β: 1.5 to 6 h (average: 2 to 4 h) transmucosal T 1/2 β 5 to 15 h (average 6.6 h)

F: Transmucosal ≈ 50% (range 36 to 71%); transdermal = 92%

Metabolism: Rapid hepatic *n*-dealkylation via CYP450–3A4 enzyme and hydroxylation, ≤10% unchanged

Elimination: Up to 85% in urine ≈ 3 to 4 days; 6 to 10% unchanged; metabolites

ADRs: Respiratory depression (especially with doses > 200 µg, rigidity (skeletal muscle and thoracic) — some irritation and pruritus (perinasal)

Onset: Transdermal 8 to 12 up to 24 h, duration 72 h (duragesic dose form only)

Transmucosal: Onset: 5 to 15 min; peak: 20 to 30 min; absorption: rapid 25% buccal, 75% if swallowed, and slowly from GI tract; cancer pain indication

BBB alterations change active transport in and out of brain tissue

Transdermal semipermeable membrane system: 25 µg/10 cm² increments (duragesic dose form only); avoid silicone base matrix forms, interchange or substitute not recommended

Distribution Vd: 4 L/kg; highly lipophilic, redistributes into the muscle and fat up to 75% of an initial dose undergoes first pass pulmonary uptake

Note: Almost no H_2 release, $T \geq 104 \uparrow$ fentanyl transdermal absorption

If Cl$_{cr}$ is 10 to 50, use 75% of the normal dose, and if the Cl$_{cr}$ is lower, use 50% or less of the normal dose

Patient-controlled transdermal fentanyl delivery system for acute postoperative pain management (PTCA, a needle-less credit card–sized system using the E-trans® (IONSYS®) system, is a self-contained, on-demand preprogrammed system utilizing iontophoresis for transdermal delivery of 40 µg per demand dose and operates for up to 24 h with no more than 80 doses, whichever comes first)

PG: B (D if chronic use or high dose at term), crosses placenta

References: Abramowitz, 2004; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Bennett & Adams, 1983; Carr et al., 1995; DeRuiter, 2000;Ellenhorn, 1997; Fine, 1997; Hansten & Horn, 2004; Jeal & Benfield, 1997; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Schechter et al., 1995; Scholz, Steinfath, & Schulz, 1996; Simpson et al., 1997; Stoukides & Stegman, 1992; Tatro, 2004; Wickersham, 2004

MORPHINE (PHENANTHRENE)

Mu agonist, less kappa, agonist ($K_1 K_2$) generally in the midbrain, medulla, and spinal cord and more specifically in periaqueductal and periventricular gray matter, the ventromedial medulla, and the dorsal horn on the spinal cord. CNS tissues involved in pain perception, integration responses: frontal cortex, limbic system (amygdala, hypothalamus, thalamus), area postrema chemoreceptor trigger zone (CRTZ), nucleus solitary tract cough center. Peripheral tissues: substantia gelatinosa dorsal horn spinal cord.

Duration: 4 to 5 h (IR)

F (oral): ≤40% (20 to 40% range)

Absorption: Oral route interindividual variable, rapid and incomplete 2.5 to 7 h due to variable extensive presystemic metabolism (bioavailability increased in hepatic dysfunction)

PPB%: 20 to 35% primarily to plasma albumins (M-6-G) α_1 acid glycoprotein (stress, surgery, inflammation, chronic pain, and carcinoma)

T 1/2 β: 3 h (M) range 2 to 4 h; 15 for 48 h blood levels

Vd: 1 to 6 L/kg; average 3 to 4 L/kg (lower in elderly patients)

Distribution: Following absorption: skeletal muscle, renal tissue, hepatic tissue, GI tract, spleen, and the CNS

Cl: Hepatic for morphine, renal for M-6-G

P-kin: Linear

C$_{ss}$: Several days

Hydrophilic (small amounts cross the BBB)

M-6-G analgesia ≥ than parent (T 1/2 β: 1.75 h)

M-3-G T 1/2 β: 2.75 h

Peak plasma level: ≤1 h SC/IM route

Metabolism: A CYP450-2D6 substrate followed by Phase II pathway. Hepatic: M-3-G (major metabolite) M-6-G (minor metabolite) causes seizures and some respiratory depression, nausea, and sedation under special circumstances; extrahepatic gut metabolism (gastric, small intestine) and enterohepatic recycling

PO plasma levels: 1/5 to 1/3 of parenteral route

Elimination: Bile 7 to 10%

S/E: Hypotension, dizziness, histamine release, pruritus (more common with epidural and intrathecal administration), peripheral vasodilation, sinus bradycardia, constipation

Onset: Analgesia PO (IR): 15 to 60 min, duration 4 to 6 h

Onset: Analgesia PO (SR): 2 to 4 h duration 8/12 to 17 h or more (24 h) (Kadian)

Onset: Analgesia parenteral route SC 30 to 50 min, IM 30 to 60 min

Peak analgesia, IV: 20 min

Duration of analgesia by IM or IV route: 4 to 5 h

Elimination: Excreted unchanged in the urine 8.5 to 12%, and 7 to 10% as glucuronidation in the feces

Constipation: Enhancing the tone in the long segments of the longitudinal muscle and inhibiting propulsive contraction of both circular and longitudinal muscle (prophylactic bowel management)

Cl_{cr} 10 to 50 ml/min: Utilize 75% of normal dose

$Cl_{cr} \leq 10$ ml/min: Utilize 50% or less of normal dose

PG: B (D if chronic use or high dose at term)

References: Abramowitz, 2000; American Pain Society, 2003; Barkin, 1988; Barkin & Barkin, 2001; Barkin et al., 2002; Braunwald et al., 2003; Brunk & Delle, 1974; Caldwell et al., 2002; Dampler et al., 1995; Carr et al., 1995; DeRuiter, 2000; Duthie & Nimmo, 1987; Ellenhorn, 1997; Hansten & Horn, 2004; Henry & Volans, 1985; Holdsworth et al., 1995; Jacobi et al., 2003; Jadad et al., 1992; Kaiko, 1980; Kaiko et al., 1982; Lorenz, Beck, & Bromm, 1997; Lubenow et al., 2005; Maier et al., 2002; McCarberg & Barkin, 2001; McEvoy, 2004; McRorie et al., 1982; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Richtsmeier, Barnes, & Barkin, 1997; Schug, Zech, & Grond, 1992; Tatro, 2003; Wickersham, 2004

MEPERIDINE (PETHIDINE)

Phenylpiperidine

Mu_1 Mu_2 agonist supraspinally and reuptake blockade monoamines spinally

Peak plasma level PO or IM: 1 to 2 h

F: 50 to 60%, ↑ liver disease

Duration: 2 h to 5 h, onset 10 to 45 min, peak: 0.5 to 1 h

PPB%: 55 to 75 (α_1 acid glycoprotein, an acute phase reactant) basic drug

T 1/2 β meperidine: 2.5 to 4 h (3 to 4 by IV route); liver disease: 7 to 11 h

T 1/2 β (normeperidine): Nonopioid, 15 to 30 h renal function dependent, accumulates with high doses and/or renal function compromised

Metabolism: CYP450-2D6 substrate n-demethylation → normeperidine → Phase II → de-esterified to normeperidinic acid; reduced metabolism in hepatitis; repeat doses accumulate

Lipophilic

Higher dose: Normeperidine produces anxiety, hyperactivity, dysphoria, tremors, myoclonus, seizures, and hyperflexia upon accumulation and/or repeated dosing not naloxone reversible; atropinic

Now falling into disuse, avoid administration during renal or hepatic dysfunctions

Normeperidine: CNS excitation producing neurotoxicity

Elimination: 50% as unchanged

Note: Sulfites; some preparations; may produce serotonin syndrome with SSRIs; anticholinergic, local anesthetic, orthostatic hypotension, fatality

C/I: MAOI agents (delirium, hypertensive crisis, serotonin syndrome)

PG: B (D if used chronically or at high doses at term), appears in breast milk

References: Abramowitz, 2000; American Pain Society, 2003; Armstrong & Bersten, 1986; Barkin & Barkin, 2001; Barkin & Stein, 1989; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Latta, Ginsberg, & Barkin, 2002; Leikin et al., 1990; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

METHADONE

A racemic mixture (diphenylheptane)

Mu agonist, non-opioid NMDA antagonism (d-isomer) blocks Ca^{2+} channel, lesser kappa agonist, possibly strong delta receptor activity; chronic exposure desensitizes mu and delta receptors-l-isomer, 5-HT/NE RUB (reuptake blockers)-d-isomer

Duration: 4 to 6 h (up to 8 h following chronic dosing) for analgesia, analgesic onset 30 to 60 min, analgesic peak 0.5 to 1 h; following repeat dosing, the drug accumulated with repeated dosing, necessitating frequent monitoring and dosage reductions, particularly during the first several days after starting the medication

PPB%: 80 to 89%

F: 92%

T 1/2 β: 15 to 25 h/single dose, range 13 to 47 h, 48 to 72 h (average 24 to 36 h) with multiple dosing, prolonged with alkaline pH

Vd: 3.8 L/kg — wide tissue distribution

S/E: LE, edema, (antidiuretic effect) sedation, dizziness, hypotension, bradycardia, peripheral vasodilation, palpitations, histamine release, (less euphoria), libido decrements, dysphoria

Metabolism: CYP 1A2, 2D6, 3A4, substrate *N*-demethylation; metabolite: active *N*-demethylated methadone, which is 2-ethyldene-1,5-dimethyl-3,3-diphenylpyrrolidene (EDDP) accumulation: due to long T 1/2

Elimination: 52% urine (10% unchanged)

Note: Avoid use in hepatic disease; may cause dose-related interpatient variation (torsades de pointes, which is dose related, particularly at high doses)

Absorption: PO rapid, incomplete

$Cl_{cr} \leq 10$ ml/min: tilize 50 to 75% or less of the dose

PG: C, crosses placenta

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Bartolome & Kuhn, 1983; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Fishman et al., 2002; Gardner-Nix, 1996; Garrido & Troconiz, 1999; Hansten & Horn, 2004; Kaiko et al., 1982; Krantz et al., 2002; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Morley et al., 1993; Olkkola, Hamunen, & Maunuksela, 1995; Reisine & Pasternak, 1996; Tatro, 2003; Wasserman & Yahr, 1980; Weschules et al., 2003; Wheeler & Dickerson, 2000; Wickersham, 2004

LEVORPHANOL (PHENANTHRENE, MORPHINAN DERIVATIVE)

Mu agonist, K_3 agonist, NMDA receptor antagonist

Peak plasma level: 1.5 to 2 h PO; 0.5 to 1.0 h IM

T 1/2 β: 12 to 16 h

C_{ss}: 2 to 4 days

Metabolism: Phase II, adipose tissue accumulates

S/E: Less nausea, vomiting, and constipation than morphine; fatigue, drowsiness, bradycardia, CNS depression, pruritus, peripheral vasodilation, palpitations, hypotension

Onset: Analgesia 10 to 30 min

Peak: Analgesia 0.5 to 1 h

Duration: Analgesia 6 to 8 h

Accumulates within 2 to 3 days of continuous administration

Elimination: 60% in the urine within 4 days, 7% unchanged, feces: 37% in approximately 4 days

PG: B (D if chronic use or high dose at term)

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2003

BUPRENORPHINE

Semisynthetic lipophilic thebaine derived opioid

Mu_1, partial agonist, centrally acting, some kappa opioid receptor antagonist activity seen at higher doses

Onset: Analgesia IM 10 to 30 min (mean 15 min), peak analgesia 1 h (IV: shorter onset and peak)

Duration: 6 to 8 h or longer

F: 90 to 100% IM

Peak plasma level: 4 to 5 min IV, 30 to 60 min following the IM

PPB%: 96 (α and β globulin)

Absorption: 90 to 100% parenterally, sublingually 31%

T 1/2 β: 2 to 3.5 (mean 3.7 h)

Vd: 97 to 187 L

Elimination: 70% in feces by bile, 30% in urine unchanged, up to 11 days post D/C of the drug

Metabolism: *n*-Dealkylation, CYP450-3A4; a weak analgesic; 3-G buprenorphine

Compared to placebo no significant differences in BP, HR, RR

Very slow disassociation from mu_1 receptor

Mixed agonist (mu_1) antagonist (K) (detox, opiate dependent) due in part to low physical dependence

Renal failure: Both norbuprenorphine and 3-G buprenorphine are increased

PG: C

Note: Established safety and effectiveness in children 2 to 12 years; SL dosage form alone and in combination with N haloxone is available for chemical dependency treatment

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Gal, 1989; Hansten & Horn, 2004; Harcus, Ward, & Smith, 1980; Kaiko et al., 1982; Lubenow et al., 2005; Mac Evilly & O'Carroll, 1989; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Rolandi et al., 1983; Tatro, 2003

NALBUPHINE

Kappa, sigma agonist, mu antagonism

F: 6 to 20% PO absorbed

Peak plasma level: 30 min IM

Onset: Analgesia IV 12 to 30 min, 10 to 15 min SC/IM

Peak: (IM) 60 min, IV 30 min

Duration: Analgesia 3 to 6 h

Elimination: Renal

T 1/2 β: 5 h, 2 to 3 h (elderly)

Vd: 3 to 14 L/kg

Metabolism: *n*-Dealkylation: first pass; Phase II, excreted in the stool via the bile; and excreted in the urine about 7%; no active metabolites

S/E: Limited ceiling effects, opiate abstinence, dysphoria, psychomimetic effects (less than pentazocine), HA, histamine release

May precipitate abstinence in some opiate-dependent patients

Some products contain sulfites

PG: B (D if used chronically at high doses at term)

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Errick & Heel, 1983; Gear et al., 1999; Hansten & Horn, 2004; Hoskin & Hanks, 1991; Jallion et al., 1989; Kaiko et al., 1982; Leikin et al., 1990; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004; Yoo et al., 1995

HYDROMORPHONE (PHENANTHRENE)

Dihydromorphone

Chemistry: 4,5 α-Epoxy-3-hydroxy-17-methylmorphinan-6-one HC1

Mu$_{1,2}$ (μ$_1$ μ$_2$) agonist, (δ) lesser K agonist and delta

Metabolism: To three major metabolites — hydromorphone-3-glucuronide (H-3-G) and 3-glucoside and dihydroisomorphine-6-glucuranide — and three other but minor metabolites, inhibitor (mild) of CYP1A^2, 2A6, 2C8, 2D6, 3A4; hydrophilic

Vd: 4 L/kg oral, 295 L (IV route)

C$_{max}$: 3 ng/ml (maximum exposure)

T$_{max}$: Poorly defined IR-AUC (0 to 24) ng.h/ml

Mean minimum plasma concentration ng/ml.7 ng/ml

C$_{min}$: 0.7 ng/ml

Cl: 1.66 L/h for IV

F: 51 to 62% (immediate release)

Accumulates in renal impairment (neurotoxicity, H-3-G metabolism, also seizures, myoclonus, allodynia)

Distribution: Skeletal muscle, liver, GIT, lungs, spleen, brain, plasma, urine

S/E: Myoclonus (clonazepam responsive), feelings of relaxation, euphoria, restlessness, palpitations, histamine release, (pruritus, flushing, red eye, diaphoresis, orthostatic, hypotension), peripheral vasodilation, ↑ transaminases, elevated asthenia, respirator decrements, headache, constipation, nausea, emesis, somnolence

Onset: Analgesia (IR) 30 to 60 min, duration analgesia 4 to 6 h, 5 min parenterally (peak ≤ 20 min)

Onset: Analgesia (CR) 2 to 4 h; duration analgesia 8 to 24 h

T 1/2 β: 2 to 3 h, 18.6 h (CR)

Elimination: 6% renally unchanged in ≤24 h; and elimination: ↑ concentration in bile of both parent and metabolite, found in feces

PG: B (D if used chronically or at term) crosses placenta; C, for CR form

Renal impairment: Modify doses

Metabolites found in plasma, urine, hepatocytes; two CR (24-h) dosage forms; currently one has a 10% bolus dose release action

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Honigberg & Stewart, 1980; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Moulin et al., 1991; Nasraway, 2001; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

HYDROCODONE (PHENANTHRENE)

Differs from codeine by a single bond between C-7 and C-8 and a ketone rather than OH group at C-6

Dihydrocodeinone

Absorption: Well absorbed

Elimination: Urine (26% in 72 h, 12% as unchanged)

Metabolism: Liver to hydromorphone via CYP (2D6), nor-codeine, and 12% unchanged drug by *O*-demethylation

Onset: Analgesia 30 to 60 min

Duration: Analgesia 3 to 8 h

T 1/2 β: 3.8 to 4.5 h; peak serum level: 1 h

Peak: Analgesia 2 h

PG: C

Renal: ↓ dose in ARF or CRI

Note: Association with abuse noted (euphoria), similar to oxycodone

ADRs: Anxiety; euphoria at the therapeutic doses 5 to 10 mg; addiction potential exceeds codeine and may rival oxycodone abuse

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

OXYCODONE (PHENANTHRENE)

Morphinan-6-one, 4,5 epoxy-14-hydroxy-3-methoxy-17-methyl hydrochloride $(5\alpha)(7,8$-dihydro-14-hydroxycodeinone; or $4,5\alpha$-epoxy-14-hydroxy-3-methoxy-17-methylmorhpinan-6-one-HCl) receptors: mu_1, mu_2 agonist via its metabolite, kappa agonist (strong)

F: 60 to 80% (due to lower presystemic or first-pass metabolism); increased by 15% in elderly and 50% in renal dysfunction

T $1/2$ β: 3.5 to 4 h (single dose)

Onset: Analgesia (IR): 15 to 60 min; duration analgesia: 4 to 6 h

Onset: Analgesia (CR): ≤ 1 (rapid absorption bolus dose release phase); duration analgesia 6 to 12 h, bolus release $\approx$ 37% release $\leq$ 2 h post-ingestion

C_{max}: 13 to 19 ng/ml

AUC: 72 to 84 ng $\times$ h/ml (multiple dosing)

Peak analgesia: $\leq$ 60 min

Vd: 2.6 L/kg

T_{max}: 1 to 1.6 h

PPB: 45%

C_{ss}: 24 to 36 h (CR form) with 12-h dosing

Vd at steady state: 2.39 L/kg

Distribution: Highly perfused tissues: muscle (skeletal), intestinal tract, pulmonary, spleen, CNS (brain), hepatic

ADRs: Euphoria, feeling of relaxation, constipation (decreased gastrointestinal motility), ataxia, sedation, diaphoresis, histamine release, confusion, anorexia, memory deficits, hypotension, fatigue, drowsiness, nervousness, HA, restlessness, malaise, miosis, endocrine changes, autonomic nervous system changes, respiratory depression

Metabolism: Oxymorphone (1/10 plasma concentration of oxycodone), noroxycodone by *N*-demethylated to noroxycodone and *O*-demethylation (for oxycodone to oxymorphone) to glu-

curonides — a pharmacologically active weaker analgesic

CYP450: 2D6 substrate to oxymorphone

Cl systemic: 16.7 ml/kg/min

Elimination: Excretion in urine: 33 to 61% in 24 h, 13 to 19% free (unchanged conjugated $\leq$ 50% and noroxycodone conjugated oxymorphone $\leq$ 14% not quantified free or conjugated)

Renal failure (anesthetized patient): T $1/2$ β = 3.9 h

End stage renal disease: Prolonged T $1/2$ β due to $\uparrow$ Vd and $\downarrow$ C1, if $Cl_{cr} \leq$ 60 ml/min then $\downarrow$ Cl_{cr} and $\uparrow$ AUC

Hepatic impairment: If occurs $\uparrow$ AUC

AUC = Extent of absorption

PG: B (D if used chronically or in high doses found in breast milk)

Gender: Opiate-naïve females have 25% higher plasma concentration than males

Note: Opiate dependence, prominent, addiction liability, CR dosage form provides a bolus dose of $\approx$ 38% within 1 to 2 h of ingestion

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Bruera et al., 1998; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Hansten & Horn, 2004; Kaiko et al., 1982; Kalso & Vainio, 1990; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Roth et al., 2000; Tatro, 2003; Turturro & O'Toole, 1991; Wickersham, 2004

PROPOXYPHENE

Weak mu binding for analgesia is 1/2 that of codeine and possible kappa subtype affinity, noncompetitive NMDA antagonist

Structurally similar to methadone

F: 30 to 70% due to significant hepatic first pass

Absorption: Complete

Metabolism: First pass to norpropoxyphene (a non opioid) arrhythmogenic agent and local anesthetic effect, also associated with pulmonary edema and seizures

PPB: 78%

T $1/2$ β: 6 to 12 h up to 15 h parent (37 h in elderly); norpropoxyphene: 30 to 36 h (up to 42 h in elderly patients)

Onset: Analgesia 30 to 60 min; Duration 4 to 6 h; peak plasma concentration in 2 to 2.5 h

S/E: Euphoria, false sense of well-being, hypotension, dizziness, lightheadedness, nausea, vomiting, sedation, malaise, paradoxical excitation, nightmares, insomnia, fatigue, drowsiness, auditory hallucinations, weakness, histamine

release, depression, pulmonary edema, PQRS prolongation, arrhythmias, trembling, tinnitus, subacute painful myopathy, seizures

Elimination: 20 to 25% excreted in urine

Nor-propoxyphene not reversible by naloxone and leads to cardiac arrhythmias and pulmonary edema, and accumulates

An agent falling into significant disuse; discourage use in elderly patients

A CYP450 system inhibitor at 3A 3/4

Poor analgesia but prominent euphoria, avoid use in elderly patients (metabolism reduced)

PG: C (D if chronic use); possible human teratogen, cranial/facial abnormalities, limbs absent

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Finkle, 1984; Hansten & Horn, 2004; Kaiko et al., 1982; Lawson & Northridge, 1987; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Proudfoot, 1984; Reisine & Pasternak, 1996; Stork et al., 1995; Tatro, 2003; Tennant, 1973; Wetli & Bednarczyk, 1980; Wickersham, 2004

BUTORPHANOL

Kappa$_1$ agonist and antagonist effects (methadone, propoxyphene)

Peak: IM ≤ 30 to 60 min, NS and IV ≤ 4 to 5 min

Absorption: Rapid and well

S/E: Psychomimetic anxiety, confusion, dysphoria, euphoria, somnolence, hallucinations, S, D, N, V, insomnia, peripheral edema, dizziness, vasodilation palpitations, nausea, emesis

PPB: 83%

Metabolism: Extensive first pass in the liver: hydroxylation, *N*-demethylation

T 1/2 β: 2.5 to 4 h

Elimination: 11 to 15% excreted in bile, 72% in urine within 96 h

Cl$_{cr}$: When ≤60, consider decreasing dose by 50 to 75%

Onset of analgesia: IM within 10 min

PG: B (D with chronic use or high dose at term) crosses placenta, distributes to breast milk

References: Abramowitz, 2000; American Pain Society, 2003; Barkin, 1996a; Barkin & Barkin, 2001; Barkin et al., 2002; Bennie et al., 1998; Carr et al., 1995; DeRuiter, 2000; Ellenhorn, 1997; Gaver et al., 1980; Hansten & Horn, 2004; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Melanson et al., 1997; Mokhlesi et al., 2003;

TRAMADOL

Cyclohexanol

Mu$_1$, opioid receptor effects supraspinally

5-HT, NE, reuptake blockade spinally

CYP450 substrate: 2D6 → M1 metabolite, 3A4 for MI metabolite

Analgesia ≥ codeine, hydrocodone, oxycodone, meperidine, propoxyphene

T 1/2 β: With APAP: 325 mg/tramadol/37.5 mg dosage form: 7 to 9 h (preferred dosage form)

T 1/2 β: Tramadol alone: 6 h, M1: metabolite 7 h

Maximum dosage: 8 tablets per day

Elimination: Renal: ≤10% removed by HD (hemodialysis)

F: 75%

Onset analgesia: ≤1 h, Peak analgesia 2 to 4 h, duration analgesia 6 h

Relative lack of opiate dependence

PPB: 20%

Metabolism: Demethylation, glucuronidation, sulfation

Metabolite: M1 (*N*-demethylation by CYP 2D6; M1 (deomethyltramadol) is six times more potent an analgesic with 200 more times affinity for mu$_1$ receptor

PG: C; placenta crossing

References: Abramowitz, 2000; American Pain Society, 2003; Barkin, 1995a, b, 1996b; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; Collins et al., 1997; Dayer, Collart, & Desmeules, 1994; DeRuiter, 2000; Ellenhorn, 1997; Gaver et al., 1980; Gaynes & Barkin, 1999; Hansten & Horn, 2004; Lewis & Han, 1997; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McCarberg et al., 2003; McEvoy, 2004; Mehlisch, Brown, Lefner et al., 1993; Mokhlesi et al., 2003; Rauck, Ruoff, & McGillen, 1994; Reisine & Pasternak, 1996; Ruoff, 1999; Tatro, 2003; Wickersham, 2004

KETAMINE

MOA: NMDA (*N*-methyl-D-aspartate) antagonist, chiral compound, administered as racemic mixture, S(+) isomer 2× analgesic; some opiate agonist effects (PCP similarity)

P-kin: Bi- or tri-exponential elimination pattern; potency of mixture; S(+) is 3× potency of R(–) isomer

Analgesia duration: 30 to 40 min

Unconsciousness duration: 10 to 15 min

Amnesia duration: up to 1-2 hours

Vd: 3 to 5 L/kg

PPB: 30%; basic to α_1 AAG

Metabolism: Hepatic (hydroxylation, *N*-demethylation; nor-ketamine (π activity of parent), dihyronorketamine

T 1/2 β: 1 to 3 h; α: 10 to 15 min anesthetic phase, redistribution to the peripheral tissues (from the CNS) followed by hepatic metabolism T 1/2 β: 2.5 h

Elimination: Renal, with renal impairment increased plasma concentration of metabolites (norketamine; glucuronides)

ADRs:

CV: catecholamine (NE/epi) released/elevated $\rightarrow$ sympathomimetic effects: tachycardia, $\uparrow$ CO, HTN

GI: N, V

CNS: Visual hallucinations, vivid unpleasant dreams, confusion, irrational behaviors, $\uparrow$intracranial pressure

Neuromuscular: Tonic-clonic, myoclonic movements, tremors

Miscellaneous: Emergence reaction (dysphoria/euphoria), vocalization (avoid in psychosis prone patients); residual psychomotor impairment upon awakening (hangover)

BZs useful for delirium, dysphoria, hallucinations, Sz

BZs and DPH: Useful for EPS (benzodiazepine, diphenhydramine)

BZs, α_2 agonist (clonidine), beta-blockers, calcium channel blockers

(verapamil) useful for $\downarrow$ cardiac stimulation

Atropine for hypersalivation

PG: D (crosses placenta)

References: Abramowitz, 2000; American Pain Society, 2003; Barkin & Barkin, 2001; Barkin et al., 2002; Carr et al., 1995; Clements & Nimmo, 1981; DeRuiter, 2000; Ellenhorn, 1997; Felser & Orban, 1982; Hansten & Horn, 2004; Hartvig et al., 1995; Kaiko et al., 1982; Lubenow et al., 2005; McCarberg & Barkin, 2001; McEvoy, 2004; Mokhlesi et al., 2003; Reisine & Pasternak, 1996; Tatro, 2003; Wickersham, 2004

OXYMORPHONE (PHENANTHRENE)

Chemistry: 4,5α-Epoxy-3-14-dihydroxy-17-methyl morphinan-6-one HCI (similar chemistry to hydromorphone)

Mu$_1$ agonist specifically

Linear pharmacokinetics

Absorption: PO: rapid IR: T_{max} = 0.5 h; ER: T_{max} = 2.5 to 4 h

Onset: Parenteral: 5 to 10 min

PR: 15 to 30 min

Duration: PR/parenteral 3 to 4 h

Metabolism: (1) Phase II hepatic glucuronidation; extensive first pass (PO); (2) reduction to 6-OH; 6-OH analgesic potency similar to parent, about 70% of AUC; (3) very minor Phase I metabolism; CYP450 1A2, 2D6, 3A4; (4) not sufficiently metabolized CYP450

Metabolites: 0-3-G (plasma, urine), 33 to 38% 0-3-G; 6-OH 0.25 to 0.62%

Excretion: Enterohepatic recycling bilary — parent and metabolite, urine ($\leq$1% unchanged, parent)

PPB: Not extensive (10 to 12%)

C_{max} (μg/ml):1.16 (0.17)

T 1/2 β: 13.46 (3.38) h

C_{ss}: 3 days

Solubility: Lipophilic (access to neurovascular membrane–BBB–spinal cord)

Remains in CNS aqueous phase without redistribution; slow dissociation from CNS receptor sites

Linear dose–response curve

ADRs:

CV: Hypotension

CNS: Fatigue, drowsiness, dizziness

Skeletal/neuromuscular: Weakness

Miscellaneous: Histamine release, ureteral spasm, diminished micturation

CNS: Nervousness, cephalgia, restlessness, malaise, confusion

GI: anorexia, abdominal cramps and xerostomia, biliary spasms

Local: Injection site pain

PG: B/D, prolonged use or high dose at term; excreted in breast milk

Sulfites: Some preparations (parenteral) contain

Forms: Oral (IR, ER as 12 h), these two new dosage forms to be released shortly; CR: low fluctuations; parenteral rectal

Natural Supplements in Pain Management: A Primer and Evidence-Based Review

Robert A. Bonakdar, MD

INTRODUCTION

Herbal and dietary supplements account for more than $15 billion in yearly sales, with pain management as one of the most common reasons for utilization. The use of dietary supplements, which is often done without the input or monitoring of a clinician, introduces many important issues of which the health care provider should be aware. These primarily include understanding the regulation, marketing, and efficacy of supplements as well as sensitivity to the demographics and ideology of those using supplements in order to improve discussion and management. Dietary supplements commonly used for pain management and evaluated in clinical trials are reviewed.

The typical journey of the patient with pain (and similarly patients with a chronic condition) involves consultations and information gathering regarding potential treatment options. At some point during this investigation, the possibility of using dietary supplements will inevitably be introduced. Compared with the general population, patients experiencing pain as a whole, as well as those fitting certain demographics, will be more likely to consider, use, and continue with dietary supplementation as a treatment option. This scenario inspires several important questions for the practitioner:

- How many of my patients are using supplements?
- Are my patients discussing their supplement use with me?
- Why did the patient start using supplements?

- Are the supplements safe and well-regulated?
- Are the supplements effective?
- Where did my patients learn about and obtain their supplements?
- How do I effectively counsel and manage patients on supplements?
- How do I find evidence-based resources and information on supplements?

The answers to these questions can be quite surprising and contrast sharply with respect to the properties of prescription medications. An overview of dietary supplements, including definition, prevalence, rationale, and regulation is offered in the first section of the chapter as a primer for the clinician. The second section discusses efficacy and utilization issues related to common pain management supplements evaluated in clinical trials.

DIETARY SUPPLEMENTS OVERVIEW

DEFINITION

Dietary supplements have various definitions and are typically thought of as commonly used herbal products — *Echinacea,* feverfew — or nonherbal products — glucosamine, *S*-adenosyl methionine (SAMe). However, the definition as listed in the Dietary Supplement Health and Education Act (DSHEA) of 1994 is more encompassing and includes any single or combination ingredient products containing the following (with examples in parentheses):

- A vitamin (riboflavin)
- A mineral (magnesium)
- An herb or other botanical (feverfew)
- An amino acid (L-tryptophan)
- A dietary substance for use by humans to supplement the diet by increasing the total dietary intake (proteolytic enzymes from pineapple)
- A concentrate, metabolite, constituent or extract (white willow bark extract) (Food and Drug Administration, 2002)

The definition effectively incorporates most substances used by consumers or patients outside the realm of prescription or over-the counter (OTC) medications. Because of the broad definition, clinician should be clear in asking about all categories of dietary supplements potentially used.

PREVALENCE AND RATIONALE

Dietary supplement sales have grown steadily, at times dramatically, since the early 1990s with an approximate 400% increase since that time (Eisenberg et al., 1993, 1998). Since the late 1990s supplements have demonstrated a variable picture where certain markets (Internet, catalogs, and health food stores) have increased while others have slowed. Additionally, individual supplements demonstrate stronger (glucosamine) or weaker (Kava) sales based on recent studies, advertising, or government warnings. Overall, the supplement industry continues to demonstrate impressive numbers with greater than $15 billion in total sales by the most recent estimates (*Nutrition Business Journal,* 2001).

Currently, 50% or more of Americans use a vitamin/mineral formula and 18% an herbal formula on a regular basis (Gugliona, 2000; Harris Interactive Health Care News, 2002). The use of dietary supplements is predicted by several demographic characteristics. The typical user of dietary supplement tends to be a female with higher education and income, with potentially more severe and long-standing medical issues than a nonuser (Astin, 1998; Begbie et al., 1996; Gray et al., 2002; Leung et al., 2001). The rationale for supplement use is additionally correlated with a number of factors including the type of medical diagnoses as well as patient belief systems. A diagnosis of pain is one of the top conditions prompting supplement use (Astin, 1998; Consumer Health Products Association, 2001; Leung et al., 2001). Surveys have demonstrated that those in chronic pain have greater than 40% use of at least one complementary and alternative medicine (CAM) modality. The most common modalities vary by condition but typically including dietary supplements, acupuncture, massage, and manipulation (Bruneli et al., 2004; Nayak et al., 2001). Certain pain conditions (such as osteoarthritis and fibromyalgia) tend to attract greater

CAM and supplement use due to several factors including the psychosocial factors associated with the condition as well as availability of effective conventional treatments. For example, in patients with osteoarthritis awaiting joint replacement, 40% used some type of dietary supplement with usage correlated with higher levels of pain (Zochling et al., 2004). One of the highest levels of dietary supplement usage is seen with patients with fibromyalgia who had a 91% CAM utilization rate versus 63% in a matched rheumatology population (Pioro-Boisset et al., 1996).

The health beliefs and values of the person considering supplements are also quite important and often misinterpreted. Those who are involved in "active coping behaviors," such as greater physical activity, tend to view supplement use in a similar manner. Also, several surveys demonstrate that those with a more "holistic outlook" wish to utilize complementary methods including dietary supplements, which may take this viewpoint into consideration. Although there has been speculation regarding the use of CAM and dietary supplements as secondary to dissatisfaction with conventional care, the more prevalent theme is that of CAM utilization for optimization of care. In fact, dissatisfaction with conventional care did not predict use of CAM in a previous national survey and less than 5% of CAM users did so in isolation from conventional care. Most CAM users state their motivations for CAM incorporation encompass more global control over their health care with up to 80% reporting substantial benefit from its use (Astin, 1998). In their pursuit of CAM, users have actually been found to have more frequent relationships with a primary care physician, regular physician follow-up, and compliance with recommended preventative health behaviors such as regular mammography (Astin et al., 2000).

KNOWLEDGE BASE

The knowledge base of the average clinician and consumer regarding dietary supplements has been shown to be suboptimal. Physician surveys have found that physicians in training may have a low general understanding of commonly used supplements as well as their safety, interaction, and regulation profiles. Similarly, consumers and patients tend to receive their information regarding supplements from nonclinical sources including magazines, friends, and family, with clinician consultation occurring rarely. As pointed out by a recent Harris Poll, the outcome of inaccurate or biased supplement information may be overestimation of the regulatory and evidence basis of dietary supplements. The poll demonstrated that 55% of consumers believed that the government does not allow claims of safety without supporting evidence, 59% believed that products must be preapproved by the FDA before sale, and 68% believed the government required

labels to have warnings about potential side effects (Harris Interactive, 2002).

DISCUSSION

One of the other key deficiencies in the dietary supplement scenario is the level of clinician–patient discussion. Initial survey found that in approximately 70% of encounters, there was no discussion of CAM use, including dietary supplements (Eisenberg et al., 1993). More recently the percentage appears to be lower and closer to 50%, which still leaves many encounters in which neither the patient nor clinician introduces the topic. More disconcerting is the fact that if a patient is hospitalized by a specialist, CAM use is not identified up to 88% of the time (Azaz-Livshits et al., 2002). The importance of identifying, discussing, and charting CAM and supplement use cannot be understated. The immediate motivation for discussing dietary supplements involves identification of any potential interactions or adverse effects of which the patient may not be aware. More importantly, full discussion enables a better understanding of patient rationale for consideration and utilization of supplements. As mentioned previously, supplement users share health behaviors which, when identified by clinicians, enable improved coordination and guidance of conventional and complementary treatment options.

To help improve discussion, it is important to better understand why patients do not disclose supplement (or other CAM) use. Surveys indicate that factors including anticipation of negative or disinterested clinician response, as well as belief that the clinician will not provide useful information, motivated nondisclosure (Adler et al., 1999). However, most important may be clinician inquiry, with patients demonstrating willingness to disclose supplements use, but only if asked by a clinician directly (Hansrud et al., 1999). Unfortunately, a recent survey of physicians found that few of those surveyed felt comfortable discussing CAM with their patients. One of the major reasons for the lack of comfort was related to a need to improve their knowledge base regarding CAM (84% of responders). It is hypothesized that with improved education about CAM, physicians may be more willing to discuss CAM and counsel patients (Corbin-Winslow et al., 2002).

There are a number of resources available to clinicians interested in better understanding dietary supplements as a means of increasing and improving patient communication. These resources are listed in Table 55.1 and include print and online information on evidence-based use of supplements as well as continuing medical education courses available to clinicians. In addition, the H-E-R-B-A-L mnemonic is offered in Table 55.2 as an additional practice tool for alerting clinicians to the most important steps involved in managing dietary supplement use.

REGULATION

The general regulation of dietary supplements in the United States is in evolution, but is currently based on the DSHEA of 1994. The key components of this act are important for all practitioners to review to better understand how regulation differs from prescription medications. First, unlike prescription medications that need to proceed through multiphase trials to gain premarketing approval from the FDA, supplements (with established ingredients) are not required to have safety, efficacy, or bioavailability data prior to marketing. Ensuring these important qualities, along with having a clear and truthful label, is solely the responsibility of the manufacturer. Second, because supplements are not required to go through premarketing clearance, they also fall into a different labeling scheme than prescription products. In short, supplements may have only "structure or function" claims that cannot imply prevention, treatment, or cure of a condition. The line can at times be difficult to distinguish with a number of manufacturers being cited for going beyond allowed standards (Federal Trade Commission [FTC] for the Consumer Newsletter, 2003).

The key role of the FDA (and in the case of advertising, the FTC) begins after the supplement is marketed and involves monitoring safety, label claims, and product advertising. Thus, the typical premarketing steps needed for prescription medication approval are replaced with postmarketing surveillance. In this scenario, the FDA must utilize adverse drug reports and product analysis to prove a supplement poses significant health risks. Two recent examples of this are the banning of ephedra secondary to adverse reactions and "PCSPES" (a dietary supplement marketed to patients with prostate cancer) because of product adulteration (FDA Press Release, 2002, 2003).

As it currently stands, the supplement regulatory system contrasts greatly to that for prescription medication and will likely see additional scrutiny and amendments in the near future. Although many manufacturers utilize proper standards, the publicity of an adulterated or unsafe supplement tarnishes the standing of well-regulated supplements as well as decreases the confidence of practitioners and consumers wishing to incorporate evidence-based supplements. The incorporation of new good manufacturing practice (GMP) standards as published in 2003 will be helpful in standardizing the manufacturing process. Also greater organizational support for monitoring claims, advertising, and adverse events should improve the enforcement of existing statutes.

EXTERNAL REGULATION

Several independent agencies now offer testing and monitoring services, allowing manufacturers the opportunity to demonstrate their adherence to regulatory standards.

Manufacturers may voluntarily submit their product for review, which can take various forms including ingredient verification, manufacturing site monitoring, and random off-the-shelf testing. Those that pass inspection may carry an independent "Seal-of-Approval" on their label and advertising. Several of the government agencies as well as independent agencies currently involved in testing are listed in Table 55.3. Although there is no absolute standard for external regulation, nor is external regulation a replacement for continued vigilance by the consumer or federal regulators, it may help to improve and establish stronger manufacturing standards.

SAFETY AND ADVERSE EFFECTS

The rate and severity of adverse effects associated with dietary supplements are difficult to estimate. This is due to minimal if any premarketing safety data as well as a suboptimal system of capturing and verifying postmarketing events. One of the proposed DSHEA regulatory changes is establishment of a mandatory adverse events reporting system by manufacturers. Currently, because of the lack of initial communication and subsequent discussion regarding dietary supplements, the involvement of the clinician in detecting and reporting adverse effects and potential inter-

TABLE 55.2
The H-E-R-B-A-L Mnemonic©

<div align="center">Hear the Patient out with Respect</div>

More patients will disclose supplement use when asked openly and directly

Most patients desire discussion but do not initiate it on their own

Ask in a nonjudgmental, inclusive manner: "Some of my other patients are using herbs and supplements for various conditions. Have you tried any of these?"

Remember that there may be a fear of ridicule or indifference with disclosure

Understand that the patient may have important personal reasons for choosing supplements which may include:
- Previous positive experience
- More time to discuss health issues with alternative health practitioner or health food salespersons
- Anecdotal evidence, "It worked for my friend"
- Issues with current conventional care

Thank them for taking an active role in their health care. Discuss other ways they can do this that you can agree upon: diet, exercise, stress management, etc.

<div align="center">Educate the Patient</div>

Supplements are potentially powerful agents that can have benefit as well as serious side effects and interactions, just like prescription medication

Your job is not to be an expert, but simply to dispel the myths and balance the picture

Give the patient resources that are objective and reliable (www.healthfinder.gov, http://NCCAM.NIH.GOV, www.naturaldatabase.com)

<div align="center">Record</div>

Treat supplements like other medications: chart all supplement use in the progress note and medication section for your benefit as well as for other practitioners viewing the chart

Try to record an evaluation date to discuss if the supplement has shown any benefit for treatment. If no benefit is seen discuss options including changing dosage or brand, stopping or switching supplements.

<div align="center">Beware</div>

If the patient develops new or worsening side effects or abnormal laboratory values (especially prothrombin time/international normalized ratio [PT-INR]) and the usual suspects have been ruled out — **Think Supplements**

Monitor patients with polypharmacy, especially those on anticoagulants

<div align="center">Agreement to Discuss</div>

Forge an agreement that all new supplements will be discussed before commencement, which gives you and your staff a chance to balance the mostly anecdotal/testimonial information the patient hears through the media, mailings, and the Internet

<div align="center">Learn about New Supplements</div>

Try to keep up with what the patient is hearing about and considering using

A wide variety of peer-reviewed resources are available to help decipher the increasing amount of information on supplements (see Table 55.1)

action is hindered. Additionally, patient reporting of adverse effects to dietary supplements appears to occur less often than with prescription medication. A 1998 study that interviewed dietary supplement users found that they would act differently based on the type of product that caused the adverse effect. Surprisingly, 26% would consult their primary care provider for serious adverse effects of a conventional OTC medication, but not for a similar adverse effect of an herbal remedy (Barnes et al., 1998).

The discrepancy in how patients view supplements, their safety, and the need for reporting is especially important in certain populations who may have relative or absolute contraindications to supplement use. These populations include pregnant or breastfeeding women, young children, or patients with certain conditions (such as dialysis or transplant patients) who may be on a narrow therapeutic regimen or medications with high interaction

potential. These advisories are unfortunately currently more theoretical than actual and largely based on mechanistic studies, varying quality case studies, and rare prospective trials. An example of this model would be a pregnant patient considering supplements for headache management. She may not know the difference in safety between feverfew, which has been correlated with uterine activity, and magnesium, which is generally considered safe in typical doses. Thus, in many cases, the pregnant patient, as a model of the vulnerable patient, should have a higher level of clinician counseling regarding the safety issues of any supplement she may be considering.

The reported adverse effects in clinical trials of dietary supplement for pain management appear to be low. As detailed in several of the trials in the next section, the most common side effects tend to be minor gastrointestinal (GI) reactions. These may include bloating, nausea, or changes

in gastric motility, typically because of GI active ingredients such as tannins. Other side effects tend to occur rarely and are not more common than placebo, other than when reported below. Of particular comparison are GI side effects including symptomatic ulceration and bleeding, which are increased fourfold with chronic nonsteroidal anti-inflammatory drug (NSAID) use (Garcia-Rodriguez et al., 2004; Hernandez-Diaz et al., 2000). According to Arthritis, Rheumatism, and Aging Medical Information System prospective data, of every 1,000 patients on chronic NSAIDs, 7.3 patients with osteoarthritis and 13 patients with rheumatoid arthritis will develop serious GI complications (Singh et al., 1999). Although reporting and monitoring need to improve, these serious GI adverse events have thus far not been associated with dietary supplements and may be one particularly attractive feature for patients needing alternative therapeutic options for chronic pain management.

Data on the occurrence or potential for herb–drug interactions (HDIs) also are quite preliminary. Broad estimates indicate that from approximately 20 to 43% of patients take dietary supplements along with prescription medications (Eisenberg et al., 1998; Peng et al., 2004). In most cases this use may pose little actual danger as determined by a recent survey that found a 3 to 6% occurrence of concomitant use of a medication with a potentially interacting supplement. However, certain scenarios should prompt further discussion, monitoring, or supplement/medication alteration to avoid the potential for negative interactions. The most common scenario for the pain clinician is that of a patient on dietary supplements with a bleeding potential. When the supplement is concomitantly used with prescription agents with similar properties or in the setting of surgery, increased caution is advised. In recent surveys, up to 22% of presurgical patients routinely used herbs (8% reported multiple herbs) and 51% routinely used vitamins. Of the products reviewed 27% of patients used herbs that could potentially interfere with blood clotting (Norred, Zamudio, & Palmer, 2000; Tsen et al., 2000). A list of dietary supplements with such a potential is given in Table 55.4. Although extremely rare, this combination has been implicated in cases of hemorrhage (Norred et al., 2000). Overall, the field of HDI identification, monitoring, and management is quite preliminary and likely overstating its true impact. However, until more is known on the subject, it behooves the clinician to have continued vigilance in discussing and monitoring patients in certain clinical scenarios to minimize patient risk.

Last, the topic of interactions would not be complete without a brief discussion of the potentially beneficial GI interactions of several supplements. This type of interaction can be described as an antagonistic pharmacodynamic interaction in nature in which one agent counteracts the actions of another agent at a specific site. In this case, supplements may counteract the depletion of mucosal integrity potentiated by pain medications (NSAIDs and corticosteroids) by mechanisms including promotion of mucin production. Several animal and human studies of capsicum (*Capsicum* spp.), licorice (*Glycyrrhiza glabra*), turmeric (*Curcuma longa*), ginger (*Zingiber officinale*), and cat's claw (*Uncaria tomentosa*) have demonstrated a decrease in various models of GI toxicity (Al-Yahya et al., 1989; Goso et al., 1996; Rafatullah et al., 1990; Yeoh et al., 1995). Additionally, many of the potentially GI protective supplements also possess pain-modulatory properties. This has translated into drug (NSAID)-sparing effects in some trials that may portend a decreased adverse effects incidence.

TABLE 55.4
Herbs Associated with Antiplatelet/Blood Thinning Potential

Herb	Botanical Name	Herb	Botanical Name
Agrimony	*Agrimonia eupatoria*	Horse chestnut	*Aesculus hippocastanum*
Alfalfa	*Medicago sativa*	Horseradish	*Armoracia rusticana*
Angelica	*Angelica archangelica*	Licorice	*Glycyrrhiza glabra*
Anise	*Pimpinella anisum*	Northern prickly ash	*Zanthoxylum americanum*
Asafoetida	*Ferula assa-foetida*	Onion	*Allium cepa*
Aspen	*Populi cortex*	Papain	*Carica papaya*
Bladderwrack	*Fucus vesiculosis*	Passionflower	*Passiflora incarnata*
Black cohosh	*Cimicifuga racemosa*	Pau d'arco	*Tabebuia impetiginosa*
Bogbean	*Menyanthes trifoliate*	Plantain	*Plantago major*
Dong quai	*Angelica sinensis*	Poplar	*Populus tacamahacca*
Boldo	*Peumus boldus*	Quassia	*Quassia amara*
Borage seed oil	*Borago officinalis*	Red clover	*Trifolium pratense*
Bromelain	*Ananas comosus*	Roman chamomile	*Chamaemelum nobile*
Capsicum	*Capsicum frutescen*	Safflower	*Carthamus tinctorius*
Celery	*Apium graveolens*	Southern prickly ash	*Zanthoxylum clava-herculis*
Clove	*Syzygium aromaticum*	Stinging nettle	*Urtica dioica*
Danshen	*Salvia miltiorrhiza*	Sweet clover	*Melilotus officinalis*
European mistletoe	*Viscum album*	Sweet vernal grass	*Anthoxanthum odoratum*
Fenugreek	*Trigonella foenum-graecum*	Tonka bean	*Dipterux odorata*
Feverfew	*Tanacetum parthenium*	Turmeric	*Curcuma longa*
Garlic	*Allium sativum*	Wild carrot	*Daucus carota*
Ginkgo	*Ginkgo biloba*	Wild lettuce	*Lactuca virosa*

NATURAL SUPPLEMENTS IN PAIN MANAGEMENT: AN EVIDENCE-BASED REVIEW

This summary focuses on natural supplements commonly utilized for pain management with special focus on those evaluated in clinical trials. Categorization is performed on a clinical basis (phyto-anti-inflammatories, joint pain, and headaches) as opposed to supplement type (vitamin, herb, mineral). Several supplements can be placed in more than one heading, but are placed in categories based on their mechanism or more common indication. White willow bark (WWB) is discussed in detail because of its proto-typic role as a phyto-anti-inflammatory. It has benchmark data related to its use and research, including history of traditional use, evidence for biomarkers/bioactivity, efficacy data against placebo and prescription medications, and statistics on safety and cost efficacy. A listing of pain management supplements as evaluated in clinical trials appears in Table 55.5. Listings of additional pain management supplements, which are beyond the scope of this review, are found in Table 55.6. These additional supplements deserve mention because they possess various levels of use in the traditional, clinical, or research setting and

may be recommended or sold for pain management in the United States. The reader looking for more comprehensive or detailed dietary supplement information is again referred to Table 55.1 for additional resources.

PHYTO-ANTI-INFLAMMATORIES

Willow Bark (*Salix* spp.)

WWB has a long history of use in medicine with records describing Hippocrates recommending its use for pain relief. Rev. Edmond Stone formally described WWB in 1763 as helpful in the treatment of inflammatory and febrile conditions with the active component salicylic acid being isolated in 1860. Shortly thereafter in 1898, aspirin (acetylsalicylic acid) was discovered and became a leading pain-relieving agent. Although WWB led the way to aspirin's discovery, these two compounds are not simply natural and synthetic counterparts; WWB has many additional constituents that deserve attention.

As an example, a clinically therapeutic WWB dose in healthy subjects resulted in a blood salicylate level of 1.4 µg/ml, which is subtherapeutic compared with the 35 to 50 µg/ml level obtained from a 500-mg dose of aspirin (Schmid, Kotter, & Heide, 2001). Therefore,

TABLE 55.5
Pain Management Supplements Reviewed in Clinical Trials

Name	Source/Botanical Name	Dosage in Trials
Anti-Inflammatory		
White willow bark	*Salix* spp.	Dose varies, typically standardized to 240 mg salicin/day
Essential oils	Marine animal fat and vegetable oils: various sources: fish oils, GLA, borage and flax seed oil, etc.	1–3 g/day starting dose
Phytodolor	*Populus tremula, Fraxinus excelsior, Solidago virguarea* standardized to 1 mg salicin/ml, 0.07 mg/ml flavanoids, and 0.14 mg/ml isofraxidine	30 drops (ml) of standardized extract, three times daily
Devil's claw	*Harpa gophytum procumbens*	50–100 mg harpagosides/iridoid content of 1.5–3%
Stinging nettle	*Utica dioica*	Varies based on formulation
Ginger	*Zingiber officinale*	Typical 500–1,500 mg/day
Joint Health		
Glucosamine	Marine exoskeletons	1,500 mg/day
Chondroitin	Bovine cartilage	1,200 mg/day
SAMe	Methionine by-product	200–600 mg/day with titration to 1,600 mg/day
Avocado–soybean unsaponifiables (ASU)	Vegetable oil derivative	300–600 mg/day
Headache		
Feverfew[+]	*Tanacetum parthenium*	50–100 mg/day
Magnesium[+]	Magnesium salts	300 mg/day or higher
Riboflavin[+]	Vitamin B_2	400 mg/day
Butterbur*	*Petasites hybridus*	100 mg/day 2–10 mg/day
Capsicum	*Capsicum* spp.	Intranasal spray
Coenzyme Q-10	Proprietary fermentation process with beets, sugar cane, and yeast	150–300 mg/day

[+] Available as Migralief, a proprietary combination of feverfew, magnesium, and riboflavin.

* Available as Petadolax, a proprietary butterbur product.

the clinical efficacy of WWB as described below cannot be explained by its salicin content alone and may be attributed to WWB's other active ingredients including glycosides, phenolic glucosides, flavanoids, polyphenols, procyanidins, and tannins. *In vitro*, WWB has demonstrated cyclooxygenase-2 (COX-2), prostaglandin E_2 (PGE-2), and leukotriene (LT) inhibitory activity. The inflammatory cascade is pictured in Figure 55.1 to illustrate how WWB and other supplements mentioned below can block or shift inflammatory mediators. Another departure from aspirin comes in the GI tolerability and platelet activity of WWB. One of the main constituents of WWB, salicin, is relatively inactive until traveling past the stomach and appears to have minimal GI ulceration and platelet deactivation potential. Although GI and bleeding potential warnings typically used with aspirin are paralleled for WWB, these may

become less pertinent as more research draws definitive distinction between these two compounds.

Clinically, WWB has been tested for efficacy in several conditions including low back pain and arthritis. A randomized, double-blind, placebo-controlled (RDBPC) study of 78 patients with hip or knee osteoarthritis treated with placebo or WWB containing 240 mg of salicin over a 2-week period demonstrated a statistically significant improvement in WOMAC (Western Ontario and McMaster Universities Osteoarthritis Index) pain scores in the WWB group (Schmid et al., 1998). Similar results were exhibited in a smaller randomized, double-blind, placebo-controlled trial (RDBPCT) of 21 subjects taking WWB containing 240 mg of salicin over a 2-week period for knee and hip osteoarthritis. Results of the study demonstrated a decrease in WOMAC scores of 40% in the WWB group vs. 18% in the placebo group (Schaffner, 1997).

TABLE 55.6
Listing of Dietary Supplements Utilized for Pain Management

Herbal Supplements

Ashwaganda (*Withania somnifera*)
Ash bark (*Fraxinus spp.*)
Barberry (*Berberis vulgaris*)
Birch bark (*Betula alba*)
Boswellia (*Boswellia serrata*)
California poppy (*Eschscholzia californica*)
Cat's claw (*Uncaria tomentosa*)
Holy basil (*Ocimum sanctum*)
Garlic (*Allium sativum*)
Jamaica dogwood (*Piscidia piscipula*)
Motherwort (*Leonurus cardiaca*)
Passion flower (*Passiflora incarnata*)
Poplar (aspen) bark (*Populus tremula*)
Rue (*Ruta graveolens*)
Skullcap (*Scutellaria laterfilora*)
St. John's wort (*Hypericum perforatum*)
Tea (*Camellia sinensis*)
Thunder god vine (*Tripterygium wilfordii*)
Turmeric (*Curcuma longa*)
Wild lettuce (*Lactuca virosa*)

Nonherbal Supplements

5-HTP
Adenosine
Boron
Calcium
Dietary enzymes
L-Arginine
L-Tryptophan
Manganese
Methylsulfonylmethane

Topical Agents Including Essential or Volatile Oils

Aloe (*Aloe* spp.)
Arnica (*Arnica montana*)
Calendula (*Calendula officinalis*)
Camphor (*Cinnamomum camphora*)
Capsicum (*Capsicum* spp.)
Lemongrass (*Cymbopogon citrates*)
Peppermint (*Mentha piperita*)
Spearmint (*Mentha spicata*)
Wintergreen (*Gaultheria procumbens*)

WWB appears to be a therapeutic option as well as demonstrating a dose–response range in the difficult scenario of acute exacerbation of low back pain. In one study, 119 subjects with acute exacerbation of low back pain were randomized to WWB standardized to 120 or 240 mg of salicin vs. placebo over 4 weeks. The study demonstrated complete relief of pain in 39% in the high-dose WWB group, 21% in the low-dose WWB group, and 6% in the placebo group ($P < 0.001$). Of note, the pain relief in the high-dose group was not immediate, but typically occurred

Membrane Phospholipids

Phospholipases

Arachadonic Acid

5-lipoxygenase   Cyclooxygenase

Leukotrienes (LT)   **Prostaglandin H2 (PGH2)**

Prostaglandins (PG)   **Thromboxanes (Tx)**

within 1 week of initiating treatment. Additionally, one patient suffered an allergic reaction attributed to WWB (Chrubasik et al., 2000). In addition to dose responsivity, WWB is one of the few natural products with comparative data against a prescription analgesic (see also devil's claw and SAMe). A randomized, open-label study of standardized WWB (Assalix) containing 240 mg salicin versus 12.5 mg of rofecoxib (Vioxx®) in 228 patients with acute exacerbation of low back pain was carried out for 4 weeks. When compared by visual analogue scale (VAS), Total Pain Index, and need for additional medication, no significant difference in efficacy was noted between groups. Additionally, treatment with WWB was noted to be approximately 40% less expensive than that with rofecoxib (Chrubasik et al., 2001).

The safety profile of WWB appears to demonstrate better GI tolerability and decreased platelet interaction than typically seen with NSAIDs. However, because of its salicylate content, WWB has been implicated in rare allergic reactions, including as a probable source of anaphylaxis in a patient with a history of aspirin allergy (Boullata et al., 2003). Patients should continue to be asked about their medications and allergies, as well as GI and bleeding disorders and receive appropriate counsel regarding the risks and benefits of WWB use. Currently, WWB, standardized to 240 mg of salicin, appears to be a relatively safe, effective, and cost-effective option, especially in the setting of acute exacerbation of low back pain.

Essential Oils

The use of essential oils for the treatment of pain is a broad and difficult-to-summarize topic. The variation in research results stems from factors including the source (e.g., fish oil, borage oil, evening primrose oil). the constituent concentration (i.e., eicosapentaenoic acid or EPA, docosahexaenoic acid or DHA), as well as background dietary pro- and anti-inflammatory intake, which can

strongly influence results. In general, polyunsaturated fats are sources for both omega-3 fatty acids and omega-6 fatty acids with the latter producing gamma linoleic acid (GLA) as a by-product. Omega-3s have *in vitro* anti-inflammatory effects, shifting both the cyclo- and lipo-oxygenase pathways by decreasing PGE-1 and PGE-2, increasing PG-3 with eventual decease in proinflammatory markers including interleukins (IL-1, IL-6) and tumor necrosis factor-alpha (TNFα). GLA appears to have anti-inflammatory effects through inhibition of leukotriene B 5 and 12 with subsequent decrease of PGE-2 and prostaglandin I (MacLean et al., 2004). See Figure 55.1 for further details of the inflammatory cascade.

Several trials have attempted to ascertain the dietary and supplement intake necessary for clinical efficacy. In one, 51 patients with rheumatoid arthritis were randomized to 3.6 mg of omega-3 fish oils versus capsules containing standard dietary fats. After 12 weeks, those on fish oil were noted to have small but significant improvement in morning stiffness, joint tenderness, and C-reactive protein values while not showing any benefit in other category measures. There were also no serious side effects noted versus the placebo group (Faarvang et al., 1994). A previous multicenter study utilizing the same protocol found similar findings in morning stiffness and joint tenderness (Nielsen et al., 1992). Similar modest, but clinically significant improvements were demonstrated in a DBPCT of 56 patients with rheumatoid arthritis with use of 2.8 g/day of GLA (Zurier et al., 1996). A recent survey of the literature concluded that in patients with rheumatoid arthritis, doses of 2 to 8 g of GLA/day are required for 12 weeks in order to exhibit an anti-inflammatory effect that compared to therapy with NSAIDs.

The effect of background diet on the potential benefit of essential oil supplementation was shown to be additive to an anti-inflammatory diet. In one study, 68 patients with rheumatoid arthritis were randomized for 3 months with a 2-month washout to a typical Western diet (WD) or an anti-inflammatory diet (AID) in which arachidonic acid intake was less than 90 mg/day. Patients in both groups were additionally randomized to receive placebo or fish oil supplements at 30 mg/kg. With placebo supplementation, the AID decreased swollen joints by 14% as compared with WD. With addition of fish oil, a significant difference in tender (28% vs. 11%) and swollen (34% vs. 22%) joints was noted ($P < 0.01$). Serological studies also demonstrated that the AID, especially with the combination of fish oils, has significant decreases in LT B(4), 11-dehydro-thromboxane B(2), and PG metabolites. The authors concluded that an anti-inflammatory diet improves symptoms of rheumatoid arthritis and can augment the beneficial effects of fish oil supplements Adam et al., 2003).

Essential oils have also been studied in nonrheumatologic pain conditions, including sickle cell disease, with benefit possibly secondary to modulation of vascular inflammation. One study examined the ability of dietary n-3FA (omega-3 fatty acid) to alter pain episodes in 10 patients with sickle cell disease. Over the course of a year, n-3FA decreased yearly hospital pain episodes from 7.8 to 3.8 ($p < 0.01$) with no significant change noted in the placebo group. n-3FA dietary modification was also associated with decrease in serum markers of thrombosis including D-dimer and plasmin-antiplasmin complex (Tomer et al., 2001).

Although essential fatty acids have clearly documented positive changes in *in vitro* and *in vivo* markers controlling inflammation, there are a number of important notes regarding its use. First, not all clinical trials have demonstrated benefits. There have been a number of nonsignificant trials with use of essential fatty acid including the use of alpha-linoleic acid from flax seeds as a precursor of EPA and DHA to treat rheumatoid arthritis (Nordstrom et al., 1995). Side effects with use of essential oils are typically dose dependent and include GI symptoms of belching, bloating, increased peristalsis, and diarrhea. The potential for symptoms or drug-sparing benefit appears to be strongly related to the type and dose of the treatment as well as the disease state and background diet of those studied. At this point the strongest evidence appears in the literature for those consuming a 2 g or greater amount of GLA or fish oil supplement while limiting their proinflammatory intake of arachadonic acid (<90 mg/day) or (n-6) fatty acid intake (<10 g/day) (Volker et al., 2000). The latter dietary factor deserves greater attention when developing future trials or when considering recommendation of essential fatty acids in practice.

Phytodolor

Phytodolor is a patented supplement from Germany that contains *Populus tremula, Fraxinus excelsior, Solidago virguarea* standardized to 1 mg salicin/ml, 0.07 mg/ml flavanoids, and 0.14 mg/ml isofraxidine. The active constituents are diverse and including the previously discussed anti-inflammatory actions of salicin (as discussed under WWB), as well as other potential activity including the antispasmodic actions of *Solidago* (von Kruedener et al., 1995). A number of trials have examined Phytodolor in various conditions including osteoarthritis, rheumatoid arthritis, low back pain, and epicondylitis. The studies include a randomized controlled trial (RCT) of 108 inpatients with rheumatic pain randomized to 30 drops three times a day of Phytodolor, placebo, or piroxicam 20 mg/day for up to 4 weeks. There were significant benefits in reducing pain at 2 and 4 weeks for both active groups over placebo without significant differences noted between active groups. Additionally, a DBPCT of 40 subjects with mixed rheumatologic diagnosis already on medication management demonstrated a significant reduction in conventional medication dosing required at 3 weeks

when using 30 drops of Phytodolor three times daily. At least four other small trials demonstrate Phytodolor's efficacy in reducing pain or medication requirement with no serious side effects noted (Ernst & Chrubasik, 2000).

Ginger (*Zingiber officinale*)

Ginger (*Zingiber officinale*) has been used for longer than 2,500 years in traditional Chinese, Ayurvedic (Indian), and Tibetan medicine for rheumatological, GI, and oncological conditions. More recently, a number of active ingredients have been isolated from the ginger plant. These include the gingeroles, which exert direct anti-inflammatory activity, as well as galanolactones that have serotonin receptor activity and likely modulate GI actions as well as indirectly affect pain inhibitory activities. Additionally, animal studies have demonstrated that some ginger subspecies have documented COX-2 and PGE-2 inhibitory activities (Garcia-Rodriguez et al., 2004; Hernandez-Diaz & Rodriguez, 2000; Murakami, 1992; Thomson, 2002).

In clinical pain trials, ginger has been utilized mostly for osteoarthritis of the knee. In a 6-week RDBPCT of 261 subjects with knee osteoarthritis, a specialized ginger species containing *Z. officinale* and *Alpinia glanga* (EV.EXT 77) was evaluated in an intent-to-treat analysis. There was moderate improvement noted in knee pain on standing ($P = 0.048$) and pain on walking ($P = 0.016$). There were mild GI side effects in the ginger group that were statistically greater than in the control group (Altman et al., 2001). In a more recent small trial, an extract of *Zingiberis Rhizoma* (Zintona EC) was tested versus placebo in 29 patients with knee osteoarthritis. Patients were randomized to 1,000 mg/day or to placebo with crossover taking place at 3 months. The results demonstrated significant improvement over placebo starting only at the 6-month mark (Wigler et al., 2003). At this point, ginger is known to have a number of pain modulatory constituents with future research requiring a focus on the type of ginger used, dosage titration, proper blinding, and long-term treatment in order to measure clinical significance.

Devil's Claw (*Harpagophytum procumbens*)

Devil's claw is a traditional South African plant used for arthritis and myalgia, and as an external ointment for burns and sores. Its efficacy has been attributed to a number of active ingredients, most notably harpagosides, which have demonstrated *in vitro* activity against the lipo- and cyclooxygenase-mediated inflammatory pathways as well as inhibiting PGE-2 and TNFα synthesis (Fiebich et al., 2001; Jang et al., 2003; Loew et al., 2001). Clinically it has been used most commonly in the setting of osteoarthritis and low back pain. Four RCTs (two examining osteoarthritis, two low back pain) with 50 to 197 treated with 50 to 100 mg harpagosides for up to 8 weeks demonstrated a positive trend (statistically significant in three of four trials) for pain reduction and/or joint mobility with mild and infrequent GI symptoms reported in the active group (Nielsen et al., 1992).

Devil's claw, similar to WWB, has been tested against rofecoxib (Vioxx) for treatment of acute exacerbations of low back pain. In an RDBPCT, 88 patients were randomized to a standardized devil's claw extract (Doloteffin) containing 60 mg of harpagoside daily or 12.5 mg/day of rofecoxib for 6 weeks. Clinical response was measured with the Arhus Index, with the mean pain component decreasing by 23 in devil's claw and 26 in the NSAID group. Additionally, 18 devil's claw and 12 rofecoxib subjects had greater than 50% reduction in weekly averages of their pain scores between the start and end of the trial. Side-effect profiles were similar, although rofecoxib had more dropouts secondary to GI symptoms. Overall, there were no significant differences between groups with the authors noting that larger trials are required before definitive efficacy and safety differentiations can be made Chrubasik et al., 2003).

Stinging Nettle (*Utica dioica*)

Stinging nettle, whose active ingredients include caffeic malic acid and caffeoylmalic acid, has been shown, mostly *in vitro*, to alter numerous aspects of the inflammatory cascade including IL-1B, IL-2, interferon-gamma, NF-κB, lipopolysaccharide-induced release of the cytokine TNFα, and cyclo- and lipooxygenase by-products (Klinghoefer et al., 1999; Riehemann et al., 1999). Clinically, stinging nettle containing 20 mg of caffeoylmalic acid was administered for 2 weeks in a controlled trial to 26 patients with acute arthritis. The subjects were also on a subtherapeutic dose of diclofenac at 50 mg (therapeutic dosing is typically 150 mg/day). The combination of 50 mg diclofenac and stinging nettle was comparable in pain relief with 200 mg of diclofenac administered to 19 control patients (Chrubasik et al., 1997). Adverse effects were minor in this stinging nettle group.

Bromelain Extract (*Ananus comosus*)

Bromelain is an extract of the pineapple plant containing a number of enzymatic complexes including glycoproteins, glucosidases, peroxidases, and phosphates. Bromelains *in vitro* activity centers on decreases in kinnins and bradykinnins, as well as more traditional decreases in PGE-2 and thromboxane B2. In an RDBPCT of 73 patients with osteoarthritis of the knee, a mixture of bromelain, trypsin, and rutin was compared with diclofenac. The trials demonstrated similar improvement in pain and joint mobility (Klein et al., 2000).

Natural Supplement for Joint Pain

Glucosamine and Chondroitin

Glucosamine and chondroitin are discussed here jointly because of their general similarity in structural joint function as well as their combination use in commonly used preparations. Both ingredients have been implicated in reducing the progressive degradation of articular cartilage as well as helping to stimulate proteoglycan synthesis in *in vitro* trials (Bassleer et al., 1998; Uelbelhart et al., 1998). In clinical trials, glucosamine and chondroitin have been evaluated for their ability to improve pain and functional ability, typically of the knee and hip. Additionally, isolated glucosamine has some data demonstrating joint space narrowing. The Cochrane Review of glucosamine summarizes that 15 of 16 trials versus placebo were positive, and in 4 trials vs. an NSAID, 2 were equivalent and 2 demonstrated superiority over medication in long-term pain relief (Towheed et al., 2001). Two additional meta-analyses, one by McAlindon et al. and more recently Richy et al. have examined glucosamine and chondroitin in the treatment of osteoarthritis. These trials examined approximately 15 RDBPC trials with greater than 1,500 patients. The later analysis found that glucosamine at 1,500 mg/day was associated with decrease in progression of joint space narrowing. Additionally, glucosamine at this dose, as well as chondroitin at varying doses (200 to 1,200 mg/day), was associated with statistically significant pain relief and improvement in joint mobility at 4 weeks. The number needed to treat (NNT) was 5 with no significant adverse effects as compared with placebo (McAlindon et al., 2000; Richy et al., 2003).

Several important clinical notes exist regarding these formulations. First, the Cochrane Review points out in its conclusions that the majority of studies were performed on the Dona Glucosamine brand and that results may be difficult to extrapolate to other brands (Towheed et al., 2001). Additionally, studies have demonstrated wide variations in glucosamine formulations. Last, the Richy et al. (2003) meta-analysis deemed the chondroitin trials to be of overall low quality with the combination of the two products not being evaluated. Products with glucosamine and chondroitin typically state that the two combined work better than either alone. Unfortunately, this has not yet been established nor has the question of who may benefit more from one therapy over the other. In clinical practice, when combination therapy does not have a clear advantage, it is prudent to start with a single ingredient to assess clinical response before changing or adding therapy. The results of the ongoing National Institutes of Health Glucosamine/Chondroitin Arthritis Intervention Trial (2004) should be helpful in determining the answers to important questions regarding combination dosing.

SAMe

S-Adenosyl methionine is a sulfur-containing dietary supplement synthesized from reactions between adenosine triphosphate (ATP) and methionine and promoted for treatment of a number of conditions including depression, liver, and joint disease. Its role in these conditions is derived from possible intrinsic anti-inflammatory, serotonergic, and proteoglycan stimulatory mechanisms (Harmand et al., 1987; Parcell, 2002; Stramentinoli et al., 1987). A number of earlier clinical trials demonstrated the treatment potential of SAMe in open trials. A recent meta-analysis of RCTs found 11 trials demonstrating improvement in functional ability and pain levels when compared with placebo or NSAIDs (Soeken et al., 2002). Also there were significantly fewer complaints of side effects when compared with NSAID therapy and similar complaints to placebo.

A more recent RDBPCT compared SAMe (1,200 mg) with celecoxib (200 mg) in 61 subjects with knee osterarthritis over 16 weeks (Najm et al., 2004). After 1 month of intervention, celecoxib demonstrated greater pain reduction over SAMe ($p = 0.024$). However, from the second month onward, there was no significant difference between groups, with both interventions demonstrating improvement in pain scores and functional joint ability. The authors concluded that SAMe had a slower onset of action but similar efficacy as celecoxib. Those considering SAMe should be monitored for concomitant use of serotonergic medication because of synergistic potential. One significant drawback to this supplement is its current cost that makes it one of the more expensive supplements on the market. Typical initial dosing is 600 mg/day usually divided into three daily doses with titration up to 1,200 mg/day. Doses up to 1,600 mg/day have been used in selected settings with monitoring.

Avocado–Soybean Unsaponifiables (ASU)

Although not yet readily available in the United States, this combination product does deserve mention because of it promising results in osterarthritis. The unsaponifiable portion of vegetables oils has been regarded for its potential bioactivity due to its sterol, tocopherol, and squalene levels (Rosenblat et al., 1995). A specific mixture derived from the unsaponifiables of avocado and soybean, typically in a ratio of 2:1, has been examined since the 1970s for use in several conditions including scleroderma and periodontal and degenerative diseases (Reginster et al., 2000). Recent *in vitro* chrondrocyte research has demonstrated the ability of ASU to decrease several key agents implicated in joint degradation and inflammation including IL-1-beta-induced collagenase release, stromelysin, IL-6 and IL-8, and PGE-2 (Henrotin et al., 2003). In addition, there is *in vitro* evidence regarding its supportive role in maintaining the joint matrix including upregulation

of transforming growth factor-beta and aggrecan synthesis (Boumediene et al., 1999; Reginster et al., 2000.)

Clinically, ASUs have been utilized mainly in the symptomatic treatment of knee and hip osterarthritis. In one multicenter RCT, 300 or 600 mg/day of ASU was compared with placebo in patients with knee osterarthritis. At 3 months the number of patients decreasing NSAID or analgesic intake by more than 50% in the either ASU dosage group was 71% versus 36% in the placebo group. There were also clinical improvements noted ($P < 0.01$) in a number of parameters included Lequesne's index, which decreased by 3.2 and 2.9 points (with the 600 and 300 mg dosing, respectively) versus 1.6 points in the placebo group (Appelbloom et al., 2001). A second trial demonstrated treatment benefit up to 8 months, including a 2-month follow-up while not on the supplement (Maheu et al., 1998).

A more recent systematic review of RCTs meeting high methodological criteria found that three of four trials demonstrated efficacy with use of ASUs (Ernst, 2003). The negative trial was one with the longest length of follow-up. Joint space narrowing has also been discussed with use of ASUs, but only seen in research populations with the worst levels of joint deterioration. Of note, there were no significant differences between 300 and 600 mg dosage efficacy, and side effects have been shown to be similar to placebo and typically GI in nature. At this point the use of ASUs is promising with long-term efficacy trials needed to confirm their clinical and potential structural benefit in practice.

NATURAL SUPPLEMENTS FOR HEADACHE

Feverfew (*Tanacetum parthenium*)

Feverfew is a member of the chrysanthemum family originally recognized by first century A.D. Greek physicians for its analgesic and antipyretic properties. It was typically used in a number of clinical scenarios including treatment of fever and dysmenorrhea. Feverfew has exhibited a number of active constituents including the sesquiterpene lactone parthenolide (typically used for standardization), tanetin, and many other bioflavanoids. Unfortunately, previous examination of feverfew samples has identified certain products that in contrast to label claims, contained little or no actual parthenolide, thus emphasizing the importance of finding well-regulated supplements (Nelson, Cobb, & Shelton, 2002). Feverfew has also demonstrated a number of activities related to inflammation and headache activation including inhibition of PG synthetase, 5-lipoxygenase, cyclooxygenase, platelet phospholipase, and serotonin secretion in platelets (Heptinstall et al, 1985; Makheja & Bailey, 1982; Pugh & Sambo, 1988; Sumner et al., 1992).

Clinically, four DBPCTs have been performed with three trials demonstrating a reduction in the severity, duration, and frequency (of approximately 24%) of migraine headaches using a dried powder preparation. The fourth

trial using an alcohol extract had nonsignificant results (De Weerdt, Bootsma, & Hendriks, 1996; Johnson et al., 1985; Murphy, Heptinstall, & Mitchell, 1988; Palevitch, Earon, & Carasso, 1997). A meta-analysis of these trials states that further long-term trials with focus on the type of preparation utilized are needed to better establish feverfew's efficacy (Pittler, Vogler, & Ernst, 2000). Feverfew extracts utilized should be standardized to a minimum of 0.2% parthenolide content and those using the herb should be told that 1 to 2 months of use may be needed before any appreciable improvement is noted. Allergies are rarely reported in subjects with sensitivity to the chrysanthemum family. Side effects are also rare and typically reported as GI upset or withdrawal headache with rapid discontinuation. Because of feverfew's platelet inhibitory activity, caution should be taken in patients on other blood thinners or with history of platelet dysfunction.

Magnesium

Magnesium (Mg) is a ubiquitous mineral necessary for >300 enzymatic reactions including nerve conduction, skeletal and cardiac muscle contraction, protein synthesis, and energy reactions involving ATP. Magnesium is also involved in functions that may be especially influential on headaches including platelet aggregation, vasospasm, and calcium channel antagonism. Subjects with poor neurovascular tone demonstrate low cerebrospinal fluid Mg levels, and low Mg with high calcium/Mg ratios also appear to modulate cerebral serotonin receptors (Altura, 1985; Ramadan et al., 1989).

Clinical studies on magnesium demonstrate that intravenous Mg has a variable effect on acute treatment of migraine that may depend on magnesium levels. In one trial using intravenous Mg, 85% of responders had low ionized Mg levels <0.54 mmol/L with 85% of nonresponders having normal ionized Mg levels with no correlation noted with levels of serum Mg. Studies of oral Mg as a prophylactic agent have noted two short-term positive DBPCTs in adults with an approximate 25% decrease in headache frequency and one DBPCT in children demonstrating improvement in headache frequency ($P = 0.0037$) and severity ($P = 0.0029$) relative to the placebo group (Faccinetti et al., 1991; Peikert, Wilimzig, & Kohne-Volland, 1996; Wang et al., 2003). A negative study involving Mg aspartate was discontinued early secondary to drop out mainly from GI symptoms (Pfaffenrath et al., 1996). The dosage and Mg formulation may be critical in potential benefit and tolerability of Mg. Various formulations, including those that are chelated, in addition to consideration of intracellular testing to monitor titration, may be needed to improve compliance and subgroup efficacy variations. The typical dose used for prophylaxis is Mg at 300 mg/day or higher with dose titration based on GI tolerance.

Riboflavin (Vitamin B$_2$)

Riboflavin is an important vitamin in its actions as a precursor of flavin adenine dinucleotide and flavin mononucleotide. Dysfunction of these coenzymes has been linked to electron transport chain abnormalities and poor cerebrovascular tone, both of which have a potential role in migraine pathogenesis (Welch & Ramadan, 1995). An intention-to-treat analysis of 55 patients using 400 mg/day over 3 months demonstrated decreased headache days by 59% versus 15% for placebo. In this study the NNT to reach significance was 2.3. As with other supplements, an extended use of supplement for several months was necessary before clinical improvement was noted. Side effects are rare and typically GI in nature.

Of note, a patented formulation of feverfew (50 mg), Mg (300 mg), and riboflavin (400 mg) is available under the brand name Migralief. This formulation is currently undergoing an RDBPCT to demonstrate clinical efficacy beyond that seen with the isolated ingredients.

Butterbur (*Petasites hybridus*)

Butterbur is an herbal supplement with a history of benefits in a number of conditions including asthma, hypertension, and migraine. The active ingredients include the sesquiterpene petasines, which have demonstrated activity including LT inhibition and calcium channel antagonism. Clinically, butterbur is available most commonly as Petadolax®, which is an unsaturated pyrrolizidine alkaloids-free formulation standardized to 7.5 mg of the constituents petasin and isopetasin. One trial of Petadolax randomized 60 patients to 100 mg/day or placebo. Results at 3 months demonstrated a significant improvement in headache frequency and headache responder rate (improvement of migraine frequency ≥ 50%) of 45% versus 15% in the placebo group (Diener, Rahlfs, & Danesch, 2004). A more recent three-arm, parallel group, randomized trial compared 50 and 75 mg of Petadolax (p = 0.0012 vs. placebo), 36% at 50 mg bid (p = 0.127 vs. placebo), and 26% with the placebo. Side effects were minimal and included GI upset.

Butterbur's safety has been demonstrated in animal and human trials with the most likely adverse effect seen at a typical daily dosage of 100 mg/day, GI intolerance, occurring rarely (Danesch & Rittinghausen, 2003). There has been some concern regarding pyrrolizidine alkaloid levels in some butterbur preparations, which have been linked to rare cases of cholestatic hepatitis with incidence by one estimate of 1:175,000 (Kalin, 2003). Newer methods for extraction make this possibility less likely, with monitoring still prudent in patients on long-term therapy.

Other Supplements for Headache (Melatonin, Capsicum, and Coenzyme Q10)

A number of additional supplements have preliminary data for the treatment of headache. Melatonin has dem-onstrated variable results in treatment of cluster headache in several small trials. The trend may have to do with circadian influences as well as dosing, with the nonsignificant trial dosing at 2 mg/day and the two positive trials utilizing 9 to 10 mg/day (May & Leone, 2003). Topical intranasal capsicum has one RCT demonstrating efficacy in cluster headaches (Marks et al., 1993). An open-label trial of coenzyme Q10 at 150 mg/daily in 32 patients with migraine demonstrated a reduction in migraine frequency of 13% at 1 month and 53% at 3 months (Rozen et al., 2002). A more recent randomized controlled trial evaluated CoQ10 taken 100 mg TID versus placebo in 42 migraine patients. In the third treatment month, CoQ10's 50% responder rate for attack frequency was 47.6% versus 14.4% for placebo. This response demonstrates a low number-needed-to-treat of 3. Additionally, CoQ10 was well tolerated and demonstrated superiority versus placebo for headache-days and days-with-nausea by the third treatment month. The potential benefit of CoQ10, once confirmed in further studies, may be attributed to regulation of the electron transport chain, similar in many respects to the actions of riboflavin.

MISCELLANEOUS SUPPLEMENTS IN PAIN MANAGEMENT

A number of supplements, including several of those reviewed above, have been used in additional pain-related clinical trials. Minerals with preliminary benefits include intravenous Mg for short-term relief of cancer-associated neuropathic and posthysterectomy pain and oral calcium at 1,200 mg/day for premenstrual syndrome-associated pain (Crosby, Wilcock, & Corcoran, 2000).

Topical agents such as camphor and capsicum are found in OTC approved preparations for temporary pain relief, with positive results, especially for the latter in rheumatoid arthritis, osterarthritis, and diabetic- or shingles-associated neuropathy. Ginkgo biloba and L-arginine have also been associated with a decrease in vascularly mediated pain in claudication and angina pectoris, respectively (Blum et al., 1999; Pittler & Ernst, 2000).

CONCLUSIONS

Although the type and avenue for purchase of dietary supplements will change over time, they will continue to be an increasingly present aspect of patient care. This phenomenon appears even more prevalent for pain practitioners whose patients often turn to dietary supplement as a treatment option. The first section of this chapter served as a primer offering key points regarding the regulation, utilization, and management of dietary supplements in the United States. With dietary supplement use expanding, it is imperative for clinicians to be aware of key regulatory distinctions as well as to be able to discuss them openly with patients.

The second section reviewed commonly used supplements that have been evaluated in preclinical and clinical trials in order to demonstrate their safety and efficacy. Several of these supplements have pain modulatory properties that should prompt careful considerations regarding their incorporation in patient care. Additionally, the review provides many areas of opportunity for research to explore and expand what is known regarding supplements. Ultimately, the field of natural supplements is dynamic and requires increased patient–clinician discussion and collaboration in order to best guide care. The following key points are offered regarding natural supplements in pain management:

- Discussion is key. Pain patients have a high rate of supplement use, which influences their conventional care and deserves education and guidance.
- Patients are mostly using supplements in conjunction with conventional care. In this setting clinicians should be cognizant of the potential drug-sparing effects of supplements.
- The background diet of patients may influence the efficacy of certain supplements. This needs to be discussed to optimize the potential benefit of supplements.
- All supplements are not created or researched equally. Regulation is variable and vigilance is needed by clinicians and patients to find the best-researched and regulated supplements.
- Supplements, especially botanical products, have diverse bioactivity that cannot typically be explained by one isolated constituent. This may be beneficial in treating multiple conditions (e.g., magnesium: headache and hypertension; butterbur: headache and allergic rhinitis) or problematic, especially when other medication are involved (St. John's Wort and indinivar).
- Supplements may often have a slower onset of action than conventional prescription agents. Warn patients to expect this so that expectations are reasonable and compliance is optimized.
- Supplements often combat more than inflammatory mediated pain. In addition to inflammation, vascular, thrombotic, neurogenic, psychogenic, hormonal, and environmental factors my cause or contribute to pain. Supplements may influence one or more of these factors through their individual or synergistic mechanisms of action.

The Role of Cannabis and Cannabinoids in Pain Management

Ethan Russo, MD

INTRODUCTION

The herb cannabis is derived from the Old World species *Cannabis sativa* L. It is generally conceived that cannabis is a monotypic species (Merzouki, 2001), but *C. afghanica* may also merit species status (Clarke, 1998). Cannabis has a history as an analgesic agent that spans at least 4,000 years, including a century of usage in mainstream Western medicine. Quality control issues and, ultimately, political fiat eliminated this agent from the modern pharmacopoeia, but it is now resurgent. The reasons lie in the remarkable pharmacological properties of the herb, and new scientific research that reveals the inextricable link that cannabinoids possess with our own internal biochemistry. In essence, the cannabinoids form a system in parallel with that of the endogenous opioids (endorphins/enkephalins) in modulating pain. More importantly, cannabis, and its endogenous and synthetic counterparts, may be uniquely effective in pain syndromes such as neuropathic pain and migraine where opiates and other analgesics fail.

Despite hundreds of supportive journal articles over the last 15 years, the news about cannabis and cannabinoids has only slowly filtered into public and even professional acknowledgment. The attendant politics remain contentious, with certain states and countries acknowledging a role for cannabis in medicine, while other governmental bodies languish in inactivity or outright opposition.

Before the previous edition of this book (E. B. Russo, 2002a), no major medical text on pain had covered this topic to the author's awareness. This chapter may then represent a point of departure in what the author believes will be a major renaissance of interest in this plant, its healing attributes, and what it may tell us about our own internal mechanisms of analgesia. A unique set of clinical tools may be added to an armamentarium in pain management that never seems wholly adequate to the task at hand.

We examine the use of cannabis and cannabinoids historically, scientifically, and anecdotally in relation to a variety of pain syndromes. The author has previously addressed this topic with respect to migraine (E. Russo, 1998; E. B. Russo, 2001a, 2001b), chronic musculoskeletal pain (E. B. Russo et al., 2002a), obstetrics and gynecology (E. Russo, 2002b), and fibromyalgia and idiopathic bowel syndrome (E. B. Russo, 2004a). Additional history of medicinal cannabis usage is also available (E. B. Russo, 2001, 2004b).

CANNABIS AND PAIN TREATMENT: A HISTORICAL SURVEY

CHINA

Traditional knowledge of cannabis in China may span 5,000 years, dating to the legendary emperor and "Divine Plowman," Shên-Nung. Julien (1849) wrote of the physician Hoa-tho in the early second century and his use of a cannabis extract in surgical anesthesia (p. 197):

> He gave to the sick person a preparation of hemp (Ma-yo), and, in a few moments, he became so insensible that it were as if he was plunged into rapture of loss of

life. Then, following this instance, he practiced some overtures, incisions, amputations, and removed the cause of the malady; then he repaired the tissues with suture points, and applied liniments. [translation EBR]

INDIA

The *Atharvaveda* of India dates to between 1400 and 2000 B.C.E. and mentions a sacred grass, *bhang,* which remains a modern term of usage for cannabis. Medical references to cannabis date to Susruta in the sixth to seventh centuries B.C.E. (Chopra & Chopra, 1957). Dwarakanath (1965) described a series of Ayurvedic and Arabic tradition preparations containing the herb indicated for migraine, neuralgic, and visceral pains. These ancient claims in cannabis therapeutics have almost uniformly been supported by modern experimentation (E. B. Russo, 2005).

EGYPT

Previous scholars had thought cannabis to be absent from Ancient Egypt, but Nunn (1996) cited six supporting experts that it was utilized medicinally. These authors agree with the view of Dawson that the hieroglyphic *shemshemet* represents cannabis. Physical proof includes discoveries of hemp remnants in the tomb of Akhenaten (Amenophis IV) around 1350 B.C.E., and cannabis pollen in the tomb of Rameses II, who died in 1224 B.C.E. (Mannische, 1989). Cannabis has remained in the Egyptian pharmacopoeia since pharaonic times, administered orally, rectally, vaginally, on the skin, in the eyes, and by fumigation.

Mannische cites the following from Papyrus Ramesseum III, 1700 B.C.E. (Mannische, 1989, p. 82): "A treatment for the eyes: celery; hemp; is ground and left in the dew overnight. Both eyes of the patient are to be washed with it early in the morning." This suggests a parallel to modern use of cannabis in glaucoma treatment (Jarvinen, Pate, & Laine, 2002).

Another passage (Ebers Papyrus 821) is reminiscent of 19th century use of cannabis as an aid to childbirth (Ghalioungui, 1987, p. 209): "Another: *smsm-t* [shemshemet]; ground in honey; introduced into her vagina *(iwf)*. This is a contraction." The passage E618 refers to treatment of a toenail with a bandage containing hemp resin (Ghalioungui, 1987).

SUMER/AKKAD/ASSYRIA

Thompson (1924, 1949) documented 29 citations of use of cannabis in Assyrian medical documents, and attested to its analgesic and psychogenic effects by various methods including fumigation. The bulk of the references date to the second millennium B.C.E. and pertain to *A.ZAL.LA* in Sumerian, and *azallû* in Akkadian. Through philological arguments the author concluded (Thompson, 1924, p. 101):

The evidence thus indicates a plant prescribed in AM [Assyrian manuscripts] in very small doses, used in spinning and rope-making, and at the same time a drug used to dispel depression of spirits. Obviously, it is none other than hemp, *Cannabis sativa,* L.

Specifically, according to Thompson (1949), hemp, or *azallû,* was employed to bind the temples (possibly for headache?). Furthermore, the Sumerian texts recommended internal use for depression and staying the menses, and "for 'poison' of all limbs, dry, pound, sift, and fumigate."

ANCIENT ISRAEL/PALESTINE/JUDEA

Physical evidence of medicinal cannabis use in Israel has been discovered (Zias et al., 1993) in a burial tomb in Beit Shemesh where the skeleton of a 14-year-old girl was found along with fourth century bronze coins. Contained in her pelvic area was the skeleton of a term fetus, of sufficient size to render a successful vaginal delivery unlikely. In her abdominal area, gray carbonized material was noted and analyzed, yielding chromatographic and nuclear magnetic resonance spectroscopy evidence of delta-6-tetrahydrocannabinol, a stable metabolite of cannabis. The authors stated (p. 215), "We assume that the ashes found in the tomb were cannabis, burned in a vessel and administered to the young girl as an inhalant to facilitate the birth process." They further remarked that cannabis retained an indication as an aid to parturition into the 19th century.

GREEK AND ROMAN EMPIRES

In the first century of the Common Era, Dioscorides published his *Materia Medica* and described the analgesic role of cannabis (1968, 3.165, p. 390): "Cannabis is a plant of much use in this life for ye twistings of very strong ropes, ... but being juiced when it is green is good for the pains of the ears."

Pliny described additional indications for hemp (1951, Book XX, XCVII, p. 153): "The root boiled in water eases cramped joints, gout too and similar violent pains. It is applied raw to burns."

THE ISLAMIC WORLD

In the ninth century, Sabur ibn Sahl in Persia cited use of cannabis several times in his dispensatorium, *Al-Aqrabadhin Al-Saghir* (Kahl, 1994). According to the translation and interpretation of the text by Dr. Indalecio Lozano (personal communication, 2000), ibn Sahl prescribed a compound medicine containing cannabis juice that was used to treat a variety of aching pains and migraine that was instilled into the nostril of the afflicted patient.

Also in the 12th century, Al-Biruni noted (Biruni, Said, & Hamdard National Foundation-Saydanah, 1973, p. 346): "Galen says: 'The leaves of this plant [cannabis] cure flatus — Some people squeeze the fresh (seeds) for use in ear-aches. I believe that it is used in chronic pains.'"

Umar ibn Yusuf ibn Rasul also suggested cannabis for ear and head pains (Lewis, Menage, Pellat, & Schacht, 1971) at the end of the 13th century.

Some time later, an electuary named *bars,* or *barsh,* containing a variety of ingredients, sometimes including cannabis, became popular as an analgesic treatment in the Arab world (Lozano Camara & Arabe, 1990).

At the close of the 17th century in Indonesia, Rumphius studied cannabis use (Rumpf & Beekman, 1981) including treatment of pleuritic chest pains and hernias.

WESTERN MEDICINE

Medicinal use of cannabis also evolved from early times involving hemp strains that in all likelihood contained cannabidiol (CBD), but no Δ^9-tetrahydrocannabinol (THC), unlike the cannabis strains of the East. An early citation derives from the ninth century in the *Old English Herbarium Manuscript V,* translated from Anglo-Saxon (Pollington, 2000, p. 301): "For pain of the innards take the same plant [hemp], give it to drink, it takes away the pain." Such uses persisted in England, as Gerard continued to recommend hemp for colic in 1597 (Gerard & Johnson, 1975). Similarly, in 1640 in the *Theatrum Botanicum, The Theater of Plantes* (Parkinson, Bonham, & L'Obel, 1640), Parkinson indicated (p. 598):

Hempe is cold and dry … the *Dutch* as one saith doe make an Emulsion out of the seede, … for it openeth the obstructions of the gall, and causeth digestion of choller therein: … the Emulsion or decoction of the seede, stayeth laskes and fluxes that are continuall, easeth the paines of the collicke: and allayeth the troublesome humours in the bowels: … The decoction, of the roote is sayd to allay inflammations in the head or any other part, the herbe it selfe, or the distilled water thereof performeth the like effect; the same decoction of the rootes, easeth the paines of the goute, the hard tumours, or knots of the joynts, the paines and shrinking of the sinewes, and other the like paines of the hippes: it is good to be used, for any place that hath beene burnt by fire, if the fresh juyce be mixed with a little oyle or butter.

In 1758, Marcandier published his *Traité du chanvre* [Treatise on hemp] (Marcandier, 1758), which was translated into English several years later (Marcandier, 1764, pp. 24, 26):

The grain and the leaves being squeezed, while they are green, and applied, by way of cataplasm, to painful tumours, are reckoned to have a great power of relaxing and stupefying.… The root of it boiled in water, and

applied in the form of a cataplasm, softens and restores the joints of fingers or toes that are dried and shrunk. It is very good against the gout, and other humours that fall upon the nervous, muscular, and tendinous parts. It abates inflammations, dissolves tumours, and hard swellings upon the joints. Beat and pounded in a mortar, with butter, when it is still fresh, it is applied to burns, which it relieves greatly when it is often renewed.

Linnaeus acknowledged the pain-reducing properties of cannabis in his list of its medical applications in his *Materia Medica* (Linné, 1772, pp. 213–214), "narcotica, phantastica, dementans, anodyna, repellens."

In France, Chomel (1782) noted once more the benefits of hemp seed oil on burn treatment, promoting both pain and healing.

The medical use of cannabis*,* or what became known as "Indian hemp" was reintroduced to the West by O'Shaughnessy in 1839 (O'Shaughnessy, 1838–1840). His treatise on the subject dealt with the apparent utility of a plant extract administered to patients suffering from rabies, cholera, tetanus, and infantile convulsions, but also a series of painful rheumatological conditions.

Shortly after Indian hemp came to England, Clendinning described his results of treatment of 18 patients (1843): three with headaches, one with abdominal pain secondary to tumor, one with pain secondary to a laceration, two with rheumatic joint pain, and one with gout. In each case, the tincture of Indian hemp provided relief, even in cases of morphine withdrawal symptoms. He observed (p. 209):

I have no hesitation in affirming that in my hand its exhibition has usually, and with remarkably few substantial exceptions, been followed by manifest effects as a soporific or hypnotic in conciliating sleep; as an anodyne in lulling irritation; as an antispasmodic in checking cough and cramp; and as a nervine stimulant in removing languor and anxiety, and raising the pulse and spirits; and that these effect have been observed in both acute and chronic affections, in young and old, male and female.

In Ireland in 1845, Donovan extensively described his own extensive trials with small doses of cannabis resin, mainly in patients with various types of neuropathic and musculoskeletal pain. Effects were fairly uniformly impressive, with few side effects. He also described the benefits of local application of hemp leaf oil on hemorrhoids and neuralgic pains.

Christison (1851) endorsed benefits of cannabis in treating tetanus, augmenting labor, and treatment of neuralgic and musculoskeletal pain.

Grigor in 1852 examined the role of cannabis in facilitating childbirth. In nine cases, little was noticeable, but in seven, including five primiparous women (p. 125), "the

contractions acquire great increase of strength … it is capable of bringing the labour to a happy conclusion considerably within a half of the time that would other have been required." No ontoward effects were observed on mother or child.

Over the next decades, numerous authorities recognized cannabis as helpful for painful conditions. Sir John Russell Reynolds was eventually to become Queen Victoria's personal physician. Popular legend supports that he successfully treated her dysmenorrhea with a cannabis extract throughout her adult life. Reynolds (1868) reported on various successes with Indian hemp, theorizing (p. 160):

> This medicine appears capable of reducing over-activity of the nervous centres without interfering with any one of the functions of organic, or vegetal life. The bane of many opiates and sedatives is this, that the relief of the moment, the hour, or the day, is purchased at the expense of to-morrow's misery. In no one case to which I have administered Indian hemp, have I witnessed any such results.

In 1870, Silver reported five cases in detail of menorrhagia and dysmenorrhea, all relieved nicely with cannabis. He also referred to a colleague, who had never failed in over 100 cases to control pain and discomfort in these disorders within three doses.

In 1874, a popular textbook, *Practical Therapeutics,* stated of cannabis (Waring, 1874, p. 159): "Of a good extract, gr. 1/4 to gr. 1/2, rarely gr. j, in the form of pill, is very effective in some forms of neuralgia."

In the French literature, Michel (1880) extensively reviewed and endorsed the success of cannabis in treating neuralgic afflictions.

In 1883, two letters to the *British Medical Journal* attested to the benefits of extract of *Cannabis indica* in menorrhagia, treating both pain and bleeding successfully with a few doses (Batho, 1883; Brown, 1883).

Rennie reported from India on the therapeutic value of a cannabis tincture in curing acute and chronic dysentery and its attendant pain in some dozen patients (Rennie, 1886).

In 1887, Dr. Hobart Hare published an article that dealt at length with the indications of cannabis (pp. 225–226):

> CANNABIS INDICA has been before the profession for many years as a remedy to be used in combating almost all forms of pain, yet, owing to the variations found to exist as to its activity, it has not received the confidence which I think it now deserves.… I have found the efficient dose of a pure extract of hemp to be as powerful in relieving pain as the corresponding dose of the same preparation of opium.… During the time that this remarkable drug is relieving pain a very curious psychical condition sometimes manifests itself; namely, that the diminution of the pain seems to be due to its fading away in the distance, so that the pain becomes

less and less, just as the pain in a delicate ear would grow less and less as a beaten drum was carried farther and farther out of the range of hearing.

Soon after, Farlow penned a treatise on the use of rectal preparations of cannabis (1889, p. 508), "Cannabis has few equals in its power over nervous headaches such as women with pelvic troubles are subject to."

Aulde (1890) lauded the drug as follows (p. 526): "As a remedy for the relief of *supraorbital neuralgia* no article perhaps afford better prospects than cannabis."

In the French literature, Sée submitted a detailed report on use of cannabis in the treatment of various disorders producing gastric and intestinal pain (1890). He found it preferable in efficacy and side effects to other agents of the day, including opiates and bismuth that remain on the modern scene.

In the article "On the Therapeutic Value of Indian Hemp," Suckling (1891) declared (p. 12), "I have met with patients who have been incapacitated for work from the frequency of the attacks [of migraine], and who have been enabled by the use of Indian hemp to resume their employment." This echoes modern claims of clinical cannabis users who partake lightly of the drug and return to work or study.

Mattison was effusive in his praise in 1891 (pp. 270–271):

> Indian hemp is not here lauded as a specific. It will, at times, fail. So do other drugs. But the many cases in which it acts well, entitle it to a large and lasting confidence. My experience warrants this statement: cannabis indica is, often, a safe and successful anodyne and hypnotic.

Mackenzie (1894) described the utility of cannabis in treating neuralgias, headache (including chronic daily headache), tabetic (syphilitic) pain, functional gastrointestinal pain (corresponding to modern idiopathic bowel syndrome), and pruritic disorders.

That year in India, among many other indications, the encyclopedic Indian Hemp Drugs Commission (1894) reported that a small piece of *charas* (hashish) placed in a carious tooth would relieve aching pain.

An 1898 American drug handbook stated the following quaint prose under "Actions and uses" for cannabis (Lilly, 1898, p. 32): "Not poisonous according to best authorities, though formerly so regarded. Antispasmodic, analgesic, anesthetic, narcotic, aphrodisiac. Specially recommended in spasmodic and painful affections."

Dixon (1899), a famed British pharmacologist, studied cannabis extensively and recognized its value "as a useful food accessory," supporting its current indications in the cachexia of cancer chemotherapy and HIV-positive patients in 1899. He also reintroduced the concept of smoking the drug to Western medicine (p. 1356):

In cases where an immediate effect is desired the drug should be smoked, the fumes being drawn through water. In fits of depression, mental fatigue, nervous headache, and exhaustion a few inhalations produce an almost immediate effect, the sense of depression, headache, feeling of fatigue disappear and the subject is enabled to continue his work, feeling refreshed and soothed. I am further convinced that its results are marvelous in giving staying power and altering the feelings of muscular fatigue which follow hard physical labour.

The same year, Shoemaker (1899) reported on a large series of patients with pain conditions, including migraine, dental neuralgia, gastralgia, enteralgia, cerebral tumor, and herpes zoster, all successfully treated with *Cannabis indica.*

As late as 1915, Sir William Osler, the acknowledged father of modern medicine stated of migraine treatment (Osler & McCrae, 1915, p. 1089): "*Cannabis indica* is probably the most satisfactory remedy. Seguin recommends a prolonged course of the drug." This statement provided support of its use for both acute and prophylactic treatment of migraine.

In 1918, *The Dispensatory of the United States of America* stated (Remington et al., 1918, p. 280), "Cannabis is used in medicine to relieve pain, to encourage sleep, and to soothe restlessness.… For its analgesic action it is used especially in pains of neuralgic origin, such as *migraine,* but is occasionally of service in other types."

In 1922, Hare still advocated use of cannabis noting (p. 181), "For the relief of *pain,* particularly that depending on nerve disturbance, hemp is very valuable."

As late as 1930, the ability of cannabis to achieve a labor with pain burden substantially reduced or eliminated, followed by a tranquil sleep, was noted (Anonymous, 1930). It was stated (p. 1165), "As far as is known, a baby born of a mother intoxicated with cannabis will not be abnormal in any way."

In 1941, despite its political disenfranchisement, Morris Fishbein, the editor of the *Journal of the American Medical Association* still advocated oral preparations of cannabis in treatment of menstrual (catamenial) migraine (Fishbein, 1942).

Cannabis remained in the British armamentarium until 1961, and was extolled above opiates and barbiturates in the treatment of the pain of hospitalized patients with duodenal ulcers (Douthwaite, 1947).

MODERN ETHNOBOTANY OF CANNABIS IN ANALGESIA

In Tashkent in the 1930s, cannabis or *nasha* was employed medicinally, despite Soviet prohibition (Benet, 1975; pp. 46–47): "A mixture of lamb's fat with *nasha* is recommended for brides to use on their wedding night to reduce the pain of defloration. The same mixture works well for headache when rubbed into the skin; it may also be eaten spread on bread."

In Southeast Asia, cannabis remains useful (M. A. Martin, 1975, p. 70):

> Everywhere it is considered to be of analgesic value, comparable to the opium derivatives. Moreover, it can be added to any relaxant to reinforce its action. Cooked leaves, which have been dried in the sun, are used in quantities of several grams per bowl of water. This decoction helps especially to combat migraines and stiffness.

A very recent study documents the ethnobotanical uses of cannabis by the Hmong minority in the China–Vietnam border region (Gu & Clarke, 1998, p. 6): "Some older Hmong men may rarely smoke cannabis to 'relieve discomfort,' but they are not daily smokers."

In a book about medicinal plants of India (Dastur, 1962), we see the following (p. 67):

> Charas is the resinous exudation that collects on the leaves and flowering tops of plants [equivalent to the Arabic *hashish*]; it is the active principle of hemp; it is a valuable narcotic, especially in cases where opium cannot be administered; it is of great value in malarial and periodical headaches, migraine, acute mania, whooping cough, cough of phthisis, asthma, anaemia of brain, nervous vomiting, tetanus, convulsion, insanity, delirium, dysuria, and nervous exhaustion; it is also used as an anaesthetic in dysmenorrhea, as an appetizer and aphrodisiac, as an anodyne in itching of eczema, neuralgia, severe pains of various kinds of corns, etc.

In Colombia the analgesic effects of a cannabis tincture were lauded (Partridge, 1975, p. 161): "the knowledge that cannabis can be used for treatment of pain is widespread." Rubin documented extensive usage of cannabis in Jamaica for a variety of conditions (V. Rubin, 1976; V. Rubin & Comitas, 1972), including headache. In Brazil, Hutchinson noted (1975, p. 180):

> Such an infusion [of marijuana leaves] is taken to relieve rheumatism, "female troubles," colic and other common complaints. For toothache, marijuana is frequently packed into and around the aching tooth and left for a period of time, during which it supposedly performs an analgesic function.

MODERN DATA ON CANNABIS AND ANALGESIA

RECENT THEORY AND CLINICAL DATA

A popular treatise on marijuana noted medicinal effects (Margolis & Clorfene, 1969, p. 26):

You'll also discover that grass is an analgesic, and will reduce pain considerably. As a matter of fact, many women use it for dysmenorrhea or menorrhagia when they're out of Pamprin or Midol. So if you have an upset stomach, or suffer from pain of neuritis or neuralgia, smoke grass. If pains persist, smoke more grass.

Solomon Snyder (1971), the discoverer of opiate receptors, examined the pros and cons of cannabis as an analgesic commenting (p. 14):

For there are many conditions, such as migraine headaches or menstrual cramps, where something as mild as aspirin gives insufficient relief and opiates are too powerful, not to mention their potential for addiction. Cannabis might conceivably fulfill a useful role in such conditions.

Subsequent experimental studies by Noyes explored these reported analgesic effects of cannabis. One article examined pain tolerance thresholds (Milstein, MacCannell, Karr, & Clark, 1975). Both naïve (8% increase) and experienced human subjects (16% increase) noted statistically significant increases in pain threshold after smoking cannabis. Noyes (Noyes & Baram, 1974) described case studies of five patients who voluntarily employed it to treat their painful conditions.

Another study pertained to oral THC in patients with cancer (Noyes, Brunk, Baram, & Canter, 1975). Pain relief with escalating doses significant to the $P < 0.001$ level was observed. Peak effects occurred at 3 hours with doses of 10 and 15 mg, but were delayed until 5 hours after the 20-mg oral dose.

Noyes's research group compared the analgesic effect of THC with codeine (Noyes, Brunk, Avery, & Canter, 1975). In short, 10 mg of oral THC reduced subjective pain burdens by similar decrements to 60 mg of codeine, as did 20 mg of THC versus 120 mg of codeine. The 20-mg dose was sedative and not as well tolerated in some elderly, cannabis-naïve subjects.

Hollister (1986) addressed possible cannabis indications including analgesia. He concluded that it seemed that no THC homologue would be an analgesic of choice, but that "It is too early to be sure, however" (p. 15). These were prophetic words in light of upcoming cannabinoid receptor research.

In 1991, a series of case studies on utility of cannabis in treating chronic pain were published (Randall, 1991). One pertained to Lynn Hastings, an Idaho woman with severe juvenile rheumatoid arthritis, whose symptoms of pain, spasm, and depression were resistant to standard medicine, but were effectively treated with cannabis. A state Supreme Court finding of "medical necessity" followed her initial arrest for cultivation of cannabis. Eventually, charges were dropped.

In 1993, the landmark book, *Marihuana, the Forbidden Medicine,* was first published by Grinspoon and Bakalar, and since revised (Grinspoon & Bakalar, 1997). Although criticized in some quarters as anecdotal, the book contains numerous compelling testimonials from patients and their doctors attesting to the clinical efficacy of cannabis where conventional pharmacotherapy failed. Cases of painful conditions responding to cannabis are legion: osteoarthritis, ankylosing spondylitis, pruritus from allergic dermatitis, premenstrual syndrome (PMS), menstrual cramps, labor pains, gingival pain (with local application of cannabis tincture), migraine, phantom limb pain, Crohn's disease, and "functional" gastrointestinal pain. Often these patients improved with cannabis, worsened without it, and improved once more upon its resumption. These accounts fulfill criteria of "*N*-of-1 studies" and have been accepted by epidemiologists as proof of efficacy in rare conditions or ones in which blinded, controlled trials are technically difficult (Guyatt et al., 1990; Larson, 1990).

The *American Journal of Public Health* issued a particularly strong plea for liberalization of laws pertaining to medical cannabis (Anonymous, 1996) in 1996, citing its activity in "decreasing the suffering from chronic pain."

Hollister (2000) reviewed indications for cannabis, "for exploratory purposes, any patient with pain unrelieved by conventional analgesics should have access to smoked marijuana if they so desire" (p. 5).

CANNABINOID AND ENDOCANNABINOID NEUROCHEMISTRY
