5. What is the relationship between temperament, personality development, and pain?
6. In the context of emotional development, including increasing differentiation and integra-

tion of affect, what is the relationship between affective state and pain?

7. What factors of cognitive development are important, including the development of a concept of pain?

8. What factors of social development play a role in children's pain experiences?

9. What are important pain behaviors, what are the consequences of the behaviors, and does that social learning interact with developmental factors?

10. Is there a relationship between academic achievement and pain; for example, is there an overrepresentation of children with learning deficits who experience chronic pain?

11. What key life events precipitate the onset of chronic or recurrent pain syndromes?

12. What family factors precede or maintain pain syndromes and how does the persistent pain in a child reciprocally affect the family system?

13. What sociocultural factors affect pain in children and how do those elements interact with development?

14. What roles do health care providers play in facilitating the development or maintenance of recurrent and chronic pain syndromes in children and adolescence?

There are studies available to address some elements of these issues, a review of which is beyond the scope of this chapter, but by and large this field is still in its infancy.

INTERVENTIONS FOR CHRONIC AND RECURRENT PAIN

A critical first step in working with children and families to address recurrent and chronic pain syndromes involves education. Almost unilaterally, patients and families believe that a diagnosis exists that can explain the pain condition and once that pathology can be diagnosed and treated correctly, the pain will disappear. Thus, with patients and families, as with many medical professionals, acute pain models remain the basic mind-set. However, as discussed above, acute pain models are not sufficient here as there are many important central processes that come into play. Thus, for many of these young patients, the pain itself is the disease. Facilitating that shift in concepts is a delicate and important element in the treatment process. Many practitioners have found that when patients or families do not accept this perspective, treatment is compromised and the family's search continues for practitioners who will fulfill the hope of obtaining a "definitive" diagnosis and cure.

Treatment strategies for chronic pain follow from the assessment of pain and key contextual factors. While the goal is to eradicate pain when possible, more typically a rehabilitation approach is invoked, emphasizing the improvement of coping so that more adaptive functioning will ensue (Bursch et al., 1998). Treatment goals tend to emphasize increasing adaptive and independent functioning, including school attendance, activities of daily living, and physical activity. Because children and families maintain an acute pain perspective, there is the belief that the child should refrain from normal activities until the answer is found and the pain remits. Unfortunately, in many cases (e.g., CRPS) disuse will lead to increasing pain and disability and a very maladaptive cycle is in place. By addressing pain perception and pain behavior, both key aspects of this cycle are addressed.

One of the best indicators of a child's coping with chronic or recurrent pain is school attendance (Dunn-Geier, 1986), and school absenteeism has been shown to be greater among children with pain conditions, such as chronic abdominal pain, headaches, fibromyalgia, and juvenile rheumatoid arthritis, as compared with pain-free controls (Reid, Lang, & McGrath, 1997; Walker et al., 1998). The importance of school attendance for a child parallels that of an adult maintaining work. In addition to the necessary academics, children develop interpersonal skills and discipline by attending school. As a result, great emphasis is placed on facilitating the child's return to school after frequent absences or sporadic attendance due to pain. To achieve these goals, various psychological, physical, and pharmacological strategies have been invoked. They are reviewed briefly.

COGNITIVE BEHAVIORAL INTERVENTIONS

Although there are very few controlled studies to show the impact of psychological interventions for pain associated with chronic illness, available case studies and clinical series indicate that such strategies are useful to reduce subjective pain and facilitate more adaptive behavior (Walker et al., 1998). For other recurrent and chronic pain syndromes, however, there is fairly substantial evidence to support the efficacy of psychological therapies. Holden, Deichmann, and Levy (1999) reviewed 31 studies of treatments for children with chronic headache and found good evidence for the efficacy of relaxation and self-hypnosis in reducing pain. Hermann, Kim, and Blanchard (1995) reviewed the data on pediatric migraine and found biofeedback and muscle relaxation to be more efficacious than placebo treatments and prophylactic drug treatments in controlling headache. Recurrent abdominal pain is a difficult area to investigate due to the heterogeneity of symptoms and treatment approaches (Walker, 1999); however, a review of the literature indicates that cognitive-behavioral approaches to treatment show promise (Janicke

& Finney, 1999). In a systematic review of controlled trials of psychological therapy for chronic pain, Eccleston et al. (2002) concluded that there is evidence to support the use of cognitive behavioral approaches to treat headaches, and they encouraged controlled randomized trials of other types of recurrent and chronic pain.

Two major psychological modalities may be invoked in the context of chronic or recurrent pain: *pain perception regulation*, using specific cognitive-behavioral or self-regulatory strategies to facilitate coping with or modifying subjective pain experiences, and *pain behavior modulation*, focusing on operant paradigms intended to increase adaptive behavior while minimizing pain or "sick" role behavior (Varni, Walco, & Wilcox, 1990). In addition, if there are concerns about major contextual factors, those too must be addressed.

Consider a child who has not attended school for several months and who spends most of the day at home on the couch or in bed. Structured and manageable changes in behavior would be necessary to successively approximate regular, full-time school attendance. Steps might include waking up at a prescribed time, maintaining a defined morning routine, sitting in a chair doing schoolwork for a specific length of time (that approximates the duration required while in school), and time out of the chair and moving around for a specific length of time (to approximate recess or transitions between classes). To facilitate and maintain this behavioral set, specific cues might be put in place and contingent outcomes identified to increase or maintain behaviors. Pain behaviors are typically ignored while well behaviors are encouraged and positively reinforced. It is important to note that subjective pain reports are of minimal utility in this paradigm as they may be influenced by a number of interpersonal and environmental variables, making them somewhat unreliable in this context.

Pain perception regulation strategies are self-regulatory in nature and use modalities such as progressive muscle relaxation, meditative breathing, guided imagery, and self-hypnosis. Each of these is used to provide the child with a predictable routine aimed at modifying the subjective pain experience. It is useful to assess which strategies the child uses naturally and build on these and tailor them to the individual child (Walco, Varni, & Ilowite, 1992). Another important component is to make the strategies generalizable so they may be implemented across settings (i.e., at home, in school, in clinic).

PHYSICAL INTERVENTIONS

Consistent with a rehabilitation model, the goals of treatment using physical modalities are restoration of function and reduction of disability. Some interventions also focus on modifying aspects of the subjective pain experience. Many physical therapy strategies emphasize strengthen-

ing, weight bearing, range of motion, and endurance. Some data indicate, for example, that movement of a painful body part will increase pain thresholds (Kalkigi, Matsuda, & Kuroda, 1993). Other physical strategies include the use of heat and cold, as well as transcutaneous electrical nerve stimulation (TENS; McCarthy, Shea, & Sullivan, 2003).

PHARMACOLOGIC INTERVENTIONS

The pharmacologic treatment of chronic pain depends on the neurophysiologic and neurochemical contributors to the pain. Tricyclic antidepressants, such as amitriptyline or nortriptyline, are commonly used for chronic pain, especially when there is a neuropathic component (Max et al., 1998). This class of drugs has the added benefit of causing sedation as a side effect, which is useful in pain syndromes where initiation and maintenance of sleep is a concern (e.g., fibromyalgia syndrome). Tricyclic antidepressants are commonly used to treat headaches (Levin, 2001) and irritable bowel pain (Weydert, Ball, & Davis, 2003). Tricyclic antidepressants may also be useful for CRPS (Olsson, 1999; Wilder et al., 1992). Anticonvulsants are most frequently used in the treatment of neuropathic pain. In particular, gabapentin has been found to be useful in some chronic pain states, particularly CRPS (Olsson, 1999).

The use of opioids in the treatment of chronic nonmalignant pain in children is somewhat controversial. The unilateral statement that children should never be prescribed chronic opioids has been replaced by encouragement to conduct a careful cost–benefit analysis in which the benefit of pain relief and improved quality of life is juxtaposed to the cost of side effects and potential for abuse. In pediatric rheumatology, for example, there is an increasing recognition that more aggressive pain treatment with opioids may be preferable to ongoing escalation of disease-modifying agents, such as steroids, in that opioids are effective and may in fact have fewer short- and long-term deleterious side effects (Anthony & Schanberg, 2003). Clearly, however, careful monitoring of clinical effects, untoward side effects, and pattern of usage is essential in these circumstances. Furthermore, pharmacologic management of chronic pain must be integrated into a comprehensive rehabilitation approach that includes educational, psychological, family, and environmental interventions, as well as physical approaches.

CONCLUSIONS

Chronic and recurrent pain syndromes in children and adolescents present all of the complicated issues of such syndromes in adults, with the added dimensions of development. As a result, these problems present a significant clinical challenge and recent data indicate that these syndromes are likely more common than previously thought.

Appropriate assessment, including developmentally appropriate measures and evaluation of key contextual factors, is necessary to devise optimal treatment and management. Treatment paradigms should integrate pharmacological, psychological, and physical strategies, principally aimed at a rehabilitative approach. Clearly, significantly more quality studies are needed to assist with model development and validation, improved assessment strategies, and optimal treatment modalities for these problems. Longitudinal studies elucidating the developmental continuum of pediatric chronic pain problems to similar syndromes in adults would be extremely worthwhile. Needless to say, both the clinical and research endeavors will require a multidisciplinary approach so that the array of important variables may be addressed adequately.

Procedural and Perioperative Pain Management for Children

Stephen R. Hays, MD, FAAP, Christine L. Algren, RN, MSN, EdD, and John T. Algren, MD, FAAP

INTRODUCTION

Pain management in children represents an ongoing challenge for health care providers. The ability of children to experience pain has historically been denied or ignored, and the capacity of children to tolerate anesthesia questioned (Eland & Anderson, 1977; Schechter, 1989), causing many pediatric patients to undergo procedures including surgery without adequate analgesia and sedation. Although continued progress remains to be made, recent increased interest in pediatric pain, along with philosophical shifts and technical advances, have prompted evolution of numerous innovative pediatric pain management strategies and improved care of children undergoing a wide range of diagnostic and therapeutic procedures (American Academy of Pediatrics Task Force on Pain in Infants, Children and Adolescents, 2001; Howard, 2003). This chapter discusses procedural and perioperative pain management for children.

PROCEDURAL PAIN MANAGEMENT FOR CHILDREN

Children of all ages experience pain, the type and intensity of which may vary considerably. Brief, intermittent pain is frequently associated with minor traumatic injuries and common childhood illnesses, for which children often receive care at home, in a health care provider's office, or in the emergency department. Care in such settings may require interventions that cause additional pain, for which children too often receive inconsistent or inadequate pain management (Alexander & Manno, 2003; Hostetler, Auinger, & Szilagyi, 2002). Hospitalized children frequently undergo numerous potentially painful diagnostic and therapeutic procedures other than surgery, from venipuncture and intravenous catheter insertion to lumbar puncture and bone marrow aspiration. Such procedures characteristically cause brief but significant pain and are often described by children as the most distressing aspect of their illness or hospitalization (Eland & Anderson, 1977). Inadequate procedural pain management may have profound negative emotional and physiologic consequences, particularly in children given their greater developmental vulnerability. Appropriate procedural pain management may help prevent such consequences, yielding short- and long-term benefits.

Diagnostic and therapeutic procedures induce anxiety and stress in patients and families. Appropriate procedural pain management for children should provide adequate analgesia and appropriate sedation, enhancing patient cooperation and facilitating successful completion of the procedure (Selbst & Zempsky, 2003). Optimal management takes into consideration type of procedure performed as well as individual factors such as patient age, physical condition, developmental maturity, and emotional state. Numerous nonpharmacologic techniques and a variety of medications may be employed (Acute Pain Management Guideline Panel, 1992). With appropriate intervention, most children should be able to undergo diagnostic and therapeutic procedures with little or no pain and with minimal anxiety and stress.

TABLE 86.1
Continuum of Sedation

Stage of Sedation	Minimal (anxiolysis)	Moderate (conscious sedation)	Deep (deep sedation)	General Anesthesia
Responsiveness	Normal	To verbal stimulation	To painful stimulation	None
Airway	No intervention	No intervention	Possible intervention	Possible intervention
Ventilation	Adequate	Adequate	Possibly inadequate	Possibly inadequate
Hemodynamics	Normal	Usually normal	Usually normal	Possibly impaired

Note: Adapted from "Practice Guidelines for Sedation and Analgesia by Non-anesthesiologists," by American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002, *Anesthesiology, 96*(4), 1004–1017.

Monitoring and Management Guidelines

Recent medical advances have led to dramatic increases in diagnostic and therapeutic procedures in children. Although anesthesiologists provide patient care for many such interventions, practical issues of cost, logistics, and availability of personnel support the practice of procedural analgesia and sedation for children by other health care providers (Pitetti, Singh, & Pierce, 2003). To promote safe practice, the American Academy of Pediatrics Committee on Drugs (1992, 2002) has established guidelines for monitoring and management of pediatric patients undergoing procedural analgesia and sedation. Other professional organizations have developed differing guidelines (American Academy of Pediatric Dentistry, 2003; American College of Emergency Physicians, 1997; American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002), leading to considerable debate (Coté, 1994; Coté, Notterman, Karl, Weinberg, & McCloskey, 2000; Sacchetti et al., 1994). These organizations and their respective guidelines, however, share the common goal of fostering safe yet efficient practice. Regardless of perspective or bias, practitioners are urged not to allow expediency to compromise patient safety.

Any degree of sedation by definition depresses level of consciousness, increasing risk for airway obstruction, respiratory depression, and aspiration, all of which may result in significant morbidity and mortality. Children are particularly prone to such complications (Coté et al., 2000), mandating a high degree of vigilance in their care. When administering analgesics and sedatives, practitioners should consider risks of serious adverse events, as well as of minor problems such as pruritus, nausea, and prolonged sedation.

Sedation comprises a continuum ranging from mild anxiolysis to general anesthesia (Table 86.1; American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002); definition of the stages of sedation along this continuum remains con-troversial. Light sedation yielding mild anxiolysis, although frequently useful in adults, is rarely helpful in procedural pain management for children given their often vigorous response even to minimal pain or stress. Moderate, or so-called conscious, sedation is commonly described as preferred for increased depth of sedation with preservation of airway reflexes and spontaneous ventilation. Even moderate sedation, however, may be inadequate for many pediatric patients, and some practitioners have questioned its usefulness and even existence as a specific state in children (Maxwell & Yaster, 1996). Deep sedation produces greater depression of consciousness and diminished response to stimuli, and may be required for children to tolerate painful or stressful procedures. Deep sedation may also obtund airway protective reflexes, compromise ventilation, and even impair cardiovascular function, necessitating maintenance of intravenous access and continuous close monitoring of cardiorespiratory status. As a consequence of variability in individual response, administration of analgesics and sedatives for light or moderate sedation may induce deep sedation or even general anesthesia. Regardless of planned depth of sedation, practitioners should continuously and closely monitor all patients and be fully prepared to manage potential problems including airway compromise, inadequate ventilation, and cardiovascular depression.

Supervision of procedural analgesia and sedation for children by knowledgeable and competent personnel is mandatory. Many practice guidelines recommend that the individual primarily responsible for performing the procedure not also supervise sedation. Guidelines promulgated by the American Academy of Pediatrics (American Academy of Pediatrics Committee on Drugs, 2002) and American Society of Anesthesiologists (American Society of Anesthesiologists Task Force on Sedation and Analgesia by Non-Anesthesiologists, 2002) go so far as to stipulate that an appropriate practitioner be specifically assigned to supervise procedural analgesia and sedation for children, with only intermittent additional duties during administration of light or moderate sedation and no

additional duties during conduct of deep sedation. Adherence to these guidelines has been shown to reduce complications (Hoffman, Nowakowski, Troshynski, Berens, & Weisman, 2002).

In light of the small but real risks of serious adverse events associated with procedural analgesia and sedation for children, equipment and medications for emergency resuscitation should be readily available. Facilities should be of adequate size to accommodate necessary supplies and personnel, and of appropriate configuration to allow rapid access to these items when needed. All equipment and medications should be appropriate for the ages and sizes of children receiving care, and personnel should be skilled in their use. Practitioners supervising procedural analgesia and sedation for children should, at a minimum, be trained in basic pediatric life support; training in advanced pediatric life support is recommended (American Academy of Pediatrics Committee on Drugs, 2002).

Serious complications associated with procedural analgesia and sedation for children are best avoided by adequate evaluation of the patient prior to sedation, appropriate preparation of the patient prior to the procedure, and close monitoring and early detection of changes in patient status during and after administration of analgesics and sedatives. Suitable candidates for pediatric procedural analgesia and sedation are American Society of Anesthesiologists Physical Status Class I or II patients (Table 86.2). Sedation of Class III or higher patients by non-anesthesiologists should be approached with caution because of the presence of symptomatic systemic disease that increases risk of complications. Evaluation of any patient as a candidate for procedural analgesia and sedation includes focused examination of the airway. Decreased mobility of the neck or jaw, impaired mouth opening, craniofacial malformations, large tongue, signif-

TABLE 86.2
American Society of Anesthesiologists (ASA) Physical Status Classification

ASA Class	Description
I	Healthy patient without systemic disease
II	Mild systemic disease without functional limitation
III	Symptomatic systemic disease with functional limitation
IV	Severe systemic disease posing a constant threat to life
V	Moribund patient not expected to survive > 24 hours with or without surgery

Note: ASA Class VI is sometimes used to indicate a brain-dead cadaveric organ donor.

icant obesity, or anatomic abnormality of the head or neck may presage difficulty if airway intervention is required. Decreased visualization of the tonsillar pillars, soft palate, and base of the uvula with the patient upright and mouth fully open has been shown to predict difficulty with laryngoscopy (Mallampati et al., 1985).

In preparation for procedural analgesia and sedation, children and families should be thoroughly informed about the planned procedure, with detailed instructions concerning preparation before and care after sedation. To minimize risk of aspiration of gastric contents, oral intake should be suspended prior to elective procedures for which sedation is planned, as for elective procedures entailing anesthesia (Table 86.3; American Society of Anesthesiologists Task Force on Preoperative Fasting, 1999). Whenever possible, unscheduled or urgent procedures should be delayed until

TABLE 86.3
Recommended Fasting Periods before Elective Procedures

Type of Intake	Minimum Recommended Fasting Period
Clear liquids, e.g., water, juice without pulp, carbonated beverages, clear tea, black coffee	2 hours
Human breast milk	4 hours
Any nonhuman milk, infant formula, light meal; typical light meal includes toast and clear liquids	6 hours
Heavy meal; particularly including fried or fatty foods or meat	8 hours or longer

Note: These recommendations apply regardless of patient age. Adapted from "Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures: A Report by the American Society of Anesthesiologists Task Force on Preoperative Fasting," by American Society of Anesthesiologists Task Force on Preoperative Fasting, 1999, *Anesthesiology, 90*(3), 896–905. With permission.

appropriate fasting periods have been observed. Some situations may require that sedation be provided despite recent oral intake. In such settings it is appropriate to obtain documentation from the provider performing the procedure that the urgency of the intervention justifies proceeding, and to administer sedation cautiously to minimize depression of airway reflexes and risk of aspiration. Agents such as metoclopramide and ranitidine that augment gastric motility, increase gastric pH, and decrease gastric volume may be appropriate (American Society of Anesthesiologists Task Force on Preoperative Fasting, 1999). In situations where appropriate fasting periods cannot be observed and deep sedation is likely to be necessary, airway protection with rapid-sequence induction of anesthesia and endotracheal intubation may be advisable.

Following appropriate patient evaluation and preparation, monitoring in procedural analgesia and sedation for children should include determination of baseline vital signs, with ongoing patient assessment throughout sedation and subsequent recovery. Assessment should include continuous monitoring of oxygen saturation and heart rate, intermittent monitoring of blood pressure, and intermittent or continuous monitoring of ventilation depending on depth of sedation provided. Documentation of these parameters is commonly at 5-minute intervals during procedures and at 15-minute intervals during recovery, although either interval may be shortened if dictated by patient status. Patients may be discharged while still somewhat sedated, but only if they have demonstrated sufficient recovery of vital functions to ensure safety. This should include return of airway protective reflexes, demonstration of stable and satisfactory respiratory and cardiovascular function, recovery of baseline neurologic function appropriate for age and developmental maturity, and adequate hydration.

PERIOPERATIVE PAIN MANAGEMENT FOR CHILDREN

Children undergoing surgery frequently express fear regarding perioperative pain; all too often, such fear becomes reality. Historically, up to 40% of children undergoing surgical procedures have reported moderate to severe pain on the first postoperative day (Mather & Mackie, 1983). Although many children continue to experience such pain, evolution of integrated, multidisciplinary approaches has dramatically improved perioperative pain management for children (Polkki, Pietila, & Vehvilainen-Julkunen, 2003). Such comprehensive approaches include preoperative, intraoperative, and postoperative strategies for minimizing perioperative pain, based on planned surgical procedure, anesthetic technique, anticipated severity of postoperative pain, and expected course of recovery (Acute Pain Management Guideline Panel, 1992). Periop-

erative pain management for children begins with appropriate preparation of patients and families for surgery, and continues with a variety of nonpharmacologic techniques combined with appropriate analgesics and sedatives before, during, and after the procedure. Children are reassessed at frequent intervals, and regimens modified as needed.

HYPERSENSITIZATION AND PREEMPTIVE ANALGESIA

Acute pain serves as a warning of potential or actual tissue injury. Persistent or severe pain, however, may contribute to pathophysiologic processes that impair normal mobility and function. Following thoracic or abdominal surgery, pain may restrict breathing and compromise pulmonary toilet with resultant ventilatory insufficiency, atelectasis, and pneumonia (Duggan & Drummond, 1987; Ready, 2000). Tissue injury and pain also induce a neuroendocrine stress response, increasing sympathoadrenergic activity and releasing a wide range of stress hormones and inflammatory mediators including catecholamines, cortisol, growth hormone, glucagon, vasopressin, interleukin-1, substance P, and tumor necrosis factor (Fitzgerald & Anand, 1993; Fitzgerald & Howard, 2003; Kehlet, 1989). The hypermetabolic, catabolic state that ensues may be complicated by impaired immune function and increased perioperative morbidity and mortality (Kehlet, 1989).

Tissue injury and inflammation accentuate peripheral nociceptor activity, resulting in hypersensitivity to mechanical and chemical stimuli. In addition, dorsal horn neurons respond to sustained afferent stimulation with neurophysiologic and morphologic changes consistent with increased excitability (Fitzgerald & Howard, 2003; Woolf & Chong, 1993). Development of peripheral and central hypersensitivity may alter normal sensory perception (dysesthesia), accentuate pain due to noxious stimuli (hyperalgesia), and produce pain in response to normally innocuous stimuli (allodynia), suggesting that hypersensitization at the cellular and neurophysiologic level correlates with clinical hypersensitivity to pain.

Administration of analgesia prior to tissue injury may inhibit stimulation of nociceptive pathways, blunting neuroendocrine stress response and preventing development of peripheral and central hypersensitivity (Woolf & Chong, 1993). General anesthesia alone is ineffective for such preemptive analgesia; nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and a variety of regional anesthetic techniques using local anesthetics have been employed with variable results. Despite suggestions from animal models that preemptive analgesia decreases overall pain severity and duration following noxious stimuli, clinical human studies have yielded conflicting and frequently negative results, particularly in children (Ho, Khambatta, Pang, Siegfried, & Sun, 1997; Kundra, Deepalakshmi, & Ravishankar, 1998; Suresh, Barcelona, Young, Heffner, & Coté, 2004). Preemptive analgesia as a strategy for blunting hypersensitization

and reducing perioperative pain thus remains a subject of ongoing investigation and controversy (Dahl & Kehlet, 1993; Kissin, 2000; Moiniche, Kehlet, & Dahl, 2002).

NONPHARMACOLOGIC TECHNIQUES

Nonpharmacologic techniques are important adjuncts in procedural and perioperative pain management for children (Rusy & Weisman, 2000). These techniques seek to enhance patients' ability to cope with pain by modifying pain perception and, in the case of various biophysical modalities, by modulating nociceptive transmission. Integrated pain management strategies employ nonpharmacologic techniques in combination with appropriate medications to optimize pain relief, minimize side effects, and facilitate recovery.

Pain includes cognitive, affective, and behavioral components. Children are highly responsive to pain control strategies that involve their imagination, high degree of suggestibility, and sense of play (Brown, 1995). Assisting children to cope with painful events also empowers them with a sense of mastery and self-control that may be applied to future painful situations. Procedural and perioperative pain is commonly associated with stress, fear, and anxiety. Numerous cognitive-behavioral interventions may be helpful in reducing such anxiety and facilitating patient cooperation. These interventions may also be utilized in the management of chronic and recurrent pain. Noninvasive and generally inexpensive, nonpharmacologic techniques frequently provide children and families a sense of personal involvement in their pain management. Promoting family involvement in nonpharmacologic techniques increases their effectiveness (Christensen & Fatchett, 2002).

PREPARATION

Stress, fear, and anxiety intensify pain perception; any technique that reduces anxiety may alleviate pain. Developmentally appropriate preparation is one of the most widely used nonpharmacologic interventions in procedural and perioperative pain management for children. Explanations about procedures increase understanding on the part of children and families and reduce fear of the unknown. If possible, children should be encouraged to express fears, and time should be allowed for questions and answers. Age-appropriate information about why the procedure is being performed, what will be done during the procedure, and sensations that might be experienced should be discussed. Children might be told, for example, that they may feel a small pinch or prick with administration of local anesthetic or placement of intravenous access. Information provided should always be honest and straightforward, while presented in an age-appropriate and developmentally appropriate manner. Various methods, such as tours, coloring books, dolls, puppets, and play therapy, may be used to prepare children for procedures.

Suggestions for coping strategies should be included, allowing children to practice such strategies and families to rehearse supportive roles.

DISTRACTION

Distraction, one of the simplest nonpharmacologic techniques, may be a powerful coping strategy in procedural and perioperative pain management for children. Pain worsens with increasing focus on pain sensation. Distraction engages children in another activity and refocuses attention on something other than the painful stimulus. Distraction does not reduce intensity of noxious stimuli, but alters pain modulation and thereby improves pain tolerance.

Health care personnel should first assess patient age, developmental level, and interests. Distraction may then be accomplished by focusing attention on something other than the unpleasant intervention. Listening to music with a headset, talking about pets or school, blowing bubbles, squeezing someone's hand, and singing or counting are effective distraction techniques. Interactive computer and video games may provide distraction for older children and adolescents. Pain perception is only altered during the distracting activity; when distraction ceases, pain awareness and irritability may return.

RELAXATION AND IMAGERY

In children capable of abstract thinking, relaxation and guided imagery are effective adjunctive therapies in procedural and perioperative pain management; such techniques need not be complex to be effective. Muscle tension intensifies pain, and may be alleviated by methods such as deep breathing and progressive relaxation exercises (McDonnell & Bowden, 1989). Soothing music and talking in a soft, calm voice may also produce relaxation. These techniques give children a feeling of control rather than a sense of helplessness. Controlled breathing may be used alone or in combination with other techniques to promote relaxation. Children may be guided to take slow deep breaths through the nose, exhaling through pursed lips and "blowing away the pain." Young children are especially receptive to this technique.

Imagery is a popular cognitive technique to minimize painful sensation. Imagery, a relaxation strategy, dulls awareness of reality by encouraging children to use their imaginations to focus on something unrelated to the unpleasant intervention. Some experts consider imagery a form of self-hypnosis. Children aged 3 or older may be guided or coached into imagining pleasant images such as a favorite place or activity. Children may also use fantasy to imagine medication traveling through the body to the site of pain or superheroes attacking the pain. Imagery appears to be more effective when multiple senses are enlisted. Guided imagery of playing at the beach, for

example, might include imagining the touch of sand, the sound of waves, the sight of sunshine, the smell of ocean, and the taste of favorite foods, focusing on how these combined sensations feel.

MUSIC THERAPY

Music therapy has been used to provide distraction and relaxation in children, decreasing anxiety and improving comfort while fostering a sense of well-being. Positive outcomes have been reported in a variety of health care settings including the operating room (Moss, 1988), postanesthesia care unit (Mullooly, Levin, & Feldman, 1988), neonatal intensive care unit (Collins & Kuck, 1991), and oncology ward (Sahler, Hunter, & Liesveld, 2003). Music selection should be based upon patient age, culture, and personal preference.

HYPNOSIS

Hypnosis may be a valuable tool in procedural and perioperative pain management for children, particularly patients aged 8 to 12. Like other cognitive strategies, hypnosis modifies pain perception and nociceptive responses. Children's pain tolerance is improved by capitalizing on their prolific imagination and high degree of suggestibility to induce a hypnotic state. Hypnosis has been used successfully for pediatric oncology patients undergoing bone marrow aspiration and lumbar puncture (Zeltzer & LeBaron, 1982), and in emergency departments during fracture reduction and laceration repair. Children receiving burn therapy and children with sickle cell disease and pain from vaso-oclusive crisis may also benefit from hypnosis (Kuttner & Solomon, 2003). When combined with guided imagery, hypnosis has been shown to decrease pain scores, reduce patient anxiety, and shorten duration of hospitalization in pediatric surgical patients (Lambert, 1996). Practice of hypnosis, particularly in children, requires specific training and expertise.

POSITIVE REINFORCEMENT

Positive reinforcement is a simple strategy for encouraging children's cooperation and potentially improving their experience of an unpleasant intervention. Children might be verbally encouraged during a procedure and praised for holding still, for example, or offered a tangible reward such as a badge of courage, sticker, or toy. Children should receive positive reinforcement for any helpful behavior, but should never be punished or ridiculed for being frightened or uncooperative.

BIOPHYSICAL MODALITIES

Several biophysical modalities may be used in procedural and perioperative pain management for children to mod-

ify pain perception by altering nociceptive transmission. Biophysical modalities are frequently and most successfully used in combination with other nonpharmacologic techniques and in conjunction with appropriate analgesics and sedatives.

Cutaneous and Oral Stimulation

Cutaneous and oral stimulation are valuable noninvasive techniques in procedural and perioperative pain management for children. Pleasant cutaneous stimulation, such as stroking, patting, or massaging the feet, hands, or back produces muscle relaxation and reduces pain during injection, suturing, lumbar puncture, and venipuncture. Massage therapy has been shown to reduce pain associated with dressing changes in pediatric burn patients (Hernandez-Reif et al., 2001). Infants may frequently be soothed with pleasant cutaneous stimulation, such as gentle rubbing of the head, and respond particularly well to oral stimulation, such as suckling on a pacifier. Allowing infants small amounts of sugar water provides analgesia for painful procedures such as heel stick blood collection (Harrison, Johnston, & Loughnan, 2003), and is synergistic with pacifier use (Akman, Ozek, Bilgen, Ozdogan, & Cebeci, 2002). Families may often perform these techniques, providing reinforcing emotional benefits.

Cold and Heat Therapy

Application of cold or heat is another cutaneous stimulation technique. Cooling reduces local pain perception by retarding chemical reactions associated with inflammation and reducing nerve activity and conduction velocity (Ernst & Fialka, 1994). Interventions such as rubbing ice above and below an injury or applying ice or ethyl chloride spray prior to an injection or immunization may decrease inflammatory response and reduce pain. Care should be taken to avoid excessive cooling that may cause skin irritation, cellular injury, and even frostbite.

In contrast, heat promotes circulation, relaxes muscles, and reduces edema and stiffness. Heat application for 15 minutes prior to venipuncture promotes vasodilation and reduces pain. Heat is also an effective home therapy for pain in children with sickle cell disease (Conner-Warren, 1996). Hydrotherapy combines benefits of heat with those of water immersion. Physical therapists frequently utilize hydrotherapy to promote circulation, relax muscles, facilitate movement, and reduce pain. Hydrotherapy may be useful in the management of patients with joint and muscle pain or with chronic regional pain syndromes.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) delivers weak electrical current to the skin via superficial elec-

TABLE 86.4
Sedative-Hypnotic Agents

Drug	Dose	Comments
Chloral hydrate	50–100 mg/kg PO/PR (maximum 2 g)	Higher doses may cause respiratory depression
		Significant rates of agitation or failed sedation
Pentobarbital	2–6 mg/kg PO/PR/IM/IV	Intravenous titration preferred
Midazolam	0.5–1 mg/kg PO/PR (maximum 20 mg)	Higher doses may cause respiratory depression
	0.3 mg/kg SL/nasal (maximum 5 mg)	Potentiated by other sedative-hypnotics
	0.05–0.1 mg/kg IV (maximum 2 mg) initial dose, then	Potentiated by opioids
	0.025–0.05 mg/kg IV (maximum 1 mg) q 5–10 min PRN	May be reversed with flumazenil (see Table 86.5)
Ketamine	4–10 mg/kg PO	Concomitant atropine or glycopyrrolate will reduce sialorrhea
	3–5 mg/kg IM	Concomitant benzodiazepine may prevent agitation
	0.5–1 mg/kg IV	Increases intracranial pressure; may precipitate seizures
Propofol	1 mg/kg IV initial dose, then	Higher or repeated doses induce anesthesia
	0.5 mg/kg IV q 5 min PRN	Prolonged infusion contraindicated in children
	100–200 μg/kg/min IV infusion	

Note: With the exception of ketamine, these sedative–hypnotic agents have no analgesic properties; appropriate analgesia should be provided for painful procedures.

Abbreviations: IM, intramuscular; IV, intravenously; PO, orally; PR, rectally; PRN, as needed; SL, sublingually.

trodes and is thought to provide analgesia by modulation of pain perception at the level of the spinal cord; TENS may also induce release of endorphins and other endogenous neurotransmitters in a manner similar to acupuncture (Eland, 1993). TENS has been used effectively for children undergoing a variety of procedures including venipuncture (Lander & Fowler-Kerry, 1993), dressing changes (Merkel, Gutstein, & Malviya, 1999), and even dental restoration (Harvey & Elliott, 1995), and has been used as an adjunctive modality in pediatric chronic pain management (Eland, 1991). In some cases, TENS may reduce requirement for pharmacologic analgesia (Merkel et al., 1999). Physical therapists typically oversee TENS therapy and instruct patients and families in its use. Conventional TENS delivers electrical pulses of high frequency (50 to 100 Hz), short duration (100 μs or less), and low intensity, adjusted to provide strong but not unpleasant stimulation (usually 10 to 60 mA). This causes a nonpainful tingling sensation. TENS is usually well tolerated by patients old enough to understand a simple explanation of its use, although some children may find the tingling sensation unpleasant. Lower-frequency, longer-duration, higher-intensity TENS may be used, but its application in children is limited by their tolerance of the stronger stimulation delivered (Eland, 1993).

Acupuncture

Acupuncture is gaining acceptance in Western medicine and is practiced by both physicians and licensed acupuncturists in the United States (Lin, 2003). Although mechanisms for its purported analgesia are not understood, acupuncture is undergoing increasing scientific scrutiny (Pomeranz, 1996). There is some evidence that acupuncture may precipitate release of endorphins, enkephalins, serotonin, and possibly other endogenous neurotransmitters within the central nervous system (Adams, Brase, Welch, & Dewey, 1986), inhibiting nociceptive pathways and reducing pain perception. Pediatric experience with acupuncture in the United States is limited, with use described primarily as adjunctive therapy for children with chronic pain (Kemper et al., 2000). Acupuncture is not effective for antiemetic prophylaxis in children undergoing tonsillectomy (Shenkman et al., 1999).

SEDATIVE–HYPNOTIC AGENTS

Numerous sedative–hypnotic agents are available as components of procedural and perioperative pain management for children (Table 86.4). Drug selection should be based on anticipated level of sedation required, type and duration of procedure to be performed, risk of potential side effects, and available routes of administration.

Chloral Hydrate

Chloral hydrate is a sedative–hypnotic agent devoid of analgesic properties. Chemically an alcohol, it is rapidly metabolized to trichloroethanol and induces a state of intoxication. Chloral hydrate is available in liquid and suppository preparations, and has been widely used for procedural and perioperative sedation in infants and children primarily due to low risk of serious adverse effects. When administered at a dose of 35 to 75 mg/kg orally or rectally (PO/PR) for computerized tomography (CT) scan-

ning, onset of sedation ranged from 30 to 105 minutes with recovery after 60 to 120 minutes; sedation was inadequate in 13% of patients (Strain, Harvey, Foley, & Campbell, 1986). Doses of 50 to 100 mg/kg PO/PR (maximum 2 g) may be used to accelerate onset and deepen sedation, but may prolong recovery and increase risk of respiratory depression (Anderson, Zeltzer, & Fanurik, 1993).

Chloral hydrate's hepatotoxic metabolites and structural similarity to several known carcinogens have prompted considerable concern. Toxicologic studies suggest increased incidence of malignancy, particularly hepatocellular carcinoma, in rodents following chronic chloral hydrate administration (Salmon, Kizer, Zeise, Jackson, & Smith, 1995; U.S. Department of Health and Human Services National Toxicology Program, 2002), but such an association has never been observed in humans despite many decades of widespread use. Disadvantages of chloral hydrate include pungent preparations, slow onset of action, prolonged recovery, lack of reversal agent, and significant rates of agitation and inadequate sedation. Risk of respiratory and hemodynamic depression with higher doses warrants continuous cardiorespiratory monitoring. Nevertheless, due to relative ease of administration and overall safety, chloral hydrate remains a popular sedative for nonpainful procedures in children such as CT scanning and magnetic resonance imaging (MRI) (Keeter, Benator, Weinberg, & Hartenberg, 1990). Because chloral hydrate lacks analgesic properties, appropriate analgesia should be provided for painful procedures.

PENTOBARBITAL

Barbiturates are sedative–hypnotic agents devoid of analgesic properties. Their mechanism of action likely derives from stimulation of GABAergic inhibitory pathways in the central nervous system. Historically barbiturates have been thought to have hyperalgesic properties accentuating pain perception, but this is not now generally thought to be clinically relevant in humans at usual doses. The short-acting barbiturates methohexital and thiopental have been widely used for induction of general anesthesia; these agents produce dose-dependent respiratory and cardiovascular depression. Methohexital and thiopental may be administered rectally to provide sedation in children, but absorption and degree of sedation are variable. Both agents may rapidly induce deep sedation and general anesthesia.

In contrast, pentobarbital is a highly useful agent for pediatric procedural sedation, particularly for radiologic studies (Moro-Sutherland, Algren, Louis, Kozinetz, & Shook, 2000). Pentobarbital has an intermediate duration of action and lends itself well to oral, rectal, intramuscular, or titrated intravenous administration (Strain et al., 1986). A single intramuscular (IM) dose of 5 to 6 mg/kg produced effective sedation within 30 to 45 minutes in 86% of patients; intravenous (IV) administration was titrated to achieve satisfactory sedation, requiring an average dose of 4.4 mg/kg with a range of 2 to 6 mg/kg. Intravenous administration was preferred due to more rapid onset (1 to 2 minutes), shorter recovery time (55 minutes), and extremely low rate of inadequate sedation (0.5%). Pentobarbital, like all barbiturates, lacks analgesic properties; appropriate analgesia should be provided for painful procedures.

MIDAZOLAM

Benzodiazepines are sedative–hypnotic agents devoid of analgesic properties. Unlike chloral hydrate and barbiturates, benzodiazepines have specific anxiolytic and amnestic efficacy enhancing their utility in procedural and perioperative sedation. Acting on the benzodiazepine receptor of the GABA receptor complex in the central nervous system, benzodiazepines provide sedation, reduce anxiety, and prevent recall. Another advantage of benzodiazepines lies in the availability of the benzodiazepine receptor antagonist flumazenil that rapidly reverses benzodiazepine effects (Table 86.5).

Given its rapid onset and short duration of action, midazolam is by far the most widely used benzodiazepine for procedural and perioperative sedation in children. Because of its limited oral bioavailability, doses of 0.5 to 0.75 mg/kg PO (maximum 20 mg) have been used for preoperative sedation (Feld, Negus, & White, 1990); doses of 1 mg/kg PO may be required, particularly when midazolam is the sole sedative. Oral midazolam at these doses has gained wide acceptance for premedication of pediatric surgical patients. Midazolam may be given rectally at the same dose to patients unwilling or unable to tolerate oral administration; this is particularly useful in infants and children not yet toilet trained. Midazolam 0.3 mg/kg (maximum 5 mg) has been used in children via nasal and sublingual routes (Karl, Rosenberger, Larach, & Ruffle, 1993). Nasal or sublingual transmucosal absorption increases bioavailability, reducing dose and shortening time of onset. However, currently available preparations have a bitter taste and sting the nasal mucosa, and children often find these routes of administration unpleasant. Intravenous midazolam produces rapid onset of sedation, anxiolysis, and amnesia, and is well suited to incremental titration. The usual intravenous dose of midazolam is 0.05 to 0.1 mg/kg (maximum 2 mg); additional intravenous doses of 0.025 to 0.05 mg/kg (maximum 1 mg) may be repeated every 5 to 10 minutes as needed. Midazolam 0.1 mg/kg IV is often sufficient for gastrointestinal endoscopic procedures in children (Tolia, Brennan, Aravind, & Kauffman, 1991), while 0.2 mg/kg IV may be required for pediatric oncology patients undergoing lumbar puncture and bone marrow aspiration (Sandler et al., 1992). Because midazolam lacks analgesic

TABLE 86.5
Reversal Agents

Drug	Receptor Antagonized	Dose	Comments
Flumazenil	Benzodiazepine	0.01 mg/kg IV q 1–2 min PRN (usual maximum 1 mg; higher doses may be required)	May not reverse respiratory depression Resedation may occur May precipitate seizures May precipitate withdrawal in benzodiazepine-dependent patients
Naloxone	Opioid	1–100 µg/kg IV q 1–2 min PRN: 1 µg/kg for mild sedation, respiratory depression 10–100 µg/kg for obtundation, apnea (usual maximum 400 µg; higher doses may be required)	Resedation may occur Higher doses may cause pulmonary edema May precipitate withdrawal in opioid-dependent patients

Abbreviations: IV, intravenously; PRN, as needed.

properties, appropriate analgesia should be provided for painful procedures.

The principal significant adverse effect of midazolam is respiratory depression, risk for which increases with higher dose and with concomitant administration of opioid analgesics or other sedatives. Appropriate monitoring of children following midazolam administration is imperative. Other side effects such as nausea, vomiting, and hallucinations are uncommon. Recovery from single-dose midazolam usually occurs within 1 to 2 hours, although prolonged sedation may be observed after oral or rectal administration, particularly at higher doses. Persistent sedation may be reversed with the benzodiazepine receptor antagonist flumazenil (Table 86.5), which has also been reported to antagonize at least partially the respiratory depressant effects of midazolam (Gross, Weller, & Conard, 1991). Flumazenil is a proconvulsant and should be used cautiously in patients with predisposition to seizures.

KETAMINE

Ketamine is a sedative–hypnotic agent similar in structure to the now illicit drug of abuse phencyclidine. Unlike most other sedative–hypnotic agents, ketamine has potent analgesic properties, related to its induction of a dissociative state in which pain may be felt but is not perceived as unpleasant. Although its mechanisms of action are incompletely understood, ketamine has significant activity at central nervous system N-methyl-D-aspartate (NMDA) receptors, as well as weaker activity at opioid receptors. Ketamine produces dose-dependent analgesia and sedation, with induction of general anesthesia at higher doses; amnesia is not so pronounced as with benzodiazepines. Ketamine increases cerebral metabolism and oxygen consumption, thereby increasing intracranial pressure, and is a proconvulsant. Although airway reflexes and spontane-

ous ventilation tend to be preserved, ketamine causes increased salivation that may be significant. Ketamine also induces bronchodilation. In contrast to most other sedative–hypnotics, ketamine promotes release of endogenous catecholamines, tending to preserve or even increase heart rate and blood pressure in most patients. As with other phencyclidine derivatives, hallucinations and delirium are not uncommon.

Ketamine has been recommended for procedural analgesia and sedation in children in a variety of settings (Green, Nakamura, & Johnson, 1990; Tobias, Phipps, Smith, & Mulhern, 1992) and has become particularly popular in pediatric emergency departments given its favorable safety profile (Petrack, Marx, & Wright, 1996; Pitetti et al., 2003). Doses of ketamine for procedural analgesia and sedation in children are commonly 4 to 10 mg/kg PO, 3 to 5 mg/kg IM, or 0.5 to 1 mg/kg IV; rates of adequate analgesia and sedation are high, while rates of serious complications are low. Emergence may be prolonged after oral administration, particularly with higher doses, and agitation during emergence is not uncommon. Concomitant administration of anticholinergic agent such as atropine or glycopyrrolate to prevent sialorrhea is recommended. Concomitant administration of low-dose benzodiazepine such as midazolam may decrease likelihood of hallucinations and delirium, although these appear to be less frequent and less severe in younger patients (Green et al., 1990). Although airway reflexes and spontaneous ventilation tend to be preserved, appropriate monitoring is mandatory. Risk of respiratory complications including laryngospasm and bronchospasm may be increased in young infants and in children with respiratory infections. Ketamine should be used cautiously in patients with potentially increased intracranial pressure or predisposition to seizures.

TABLE 86.6
Non-Opioid Analgesics

Drug	Dose	Comments
Acetaminophen	20 mg/kg PO load if desired, then 15 mg/kg PO (maximum 1000 mg) q 4 h; 40 mg/kg PR load if desired, then 20 mg/kg PR (maximum 1300 mg) q 4 h (maximum 4 g/24 h PO/PR)	Hepatic toxicity with overdose Good antipyretic
Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)		
Choline magnesium trisalicylate	10 mg/kg PO/PR (maximum 1000 mg) q 6 h (maximum 4 g/24 h)	Only NSAID without platelet dysfunction No association with Reye syndrome Good antipyretic
Ibuprofen	4–10 mg/kg PO/PR (maximum 800 mg) q 6 h (maximum 4 g/24 h)	Good antipyretic
Ketorolac	0.5 mg/kg IM/IV (maximum 30 mg) q 6 h (duration of therapy must be <5 days)	Only IV NSAID for analgesic use Oral use not approved for children Significant platelet dysfunction Poor antipyretic

Abbreviations: IM, intramuscular; IV, intravenously; PO, orally; PR, rectally.

PROPOFOL

Propofol is a sedative–hypnotic agent devoid of analgesic properties commonly used for induction and maintenance of general anesthesia. Chemically unrelated to any other sedative–hypnotic agent, its mechanisms of action are unknown. Supplied in a lipid emulsion with a highly alkaline pH, propofol may cause significant pain on injection and is available only for intravenous administration. Propofol has some antiemetic efficacy and, like ketamine, promotes bronchodilation. Propofol has an extremely rapid onset of action and, with relatively prompt hepatic conjugation and renal excretion, allows for rapid recovery when given by intermittent bolus dose or brief infusion. Propofol's high lipid solubility and tissue accumulation lengthen its effective half-life with repeated administration or sustained infusion. Particularly in children, prolonged propofol infusion is associated with a rare but catastrophic syndrome of metabolic acidosis and cardiovascular failure that is often fatal (Parke et al., 1992). It is currently recommended that duration of propofol infusion in children not exceed 48 hours, although death has been reported with shorter durations or with reexposure to the drug (Holzki, Aring, & Gillor, 2004).

Propofol induces dose-dependent sedation, but also causes dose-dependent loss of airway reflexes, hypoventilation, apnea, and cardiovascular depression; higher doses induce general anesthesia. Propofol is nonetheless increasingly popular for pediatric procedural sedation, comparing favorably with other agents including midazolam and ketamine (Seigler et al., 2001). Although there has been considerable concern over safety of propofol

administration by non-anesthesiologists (Litman, 1999), evidence suggests that such use may be reasonable under appropriate circumstances. Propofol has been safely and successfully used for pediatric procedural sedation in numerous settings including the intensive care unit (Wheeler, Vaux, Ponaman, & Poss, 2003), burn unit (Sheridan et al., 2003), radiology suite (Hasan, Shayevitz, & Patel, 2003), emergency department (Bassett, Anderson, Pribble, & Guenther, 2003), ambulatory procedure center (Guenther et al., 2003), and dental clinic (Hosey, Makin, Jones, Gilchrist, & Carruthers, 2004). Although such success is impressive, patient safety was protected by restriction of propofol use to appropriately trained personnel working in the context of a dedicated sedation team, following carefully designed protocols and adhering to appropriate standards for patient monitoring and management (Barbi et al., 2003). The usual initial bolus dose of propofol for procedural sedation is 1 mg/kg IV, with subsequent doses of 0.5 mg/kg IV every 5 minutes as needed; usual infusion rates are 100 to 200 µg/kg/min titrated to effect. Higher or repeated doses will rapidly induce deep sedation and general anesthesia. Because propofol lacks analgesic properties, appropriate analgesia should be provided for painful procedures.

NON-OPIOID ANALGESICS

Although often overlooked, non-opioid analgesics are important adjunctive agents in procedural and perioperative pain management for children. Non-opioid analgesics frequently provide adequate analgesia for conditions and procedures associated with mild to moderate pain,

and may reduce opioid requirement in treating moderate to severe pain (Kokinsky & Thornberg, 2003). As with nonpharmacologic techniques, non-opioid analgesics are most effectively used in the context of an integrated pain management strategy. Unlike opioids, NSAIDs demonstrate a ceiling effect: exceeding recommended doses does not significantly improve analgesia, although risk for side effects is increased (Maunuksela & Olkkola, 2003). Commonly used non-opioid analgesics in procedural and perioperative pain management for children include acetaminophen and various NSAIDs (Table 86.6).

ACETAMINOPHEN

Acetaminophen remains widely popular for management of mild to moderate pain in children, and as an antipyretic. Acetaminophen is a potent inhibitor of cyclooxygenase, but unlike the NSAIDs has virtually no anti-inflammatory activity and therefore no associated gastrointestinal, renal, or hematologic complications. The primary toxicity of acetaminophen is hepatic injury, seen with both acute and chronic overdose. Given widespread availability and use, acetaminophen ingestion is common in children and may be fatal if potential toxicity is not recognized and treated promptly.

Acetaminophen in the United States is available in a variety of oral and rectal preparations; intravenous preparations are available in other countries. The usual oral dose of acetaminophen is 15 mg/kg (maximum 1,000 mg) every 4 hours, although an oral loading dose of 20 mg/kg may be given, particularly for procedural or perioperative analgesia. Total dose should not exceed 4 g per day.

Rectal absorption of acetaminophen is slower and bioavailability somewhat variable, requiring higher doses for equivalent analgesia (Rusy, et al., 1995). Although rectal acetaminophen has been shown to reduce pain scores and spare opioid requirement following procedures such as myringotomy tube placement and inguinal hernia repair (Korpela, Korvenoja, & Meretoja, 1999), at least 40 mg/kg must be given (Romsing, Moiniche, & Dahl, 2002). Maintenance rectal acetaminophen 20 mg/kg (maximum 1,300 mg) every 4 hours may be used in patients unwilling or unable to tolerate oral administration; total dose should not exceed 4 g per day. Procedural and perioperative analgesia with acetaminophen is enhanced by NSAIDs (Romsing et al., 2002).

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Like acetaminophen, NSAIDs may provide adequate analgesia for conditions and procedures associated with mild to moderate pain, and are useful in conjunction with opioids in the management of moderate to severe pain (Kokki, 2003; Watcha, Jones, Schweiger, Lagueruela, & White, 1991). NSAIDs are particularly effective in reducing musculoskeletal pain. Unlike acetaminophen, NSAIDs have significant anti-inflammatory activity, from which may arise various gastrointestinal, renal, and hematologic complications. NSAIDs reduce splanchnic and renal perfusion and impair platelet function, potentially causing gastrointestinal ischemia, renal insufficiency, and bleeding. These usually occur only with higher doses or prolonged administration.

Choline magnesium trisalicylate is the only NSAID that does not cause platelet dysfunction, and may be useful in patients with medical coagulopathy or at risk for surgical bleeding. Pediatric aspirin use has declined dramatically since a described association with Reye syndrome in children with primary varicella (Maunuksela & Olkkola, 2003). Although choline magnesium trisalicylate is an aspirin derivative, it has no known association with Reye syndrome. Nonetheless, it may be prudent to limit choline magnesium trisalicylate use in children to patients who have previously had primary varicella or received varicella immunization. Choline magnesium trisalicylate is available in liquid and tablet preparations, and is usually given at a dose of 10 mg/kg PO/PR (maximum 1,000 mg) every 6 hours. Total dose should not exceed 4 g per day. The liquid preparation may be given rectally at the same dose to patients unwilling or unable to tolerate oral administration.

With the dramatic decline in pediatric aspirin use due to concern over Reye syndrome, use of other NSAIDs in children has increased. The most widely used oral NSAID in children in the United States is ibuprofen, available in a variety of liquid, tablet, and capsule preparations. Ibuprofen is a moderate-potency analgesic and excellent antipyretic with an impressive pediatric safety record, but is still probably underused for procedural and perioperative pain management in children (Kokki, 2003). The usual dose of ibuprofen is 4–10 mg/kg PO (maximum 800 mg) every 6 hours. Total dose should not exceed 4 g per day. The liquid preparation may be given rectally at the same dose to patients unwilling or unable to tolerate oral administration.

Ketorolac is the only NSAID available for intravenous use as an analgesic; indomethacin may be given intravenously, but is approved only for medical closure of patent ductus arteriosus in infants. Ketorolac is a high-potency NSAID with analgesic efficacy approaching that of the opioids. Initially approved only for intramuscular administration, ketorolac is safe and effective when given intravenously (Reinhart, Palladinetti, Patel, Raja, & Courtney, 1992). Oral ketorolac administration has been approved for adult patients but not for children. The usual dose of ketorolac is 0.5 mg/kg IM/IV (maximum 30 mg) every 6 hours. As the most potent NSAID, ketorolac also has the highest incidence of side effects: total duration of ketorolac therapy must not exceed 5 days to avoid potentially serious gastrointestinal and renal complications.

TABLE 86.7
Agents for Management of Opioid Side Effects

Side Effect	Agent	Dose	Comments
Pruritus	Diphenhydramine	0.5–1 mg/kg PO/IV (maximum 50 mg) q 6 h PRN	May cause somnolence
Pruritus	Nalbuphine	0.05 mg/kg IV (maximum 5 mg) q 4 h PRN	For pruritus from neuraxial opioid
Pruritus	Naloxone	1 µg/kg/h IV infusion	For pruritus from neuraxial opioid
Nausea	Metoclopramide	0.1 mg/kg IV (maximum 10 mg) q 6 h PRN	May cause extrapyramidal reactions
Nausea	Ondansetron	0.1 mg/kg IV (maximum 4 mg) q 6 h PRN	Expensive
Nausea	Promethazine	0.25–0.5 mg/kg PO/PR/IM/IV (maximum 25 mg) q 6 h PRN	May cause somnolence

Abbreviations: IM, intramuscularly; IV, intravenously; PO, orally; PR, rectally; PRN, as needed.

Significant platelet dysfunction may develop after a single dose of ketorolac, and its use in patients at high risk for surgical bleeding is controversial. Initial experience suggested greater intraoperative blood loss during tonsillectomy in children receiving perioperative ketorolac (Rusy et al., 1995), and retrospective studies indicated higher rates of postoperative hemorrhage (Gallagher, Blauth, & Fornadley, 1995; Judkins, Dray, & Hubbell, 1996). Other retrospective studies suggested otherwise (Agrawal, Gerson, Seligman, & Dsida, 1999), and prospective randomized trials have primarily shown only nonstatistically significant trends toward increased bleeding (Bailey, Sinha, & Burgess, 1997). Ketorolac product literature warns against its use in patients at high risk for surgical bleeding; it is probably prudent to avoid ketorolac administration in such patients, and in patients with medical coagulopathy, until more definitive information is available.

OPIOID ANALGESICS

Reluctance to use opioids in children has historically been an important reason for inadequate pediatric pain management. Opioids remain the mainstay of pharmacologic therapy for moderate to severe pain, however, and have established roles in procedural and perioperative pain management for children (Yaster, Kost-Byerly, & Maxwell, 2003). Acting on various subtypes of opioid receptors throughout the central nervous system, opioids cause dose-dependent pain relief as well as respiratory depression; other opioid-mediated side effects include somnolence, pupillary constriction, decreased gastrointestinal motility, nausea, and urinary retention. Many opioids induce histamine release, causing urticaria, pruritus, nausea, bronchospasm, and occasionally hypotension. Pruritus is more common and typically more intense with neuraxial administration, likely due to central nervous system opioid effect rather than to histamine release. Pruritus and nausea secondary to opioid therapy may be managed with a variety of agents (Table 86.7).

Opioid analgesics do not generally have maximum effective doses. Recommended doses are for initial administration in opioid-naïve patients; titration to clinical effect is necessary, and higher doses may be required. Opioid therapy longer than 7 to 10 days may result in physical dependence, requiring a period of weaning prior to discontinuation of therapy (Shannon & Berde, 1989). Psychopathologic addiction rarely develops in children receiving opioids for analgesia, and is not a valid reason to withhold appropriate pain management.

The opioid receptor antagonist naloxone rapidly reverses opioid effects (Table 86.5). Naloxone may precipitate withdrawal in opioid-dependent patients, and pulmonary edema has been reported with higher doses. Mild opioid-induced respiratory depression may be treated with naloxone 1 µg/kg IV titrated every 1 to 2 minutes as needed, while doses of 10 to 100 µg/kg IV should be reserved for obtundation or apnea secondary to opioid overdose.

Opioids are commonly administered in conjunction with various sedative–hypnotic agents, particularly benzodiazepines, increasing risk for respiratory depression (Bailey et al., 1990; Yaster, Nichols, Deshpande, & Wetzel, 1990). Midazolam combined with morphine or fentanyl provides safe and effective procedural analgesia and sedation in pediatric oncology patients, but transient desaturation is common (Sievers, Yee, Foley, Blanding, & Berde, 1991). Concomitant administration of opioids and sedative–hypnotic agents requires particularly careful titration of doses, appropriate monitoring, and full capability to manage complications including respiratory depression and apnea. Appropriate reversal agents should be available (Table 86.5).

The lytic cocktail, or DPT (Demerol®, Phenergan®, Thorazine®), is a combination of meperidine, promethazine, and chlorpromazine for intramuscular injection. Although the DPT lytic cocktail has been used extensively in children to provide analgesia and sedation for minor procedures such as laceration repair and fracture reduction, sedation is sometimes inadequate, recovery is often prolonged, and respiratory depression may occur (Nahata, Clotz, & Krogg, 1985). Numerous more appropriate agents are available (Petrack et al., 1996), with

TABLE 86.8
Lower-Potency Oral Opioids

Drug	Dose	Comments
Codeine	1 mg/kg PO q 4 h	Tablet and liquid preparations usually as combination products with acetaminophen High rate of gastrointestinal side effects
Hydrocodone	0.2 mg/kg PO q 4 h	Tablet and liquid preparations usually as combination products with acetaminophen or NSAID Lower rate of gastrointestinal side effects than codeine
Oxycodone	0.1 mg/kg PO q 4 h	Tablet preparations as oxycodone or as combination products with acetaminophen or NSAID Liquid preparation as oxycodone Low rate of gastrointestinal side effects Sustained-release preparation available for chronic therapy

Abbreviations: NSAID, nonsteroidal antiinflammatory drug; PO, orally.

individualized titration preferred to provide rapid onset, predictable depth of analgesia and sedation, and prompt recovery. Use of the DPT lytic cocktail is no longer recommended (American Academy of Pediatrics Committee on Drugs, 1995).

ORAL OPIOIDS

When gastrointestinal function permits, oral opioids offer the benefits of sustained pain relief and freedom from parenteral therapy. Several lower-potency oral opioids are used commonly in procedural and perioperative pain management for children (Table 86.8), often providing adequate analgesia for conditions and procedures associated with mild to moderate pain. Onset of action is relatively slow, rendering oral opioid therapy generally unsuitable for acute management of severe pain.

Codeine, available in tablet and liquid preparations usually in combination with acetaminophen, may be given at a dose of 1 mg/kg PO every 4 hours, but has a high rate of gastrointestinal upset. Hydrocodone, available in tablet and liquid preparations usually in combination with acetaminophen or NSAID, may be given at a dose of 0.2 mg/kg PO every 4 hours and tends to cause less gastrointestinal upset than codeine. Oxycodone is available in tablet preparations as an isolated product or in combination with acetaminophen or NSAID; oxycodone liquid preparations contain only oxycodone. Oxycodone causes little histamine release or gastrointestinal upset and is generally well tolerated. The usual dose of oxycodone is 0.1 mg/kg PO every 4 hours. Sustained-release oxycodone is available for chronic therapy.

Although often given intravenously, higher-potency opioids may also be given orally (Table 86.9). Morphine may be given at a dose of 0.3 mg/kg PO every 3 hours. The histamine release induced by morphine may cause urticaria, pruritus, bronchospasm, and even hypotension at higher doses, although these are less common with oral administration. Sustained-release oral morphine is available for chronic therapy. Hydromorphone may be given orally at a dose of 20 to 40 µg/kg every 3 hours, and causes less histamine release than morphine. Meperidine may be given orally at a dose of 1 mg/kg every 3 hours, but should not be used for prolonged therapy given risk for seizures with accumulation of the neurotoxic metabolite normeperidine. Normeperidine is renally excreted, and risk for seizures is increased in patients with renal disease. Methadone may be given orally at a dose of 0.1 mg/kg every 6 to 12 hours and is particularly useful for chronic therapy in opioid-dependent patients (Tobias, Schleien, & Haun, 1990). Methadone maintenance therapy to treat psychopathologic opioid addiction may be undertaken only at federally licensed facilities.

Oral transmucosal fentanyl citrate (OTFC) is an innovative formulation of fentanyl in a candy matrix lozenge attached to a stick. OTFC may provide effective preanesthetic sedation in children (Friesen, Carpenter, Madigan, & Lockhart, 1995; Streisand et al., 1989), as well as analgesia and sedation for painful procedures (Schechter, Weisman, Rosenblum, Bernstein, & Conard, 1995), although the product is no longer marketed for these indications. Newer preparations of OTFC are currently under investigation for use in children with oncologic disease and other chronic painful conditions. Sucking the fentanyl lozenge causes transmucosal absorption of approximately 25% of the administered dose; the remainder is swallowed, resulting in a total bioavailability of approximately 50%. Nausea and emesis are common. The usual dose is 5 to 15 µg/kg (maximum 400 µg); children may require higher doses than adults. OTFC administration in children requires appropriate monitoring (Yaster, 1995).

INTRAVENOUS OPIOIDS

Intravenous opioids remain the mainstay of therapy for moderate to severe pain (Table 86.9). Analgesic require-

TABLE 86.9
Higher-Potency Opioids

Drug	Dose	Comments
Fentanyl	5–15 µg/kg PO (interval dosing not defined)	Oral preparation largely for single dose use
	0.5–1 µg/kg IV q 1 h	Rapid infusion may cause chest wall rigidity in infants
	PCA: 1 µg/kg/h basal, 1 µg/kg demand	Transdermal patch not for acute management
	Patch: 25 µg = 1 mg/h IV morphine	
Hydromorphone	20–40 µg/kg PO q 3 h	Less histamine release than morphine
	10–20 µg/kg IM/IV/SC q 3h	
	PCA: 4 µg/kg basal, 4 µg/kg demand	
Meperidine	1 mg/kg PO/IM/IV/SC q 3 h	Neurotoxic metabolite, may precipitate seizures
	PCA: not recommended	No hepatobiliary advantage at usual doses
Methadone	0.1 mg/kg PO q 6–12 h	Useful for long-term therapy, especially in palliative care
	0.05 mg/kg IV q 6–12 h	Treatment of opioid addiction must be in licensed facility
Morphine	0.3 mg/kg PO q 3 h	Histamine release may cause urticaria, pruritus, bronchospasm, hypotension
	0.1 mg/kg IM/IV/SC q 3 h	High dose and rapid administration increase risk for histamine release
	PCA: 0.02 mg/kg basal, 0.02 mg/kg demand	Sustained-release oral preparation available for chronic therapy

Note: Doses are for initial administration in opioid-naïve patients; titration to clinical effect is necessary; higher doses may be required. Doses should be reduced to 25–50% of the above in neonates and young infants.

Abbreviations: IM, intramuscularly; IV, intravenously; PCA, patent-controlled analgesia; PO, orally; SC, subcutaneously.

ments vary among individuals and over the duration of pain in each patient, requiring ongoing assessment of analgesia and adjustment of pain management regimens. Intravenous opioids offer the advantages of rapid onset, potent analgesia, and ease of titration. Side effects are more common with intravenous opioids and potentially more serious, mandating appropriate monitoring and prompt management of complications. Equipotent doses of opioids carry similar risks of side effects (Yaster et al., 2003).

Morphine is the traditional intravenous opioid analgesic, given at a dose of 0.1 mg/kg IV every 3 hours. Morphine and its congeners should be used with caution in neonates, who are more sensitive to the depressant effects of morphine due to immaturity of the blood–brain barrier. Morphine clearance may also be prolonged in infants less than 3 to 6 months of age (Shannon & Berde, 1989). Young infants receiving intravenous opioids should be observed closely with continuous respiratory monitoring, and doses should probably be reduced to 25 to 50% of usual. Hydromorphone may be given at a dose of 10 to 20 µg/kg IV every 3 hours, and causes less histamine release than morphine. Meperidine may be given at a dose of 1 mg/kg IV every 3 hours, but should not be used for prolonged therapy given risk for seizures with accumulation of the neurotoxic metabolite normeperidine. Normeperidine is renally excreted, and risk for seizures is increased in patients with renal disease. Although historically popular, meperidine offers no significant advantages over morphine and, in particular, causes no less hepatobiliary spasm than any other opioid at usual equipotent doses. Methadone may be given at a dose of 0.05 mg/kg IV every 6 to 12

hours, although there is usually little reason to prefer intravenous to oral administration. Fentanyl, a potent synthetic opioid, is used commonly in procedural and perioperative pain management for children because of its rapid onset and short duration of action. The usual dose is 0.5 to 1 µg/kg IV every hour, with more frequent titration during and immediately after procedures. Incremental doses of fentanyl up to 4 µg/kg IV have provided satisfactory analgesia for pediatric oncology patients, although patients tended to prefer midazolam, perhaps because of its amnestic properties (Sandler et al., 1992).

PATIENT-CONTROLLED ANALGESIA

Optimal management of moderate to severe pain mandates that analgesia be provided on a scheduled rather than an as-needed basis, as the latter often delays treatment and compromises pain control. Intramuscular injection of opioid is undesirable, as this is more painful and less effective than other alternatives (Berde, 1989; Berde, Lehn, Yee, Sethna, & Russo, 1991). Opioid administration by intravenous infusion using patient-controlled analgesia (PCA) modalities provides scheduled analgesia via an acceptable route and affords excellent procedural and perioperative pain management for children (Wilder, Berde, Troshynski, Cahill, & Sethna, 1992). With age-appropriate instruction, most school-age children may safely and effectively control opioid delivery by PCA (Berde et al., 1991; Gaukroger, Tomkins, & van der Walt, 1989). Nurse- or parent-controlled PCA may be used for children unable or unwilling to control their own pump (Algren, Deegear, Skjonsby,

TABLE 86.10
Topical Anesthetic Formulations

Formulation	Local Anesthetic	Comments
EMLA cream	Lidocaine 2.5%/prilocaine 2.5%	Requires 1–4 hours of application Requires occlusive dressing Rare risk for methemoglobinemia in infants
ELA-Max	Liposomal lidocaine 4% or 5%	Requires 30 minutes of application No occlusive dressing Nonprescription
Numby Stuff	Iontocaine (lidocaine 2% + epinephrine 1:100,000)	Requires 10 minutes of application Tingling sensation may frighten some children
TAC	Tetracaine 0.5–1% + epinephrine 1:2,000–4,000 + cocaine 4–11.8%	Requires 20 minutes of application Avoid mucous membranes Avoid terminally perfused areas Risk for cocaine toxicity

& Algren, 1998; Lloyd-Thomas & Howard, 1994; Weldon, Connor, & White, 1991), although risk of respiratory depression rises if dosing interval is not adequately increased, particularly in combination with basal infusions (Monitto et al., 2000).

Morphine is the most common choice for PCA, but hydromorphone and fentanyl may be used (Table 86.9). Meperidine PCA is not recommended because of increased risk for toxicity with sustained administration. Routine pediatric PCA regimens provide morphine 0.02 mg/kg (maximum 1 mg), hydromorphone 4 µg/kg (maximum 200 µg), or fentanyl 1 µg/kg (maximum 50 µg) IV every 8 to 15 minutes as needed for patient-controlled administration, or every 15 to 60 minutes as needed for nurse- or parent-controlled administration. Longer dosing intervals may be safer in younger or medically more fragile patients. Concomitant basal infusion to sustain drug levels during sleep has been advocated and is used by many practitioners, although this has not been shown to improve analgesia significantly (McNeely, Pontus, & Trentadue, 1992). Given potential for drug accumulation and respiratory depression, it may be prudent to restrict basal infusions to patients with severe pain unlikely to be controlled with interval dosing alone.

Patients receiving PCA should be assessed frequently, and doses and intervals adjusted to ensure adequate analgesia and patient safety. Continuous pulse oximetry is recommended for children on any opioid infusion at least until steady state has been achieved, usually 24 to 48 hours. Prolonged monitoring may be appropriate in younger or medically more fragile patients, or if the PCA regimen is significantly modified. Thorough instruction of patients, families, and caregivers regarding appropriate PCA use is essential.

Fentanyl is available as a transdermal patch allowing for continuous transcutaneous absorption over 72 hours mimicking an intravenous infusion; one 25-µg fentanyl patch is roughly equivalent to 1 mg/hour intravenous mor-

phine. Onset is slow, however, and absorption variable. Although useful in some settings for management of chronic pain, transdermal fentanyl is not indicated for acute pain management (Gaukroger, 1993; Yaster et al., 2003).

TOPICAL AND LOCAL ANESTHETICS

Innovations in formulation of local anesthetics have yielded several new compounds that provide effective cutaneous analgesia while reducing pain associated with local anesthetic injection (Table 86.10). Such formulations enhance usefulness of topical anesthetics for minor procedures, and in many instances reduce or eliminate need for systemic analgesia and sedation.

Eutectic mixture of local anesthetics (EMLA®) cream is a combination of 2.5% lidocaine and 2.5% prilocaine. When applied in a thick layer and covered with an occlusive dressing for at least 60 minutes, EMLA cream promotes local anesthetic penetration of intact skin, producing effective cutaneous analgesia for minor procedures such as intravenous cannulation and accessing of subcutaneous injection ports (Hallen, Olsson, & Uppfeldt, 1984). EMLA cream may be a useful adjunct for procedures such as lumbar puncture and bone marrow aspiration, and has been used for neonatal circumcision (Benini, Johnston, Faucher, & Aranda, 1993). EMLA cream has been shown to reduce pain associated with immunization in infants (Taddio, Nulman, Goldbach, Ipp, & Koren, 1994) and older children (Cassidy et al., 2001), and even to provide analgesia for chest tube removal (Rosen et al., 2000). EMLA cream is easy to apply; families may do so at home to minimize waiting. Side effects are minor and include erythema, blanching, and rash. Although the prilocaine component has caused concern over risk for methemoglobinemia, particularly with generous application or in infants, incidence of methemoglobinemia is extremely low when the product is used appropriately.

EMLA cream should be applied only to intact skin. Analgesia increases with prolonged application up to 4 hours (Cooper, Gerrish, Hardwick, & Kay, 1987).

ELA-Max® is an over-the-counter preparation of 4% or 5% liposomal lidocaine; other nonprescription preparations of 4% lidocaine for topical use are marketed under a variety of other brand names. Like EMLA cream, ELA-Max promotes local anesthetic penetration of intact skin, producing effective cutaneous analgesia for minor procedures. In contrast to EMLA cream, ELA-Max does not entail an occlusive dressing, requires only 30 minutes to achieve anesthesia, lacks prilocaine, and is available without prescription. The two preparations have been shown to provide equivalent cutaneous analgesia for children undergoing venipuncture (Eichenfield, Funk, Fallon-Friedlander, & Cunningham, 2002).

Numby Stuff® is a unique system for intradermal delivery of local anesthetic. Numby Stuff utilizes iontophoresis, employing mild electrical current to promote rapid intradermal transport of Iontocaine®, a solution of 2% lidocaine and 1:100,000 epinephrine. Iontocaine is applied and covered with specialized electrodes connected to the Numby Stuff generator. Dermal anesthesia to a depth of 10 mm is obtained within 10 minutes. Numby Stuff is effective for intravenous catheter insertion and pulsed dye laser therapy (Ashburn et al., 1997), and provides cutaneous analgesia more rapidly and effectively than EMLA cream (Squire, Kirchhoff, & Hissong, 2000). Although the system is approved for use in all ages, younger children may be frightened by the tingling sensation produced by the electrical current.

Tetracaine–adrenaline–cocaine (TAC), a solution of 0.5% tetracaine, 1:2,000 epinephrine, and 11.8% cocaine, provides effective cutaneous analgesia for repair of superficial lacerations in children (Bonadio & Wagner, 1988). Alternative effective formulations with lower risk for cocaine toxicity are 1% tetracaine, 1:4,000 epinephrine, and 4% cocaine (Smith & Barry, 1990) and 0.5% tetracaine, 1:2,000 epinephrine, and 4% lidocaine (Ernst et al., 1995). TAC was sufficient in 89% of patients with scalp and facial wounds, but 57% of patients with extremity wounds required supplemental local anesthesia (Hegenbarth et al., 1990). Usual dose of TAC is 1 to 3 ml (maximum 0.09 ml/kg), applied with gauze held in place for 15 to 20 minutes. To avoid systemic cocaine toxicity, TAC should not be applied to mucous membranes. Cocaine and epinephrine both cause vasoconstriction; TAC should not be applied to areas supplied by terminal arteries, including ears, nose, penis, and digits. Health care personnel should wear gloves when applying TAC.

Simple pH buffering helps reduce pain with injection of conventional local anesthetics and may increase efficacy. Acid pH of local anesthetic solutions enhances solubility and prolongs shelf life, but is largely responsible for pain with injection. Addition of 1 mEq sodium bicarbonate to 10 ml local anesthetic significantly reduces pain during injection without precipitation of the solution (Christoph, Buchanan, Begalla, & Schwartz, 1988). Conventional solutions of local anesthetic for infiltration may be treated in this manner; bicarbonate is added immediately before use.

REGIONAL ANESTHETIC TECHNIQUES

In addition to providing surgical anesthesia, regional anesthetic techniques may provide excellent procedural and perioperative pain management for children. In pediatric practice, these techniques are commonly performed in conjunction with general anesthesia (Dalens, 1989; Ross, Eck, & Tobias, 2000), reducing maintenance anesthetic requirements and facilitating rapid emergence. Analgesia may persist for hours or even days, depending on technique and medications utilized, reducing or eliminating requirement for supplemental systemic analgesics. In some settings, perioperative regional anesthesia in children has been shown to improve surgical outcomes (McNeely, Farber, Rusy, & Hoffman, 1997). Pediatric application of regional anesthetic techniques continues to expand both in the operating room and beyond (Tobias, 2002). Regional anesthetic techniques employed to provide procedural and perioperative pain management for children include a variety of peripheral nerve, plexus, and neuraxial blocks.

PERIPHERAL NERVE AND PLEXUS BLOCKS

Successful block of virtually any peripheral nerve or plexus may be accomplished with appropriate equipment and sufficient practitioner interest (Dalens, 2000; Ross et al., 2000; Sethna & Berde, 1994). Supraorbital and occipital nerve blocks provide analgesia over the anterior and posterior scalp, respectively, and may be used for laceration repair or to provide analgesia following craniotomy. Infraorbital nerve block and various palatal blocks provide analgesia of the upper lip and palate for procedures including cleft lip and cleft palate repair, and may be particularly useful in medically disadvantaged settings when avoidance of opioid is desired. Retrobulbar block anesthetizes orbital contents and induces profound analgesia of the globe and surrounding structures; ophthalmologists generally perform such blocks. Intercostal nerve blocks provide excellent analgesia and enhance pulmonary function following thoracotomy (Matsota, Livanios, & Marinopoulou, 2001), and lessen pain of thoracostomy tubes and rib fractures. Periumbilical compartment block is useful for umbilical hernia repair, while ilioinguinal and iliohypogastric nerve blocks are useful for a variety of unilateral inguinal and groin procedures. Numerous techniques for penile nerve block in distal penile surgery including circumcision and hypospadias repair have been described.

Although preemptive peripheral nerve blocks offer theoretical advantages of preemptive analgesia and lessened overall pain experience, this has not been reliably demonstrated in clinical practice, particularly in children (Ates, Unal, Cuhruk, & Erkan, 1998; Suresh et al., 2004).

Plexus blocks are performed less frequently in children than in adults, often due to practitioner inexperience but also to logistical challenges in applying adult techniques to pediatric patients. Brachial plexus block in children is most commonly accomplished via an axillary approach, providing analgesia to the arm below the shoulder. Interscalene brachial plexus block is performed somewhat less frequently in children, inducing analgesia of the shoulder and proximal arm but occasionally sparing the distal hand. Modern experience with supraclavicular and infraclavicular approaches to brachial plexus block in children is limited. Direct lumbosacral plexus block is uncommon in pediatric practice; peripheral regional anesthesia of the lower extremity in children is generally provided through various sciatic and femoral nerve blocks. Preemptive plexus blocks offer theoretical advantages of preemptive analgesia and lessened overall pain experience, but this has not been reliably demonstrated in clinical practice, particularly in children (Altintas, Bozkurt, Ipek, Yucel, & Kaya, 2000). Intravenous regional anesthesia of the extremities, or Bier block, has been described in children (Davidson, Eyres, & Cole, 2002), but application may be limited by risk of local anesthetic toxicity.

NEURAXIAL BLOCKS

Neuraxial blocks include spinal and epidural techniques. Spinal block, with injection of anesthetic into cerebrospinal fluid, is performed in children almost exclusively for procedures in infants at high risk for apnea following general anesthesia, or for terminal analgesia in palliative care. Epidural block, with injection of anesthetic into the potential space between ligamentum flavum and dura mater, is a far more common technique for procedural and perioperative pain management in children. Anesthetic may be administered as a single injection, or by repeated injection or continuous infusion through an indwelling catheter.

The most common neuraxial block in children is caudal block, in which the epidural space is accessed through the sacral hiatus created by the failure of fusion of the spinous process of the fifth sacral vertebra. Caudal block is most commonly performed as a single injection, 1 ml/kg of anesthetic providing reliable analgesia below the umbilicus in patients less than 30 kg. The technique is relatively straightforward, with high rates of success and low rates of complications (Broadman, Hanallah, Norden, & McGill, 1987; Dalens & Hasnaoui, 1989). Caudal block is especially popular for inguinal and groin procedures including inguinal hernia and hydrocoele repair, orchio-

pexy, hypospadias repair, and circumcision. Agents administered determine duration of analgesia.

Caudal block with local anesthetic may provide analgesia for several hours. Addition of opioid prolongs analgesia, but entails risk of opioid-mediated side effects including pruritus, nausea, urinary retention, and respiratory depression. Duration and distribution of analgesia and risk of side effects are all greater with increasing opioid hydrophilicity, which promotes uptake into cerebrospinal fluid and enhances distal spread. Opioid side effects may be treated with a variety of pharmacologic agents (Table 86.7), or reversed with naxolone if necessary (Table 86.5). Caudal fentanyl, a highly lipophilic opioid, may be used for outpatient and ambulatory surgery in children. Caudal morphine, a highly hydrophilic opioid, provides analgesia for greater than 12 hours at a dose of 0.03 to 0.07 mg/kg but entails significant risk of opioid-mediated side effects (Krane, Tyler, & Jacobson, 1989; Valley & Bailey, 1991). Caudal administration of clonidine (Sharpe et al., 2001) and ketamine (Weber & Wulf, 2003) has been described.

Excellent analgesia may be provided with administration of anesthetic by repeated injection or continuous infusion through indwelling epidural catheters, which may be placed via caudal, lumbar, or thoracic approaches to the epidural space in children (Berde, Sethna, Yemen, Pullerits, & Miler, 1990; Desparmet, Meistelman, Barre, & Saint-Maurice, 1987; Gunter & Eng, 1992). Epidural catheters may be inserted caudally and threaded to the desired vertebral level (Dalens & Hasnaoui, 1989); this is more readily accomplished in infants and young children, and is facilitated by use of styletted catheters. Epidural catheters in children may also be placed directly at the desired vertebral level by lumbar or thoracic approaches. Historical concern over safety of thoracic epidural placement in children under general anesthesia has been largely theoretical, although a neurologic complication of such placement has recently been reported (Kasai, Yaegashi, Hirose, & Tanaka, 2003).

Selection of agents for epidural infusion is based on position of the catheter tip relative to the painful area, as well as on distribution and intensity of analgesia desired. Concomitant neuraxial administration of local anesthetic and opioid enables reduction in local anesthetic concentration and opioid dose, minimizing motor block and decreasing risk of opioid-mediated side effects (McIlvaine, 1990). Numerous combinations of local anesthetic and opioid may be used for epidural infusion (Table 86.11). If the epidural catheter tip has been appropriately placed in close proximity to the painful area, dilute local anesthetic with lipophilic opioid such as fentanyl may be sufficient. If the epidural catheter tip is at a dermatomal level distant from that of the painful area, or if the painful area covers multiple dermatomes, addition of increasingly hydrophilic opioid such as hydromorphone or morphine may be necessary. As with caudal administration, duration and distribution of

TABLE 86.11
Local Anesthetics and Opioids for Epidural Infusion

Local Anesthetics	Opioids
Bupivacaine 0.0625–0.1%	Fentanyl 0.5–1 µg/kg/h
Levobupivacaine 0.0625–0.1%	Hydromorphone 2–4 µg/kg/h
Lidocaine 0.1–0.5%	Morphine 3–6 µg/kg/h
Ropivacaine 0.1–0.2%	

Note: Infusion rates are commonly 0.2–0.3, 0.3–0.4, and 0.4–0.5 ml/kg/h for thoracic, lumbar, and caudal catheters, respectively.

analgesia and risk of side effects with epidural opioid are all greater with increasing opioid hydrophilicity, which promotes uptake into cerebiospinal fluid and embraces distal spread (Taylor & Boswell, 1991); risk of side effects increases with increasing opioid hydrophilicity. Opioid side effects may be treated with a variety of pharmacologic agents (Table 86.7), or reversed with naloxone if necessary (Table 86.5).

Close observation of patients receiving epidural infusions is essential. Continuous monitoring of oxygen saturation and cardiorespiratory parameters may be employed for any patient receiving epidural opioid (McIlvaine, 1990), or such monitoring may be reserved for patients at increased risk for respiratory depression. Infants less than 6 months of age, patients with preexisting neurologic or pulmonary disorders, and patients receiving hydrophilic opioid such as morphine or hydromorphone may merit more intensive monitoring (Berde et al., 1989). Frequent assessment of level of consciousness, adequacy of pain management, degree of motor and sensory block, and presence of side effects should be performed for all patients receiving epidural infusions. Although somewhat complex and labor intensive, epidural analgesia is appropriate for patients with severe pain or unique circumstances limiting safety or efficacy of other pain management interventions.

CONCLUSION

Procedural and perioperative pain management for children entails adequate analgesia and appropriate sedation for patients undergoing a wide range of diagnostic and therapeutic procedures including surgery. Procedural analgesia and sedation for children requires supervision by competent personnel adhering to appropriate standards for patient monitoring and management. Perioperative pain management for children takes into account patient anxiety concerning surgery as well as pathophysiology of surgical pain. Nonpharmacologic techniques seek to enhance patients' ability to cope with pain by modifying pain perception and, in the case of various biophysical

modalities, by modulating nociceptive transmission. Numerous sedative–hypnotic agents are available for procedural and preoperative sedation in children; most lack analgesic properties. Non-opioid analgesics provide important adjunctive analgesia, while opioids remain the mainstay of therapy for moderate to severe pain. Patient-controlled analgesia is an appropriate modality for children requiring ongoing intravenous opioid. Several innovative formulations of topical anesthetics provide effective cutaneous analgesia for minor procedures while reducing pain associated with local anesthetic injection. Regional anesthetic techniques including peripheral nerve, plexus, and neuraxial blocks provide excellent pain control and reduce requirement for supplemental systemic analgesics. Integrated procedural and perioperative pain management for children employs nonpharmacologic techniques in combination with appropriate pharmacologic agents and anesthetic techniques to optimize pain relief, minimize side effects, and facilitate recovery.

Occupational Medicine for the Pain Practitioner

Hal Blatman, MD

INTRODUCTION

The pain management professional may interface with the field of occupational medicine in many aspects of medical practice. Several scenarios are most likely:

- Patient may have been injured at work
- Work may be perpetuating the patient's pain and injury
- Patient may be trying to continue working
- Patient may be trying to return to work after/during treatment for pain
- Patient may be disabled from work

To understand these scenarios the health care worker should be aware of the needs of the patient and the needs of the workplace. The best circumstances are when these needs are not in conflict. Sometimes the treating physician or other medical caregiver is pressured by one party or the other. In these circumstances, it is helpful to be able to put these varied needs into perspective.

MEDICAL CARE OF THE INJURED WORKER

The physician's role may be direct patient care. Employers understand that delayed return to work is predictive of long-term disability. They therefore may make every effort to bring the injured person back to work as soon as possible. Also, companies may be penalized for each day that an employee is off work. These situations are called "lost time injuries." Sometimes it is to the company's advantage to bring an employee back to work doing light duty, which in some cases amounts to doing almost nothing but lying down in the nurse's office.

In patient care, the treating physician may be contacted by the workplace and asked to return the patient to work on "light duty" instead of keeping the patient off work. Finding a balance between the needs of the patient and the needs of the company is very important. An uncompromising position may result in the patient being dismissed from his or her job. Conversely, submitting to the will of the company may put the patient in jeopardy of further injury or otherwise delay healing. The best solution is to facilitate a return to work that does not jeopardize the patient. Limited or light duty is an option for the prescribing doctor. A "return to work" note is a prescription that places physical limitations on what the company can expect the patients/employees to do in performance of their job duties. The practitioner has several choices and an opportunity for creativity. Some suggestions include:

- Limit work hours per day or per week, and/or days per week
- Limit body activities
- Specify how much weight can be lifted
- Specify how much bending and stooping
- Specify how much walking and/or standing
- Specify how much working above chest height
- Specify a need for breaks to stretch or rest
- Specify how often and how long
- Specify what needs to be stretched or rested

The prescription may be worded in a positive or negative fashion. An example of a positive-worded limitation is: May lift up to 25 lb on an occasional basis. Example of negative-worded limitations is: May not lift over 25 lb, and may not lift repetitively. Another style is to say that

the patient may return to work with accommodations, and then list each of these specifically.

In consideration of returning to work, industry has recognized that the longer patients are off work, the more difficult it is to get them back to work. From the standpoint of patient care, patients who are off work longer become more physically deconditioned. They may also become more depressed because of their inability to function and contribute. Many patients will benefit physically and psychologically by early return to work if they can be adequately protected from harm by the prescription of limitations.

Sometimes the patient may not be capable of performing at any level of light duty, and sometimes the company may not have a light duty program that can accommodate the prescribed medical restrictions. In these cases, the employer and insurance disability carrier may need to know projected length of time of disability and recommendations for rehabilitation.

Occasionally, a worker suffers injury by violence or abuse in the workplace. These cases have compounding issues beyond any physical problem.

INDEPENDENT MEDICAL EXAMINATION

An independent medical examination (IME) is an evaluation by a health care professional who is not involved in caring for and does not know the particular patient. This person is contracted by the requesting party for the purpose of providing a fresh look at particular issues (McCunney, 2003). It is generally thought that the treating professional may be biased toward the patient's interests, or even his or her own selfish interests. An IME provides for an impartial professional who can offer opinions on issues in question.

Employers and insurance companies hire doctors and therapists to provide opinions about an injured person's condition, diagnosis, treatment, and disability. The general purpose is to clarify medical and job-related issues. Reports provide information for case management and for evidence in legal proceedings. Sometimes these evaluations are based solely on medical records, and sometimes they are also based upon office testing and examination. The pain management professional may be called upon to perform such an evaluation. The patient in question will not be under this professional's care, and the examining professional is generally not allowed to establish a future doctor–patient or treatment relationship.

In this situation, it is important to carefully examine any documents presented for review, perform and document any requested examination, and then carefully answer the questions posed by the hiring agency. Anything written in the report should be based on the presented information, examination if indicated, and the examiner's training and experience. Usually the report is all that is needed. Sometimes the examiner will be asked to testify in court about the stated information.

After an IME, the treating professional may be in the position of having to write a rebuttal report. These reports should carefully address the issues, using history, examination findings, treatment results, appropriate references, and opinions.

The insurance company or employer may indeed be looking for the best answers for the person involved. In this case, opinions are sought to ascertain that the employee/insured is getting the best possible care and therefore has the best likelihood for recovery and return to work.

Alternatively, the insurance company or employer may be primarily interested in reducing costs and financial exposure. In this case, opinions are sought in an effort to minimize medical and disability costs. In general, IMEs are more likely to be requested in cases with prolonged recovery and disability. The goal may be to ascertain the necessity, effectiveness, and duration of treatment, or to assess the validity and duration of disability.

The injured or disabled worker may also request an IME. This may be requested through an attorney, or directly by the patient. Generally the purpose of the evaluation is to gather data from a "non-interested" party in order to support the need for treatment or the validity of disability.

IMEs may also be requested to obtain an opinion regarding causation of an injury. This may be a critical issue in work-related injury and liability cases. Work-related problems are defined as those that arise out of and during the course of employment. There may be preexisting chronic conditions and other exposures to injury. The practitioner may be asked to provide an opinion regarding causation to a reasonable degree of medical probability. Reasonable degree means more than a 50% chance of occurrence. An ultimate cause is one that is the initial factor that leads to the problem. A proximate cause is one that occurs just before or closest to the origin of the problem. Because a medical or psychological condition may be the result of one or several factors, it is often necessary, at some point, to portion treatment cost or disability between parties and events.

IMEs may also be requested to evaluate a person for an impairment rating. These examinations and evaluations are usually based on *The AMA Guides*, a textbook that can be purchased from the American Medical Association (Cocchiarella & Anderson, 2001). The American College of Occupational and Environmental Medicine organizes courses to train doctors in performing these evaluations.

WORK-RELATED INJURIES

Most injuries at work are caused by overexertion. These are generally lifting injuries. Injuries are also caused by

repetitive motion, vibration of tools, heat or cold stress, falls, and direct trauma.

The most frequent cause of activity limitation in people younger than 45 years is back pain (Anderson, 1997). It is also one of the most frequent reasons for visits to the doctor and a high ranking reason for surgical procedures.

Work-related musculoskeletal disorders of the upper extremity and neck come mainly from repetitive motion injuries, applying force with the hands, mechanical stresses, vibration, and sustained or awkward postures. The best-known upper extremity disorder is carpal tunnel syndrome. Other disorders include epicondylitis, tendonitis, and bursitis in various places.

Repetitive motion injuries occur when the required task of motion exceeds the body's ability to recover before it is asked to move again. If muscular contraction is more forceful, these injuries are more severe. If the muscle fails to recover, there is generally some type of tissue damage. Tissue changes can also lead to nerve compression, chronic fibrous reaction in the tendon, tendon rupture, calcium deposits, fibrous nodule formations, and trigger finger (Gorsche et al., 1998). Repetitive motion also causes muscle tightening, fascial tightening, and activation/perpetuation of myofascial trigger points (Travell & Simons, 1983).

Work performed in a static posture may also trigger chronic localized pain. Even muscle contractions of low force can activate trigger points if the muscle remains contracted to stabilize the body in a particular position for a period of time.

Examples of highly repetitive tasks include typing, meat processing, and factory assembly work. A data entry worker may perform 20,000 keystrokes per hour. Meat cutters in a processing plant may make 12,000 knife cuts per day. Assembly line workers may elevate their shoulder 7,500 times per shift (Anderson, 1997).

Workers who return to work after an injury, or even after sick time or vacation time, are extremely susceptible to repetitive motion injuries. This increased vulnerability is caused by deconditioning during time off.

Another common cause for these injuries is "speeding up the line," or suddenly increasing the worker's number of repetitive motions performed per day (Thompson, Plewes, & Shaw, 1951). In these cases, the conditioned worker is not able to suddenly perform at a higher level.

Mechanical stress results from direct force on a part of the body. An example is hand injury caused by tightly gripping a tool that has cold, sharp edges and a short handle. The use of better-designed tools has greatly reduced these types of injuries in more modern shops.

Vibration also causes injury to connective tissue and nerves. Impact drills, handheld power tools, and bench-mounted grinding tools can all transmit vibration to the hands and upper extremities (Pelmear, Taylor, & Wasserman, 1992). This vibration contributes to the development

of work-related Raynaud's phenomenon (Levy and Wegman, 2000). It may also contribute to carpal tunnel syndrome and other compressive nerve disorders (Falkiner, 2003).

Splints are commonly used to immobilize and allow an injured extremity to rest. These may be harmful if they force the worker to resist or fight the splint in order to perform regular job tasks.

Psychological factors may be important in the initial development of work related injuries, and subsequent disability.

National statistics are available for work-related injuries. The source of this data is the Bureau of Labor Statistics BLS Annual Survey of Occupational Injuries and Illnesses. This is a federal/state program where employer reports are collected from private industry (www/bls/gov).

Most new workers who perform unaccustomed strenuous or repetitive tasks will experience muscle pain. A more gradual "break-in" can allow conditioning to occur with a minimum of soreness (Parker, 1992). This issue becomes especially important for the patient with chronic pain who goes on vacation. In as little as 1 week, muscles will become deconditioned. The pain practitioner should encourage the patient to maintain an active exercise program to prevent deconditioning while on vacation.

Chronic muscle pain or myalgia can be diagnosed as myofascial pain syndrome after identification of taut bands and trigger points during physical examination. This pain can result from repetitive motion and muscle overuse. Sometimes a seemingly simple myalgia may progress to a more diffuse and chronic myofascial pain syndrome with resultant dysfunction and eventual disability.

Tendonitis and tenosynovitis are inflammatory conditions of the tendon that result from tendon injury. Tendons may be injured by mechanical stress of pulling, friction stress, and snapping or rubbing over a bony prominence. Some tendons have a protective sheath, but tendons at the elbow do not have a sheath. When these become inflamed, the medical condition is termed "tendonitis." Tendons in the hand and fingers have sheaths to assist in lubrication and protection of the tendon. When these become inflamed, the condition is termed "tenosynovitis."

Epicondylitis is a tendon inflammation at the elbow that is caused by repetitive motion of the wrist. De Quervain's tenosynovitis is an inflammation of the abductor pollicis longus and extensor pollicis brevis tendons of the thumb.

Trigger finger is also associated with repetitive hand use. This occurs when a nodule forms in a flexor tendon of the hand and becomes large enough to cause clicking when the finger joints are flexed or extended. Larger nodules may cause the finger to get stuck in a flexed position.

Ganglion cysts are also associated with repetitive joint motion. The wrist is most commonly involved. These cysts occur when the synovial lining of the joint herniates through the fibrous joint capsule, creating a bubble

attached to a stalk. Cysts tend to enlarge with physical activity, and they may shrink with a period of rest or immobilization. Needle aspiration may be successful, but definitive therapy is generally surgical removal of the cyst and stalk.

ERGONOMICS

Ergonomics is a word that comes from the Greek words *ergos*, meaning work, and *nomos*, meaning laws. It has become a buzzword that is used to describe a variety of conditions and objects from specific tasks in the work environment to tool design and seating. The terms *ergonomics* and *human factors* are sometimes used interchangeably. Most people recognize use of the term *ergonomics* in relation to seating and task analysis. The term is also used in relation to lighting and the psychology of shift work. Practically speaking, the term ergonomics relates to the interface between people and their environment. In the academic setting, the ergonomist may be found in the departments of biomechanics, engineering, medicine, and psychology.

When treating patients with pain, an awareness of basic ergonomic principles will serve the practitioner well. With an understanding of these principles, the caregiver can be more effective in helping impaired people function in their environment, both to a greater level, and with less discomfort.

SUPPLY AND DEMAND

When physical demands are placed on body tissues, these structures generally require more resources. These resources are delivered by the blood supply to the tissue. They include oxygen, nutrition, and removal of byproducts. When a muscle is resting, the cells require less nutritional support than when it is contracting. A resting muscle is softer and blood flow through the muscle is relatively unobstructed. This allows blood to flow more freely, and the tissue has plenty of resources.

When muscles contract to perform work, the muscle cells require nutrients at a higher level. This level is in proportion to the work that is being performed. Alternately contracting and relaxing muscles pump blood and therefore increase their nutrient supply.

Sustained posture occurs when a muscle is contracting to maintain a posture or position. A muscle sustaining contraction requires even more nutrients than a muscle that is alternately contracting and relaxing. Unfortunately, blood flow is hampered by the increased pressure within a contracting muscle. In this case, the nutrient requirements of the muscle are increased and the blood supply is relatively decreased. This leads to a significant imbalance with respect to nutrient "supply and demand." It

therefore costs the body more to stay in one position (sustained posture), than it costs to move.

This concept can be simply illustrated by trying to hold one arm straight out in front of the body, keeping it perfectly still. Before long, the muscles fatigue, and the arm seems to get very heavy. Later, after a few minutes of rest, hold the arm straight out in front of the body again. This time move the hand and arm in small circles. This slight movement of the arm and shoulder results in some degree of alternate relaxing and contracting of the deltoid and trapezius muscles. Even small motions will facilitate blood flow and nutrient supply. Usually with the arm making small motions, the feeling of fatigue is noticed more slowly, and the length of time this posture/motion can be maintained is significantly longer. If nutrient supply and metabolic byproduct removal are facilitated by muscular contraction and relaxation, the physical activity can be maintained for a longer period of time and with less fatigue.

The concept of muscle tissue nutrient supply and demand has clinical relevance with pain patients with pain. Many such patients relate that they do better when they are moving, and that they have problems sitting or standing in one position for any length of time. Sometimes maintaining one position causes stiffness, and sometimes it causes an increase in pain. For many people, even 15 minutes of a sustained posture is considered a prolonged period of time. It should be realized that even sitting in a "relaxed" position might require significant static contraction of supportive and balancing musculature. This "relaxation" may translate to increased stiffness and pain. Instructing patients with low back pain to slightly wiggle or otherwise move their hips every few minutes while sitting can greatly increase the length of time that seated posture can be maintained. This is likely to be important when sitting at the office as well as when riding in a car.

REPETITIVE MOTION INJURY

Repetitive motion injury (RMI) has previously been termed "repetitive strain injury" (RSI) and also "cumulative trauma disorder" (CTD). Nationally, the Bureau of Labor Statistics calls these conditions "illnesses" and not injuries. OSHA (Occupational Safety and Health Administration), NIOSH (National Institute of Occupational Safety and Health), and the National Academy of Science have replaced these terms with the more neutral "work related musculo-skeletal disorders."

Tissue pathology with respect to repetitive motion injuries is generally believed to primarily involve inflammation. Typical diagnoses that fall into this definition include tennis elbow, shoulder bursitis, tendonitis, and carpal tunnel syndrome. Treatment protocols for these conditions may include splinting, physical therapy modalities, anti-inflammatory medication, cortisone injections, and surgery.

For many people, these treatments are not effective. One reason is that pathology of RSI is not simply inflammation. Indeed, the primary pathology may be trigger points and myofascial pain. Tennis elbow, for example, is associated with myofascial trigger points in the muscles that dorsiflex and supinate the wrist. Shoulder bursitis is associated with myofascial trigger points in various shoulder girdle muscles.

MYOFASCIAL TRIGGER POINTS WITH REPETITIVE STRAIN INJURY

It is important to examine patients experiencing pain for myofascial trigger points in muscle groups that cause and/or refer pain to the area of complaint. Repetitive motion activities will cause formation of new trigger points, as well as activation of "latent" trigger points. As myofascial trigger points become more active, they generate more pain.

Sustained posture activities will cause tightening of the active muscles, as well as generalized tightening of the fascia through the muscle tissue. In addition, myofascial trigger points within the muscle will become more active. This increase in trigger point activity will cause an increase in pain, both localized and referred.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is usually suspected when there is numbness and/or tingling in the thumb, index, long finger, and the thumb-side half (radial aspect) of the ring finger. People may also be awakened at night by pain in the wrist and forearm. When symptoms progress, people experience forearm and hand weakness, and even light objects such as coffee cups may be dropped.

The condition is often job or activity related, and people who use their hands a lot may be at risk for developing the problem. CTS has been associated with wrist and hand positioning, repetitive wrist use, use of heavy or vibrating tools, trauma, and light work such as typing.

CTS has traditionally been thought of as a condition resulting from flexor tendon inflammation or swelling that is caused by repetitive motion of the forearm, wrist, and hand. It is thought that when people use their fingers and bend their wrists a lot, the tendons in the tunnel become inflamed, thereby causing them to swell. Because the borders of the tunnel are fixed and there is no extra room in the tunnel for this swelling, pressure on the median nerve increases, causing numbness, tingling, and pain in the fingers and forearm.

The size of the carpal canal is not constant. The canal is largest when the wrist is in neutral (dorsiflexed 15°) position. It gets smaller when the wrist is bent in any direction. When bent positioning compromises canal size,

an already marginal situation can be made worse, and this may induce symptoms of numbness and tingling in the fingers and forearm. To evaluate this, a Phalens test can be performed. This test is performed by palmar flexing the wrist approximately 90°. The test is considered to be positive if the thumb, index, long, or ring fingers start to tingle within 30 to 60 seconds. Usually the positive result is recorded as well as the time (in seconds) required for the numbness to be appreciated.

In accordance with this inflammation model, the treatment for CTS traditionally involves keeping the wrist in a "neutral posture" and taking anti-inflammatory medication. Wrist braces are often recommended to ensure that the wrist remains straight, especially during work and sleep. To further aid in reducing the theorized inflammation, cortisone may be injected into the canal. When these treatments do not work well enough, surgeons will cut the transverse carpal ligament so the tunnel can expand to make room for the swollen tendons. Even when surgery is helpful, the condition will usually recur when people return to their same jobs. Work modification is often an important part of returning these people to gainful employment.

There is also a very different way to think about CTS. Recent research has demonstrated that the theorized inflammation of the wrist tendons may not occur (Nathan & Keniston, 1996). Other research has indicated that there are exercises that can be done to treat and prevent CTS and that this treatment may be more successful than the traditionally prescribed medication and surgery (Seradge, Bear, & Bithell, 2000; Seradge et al., 2002).

A more modern idea to explain the pathophysiology of carpal tunnel syndrome is that it actually starts in the biceps muscle of the arm, and not in the wrist. People who use their wrists and fingers a lot, steady and support their forearms and hands with a sustained contraction of the biceps muscle. This continuous contraction of the biceps muscle eventually causes tightening of the connective tissue in the arm, called fascia. The biceps muscle crosses the elbow joint and attaches to the radius bone in the forearm. Because the biceps muscle is a part of the forearm, it also pulls on the fascia of the forearm. With time and continued sustained biceps contractions, the fascia in both the arm and forearm tightens. As this process continues, the transverse carpal ligament (fascia) also tightens. When this ligament tightens, the carpal tunnel gets smaller. Indeed, CTS may be caused by the canal itself getting smaller. This helps explain the lack of inflammation on histology, and the effectiveness of exercises in treatment.

TOOLS

Tool design is an important consideration when a job or task needs to be made more "body friendly." There are

catalogs of "ergonomic" tools for many different jobs and functions. In examining the use of tools and considering their modification, basic ergonomic principles provide important guidance.

One very important rule is that wherever possible, the tool should be bent, not the wrist. The wrist should be kept in a neutral position as much as possible, and the less the wrist deviates from neutral posture, the better. Also, the amount of grip force a hand can apply is greatly reduced when the wrist moves from a neutral to a flexed position. Bent-handled pliers, hammers, and power tools are examples of commercially available alternatives to standard gripped models. These tool modifications allow the worker leverage and mechanical strength while keeping the wrist in a neutral position.

Another consideration in evaluating tools is to investigate the quality of the surface that comes in contact with the body. Bare metal is cold. In tools run by compressed air, the surface gets even cooler with use. Sharp edges of handles can put significant pressure on the skin, tendons and nerves (Putz-Anderson, 1988). An example of poor tool handle design is a pair of metal-handled pliers where the handle has sharp square edges. Design improvements would include rounding the handles and covering them with a thin, tacky, cushioned, and insulating material.

In checking for factors that contribute to CTS, notice whether the tool handle presses directly upon the carpal canal. A cold hard surface that pounds or vibrates against the wrist can be problematic.

HEADSETS AND PHONE USE

Telephone use can be a significant factor in perpetuation of myofascial pain and tension of the head and neck. There are three major muscular force directions that are applied during ordinary phone use. First, the hand piece is held up to the level of the ear and mouth. This requires sustained postural contraction of the upper trapezius muscle. Second, most people push the earpiece into the ear in an effort to hear better and drown out outside noise. This activity demands even a more forceful contraction of muscles that raise the arm. Finally, the lateral neck muscles must contract to push back against the force of the earpiece pushing against the ear. In summary, the upper trapezius and lateral neck muscles contract more forcefully and remain contracted to maintain this posture.

An even worse scenario occurs when a patient attempts to hold the phone receiver by pinching it between the shoulder and ear. This activity requires the upper shoulder and lateral neck muscles to contract and maintain a posture with the muscles shortened. The ingredients of postural contraction and shortened muscles are very strong perpetuators for activation of myofascial trigger points and myofascial pain. Sometimes even 30 sec-
FIGURE 87.1 Adjustable and standard components of an ergonomic chair.

onds of holding the phone in this manner can cause a "stiff neck" the next day.

A headset can significantly minimize the effect of phone use as a perpetuating factor in cases of myofascial head and neck pain. The set should be comfortable, have variable amplification, and perhaps block out some outside noise. The treating physician should be sensitive to this and not hesitate to prescribe a headset for job modification when phone use is a suspected cause of a patient's head and neck pain.

ERGONOMIC SEATING

The chair should be designed to support a person's body in whatever position is best for performing necessary tasks and reducing musculoskeletal fatigue. Generally the chair is mobile and supported by five wheels. Sometimes motion is not desired, and stability requirements are such that the chair is attached to the floor. Seat pan, back rest, and arm rest positions should be variable. When these attributes are variable, the chair will be able to support more variations of body type in more positions. Better chairs are usually adjustable. This will give the worker more choices regarding available positions for which the chair can provide good body support (Dainoff, 1998).

Ergonomic chairs have several adjustable parts. These include seat back, seat pan, armrests, height adjustment, and castors (Figure 87.1).

The seat pan is the part of the chair that the buttocks sit upon. There is usually a gas shock underneath that allows easy adjustment of height. The seat pan may also tilt forward and backward to allow for variations of thigh and foot position. In some chairs, the seat pan can also be slipped forward and backward to accommodate different thigh lengths.

Seatbacks can be made to adjust forward and backward. They may or may not be adjustable independently of the seat pan. Some chairs allow for rocking and may

also allow for locking in any position of tilt. Executive chairs typically have high backs, and secretary chairs do not. Some chairs have a variable height or pressure lumbar support, and some also have a neck support.

Not all people fit their chairs. Armrests are supposed to support the arms, taking weight off the upper shoulder muscles. They can be adjustable up, down, in, out, forward, and backward. Up and down adjustments allow for varied arm and body lengths, accommodating short and tall people with short or long arms. In and out adjustment makes it easier for wide and thin people to fit in the chair. Forward and backward adjustment makes it possible to support the arms of people who need to reach forward with their forearms at desk height.

Secretary chairs traditionally do not have armrests. This practice is discouraged by ergonomists, because the typist also requires arm and shoulder support.

Foot support is part of ergonomic seating. The feet should not dangle in the air. If the feet do not comfortably reach the floor, a foot support should be provided.

POSTURE FOR KEYBOARD WORK

It used to be thought that typists should be seated in an upright position with the typewriter at desk level and the copy flat on the desk. For some people, this posture may require significant energy expenditure, causing fatigue and discomfort. Many people find that a "partial relaxed slouch" is more comfortable. Efficient posture depends upon the particular typing task that is being performed. Many data-entry workers and typists prefer the copy to be propped up on a stand next to the monitor.

COMPUTER MONITOR

Monitor positions and body postures cannot be standardized for all tasks. There are, however, some general concepts and ideas to consider.

When using a computer, the eyes should be able to look slightly downward at the monitor. Tearing, important for nutrition and lubrication of the cornea, is increased with downward gaze angle. In addition, the neck should be comfortable and not in a forward leaning posture.

Other more recent introductions into office furniture concepts place the monitor inside the desk under a glass surface. If desk or counter space constraints are of primary importance, this may be optimal for the particular situation. Forward head tilting, however, will contribute to fatigue in the upper shoulder, upper back, and neck muscles.

Sometimes the most comfortable and best-supported posture will be "slouching." This posture may be optimal when typing from copy that is propped up so that the typist can look out with only a slight downward angle. While perhaps more comfortable, this posture may restrict the operator's reach, making it more difficult to answer the phone, refer to other materials, and open a drawer. When typing without copy, it may be most comfortable to lie back, as in a dentist's chair, keyboard in the lap, with the monitor suspended above at a comfortable distance. This posture may be limited to young "hackers" who can tolerate decreased tearing that is associated with supine posture.

Upright posture seems to be more appropriate when typing from copy that is flat on the desk. This position will also allow reaching for more objects.

APPLICATION OF ERGONOMIC PRINCIPLES IN MEDICAL PAIN PRACTICE

During initial interviews and as patients progress in treatment, it will become evident that certain activities seem to be associated with an increase in pain symptoms. The activities may vary from specific job tasks to the use of tools and even posture, such as riding in a car or standing at a counter.

One of the most important considerations for the practitioner is the need to accurately understand the particular task or job environment involved. Obviously, the most direct way is to perform a site visit and see the activity in question on a firsthand basis. This, however, may be logistically difficult.

A much less expensive and often suitably effective method for performing a "site" visit is to ask the patient to bring pictures or a video of his or her worksite and activities. Two sets of pictures, each with two or three different perspectives, should be obtained. One set should include the workspace, chair, and furniture layout without the patient in the pictures. Another set of pictures should include poses in positions and postures that are used in performing the job. It is important to see the patient lift, stoop, answer the phone, type on the keyboard, go into the file, lean on the counter, etc. The patient should be instructed not to pose, but to simply act naturally. It is helpful to film realistic posture, lifting techniques, and true phone habits.

The task of taking pictures involves people in their own medical care and makes them start to think about the possibility of changing their environment. It also demonstrates that the medical practitioner is willing to "go the extra mile" in an effort to be helpful.

These pictures can be reviewed during the context of an office visit. The practitioner can see where basic ergonomic principles can be applied to support the body, and minimize sustained posture, repetitive strain, and poor lifting habits.

When giving professional advice regarding changing aspects of the work environment, it is important to make suggestions that are not costly and that can be tested easily. These suggestions should be based on basic ergo-

nomic principles and common sense. Follow-up is also very important, as the success or failure of these suggestions cannot be accurately predicted. Review of corrective actions and results of these efforts provides an environment for continued modification and refinement that is important in any ergonomic safety program. If a situation becomes too complicated and modifications do not work out as hoped, it may be time to consult with a professional ergonomist.

AMERICANS WITH DISABILITIES ACT

The Americans with Disabilities Act (ADA), Public Law 336 of the 101st Congress, was enacted on July 26, 1990. This law prohibits discrimination and ensures equal opportunity for people with disabilities in employment, state and local government services, public and commercial facilities, and transportation.

The law is based on common sense. Prospective employees must meet all the requirements of the job and be able to perform the essential functions of the job, with or without reasonable accommodation. No accommodation is required to be provided if it would result in an undue hardship for the employer, and no unqualified job applicant or employee with a disability can claim employment discrimination under the ADA.

When the pain practitioner sends a patient back to work, the patient should apply only for jobs where there is confidence that there is physical and mental ability to perform the essential functions of the job. The company is prevented from seeking information about medical disability until after a job offer has been made. This allows disabled workers an opportunity to enter the labor market without facing employer bias against them.

The accessibility portion of the law requires that public places remove architectural barriers in existing facilities when it is readily achievable. Additional information about the ADA can be found at www.ada.gov.

DRUG SCREENS

The patient with chronic pain may require medication as part of medical treatment. When these patients return to work, either at their previous job or looking for a new job, they may be required to have their urine screened for drugs as part of company policy. Many companies require these tests as part of preemployment medical screening. In these cases, the purpose of a drug screen test is to discover the prospective employee drug abuser prior to hiring. The prospective employees will fill out a form that declares what prescription medicines they are currently taking. Illicit drugs will usually be detected. Prescription pain medications may also be discovered. A medical review officer will compare the results of the test with the decla-ration form the prospective employee has filled out. Discrepancies and illicit drugs will be reported to the company. Discovery of prescription medications, even those taken for pain, is not generally supposed to be reported as a positive test.

Drug screens are also used as part of company injury prevention programs. The company may require all injured employees to undergo drug testing while in a medical facility for treatment of their injury.

PAIN MEDICATION AND RETURN TO WORK

Many patients with chronic pain are able to return to work without resolution of their pain condition, provided they are taking medication for treatment of their pain. Because this is a common practice, it is generally thought to be safe for pain patients to take such medications and work. There is particular concern with regard to patients who operate machinery, drive vehicles, fly aircraft, and depend on quick judgment in difficult situations. The prescribing physician should consider whether there might be hazards to the patient or others from the effects of these medications. Also, any potentially dangerous occupation should perhaps be avoided for several days after starting therapy with psychoactive or pain medications. This will allow stabilization of the medication and observation for any unwanted effects. If such a patient is injured or causes injury to others, the medical practitioner may be asked to testify regarding this issue.

PAIN MEDICATION AND DRIVING

Patients with chronic pain take opioid medication and drive automobiles. These medications generally preclude patients from driving jobs in public transportation and trucking, and piloting jobs in the airline industry. In private life, state laws govern this issue. In some states, a positive drug test after an automobile accident is a DUI (driving under the influence) by definition.

INDOOR ENVIRONMENTAL QUALITY

Concern about the safety of modern building environments began after several events that occurred in the 1970s and 1980s. The situations typically involved contamination levels within permissible exposure limits, and some investigators suggested that the office worker complaints were due to psychological issues. In 1976, members of the American Legion met in a Philadelphia hotel and were struck by pneumonia that caused illness in 182 people and death in 29 others. Epidemiologic investigation discovered contamination of a ventilation system with *Legionella pneumophila.* Further research resulted in the federal government's recognizing indoor air pollution as a significant

health concern. Investigators found that poor indoor air quality was associated with illness and death. They also found that many toxic substances were present at higher levels indoors than outdoors. Publications regarding this issue are available with searching the EPA Web site at www.epa.gov.

Human exposure can occur through skin contact, inhalation, and ingestion. Pollutants may be carried into a building on shoes or clothing, and may be carried home in a similar fashion causing inadvertent exposure to family members.

Building-related illnesses include hypersensitivity and allergies, infectious diseases, irritant diseases, intoxication diseases, and cancer. Examples of irritant problems are conjunctivitis, rhinitis, dermatitis, pharyngitis, and reactive airway dysfunction syndrome. Intoxication diseases may occur from exposure to carbon monoxide, heavy metals, pesticides, and volatile organic chemicals. Cancer can be caused by asbestos, radon, and other potential carcinogens.

The patient with fibromyalgia, chronic fatigue syndrome, or chronic pain may be more fragile than the general population. This may make these patients more susceptible to the effects of poor indoor air quality.

TOXIC EXPOSURES

Some patients with pain have known exposures to industrial chemicals, pesticides, or radiation. Some of these occur at work, and some occur at leisure. Some low-level toxicants have a cumulative effect. The workplace woodshop may be no more toxic than the beauty and fingernail shop. Some chemicals may contribute to pain, fatigue, and chemical sensitivities. The practitioner can obtain the material safety data sheet for any potentially toxic substance used in the workplace. Many companies are required to keep these sheets on file. The information can also be found online at www.ilpi.com/msds. The American Association of Poison Control Centers is a national organization that can also help provide information.

CONCLUSION

The pain practitioner should consider including a work and exposure history as part of the patient intake information. The work history includes job information, dates of employment, work hours, injuries, and toxic exposures.

It may be helpful to encourage a line of communication between the company and treating professionals. Companies generally appreciate responsive medical care that sees their workers quickly and understands the needs of the company in getting an employee healthy and back to work. Understanding the basics of how the system works can be very helpful for all parties.

Ergonomics is an old buzzword. Understanding basic principles will assist the pain professional in getting patients back to work more quickly and with more long term success.

Pain Management and Geriatrics

Jason DaCosta, MD

DEMOGRAPHICS

Definitions of the terms *elderly* and *geriatrics* are somewhat vague. Indeed, the distinction between younger and older adults is difficult to make on a biological basis. Functional and social needs of older patients also play a role in the definitions of elderly and geriatrics, but are difficult to quantify. From a practical standpoint, patients in the geriatric population may be considered to be elderly, and the commonest definition of the term elderly is about 75 years of age. However, this working definition may vary from 65 to 85 years of age.

The elderly represented 4.1% of the U.S. population in 1900, 12.5% in 1990, and 12.4% (35 million persons) in 2000 according to the U.S. Census Bureau. Of the 35 million elderly in 2000, 4.2 million are older than 85 years of age. The total number and percentage of the U.S. elderly population is expected to rise drastically in 2011 as the baby boomers start turning 65. By the year 2050, estimates project that 20.6% of the U.S. population will be over 65 years old. The growth of the geriatric population is due in large part to reduced mortality and longer life expectancy.

EPIDEMIOLOGY

The incidence of pain increases with age (Crook, Rideout, & Browne, 1984). Pain afflicts one out of four elderly individuals (Nolan & O'Malley, 1988). Chronic pain is reported by 25 to 50% of community-dwelling elderly and 45 to 80% of nursing home residents (Ling & Bathon, 1998). Although the elderly compose only 12.4% of the population, they consume 30% of prescription drugs and 50% of over-the-counter drugs (Davis, 1988).

Musculoskeletal disorders are a common cause of pain in the elderly (Foley, 1994; Harkins, 2001). Osteoarthritis and rheumatoid arthritis afflict more than two thirds of the elderly. Common pain syndromes experienced by the elderly include neck and back pain due to cervical and lumbar spondylosis, facet disorders (zygapophysial joints), radiculopathy from foraminal or spinal stenosis (the incidence of radiculopathy from a herniated disc is less common in elderly patients), arthritis, fractures, trigeminal neuralgia, temporal arteritis, polymyalgia rheumatica, shingles (reactivation of herpes zoster), postherpetic neuralgia, atherosclerosis, and diabetic and alcoholic neuropathies. There is a decline in headaches and dental pain (Sternbach, 1986). The clinical significance of pain in the elderly was underscored by the National Health and Nutrition Survey (1987), which documented an increased incidence of depression and impairment in activities of daily living associated with pain in the elderly.

Many of the pain problems that afflict the elderly occur in younger patients as well. Indeed, the frequency of pain among very old hospitalized patients is similar to that of younger patients (Desbiens et al., 1997). The challenge for the clinician is to make the diagnosis and provide effective treatment, with the fewest side effects possible. This obligation is difficult to meet in a young patient, and the frailty and number of medical problems that may affect an elderly patient make this a challenging endeavor. Common painful conditions in elderly patients are listed in Table 88.1.

LOW BACK PAIN

The differential diagnosis of low back pain in elderly individuals relies heavily on both physical examination

TABLE 88.1
Painful Disorders in Elderly Patients

Osteoarthritis
Shingles (reactivation of herpes zoster)
Spinal stenosis
Polymyalgia rheumatica
Temporal arteritis
Peripheral vascular disease
Diabetic peripheral neuropathies

and history and may include diagnostic injections. The pain associated with spinal stenosis, a condition characterized by degeneration of the spine causing narrowing of the spinal canal, is often exacerbated by standing or walking and may be dormant when the patient is lying comfortably in the exam room. Pain associated with spinal stenosis may be of two general types: (1) pain emanating from structures within the spine, including facet joints, ligaments, and disc and localized to the spine, and (2) neurogenic claudication, with pain referred to the thighs and legs with standing and walking. Neurogenic claudication is a nerve root problem and may present as bilateral radiculopathy or pain in a single nerve root distribution.

Examination should proceed with an erect visual examination of the spine followed by palpation of the paravertebral muscles and spinous processes. Localized tenderness may suggest compression fracture, infection, or malignancy. During the range of motion exam, flexion pain may signify a herniated nucleus pulposus or paraspinous muscle spasm, decreased extension may be seen with spinal stenosis, and decreased lateral rotation and extension can be due to apophyseal joint disease or paraspinous muscle spasm. The differential diagnosis of neurogenic claudication is vascular claudication. Therefore, pedal pulses should be assessed. If pulses are difficult to palpate or absent, then vascular studies should be considered, particularly if leg pain is more prominent with walking than standing.

Radicular pain is more likely due to degenerative changes of the spine with ligamentous and facet hypertrophy and loss of disk height than to disk herniation. Deep tendon reflexes may be attenuated or absent with increased age and therefore significant only if asymmetric. Motor function is often tested in the supine position: L3–L4 by knee extensors; L4–L5 by toe dorsiflexors; L5–S1 by knee flexors, foot evertors, and hip extensors; S1 by plantar flexors. The facet joints and sacroiliac joints should be palpated for tenderness in the prone position to rule out these common sources of spinal pain.

Other causes of low back pain should be excluded as well, including aortic aneurysmal disease, which can present with pulsatile masses, abdominal bruits, and cool skin and hair loss in the extremities. Lymphoma and spinal metastases should be ruled out particularly in patients with history of prostate, lung, and breast cancer. Pancreatic cancer and perforated duodenal ulcers can present with back pain as well.

NEUROPATHIC PAIN

The treatment of neuropathic pain requires a different approach than nociceptive pain. Although opioids may help, adjuvant medications such as antidepressants and anticonvulsants have proved to be more clinically effective, but may not be as well tolerated in elderly patients. Neuropathic conditions are common in elderly patients and pose challenges in both their diagnosis and treatment. They include classic examples such as trigeminal neuralgia, diabetic neuropathy, and postherpetic neuralgia. Shingles, also referred to as cutaneous herpes zoster, afflicts 1 to 2% of the elderly population each year (Schmader et al., 1995). Resultant postherpetic neuralgia occurs in up to 30 to 50% in the elderly population as compared with 5 to 10% in all age groups. It can also occur following a stroke or nerve injury in the peripheral or central nervous system. Clinical characteristics of shingles and postherpetic neuralgia are provided in Table 88.2.

The mechanism of pain in postherpetic neuralgia may be due to enhanced chemical and mechanical sensitivity to cytokines, prostaglandins, and catecholamines in peripheral sprouting nerve terminals as well as persistent small fiber activity in the periphery and in the dorsal root ganglia. Other mechanisms include upregulation of sodium channels in injured axons and upregulation of sympathetic neurons leading to hypersensitization. Neurologic examination determines whether there is numbness or sensory changes (hypoesthesias, dysesthesias, hyperesthesias, and allodynia). Neuropathic pain is often

TABLE 88.2
Clinical Characteristics of Shingles and Postherpetic Neuralgia

Shingles

Incidence: 130/100,000
Clear age dependence (10× higher in elderly than teenagers)
No gender difference
Blacks have lower risk than whites
Truncal and ophthalmic division of trigeminal nerve most commonly affected
Decline in cell-mediated immunity implicated

Postherpetic Neuralgia

Pain that persists after rash has healed (at least 1 month)
50% at age 60 and 75% at age 70 years; develops after herpes zoster
No gender predilection
Pain gradually improves with time
Thoracic dermatomes and face most often involved

described as being lancinating, with a sharp, shooting, or stabbing component or burning in character, and this is true after postherpetic neuralgia. The mechanisms and treatment of neuropathic pain are discussed in detail in this volume, in Chapter 24, "Neuropathic Pain."

PAIN ASSESSMENT

History taking and physical examination of elderly patients is often obfuscated by poor memory, denial, and psychomotor limitations. The history of present illness can often be facilitated by having a family member present who can corroborate or augment the patient's story. Also, complaints of pain must sometimes be coaxed from elderly patients as they often underreport pain (Harkins, 2001). An integral component to the history is an assessment of the patient's functional level, which has profound effects on quality of life and degree of independence. These are often measured by how well a patient performs "activities of daily living" such as eating and bathing as well as "instrumental activities of daily living" such as shopping and banking (Ferrell, 1996).

Pain reporting can be followed using a multitude of available tools including the Verbal Descriptor Scale, the Numerical Scale Rating, the Visual Analogue Scale, a faces-based pain scale, and the short or long forms of the McGill Pain Questionnaire. These assessments must be tailored for each patient, as not all elderly patients will be able or willing to complete them.

The physical exam should not only focus on organ systems and body regions pertinent to the pain complaint but should also include a focused neurologic, autonomic, and psychological assessment. The patient must be assessed in entirety, with integration of all components of the history, exam, and supplemental studies. For example, in a patient with an extensive smoking history who presents with lower extremity pain, stressing the extremity may reveal a pathologic fracture or percussion of the spine may suggest metastasis to the spine with a pathologic compression fracture and radiculopathy.

PHYSIOLOGY OF AGING

The pharmacokinetics of aging reflect changes in drug distribution and clearance. From ages 25 to 75 years, the percentage of body fat increases as lean body mass declines. This larger relative fat content increases the volume of distribution of lipid-soluble drugs such as benzodiazepines and barbiturates. Increased volume of distribution prolongs the elimination half-life of these lipid-soluble drugs, while the decreased volume of distribution for water-soluble drugs leads to higher peak plasma concentrations.

TABLE 88.3
Hepatic Function with Aging

Liver size and blood flow decrease with age > 50 years
First-pass metabolism reduced (drugs with high first-pass metabolism have increase blood levels, e.g., propranolol)
Microsomal hydroxylation/oxidation unchanged
Glucuronidation is microsomal — not changed; morphine metabolism by liver unchanged, but clearance is reduced
Demethylation decreased (e.g., diazepam clearance reduced by 50%)
Non-microsomal oxidation reactions preserved
Regenerative capacity of liver unchanged

Plasma protein binding changes with age as well. Acidic drugs such as benzodiazepines and barbiturates may become more active because protein binding decreases with age-related decreases in plasma albumin. Basic drugs such as local anesthetics may become less active as protein binding increases with age-related increases in alpha$_1$ acid glycoprotein. Gastrointestinal absorption of drugs is relatively unchanged with age.

The central and peripheral nervous system changes are variable, depending on heredity and daily activity. Decreases may be global, involving cholinergic, dopaminergic, norepinephrine, and serotonin systems. These decreases may lead to cognitive decline, memory loss, tremor, and depression. High-frequency mechanoreceptors in the skin show an increased threshold but no change in dynamic response to pain with increasing age. There is little evidence that the clinical perception of pain is diminished with age.

Hepatic function is for the most part unchanged with aging. The key components that decline include decreased liver blood flow resulting in decreased first-pass metabolism. Demethylation is another process that declines with aging, resulting in a virtual halving of the clearance of drugs such as benzodiazepines. The other metabolic components of the liver are largely well preserved. A summary of hepatic function in elderly patients is presented in Table 88.3.

Renal function has a consistent and slow decline with age. There is a loss of about 1 ml/min/year in creatinine clearance after age 40 years. In the elderly patient creatinine clearance may not correlate well with the serum creatinine levels, because creatinine production decreases with age. For example, a creatinine of 1.5 mg/dl in an 80-year-old, 70-kg patient may have a glomerular filtration of <40 ml/min. The calculated value in women may be slightly higher. A suitable nomogram or formula should be consulted. Drugs that are predominately renally excreted, such as gabapentin, morphine, and oxycodone, should be avoided, or require appropriate dosage reduction. Changes in renal function are summarized in Table 88.4.

TABLE 88.4
Renal Function with Aging

Functional Changes

Decreased renal blood flow 10% per decade > 20 years
1% per year decline in creatinine clearance after 40 years
Reduced glomerular filtration
Decline in number of functional renal tubules

Structural Changes

Kidney size decreased by 20% (glomerular sclerosis)
Less concentrating ability (more dilute urine)
Reduced drug clearance

ANALGESICS

ACETAMINOPHEN AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Acetaminophen is a well-known analgesic, but its mechanism of action remains poorly understood. The drug may inhibit prostaglandin synthesis in the central nervous system, although it has very little effect on peripheral cyclooxygenase (COX) and therefore has a very low side-effect profile when compared with nonsteroidal anti-inflammatory drugs (NSAIDs). Acetaminophen is rapidly absorbed from the gastrointestinal tract and undergoes significant first-pass metabolism. It is normally conjugated to inactive metabolites that are excreted in the urine. However, in large doses the available glutathione in the liver may be depleted and hepatic necrosis and renal tubular necrosis may occur. For patients consuming alcoholic beverages, consideration should be given to not taking acetaminophen products at all or advising that their usage be limited to less than 2,000 mg/day.

NSAIDs are a heterogeneous group of drugs that exhibit their primary analgesic effect by inhibiting COX-mediated prostaglandin synthesis at inflammatory sites in peripheral tissues. NSAIDs are described in detail in this textbook in Chapter 53, "Nonsteroidal Anti-Inflammatory Drugs."

Nonselective NSAIDs have an indiscriminate side-effect profile, owing to inhibition of COX-1 found in blood vessels, the stomach, and the kidneys in addition to their therapeutic effects at COX-2, induced at inflammatory sites by cytokines and other inflammatory mediators. Elderly individuals are at an increased risk of NSAID side effects, which include gastrointestinal disturbances, confusion, constipation, headaches, dizziness, tinnitus, reversible platelet inhibition, bleeding disorders, edema, hyperkalemia, interstitial nephritis, hypersensitivity reactions, fluid retention, and occasional episodes of confusion. Their nephrotoxicity is related to inhibition of the synthesis of PGE_2 and PGI_2, which maintain renal blood flow. Whether the damage is secondary to renal ischemia, inter-

stitial nephritis, or papillary necrosis, those at risk include persons with preexisting renal disease and those who are volume depleted. Additional risk factors include prolonged drug usage, high doses, and low blood flow states, such as seen in congestive heart failure.

Selective COX-2 inhibitors work similarly to traditional NSAIDs but have a several hundred- to several thousand-fold (depending on the formulation) selectivity for COX-2 over COX-1. Therefore, they lessen or avoid many of the nonrenal side effects associated with COX-1 inhibition. They have minimal ulcerogenic side effects, are well tolerated perioperatively with no change in platelet aggregation, and do not appear to prevent bone growth after total joint replacement. There is a growing trend for the selective agents to replace nonselective NSAIDs in the chronic treatment of rheumatic and inflammatory disorders, especially in elderly patients, who are at greater risk for NSAID-induced morbidity. However, it should be emphasized that current information does not indicate that the risk of renal injury is lessened with the COX-2 selective agents. Moreover, the reduction in risk of gastrointestinal ulceration with long-term COX-2 selective inhibitors is unclear, particularly if patients are also taking aspirin.

OPIOID ANALGESICS

Opioids are the gold standard family of analgesics with which all other analgesics are compared. However, they are usually reserved for pain that is resistant to the aforementioned analgesics. Many studies demonstrate age-related differences in potency and clearance of opioids. Studies indicate a twofold difference in analgesia between the extremes of adult age with morphine injection (Baillie et al., 1989). Decreased morphine clearance in the older group led to plasma morphine levels which were approximately twice those of the younger age group. Older patients reported greater peak analgesia but the principal effect was a longer duration of analgesia. This difference is thought to be primarily related to increased duration of action rather than peak effect.

The pharmacokinetics of intravenous and oral immediate and controlled-release morphine vary between young and elderly subjects. Both groups attained similar peak plasma concentrations after intravenous morphine, but the elderly group attained greater concentrations after oral doses (Baillie et al., 1989). Moreover, duration of action was prolonged for all three preparations in the elderly group, reflecting decreased clearance of the drug. Pharmacokinetic data for morphine in elderly patients are shown in Table 88.5.

Elderly patients may have an increased central nervous system sensitivity to morphine as suggested by a study that compared epidural morphine between young and elderly patients. The study showed improved quality of analgesia and prolonged duration in the elderly group after a single

TABLE 88.5
Morphine in Elderly Patients

Pharmacokinetics

Maximum plasma concentration after intravenous administration same as in young patients, but higher after oral administration in elderly patients

Area under the curve values higher in elderly subjects

Clearance and first-pass metabolism reduced

Morphine metabolites (e.g., M6G) are active and accumulate with renal insufficiency

Pharmacodynamics

Morphine more potent in elderly

Longer half-life

Greater pain relief with given dose

May require smaller doses and larger dosing intervals

dose of epidural morphine (0.07 mg/kg) despite similar plasma morphine concentrations (Moore et al., 1990).

Studies that compared patient-controlled analgesia (PCA) with morphine to intramuscular morphine showed improved analgesia and less sedation, confusion, and respiratory depression among the PCA group (Egbert et al., 1990). This is especially important in elderly patients with frail skin who may be predisposed to connective-tissue injury after repetitive needle-sticks.

It should be noted that morphine has active metabolites that are excreted by the kidneys. Morphine is metabolized to morphine-6-glucuronide, which is more potent than the parent compound, and morphine-3-glucuronide, which can cause allodynia, hyperalgesia, myoclonus, and cognitive changes. Elderly patients, particularly those with mild renal insufficiency, are prone to side effects with morphine, including sedation and cognitive problems. Hydromorphone is an alternative to morphine and does not have active metabolites that are excreted by the kidney. However, hydromorphone is about five times more potent than morphine.

The transdermal fentanyl system (Duragesic®) may be useful in some cases. This fentanyl preparation offers pharmacokinetic advantages, particularly for patients with swallowing difficulties and/or renal insufficiency. However, several caveats must be noted:

1. Transdermal fentanyl is inappropriate for acute pain management.
2. The slow onset and long duration of action of transdermal fentanyl can make titration difficult.
3. The 25 µg/hour patch, the lowest dosage preparation now available, may be excessive for frail, elderly patients.

Embarking on treatment with the transdermal fentanyl patch implies that the patient will have a long-term need for a controlled-release opioid preparation.

Oxycodone is also an alternative to morphine and is available in a controlled-release preparation. Oxycodone has about twice the potency of morphine on a milligram basis. It is not available as a parenteral drug in the United States. The pharmacokinetic and pharmacodynamic differences between young and older adults are minimal, reducing the need to adjust the dosage of oxycodone in elderly patients (Kaiko et al., 1996). However, the dose must be reduced with renal insufficiency and should be avoided in patients with a creatinine clearance less than half of normal.

In general, it should be emphasized that dosage reductions with all opioids are indicated for older adults. Opioids do appear to have increased pharmacodynamic effects, although pharmacokinetics may be similar. In addition, an increase in the dosing interval may be necessary. Titration to effect is a good rule of thumb.

Tramadol, which inhibits norepinephrine and serotonin reuptake in addition to being a mu-opioid agonist, is generally well tolerated in elderly patients and has a comparable analgesic profile to acetaminophen with codeine (Rauck et al., 1994).

Upon initiation of opioid therapy, formulations with shorter half-lives are favorable for faster onset and titration of analgesia. When therapeutic goals have been reached, these drugs may be converted to equipotent doses of drugs with longer half-lives for ease of dosing, possible lower addiction risk, and to avoid classical conditioning of patients experiencing pain to seek treatment every 4 to 6 hours. Titration of opioids aims for a balance of therapeutic efficacy weighed against the side effects. Because side effects and toxicity of opioids are more common in elderly individuals, this titration must be monitored more closely than in younger, healthier adults. Respiratory depression can occur very quickly in opioid-naïve geriatric patients. Also, opioid bowel regimens to avoid or minimize constipation must be stricter in older patients who likely already have some component of bowel dysfunction.

Many physicians remain fearful of the side effects and addictive potential of opioids and consequently underprescribe opioids for patients who may benefit from their use. Although the risk of addiction was once thought quite small, the actual incidence of addiction or abuse is unknown. Alcohol and prescription drug abuse appear to be more common than abuse of specific opioid analgesics. Of the prescription drugs, benzodiazepines and other sedative-like drugs appear to be abused most often. Nonetheless, appropriate measures should be taken to reduce the likelihood of opioid analgesic abuse, while taking the time to look for concomitant illness that may predispose to drug abuse, including depression. Urine drug screens may be useful in helping to monitor for inappropriate drug use or abuse.

Opioids have favorable side-effect profiles, especially when compared with many of the traditional NSAIDs. The

clinical end points of opioid therapy, as with any pain regimen, should focus on improved function, mood, and sleep and decreased pain instead of reduced opioid doses.

ADJUVANT ANALGESICS

Adjuvant analgesics are discussed in detail in Chapter 24, "Neuropathic Pain," in this volume. This group of drugs is effective for neuropathic pain, but can have problematic side effects in elderly patients.

The anticonvulsant carbamazepine inhibits ectopic neuronal activity by blocking sodium channels. However, the medication has numerous side effects, including bone marrow depression, elevated liver enzymes, gastrointestinal disturbances, sedation, confusion, and ataxia. Potential drug interactions, chiefly inhibition of cytochrome P450 activity, make this drug difficult to manage in any age group and particularly in elderly patients, where side effects may be poorly tolerated. Nonetheless, carbamazepine has proved efficacy for trigeminal neuralgia.

Oxcarbazepine is a metabolite of carbamazepine and is safer from the standpoint of potential hepatic toxicity and bone marrow depression, but the potential for hyponatremia requires monitoring of serum sodium levels.

Gabapentin is FDA-approved for the treatment of pain associated with postherpetic neuralgia. The drug may be useful for other neuropathic conditions, based on the current literature. The mechanism of action of gabapentin has not been fully elucidated, although it appears to enhance GABAergic activity, even though it does not bind to GABA receptors (Beydoun et al., 1995). A leading hypothesis suggests that gabapentin interacts with a novel calcium channel receptor on voltage-activated calcium channels.

Elderly patients generally tolerate starting doses of gabapentin of 300 mg/day. The need for titration to higher doses is common. Doses in the range of 1,800 to 2,700 mg/day are generally well tolerated. However, side effects are common and include fatigue, somnolence, ataxia, and vertigo. Gabapentin is excreted in the urine unchanged and the dose must be reduced appropriately in cases of renal insufficiency.

Antidepressants such as tricyclic antidepressants (TCAs) are commonly utilized for neuropathic pain treatment and appear to enhance endogenous descending inhibitory pathways involving serotonin and norepinephrine. Their side effects are almost innumerable, including sedation, constipation, dry mouth, urinary retention, postural hypotension, tachycardia, QRS widening, PR and QT prolongation, and T wave flattening. Elderly patients should be started first on TCAs with the least anticholinergic side effects such as desipramine.

Selective serotonin reuptake inhibitors are not as effective as TCAs in treating neuropathic pain, but they have much more favorable side-effect profiles. Paroxetine has proved to be effective against diabetic neuropathy, but

at much higher doses. A new selective serotonin and norepinephrine reuptake inhibitor, duloxetine, was recently approved by the FDA for the treatment of painful diabetic peripheral neuropathy. Duloxetine may prove to be a useful alternative to the other antidepressants (Briley, 2004) and may have fewer side effects, although it has not had widespread use with elderly patients.

INTERVENTIONAL PAIN MANAGEMENT

Diagnostic and therapeutic injections, including spinal injections and nerve blocks, may provide benefit in selected patients. There is growing clinical evidence that diagnostic injections can help establish a specific diagnosis in back pain and guide appropriate therapy. Indeed, there is substantial evidence that local anesthetic injections (with or without steroid) can provide clinically significant pain relief. This is an important consideration, particularly when analgesics provide inadequate pain relief or are poorly tolerated by elderly patients. Evidence-based clinical practice guidelines have been published that describe the indications and efficacy of interventional techniques for spinal pain (Boswell et al., 2005).

NONPHARMACOLOGIC THERAPY

Alternative therapies are gaining acceptance among many patients and some health insurance companies. Music therapy, aromatherapy, relaxation, meditation, and spiritual healing may subjectively help patients. Coping techniques are particularly effective in elderly patients whose perceptions of pain are more likely to be amplified by anxiety, fear, depression, and thoughts of helplessness. Hypnosis, massage, energy healing, magnetic therapy, folk remedies, and biofeedback can improve the patient's outlook and cause subjective improvements in pain perception. TENS therapy, acupuncture, and acupressure are gaining wider acceptance for pain management. Despite the controversy that will continue to enshroud these techniques, a basic understanding of their principles is valuable because patients with chronic pain will likely inquire about or request them.

Rehabilitation of elderly patients focuses more on an independent life rather than a return to work. It is an important component of the pain treatment and is managed by the physical therapist and an occupational or recreational therapist.

CONCLUSION

Pain management in elderly patients requires a different perspective from that of younger patients. Causes, comorbidities, and responses to both pain and its treatment differ between young healthy and older patients. The importance

of making a specific diagnosis if possible cannot be under-estimated. Many therapeutic end points are different as well. In addition, the treatments may have clinically important side effects in elderly patients. It is important for the successful clinician to keep these differences in mind in order to provide the most informed, efficient, efficacious and comprehensive treatment.

Hospice, Cancer Pain Management, and Symptom Control

Samira Kanaan Beckwith, CHE, LCSW, and Charles Wellman, MD

INTRODUCTION

Death is part of the life cycle yet continues to be a difficult transition for most people. In 1900, the average life expectancy was only 50 years and infant mortality was very high. Because of improved sanitation, immunization programs, antibiotics, improved management of acute illnesses, trauma care, and other improved therapies, Americans now live well into their late 70s or 80s (Emanuel et al., 1999). As a result of these advances, people now expect to have prolonged experiences of living with chronic illnesses and ultimately the end of life.

Many misconceptions exist about life's final chapter. Some 69% of patients said they would opt for suicide if they felt their pain could not be relieved (Levin et al., 1985). Fear of unacceptable pain was a major component of requests to physicians for assisted suicide (Helig, 1988; Emanuel et al., 1999). The increased awareness of the public in assisted suicide, due to the activities of Dr. Jack Kevorkian during the 1990s, and the popularity of the book *Final Exit* (Humphry, 1991) give evidence to this well-founded concern. Undertreatment of acute and chronic pain persists despite decades of efforts to provide clinicians with information about analgesics and other palliative care initiatives (American Pain Society [APS], 1995).

When the primary focus of care shifts from pursuing a cure, the emphasis shifts to palliation (Kaye, 1989). Palliative care, the focus of hospice care, affords relief and reduces the severity of bothersome symptoms, but does not produce toxicity or hasten the death of the patient (Johanson, 1988). Although palliative care should be integrated into all health care, it is critically necessary when cure is

not likely (Brescia, 1987). No specific therapy is or should be excluded from consideration. The test of palliative treatment lies in the agreement by the patient, the physician, the primary caregiver, and the hospice team that the expected outcome is relief from distressing symptoms, easing of pain, and enhancement of quality of life (National Hospice Organization [NHO], 1996). The absolute goal for palliative care is to improve the quality of the patient's life while avoiding side effects worse than the symptoms being treated (Emanuel et al., 1999).

Excellence in palliative care focuses on pain control and symptom management to help the patient avoid suffering and enhance quality of life. To realize this goal, it is essential for the clinicians involved to believe and to assess the severity of each pain complaint.

Total pain management cannot be undertaken by an individual alone, but only by individuals working together as a team (Lack, 1984). This underlying principle of working together in hospice care manifests through the use of an interdisciplinary approach and a creative process of individualized patient management. This results in an empowered patient who is able to attain comfort and dignity. Hospice care integrates the best of psychological support, physical care, and spirituality for the patient directly and provides long-term bereavement assistance for the surviving loved ones.

Hospice is based on a philosophy of caring for the person at life's final stages, embracing a number of concepts. Death is viewed as a natural part of the life cycle. When death is inevitable, hospice will seek neither to hasten nor to postpone it. Hospice exists in the hope and

belief that through appropriate care and the promotion of a caring community sensitive to their needs, patients and their families may be able to attain a degree of mental and spiritual preparation for death that is optimal for them (NHO, 1996). Despite the successful growth of the hospice movement in the United States during the past 30 years, over 50% of Americans die in hospitals and long-term care facilities, making palliative care interventions relatively unused in the settings in which most of them die (Rummans et al., 2000). Fortunately many hospitals, nursing homes, and other health care providers are exploring the development of palliative care initiatives as well as better partnerships with hospice programs. Palliative care services also help hospitals meet a number of the Joint Commission for the Accreditation of Health Care Organizations standards related to pain, continuum of care, and communications.

Pain relief and symptom control are appropriate clinical goals, with psychological and spiritual pain considered as significant as physical pain. Addressing all spheres simultaneously requires the skills and experience of an interdisciplinary treatment team. Such teams include physicians, nurses, social workers, pharmacists, aides, chaplains, homemakers, volunteers, bereavement counselors, and other therapists as needed. Additional therapies should include the standard therapies, such as physical, occupational and speech therapy, as well as the complementary therapies, such as music, art, aroma, pet, and massage therapy. Patients with their families and loved ones are the unit of care, and this care is generally provided to them regardless of their ability to pay.

Although hospice was viewed by many as unconventional at its beginning, the number of people cared for by hospice has continued to increase with an average of 30% of all deaths occurring in the hospice setting in 2003. Many misunderstandings about hospice programs exist, including the myths that people must die within 6 months and that hospice is only for cancer patients and older people. In fact, people can be certified for hospice every 60 days, hospice cares for people with all end-stage diseases and of all ages. Hospice medicine and care has become quite scientific and developed, with a large body of knowledge about providing care for people at the end of life (Appleton, 1996). Hospice medicine established new standards for medication dosing, medication selection, home care limitations, and the ability to provide "whole patient" care.

Hospice is now recognized as one of the standards for clinical practice. Based on these concepts of "whole patient" care, hospice is now a specialized health care program focusing on the provision of pain management, symptom control, emotional and spiritual support, personal care, and bereavement counseling. More cost-effective than hospital, home health, or nursing home (long-term) care, hospice provides the appropriate array of services at the end of life. Because hospice care combines the best quality and value for end-of-life patients, it is now covered by Medicare, many insurance companies, and in most states by Medicaid. A majority of hospice programs also look to their communities for additional support to assist them in providing indigent care and other specialized unreimbursed programs.

A primary focus of hospice care is to maintain patients in their home or place of residence for as long as possible. Additionally, care is also provided in inpatient hospice units, assisted living facilities, long-term care nursing facilities, and contract hospitals. Electing hospice care allows patients to make choices, control their destinies, and maintain their dignity while avoiding the sense of abandonment and solitude often associated with a hospital death.

PATIENT ASSESSMENT AND HOSPICE CARE

Our goal should be to care for the person, not just the patient that the health care system has made the person. We must care for the person, not just the disease. Therefore, patient assessment is an important skill. Whole-patient assessment clarifies the diagnosis and prognosis; coordinates the activities of the hospice team members; improves trust between patients, their families, and their professional caregivers; and leads to the best therapeutic effects (Emanuel et al., 1999). Thorough assessment allows establishment of a plan of care with the task of the interdisciplinary hospice team being to provide care that is comprehensive in scope.

Certain diseases can be expected to follow predictable courses. However, hospice is not about providing routine care, but instead focuses on providing an individualized hospice plan of care that is prepared uniquely for every new admission and continuously updated. This plan of care begins the moment the patient is referred to the hospice program and evolves as the needs of the patient change. Although the initial plan of care is the collaboration of the intake nurse, attending physician, hospice medical director, and social worker, the other members of the interdisciplinary team participate in the frequent revisions.

The patient-as-a-person view of end-of-life care encompasses many domains simultaneously. These domains include the review of the patient's complete illness and treatment summary, followed by ongoing physical, psychosocial, spiritual, and practical care assistance (Emanuel et al., 1999). The goal of this assessment is control of bothersome symptoms, improvement in function, reduction of suffering, minimization of aimless inconsequential testing, and bettering the overall quality of each day.

The referring source often has certain expectations about services for the patient, and the hospice team must consider these wishes along with the overall hospice phi-

losophy. Continuity of care for the patient and family necessitates a close relationship between the attending physician, discharge planners, and the hospice staff. Problems identified in the earliest stages of hospice involvement tend to reflect uncontrolled symptoms, care plan needs such as equipment and medication, and accessibility to the care team. Once the patient has been enrolled into the program, a number of the hospice team members visit the patient and family to develop an appropriate plan of care.

The nursing assessment focuses on the safety of the patient in the environment, the patient's main complaints, use of medications, care needs over time, and managing the plan of care. In the assessment process, the nurse gathers information from the patient that allows for understanding the pain experience and its effect on the quality of life (McCaffery & Beebe, 1989; McCaffery & Pasero, 1999). It is important to avoid making assumptions about the patient's wishes. Asking the patient for ideas and opinions makes his or her wishes known (Kaye, 1989). Inquiring "How are you right now?" lets the person know that human needs will be addressed. This helps to establish trust and build the relationship that allows screening for care requirements, such as diet, appetite, bowel function, managing unpleasant side effects, intimacy issues, and successful pain management. The interdisciplinary approach to care in conjunction with trained volunteers ensures that no person has to travel the final days alone.

The hospice physician primarily attends to the management of symptoms, serves as a consultant for the interdisciplinary team, and acts as a liaison with the attending physician. Education and support for the team members and representing the hospice program are key duties for the physician. A willingness to be available, often 24 hours a day, and to work collaboratively with the interdisciplinary treatment team adds to the services provided by the traditional medical staff in the community. The "house call," with care provided in the home of the patient rather than the office or the hospital, is the preferred method of management for the hospice patient. The hospice physician must be flexible, able to handle routine medical problems, and practice medicine in a home environment or with a minimum of the complicated technology often associated with facility-based care.

Practical care issues are important considerations for hospice care provided in the home. The patient or the primary caregiver may relocate to accommodate the care demands. Changes in living arrangements often result in disruption for everyone as new routines are established. Not only must the medical aspects of care be undertaken, but in addition, the more mundane aspects of daily living must also be addressed. Who will pay the bills? Who will feed the pets? Who will do the grocery shopping? Who will get the prescription medications filled? Who will do the chores around the house? These issues must be resolved to successfully care for any patient at home.

In a home environment there are important concerns related to the physical safety of the declining patient; thus, specialized adaptive equipment is often provided to improve the care of the patient. Emotional support coupled with extensive and practical education provides the caregivers with the confidence to assume the challenge of providing care for the patient. Despite all this wonderful support, it remains very difficult to prepare the new caregiver for the personal sacrifices that must be made to provide care for the very ill person. The simplest errand often takes on monumental qualities when caregiving needs are continuous. Caregiver stress is a very important issue. This "24/7" routine often results in the exhaustion of the caregiver, physically and emotionally, and necessitates the need for respite care. Inpatient care must also be available for symptom management.

Trust issues manifest early in the care of the hospice patient. The continuum of care with the attending physician and past health care providers must be maintained and include transition to the hospice team. Many attending physicians are not able to follow their patients at home and thus rely on the skills of the hospice team members to provide the day-to-day aspects of care. The reality that most hospice patients are older and seriously medically ill, yet are frequently cared for by younger family members, produces difficult reversals in generational hierarchies. The daughter, or daughter-in-law, who typically becomes the caregiver for her, or her husband's, parent, and the actual patient, must adjust to new patterns. Long-standing, unresolved conflicts may reappear due to the stressful conditions that exist and can lead to power struggles and other dysfunctional expressions.

Hospice care embraces the idea that psychosocial, emotional, and spiritual factors all have an impact on physical symptoms. Plato once said, "As you ought not to attempt to cure the eyes without the head or the head without the body, so neither are you to attempt to cure the body without the soul; for the part can never be well unless the whole is well; therefore, if the head and body are to be well, you must begin by curing the soul." In the 15th century, Lorenzo Sassoli, a physician, wrote to a patient: "To get angry and shout at times pleases me for this will keep your natural heat; what displeases me is your being grieved and taking all matters to heart; for it is this as the whole of physics teaches which destroys our body more than any other cause" (Sassoli, 1402).

The connections between the mind and body have continued to be the focus of attention for many researchers. Outcomes attributable to psychosocial factors range on a continuum from the readily explicable to the most controversial. These outcomes include enhanced physical comfort, increased responsiveness to medical treatment, relief from emotional anguish, extension of survival time after disease onset, and outright "psychogenic" cure. For these reasons, we believe that the psychosocial, emotional, and

spiritual components of a patient's palliative and end-of-life experience must be thoroughly addressed to understand the totality of the care needs. The experience of pain, and the resulting suffering, may be greater when the pain is accompanied by anger, anxiety, depression, fear, and the meaning given to the pain. Because many patients report less pain when they are rested, distracted, and have other symptoms under good control, many questions are raised about what specific factors influence how an individual person may experience pain. Factors considered involve the duration of the pain experience, the course the pain has taken during that time, the anticipation that the pain will be controlled, the expected interval before improvement will be realized, and the time anticipated until meaningful comfort will be attained. Patients must be given hope that their pain and suffering will be managed.

A comprehensive psychosocial assessment is important and must include an appropriate analysis of gender, present financial situation, family history, relationship patterns, previous coping strategies, previous losses, history of alcohol and substance abuse, past mental health problems, occupational history, and ethnic and cultural issues, as well as an exploration of religious and spiritual beliefs. The specific information regarding finances, environment, and care costs is necessary to develop a plan of care that is realistic and achievable as many patients and their caregivers express concern about the cost of their analgesic medications and other needed services.

It is certainly natural to be afraid of death, as death is the ultimate unknown (Ryder, 1993). However, fear is a major factor that adversely influences the experience of pain. Fear of pain takes at least two forms: fear of the pain itself and fear of the inability to control pain (Hill & Shirley, 1992). Most patients expect the pain from cancer and other diseases at the end of life to be very severe, perhaps to the point of not being able to be managed. The popular belief that most cancer pain is poorly controlled does not offer newly diagnosed cancer patients or others much reason to be hopeful about their personal pain management.

Unnecessary concerns and myths about the consequences of opioid analgesic usage, including addiction, confusion, constipation, disorientation, tolerance, and withdrawal problems, continue to prevent many patients from receiving the medications they need. Patients should never need to wish for death because of their physicians' reluctance to use adequate amounts of effective opioids and provide appropriate symptom management to control side effects (Reisine & Pasternak, 1996).

Fear also arises from concerns about loss of control, dignity, and relationships, as well as being abandoned or becoming a burden (Emanuel et al., 1999). Professional caregivers must explore patient fears and ultimately affirm their commitment to care for the patient. Failure to do this may lead to needless suffering.

Untreated anxiety and depression also worsen the pain experience, resulting in interference with restful sleep, impaired cognitive processes, and altered social patterns. Depression associated with uncontrolled pain plays a significant role in suicidal ideation, and when coupled with a sense of helplessness and hopelessness, it becomes a deadly predictor of actual suicide. Pain relief clearly enhances the sense of hope and well-being for the patients. Failure to appreciate the psychological needs of the patient will render even aggressive treatment of pain with analgesics or procedures ineffective (Patt & Isaacson, 1996).

Health care professionals must make their treatment decisions with a focus on the whole person rather than just the specific disease state. People must be the focus of care. Caregivers need to understand that having a serious, potentially end-stage condition can by itself be a reason for demoralization and loss of hope. Patients and their families need to be reassured by their professional caregivers that care, compassion, and concern will always be available to them and that they will not be abandoned. Information about the disease, expected outcomes, and treatment options, including their effects on the quality of life, must be communicated in common terms that the patient and family can understand.

Helping the family caregiver with practical day-to-day tasks can reduce the caregiver's fatigue and potential for fatigue. Using the psychosocial assessment process, resources needed can be identified and provided. Giving the patient and caregiver a flowchart with the names and duties of the professional team members can clarify the roles and relationships. Done properly, the patient and caregiver can view their appropriate place in the care continuum and feel that they are valuable team participants.

Many caregivers report that much of their day is centered on the dying person, attending to positioning, feeding, bathing, and medicating. The care needs of the patient direct the life of the caregiver. Although this routine is appropriate and encouraged during the patient's hospice care, upon the death of the patient, it is radically altered for the caregiver. This loss of activity and fulfillment of nurturing needs should be acknowledged as part of the emptiness experienced after death. Hospice programs provide bereavement support, maintaining continued involvement with the caregiver through the professional staff and volunteers, using a variety of techniques including support groups, classes, and individual counseling. The bereavement plan of care must be based on an assessment of risk indicators (Beckwith et al., 1990). Bereavement care demonstrates the hospice philosophy and communicates, "We still care for you, and we will help you get through this."

Bereavement, a separation or loss through death, is derived from the Old English *bereafian*, meaning "to rob," "to plunder," or "to dispossess" (Burnell & Burnell, 1989). Bereavement is the general state of being that results from having experienced a significant loss (Cook & Dworkin,

1992). It is the price paid in emotional pain for having meaningful relationships. All caregivers have loss experiences that color how they handle subsequent losses, and these losses need acknowledgment in preparation for healthy grieving after the loved one's death. Soon after the death, or often through the dying process, caregivers must look for ways to adjust their identities. Caregivers may experience an initial sense of relief and simultaneous feelings of emptiness when new coping patterns have not been developed. Confusion over identity arises with a shift in focus from the care needs of the patient to the personal needs of the caregiver.

Ultimately, the search for meaning and the exploration of spiritual issues can contribute to the alleviation of emotional distress for patients and their families. A review of things enjoyed and loved, such as people, places, events, and experiences, can bring genuine comfort and relief from suffering. Although formal psychiatric involvement may be needed for those with histories of prior psychiatric illness, supportive techniques, such as psychotherapy can often be helpful for most who elect to use them. This spiritual search for meaning can also influence the perception of the pain experience.

Spirituality needs require thorough exploration from the outset of hospice care. We must acknowledge that pain is not just a response to a physical problem; all facets must be addressed if we are to treat the whole person (Cosh, 1995). Almost all who connect their pain with impending death review the events of their lives and seek to determine the significance of their lives. Some return to religious values of earlier days, and others make intense demands on their faith (Lack, 1984). Rectifying previous religious traditions with present affiliations can prove problematic. When spouses are of different faith traditions or one spouse is a relative nonbeliever, the provision of spiritual care can be more complex. It is not the responsibility of the hospice team to resolve religious matters or to "save" people, but rather to assess and attempt to provide spiritual support as desired by the patient and family. Symptom control has to precede spiritual or psychosocial support; a person cannot think about the meaning of his or her life while in pain (Kaye, 1989).

PAIN MANAGEMENT

Approximately 70% of patients with advanced cancer report pain as a major symptom (Bonica, 1987). For half of them, the pain is moderate to severe in intensity; while for a third, the pain is severe to excruciating (Cleeland, 1994; World Health Organization [WHO], 1986). It is tragic that although pain in 1 in 10 patients with cancer is difficult to control, pain in 50 to 80% of patients with cancer is not satisfactorily relieved because their physicians do not aggressively treat the pain problem (Bonica, 1985). With more than 6 million newly diagnosed cancer

cases in the world each year, every physician who cares for patients with cancer or others at the end of life must be able to elicit a detailed pain history and be able to bring relief to these sufferers (WHO, 1986). Pain may be due to direct tumor progression and related pathology, operations and other invasive diagnostic or therapeutic procedures, toxicities of chemotherapy and radiation, infection, or musculoskeletal discomfort when patients have limited physical activity (Foley, 1985). In addition, many hospice and palliative care teams are now finding that over half of their referrals are for patients who do not have cancer. This requires us to be equally adept at assessing and treating noncancer pain as well as pain associated with chronic benign conditions.

The basic pain evaluation must begin with believing the pain complaint expressed by the patient (Foley, 1988). Pain is whatever the person experiencing it says it is, and it exists whenever the person experiencing it says it does (McCaffery & Beebe, 1989; McCaffery & Pasero, 1999). Because all pain is very real and distressing to the patient, trying to assign relative proportions to organic or functional causes is of little value. It is more useful to determine if the pain limits the activity of the patient and disturbs sleep, appetite, or the ability to engage in productive or pleasurable endeavors. Knowing what the patient can or cannot do, how medications have or have not worked, what the treatment expectation is, and what side effects the patient will or will not tolerate are key initial questions to be answered. It is vital that a language about the pain be developed among the patient, the caregiver, and the hospice and palliative care team to allow skillful management. Descriptive words such as mild, moderate, and severe indicate the intensity of acute pain fairly well. Words such as excruciating, incapacitating, overwhelming, and soul-stealing may better define the pain of cancer. A number of pain scales have been developed to quantify and track the pain experience, such as the descriptive (uses words), numerical (uses numbers), and visual (uses anchors of "no pain" and "worse pain") analogues. Pain scales have also been developed to help evaluate pain severity in noncommunicative patients.

To treat the pain most thoroughly, it is best to obtain the richest detail about the pain complaint that the patient and family can provide. This pain assessment would include screening for possible spiritual, psychosocial, or financial contributing factors. A careful, comprehensive physical examination should be performed, with special attention given to areas of pain or tenderness and to maneuvers that may help to define the areas or etiologies of pain. If necessary, the physician should order and personally review needed diagnostic studies to better elaborate the overall problems of the patient (Portenoy, 1988). All of the possible methods of controlling the pain — not just pharmacological means — must be considered and blended to individualize the plan of care for the patient.

Finally, the level of pain control and patient satisfaction after each intervention must be assessed. There is no point in frequently changing methods until assessment with what was previously ordered has occurred. Establishing clear and reasonable goals with the patient and the family is necessary to ensure a successful outcome. Everyone must understand that analgesics are not anesthetics; although absolute pain elimination may not be a realistic goal, improved comfort can be provided. With a clear understanding of the pain problem, a treatment plan may be developed evolving from simple analgesics to invasive interventions such as nerve blocks and other ablative techniques. Through hospice, medical equipment and supplies that are needed to facilitate even complex care of the patient can be provided either in the home setting or in the hospice inpatient unit. As we are concerned about both the patient and the family, the capacity and emotional status of nonprofessional caregivers should be assessed to be certain that they are not overwhelmed or at risk for breakdown. A balance must be struck among the capabilities of medical science, the wishes of the patient, and the realistic abilities of the caregiver. The loss or fatigue of the caregiver at home is a frequent reason for a patient needing to enter a long-term care nursing facility or an inpatient setting.

PHARMACOTHERAPY

The correct route of administration for medication is the one best tolerated by the patient. As long as the patient is able to swallow, pain can be routinely managed with oral medications. Transmucosal, transdermal, rectal, and parenteral routes may be utilized when swallowing is compromised. The important premise that the oral route is the preferred method of administration for a patient able to eat and drink leads to the recommendation that practitioners follow the WHO guidelines, as well as those of the Agency for Health Care Policy and Research (AHCPR), reorganized as the Agency for Healthcare Research and Quality (AHRQ) in 1999. These organizations systematically start with an oral nonsteroidal anti-inflammatory medication (NSAID) or acetaminophen. Level-two pain can be treated with a non-opioid and a relatively weaker, or lower potency, oral opioid. A low starting dose of a stronger, more potent opioid may also be considered for this second step. Higher doses of a strong, potent oral opioid can then be used in addition to the non-opioid for more severe pain (AHCPR, 1994; WHO, 1986). These three steps best describe the management of mild, moderate, and severe intensities of pain. At each of these steps, adjuvant medications may be added to the other medications to additionally provide pain relief, but the routine combining of multiple NSAIDs or opioids is usually unnecessary, and actually discouraged, for the majority of patients. Ultimately, instead of trying to fit patients to the

medications, the medications are adjusted to fit the patients. The right dose of any medication becomes the dose that produces comfort with minimal toxicity.

Acetaminophen, often part of combination pain medications, has little anti-inflammatory effect, but often helps with mild to moderate pain relief. A risk of hepatotoxicity exists when daily doses exceed 4 g. Patients with chronic alcoholism and liver disease, or those who are fasting, can develop hepatotoxicity at standard doses (APS, 1999).

Starting with the NSAIDs makes good sense for most pain problems, as these medications work to relieve pain in the periphery, where the nociceptive experience originates (Kanner, 1987). NSAIDs interfere with the manufacture of local pain-sensitizing and inflammation-mediating components (prostaglandins) and thereby limit pain transmission from the periphery to the central nervous system (CNS) and eventual consciousness (Insel, 1996). While aspirin irreversibly interferes with platelet aggregation, most of the other NSAIDs decrease platelet aggregation only while therapeutic levels are maintained (APS, 1989). Notable exceptions are the selective COX-2 inhibitors, nabumetone, and choline magnesium trisalicylate. Choline magnesium trisalicylate is a nonacetylated aspirin derivative that does not appear to affect the aggregation of platelets (APS, 1989; Kanner, 1987). Choline magnesium trisalicylate is a generic medication that can be used orally, as tablets or as a liquid suspension, with the same or milder side-effect profile as aspirin and the ability to follow salicylate levels if desired.

The NSAIDs in general may produce gastric upset and gastrointestinal bleeding, due to inhibition of COX-1-generated protective prostaglandins. Nabumetone and the selective COX-2 inhibitors celecoxib and rofecoxib have lower event rates for these problems (Insel, 1996; Medical Economics Company [MEC], 2000). Also, a preferential COX-2 inhibitor, meloxicam, shares this property, but all of these agents have the potential for renal problems (Smith & Baird, 2003). Unfortunately, emerging evidence of possible significant cardiac toxicity may decrease somewhat the use of COX-2 inhibitors (Topol, 2005). It is a common occurrence in the hospice setting to encounter patients with pain that is controlled quite poorly despite high-dose opioid analgesics at the time of their admission. These patients may benefit significantly from the continuation or addition of NSAIDs without further increases in the opioid analgesics. Additionally, NSAIDs should be considered when pain is due to bone metastases (Foley, 1985; Walsh, 1985), soft-tissue infiltration, and various arthritides.

CASE EXAMPLE

Mr. H was a 75-year-old gentleman with advanced prostate cancer with extensive bony metastases. He was initially able to control his pain with 2 mg hydromor-

phone orally every 4 hours. He later experienced high levels of localized pain in his lower back and pelvis. Rather than increase his opioid analgesic, he was additionally given 750 mg of choline magnesium trisalicylate four times daily, with his pain level decreasing from an "8" to a "2." As his disease progressed, he eventually required more hydromorphone to remain comfortable. His dose was adjusted to 4 mg orally every 4 hours, and he was able to die comfortably.

If the pain is not controlled with NSAIDs alone, the next step is the addition of an opioid analgesic. Routinely, Drug Enforcement Agency schedule three (C-III) combination medications or low doses of stronger opioids are prescribed after nonsteroidal agents. It is important to remember that all of the combination opioid medications, like the pure opioids, are effective analgesics if used at equianalgesic dosages (the amount of one medication that produces the same relief as another medication; see Table 89.1). The limiting factor for the schedule three agents used in the United States is the presence of the co-analgesic (acetaminophen, aspirin, or ibuprofen). Because of the toxicity associated with the co-analgesic agents (gastrointestinal upset and/or bleeding, hepatotoxicity, platelet aggregation interference, and nephrotoxicity), there is a finite limit for the number of C-III combination products that may be taken daily. This ceiling due to the co-analgesic may result in inadequate pain relief for those experiencing more than moderate pain intensity.

Contributing to some of the confusion about effectively prescribing pure opioids is the continuing observation that most standard textbooks of pharmacology describe opioid analgesic dosages with respect to acute pain, but few references mention the complexities of chronic pain management. Underdosing the patient with cancer is more commonly the rule than the exception (Hill, 1988), and fear about possible respiratory depression due to opioids is best countered by remembering that the most potent antagonist to opioid-induced respiratory depression is pain itself (Johanson, 1988). Respiratory depression is not a problem until the pain is well controlled; no one has died from opioid-induced respiratory depression while awake (APS, 1999; LeGrand et al., 2003). Also, it is unnecessary to reduce opioid dosing in the final days of life as the use of opioids does not correlate with dying more quickly (Morita et al., 2001).

In general, the relative potency of oral to parenteral opioid analgesics is about three to one, except for hydromorphone being five to one, due to the first-pass effect of hepatic metabolism and possible incomplete intestinal absorption. One must take approximately two to four times more oral medication, depending on the opioid, to obtain the same level of comfort produced by the parenteral route (Pasero et al., 1999). Oxycodone is an exception, with 60 to 87% or more of oral doses being bioavailable and escaping the first-pass hepatic metabolism (Kaiko et al., 1996; Leow et al., 1993; Poyhia et al., 1993).

The most frequent error in working with opioid analgesics is to assume that dosages are constant despite the route of administration (not accounting for first-pass liver effects). It is still common to find opioid orders written for 50 to 75 mg meperidine orally or intramuscularly every 4 to 6 hours as needed for pain. This situation shows a lack of understanding regarding pharmacokinetic principles most notably in two areas: the equianalgesic difference between oral and parenteral routes of administration (300 mg orally is equivalent to 75 to 100 mg parenterally) and the 2- to 3-hour duration of analgesic action (Pasero et al., 1999).

Most important for properly prescribing opioids is their administration on a time-contingent, by-the-clock (or around-the-clock) basis, rather than a pain-contingent, as-needed basis, so that comfort is constantly maintained instead of being continually sought. Initiation of opioid dosing, however, is often done on an as-needed basis using short-acting opioids, thereby retaining the ability to stop the medication's effects quickly if unexpected or intolerable side effects occur. The development of extended-release medications has allowed several opioids (fentanyl, morphine, and oxycodone) to provide sustained analgesic action for 8 to 72 hours. Such stable blood levels will increase overall comfort and lessen the peak and trough effect found with administering short-acting opioids.

By maintaining control of the pain around the clock, most patients experience a better quality of life (lower pain frequency and intensity, less medication toxicity, improved sleep) and use less medication (Reuben et al., 1999). From a learning theory perspective, the use of as-needed medication may cause the patient to use more medication over time because of the linkage made between having pain and taking medication to experience pain relief, thereby resulting in the development of psychological craving. The time-contingent dosing pattern dissociates pill-taking from pain relief (because medication is taken on a fixed time schedule) and thus may prevent the most feared but least likely complication of opioid analgesic use — addiction.

In reality, very little abuse of opioid medication actually occurs among hospice patients or medical patients with legitimate use of these agents. Studies of nonterminal patients with chronic pain show little justification for concern when the probability of iatrogenic addiction is 1/800 to less than 1/10,000 (Medina & Diamond, 1977; Perry & Heidrich, 1982; Porter & Jick, 1980). Although 6 to 15% of the U.S. population may have a substance abuse disorder of some type, only 3% of inpatient and outpatient consultations performed by the Psychiatry Service at Memorial Sloan-Kettering Cancer Center were requested

TABLE 89.1
Equianalgesic Dosages

Medication	Equianalgesic Dosage (in mg)			Duration of Action (hours)
	Intramuscular/ Intravenous/Subcutaneous	Oral	Rectal	
Opioid Agonists				
Codeine	130	200	N/A	3–4
Fentanyl[a]	0.1–0.2	N/A[b]	N/A	1–2
Hydrocodone	N/A	30	N/A	3–4
Hydromorphone	1.5	7.5	3	3–4
Levorphanol[c]	2	4	N/A	4–5
	(Single dose)			
	1	1		
	(Repeated doses)			
Meperidine[d]	75–100	300	N/A	3–5
Methadone[e]	10	20	N/A	4–6
	(Single dose)			
	Variable	Variable		
	(Repeated doses, see Table 89.3)			
Morphine[f]	10	60	10–15	4–5
		(Single dose)		
		30		
		(Repeated doses)		
Oxycodone[g]	10–15[h]	20	N/A	4–6
Oxymorphone	1–1.5	N/A	10	4–6
Propoxyphene[i]	N/A	300–400	N/A	4–6

[a] Transdermal fentanyl dosage is not calculated as equianalgesic to a single morphine dose. In the steady-state condition, a 25-μg/hour patch is approximately equivalent to 10 mg of oral morphine sulfate every 4 hours.

[b] Oral transmucosal fentanyl citrate absorption is variable due to both immediate transmucosal absorption and slower gastrointestinal absorption.

[c] Levorphanol has a long half-life and accumulates over time.

[d] Meperidine is not appropriate for patients with cancer due to the half-life of its metabolite, normeperidine, which is 8 to 21 hours. Meperidine should never be administered beyond 600 mg/day as the accumulation of normeperidine leads to agitation, myoclonic twitching, and seizures.

[e] Methadone has a long half-life and accumulates over time (see Table 89.3).

[f] Morphine-6-glucuronide has a longer half-life than morphine and leads to greater morphine effectiveness over time. Note: As morphine-3- and morphine-6-gluconoride both lead to increased adverse side effects in patients with renal insufficiency, morphine should be avoided in patients with renal failure.

[g] Many equianalgesic tables have oxycodone as either equianalgesic to morphine or 1.5 times more potent than morphine. The product insert for OxyContin indicates that oxycodone is two times more potent than morphine.

[h] Oxycodone is only commercially available as an oral preparation in the United States. It is used parenterally outside the United States.

[i] Propoxyphene is so weak that it is usually ineffective for cancer pain of any significance; its metabolite norpropoxyphene accumulates leading to seizures.

for the management of drug-related issues (Passik & Portenoy, 1998).

While some degree of tolerance does occur over time with continuous opioid therapy, the need to increase opioid analgesic doses in patients with cancer more often relates to the progression of their underlying disease than to the rapid development of pharmacological tolerance. Physical dependence, the need that a person has for the medication to prevent distressing symptoms secondary (withdrawal or abstinence reaction) to the absence of the agent (Hill, 1988), is not addiction (a primarily psychological disorder with eventual physiological and sociological manifestations), and patients should not be identified as addicts just because they manifest tolerance or physical dependence related to opioids. Addiction, psychological dependence, signifies that the medication is compulsively

TABLE 89.2
Opioid Analgesics in the United States

Generic Name	Proprietary Name	Routes of Administration
Buprenorphine	Buprenex®	Intravenous/intramuscular/epidural
	Suboxone®, Subutex®	Sublingual
Butorphanol	Stadol®	Intravenous/intramuscular/nasal
Codeine	Tylenol® with codeine	Oral
Fentanyl	Actiq®	Transmucosal
	Duragesic®	Transdermal
	Sublimaze®	Intravenous/intramuscular/epidural/intrathecal
Hydrocodone	Hycodan®, Lortab®, Lorcet®, Norco®, Vicodin®, Xodol®, Zydone®	Oral
Hydromorphone	Dilaudid®, Palladone®	Intravenous/intramuscular/oral/subcutaneous
Meperidine	Demerol®	Intravenous/intramuscular/oral
Methadone	Dolophine®	Oral/intravenous/subcutaneous
Morphine	Avinza®, Kadian®, MS Contin®, Oramorph®	Oral
	MSIR®	Oral
	Generic	Oral/sublingual/subcutaneous/intramuscular/intravenous/rectal
	Astramorph®, Duramorph®	Intrathecal, epidural
Nalbuphine	Nubain®	Intravenous/intramuscular/subcutaneous
Oxycodone	OxyContin®, OxyFast®, Roxicet®, Endocet®, Endodan®, Percocet®, Percodan®	Oral
Oxymorphone	Numorphan®	Rectal/intramuscular/intravenous/subcutaneous
Pentazocine	Talwin®	Oral/intramuscular/intravenous
Propoxyphene	Darvon®, Darvocet®	Oral
Tramadol	Ultram®, Ultracet®	Oral

sought and used for effects other than pain relief (APS, 1999). The palliative care (pain) patient with a constant supply of medication that is used time-contingently shows little, if any, drug-seeking behavior (Passik & Portenoy, 1998). In fact, one of the greatest barriers to compliance with the time-contingent administration of these medications when patients are relatively comfortable is the mistaken belief by patients that they will develop an addictive disorder (Breitbart et al., 1998; Foley & Inturrisi, 1987; Ward et al., 1993). Data related to the risk of addiction have been traditionally obtained by surveying known addicts rather than prospectively following patients receiving legitimately prescribed opioid analgesics. In the past 20 years, it has been observed that the true incidence of opioid analgesic abuse is insignificant among patients with medically justified opioid use. Studies have shown that addiction develops in only 1 in 800 for headache sufferers to less than 1 in 10,000 burn patients (Medina & Diamond, 1977; Passik & Portenoy, 1998; Perry & Heidrich, 1982; Portenoy, 1990; Porter & Jick, 1980). Even the U.S. government has declared the risk of addiction in patients with cancer to be "an exceedingly rare event" (AHCPR, 1994).

Once the decision to use opioid analgesics is made, the issue becomes which one of them to use (Table 89.2). For mild to moderate pain, one can start with the lower potency opioid analgesics, such as codeine or hydrocodone. Using codeine for pain management poses an interesting problem for some patients because codeine is a prodrug that must be converted to an active analgesic, morphine, via the CPY2D6 component of the hepatic P450 microsomal enzyme system and that system is lacking in 7% of Caucasians, 3% of Blacks, and 1% of Asians (Lurcott, 1999), and generally suppressed in all patients receiving the selective serotonin reuptake inhibitor (SSRI) medications fluoxetine and paroxetine (Stahl, 2000). In the United States these medications are commonly given as combination tablets containing aspirin, acetaminophen, or ibuprofen that may be more effective than the amount of the opioid analgesic involved. Codeine and propoxyphene tend to be quite toxic for some patients (elderly patients, those with renal insufficiency or opioid allergies), with hydrocodone products tending to be better-tolerated and more effective as analgesics. Tramadol hydrochloride (a weak opioid agonist that also inhibits the reuptake of norepinephrine and serotonin) is generally not used for patients with cancer and must not be given in doses greater than 400 mg per day for the relatively "healthy" younger patient, 300 mg per day for the greater than 75-year-old patient, 200 mg per day for the patient with creatinine clearance less than 30 ml/min, and only 100 mg per day for patients with cirrhosis (APS, 1999; MEC, 2000).

Some clinicians erroneously view oxycodone as a weak opioid analgesic, much like codeine, hydrocodone, and propoxyphene, but in reality, the coadministration of

acetaminophen and aspirin limits the amount of oxycodone patients can take in the form of a fixed combination medication. This leads to the mistaken belief that oxycodone is not strong enough for patients with cancer. Pure immediate-release and sustained-release oxycodone preparations are free of adjuvant analgesics and permit further titration of the medication to analgesia without the ceiling dose associated with the co-analgesics. Uniquely, immediate-release and sustained-release oxycodone, used either alone or after converting from a combination oxycodone-containing product, allow for the continued use of the same initial opioid from mild through moderate to severe pain. In the American Medical Association Project to Educate Physicians on End-of-Life Care, only oxycodone is listed as both a step 2 (moderate pain) and step 3 (severe pain) appropriate agent (Emanuel et al., 1999).

When the lower-potency opioid analgesics do not produce adequate relief, high-potency opioid analgesics are recommended. The reference gold standard for these opioid medications is traditionally morphine, because it has the distinct advantage of being available in the widest variety of formulations for ease of administration (immediate-release and sustained-release tablets, solutions of varied strengths, concentrate, suppositories, preservative-containing solutions for intramuscular and intravenous use, and preservative-free solutions for epidural and intraspinal techniques) on a worldwide basis. Morphine is the historic analgesic "gold standard" because it is an effective, relatively inexpensive opioid with a 4-hour duration of action (Twycross & Lack, 1984) and a short half-life, and is generally available throughout the world. Unlike opioid analgesics with a long half-life (methadone and levorphanol), morphine-caused complications and toxicity are usually resolved within a matter of hours. The ability to convert from one route of administration to another is quite simple with an equianalgesic table (see Table 89.1).

Sustained-release morphine allows the patient to have uninterrupted comfort and allows intact sleep for the patient and the caregiver. Sublingual morphine administration, although variable in absorption and efficacy, allows ease of administration without resorting to the parenteral or rectal routes. Morphine can also be applied topically to wounds, where the analgesic effect is probably mediated through local, peripherally located opioid receptors (Ribeiro et al., 2004). A metabolite of morphine, morphine-6-glucuronide, is an active analgesic with a longer duration of action and half-life than morphine (Andersen et al., 2003; Osborne et al., 1986). The accumulation of morphine-6-glucuronide probably accounts for the observation that repetitively administered oral morphine is one third as effective as intramuscular, while single-dose-administered morphine is only one sixth as effective (Reisine & Pasternak, 1996). Opioid equianalgesic tables in pharmacology textbooks are generally based

on acute pain models rather than patients with pain receiving chronic opioids, and they report the oral to parenteral efficacy of morphine as six to one. Hospice patients are not opioid naïve and should be dosed using the three-to-one conversion factor when estimating the oral-to-parenteral conversion of morphine.

This accumulation of morphine-6-glucuronide, leading to the observed increased effectiveness of morphine with repeat dosing, also indicates that the risk of toxicity from the metabolites morphine-3- and morphine-6-glucuronide occurs when patients with renal insufficiency are given morphine. Because of this potentially toxic outcome associated with morphine administration for compromised, sick hospice patients, morphine is no longer the sole gold standard for all patients with cancer-related pain as it was in the past now that other opioid agents are available.

All of the other opioids can be equally effective in controlling pain and are typically used as alternatives when patients are allergic to morphine, experience morphine-related toxicity, or express concern about taking morphine. The only opioid that is best avoided in patients with cancer is meperidine, due to the accumulation of the metabolite normeperidine, which is associated with the development of irritability, myoclonus, and generalized tonic-clonic seizures (AHCPR, 1994; APS, 1999; Foley & Inturrisi, 1989). Similar concerns exist with the use of higher doses of propoxyphene. Because many of patients with cancer require relatively high doses of an opioid medication, the additional use of a mixed agonist–antagonist (butorphanol, nalbuphine, and pentazocine) is also strongly discouraged because of the possible precipitation of opioid withdrawal and severe pain for these patients (APS, 1999; Foley & Inturrisi, 1987).

Opioid-related myoclonus has been reported for hydromorphone, meperidine, methadone, and morphine (Mercadante, 1998). Metabolites of these opioids may accumulate with renal insufficiency, leading to irritation of the cortex and brainstem reticular formation. Higher levels of morphine-3-glucuronide, morphine-6-glucuronide, and normorphine accumulate with renal failure and may result in generalized myoclonus when patients receive morphine (Reisine & Pasternak, 1996). The neuroexcitatory metabolites of morphine and hydromorphone may be responsible for the hyperalgesic state seen in patients with cancer treated with high doses of these medications, although this still remains controversial (Andersen et al., 2003; Mercadante, 1998).

Whether or not patients experience significant toxicity with morphine therapy, there may be times to consider changing to a semisynthetic opioid. Many of these are currently available (or soon to become available) as controlled-release preparations. Hydromorphone is frequently selected, as the duration of analgesic action and plasma half-life are the same as morphine (Pasero et al., 1999). Perhaps relatively less nauseating and CNS "toxic" than

morphine, hydromorphone is available in immediate-release oral tablets (controlled-release tablets are available outside the United States and are in clinical trials in the United States), oral solutions, suppositories, and an injectable solution (10 mg/ml). The parenteral form can be quite useful for end-stage cancer pain management, especially when higher doses may be needed (Miller et al., 1999). Hydromorphone's metabolites (primarily hydromorphone-3-glucuronide) are not thought to be pharmacologically active, although myoclonus and mental status changes have been reported with high doses of hydromorphone, potentially making it particularly useful for patients with renal failure after dosage reduction and careful titration (Kuczynska, 2004; Kurella et al., 2003).

CASE EXAMPLE

Mr. C, a 70-year-old gentleman, had advanced lung cancer complicated by sacroiliac and fifth lumbar vertebral metastases. He experienced severe pain in his left thigh with muscular wasting. He had previously tried oral morphine with an unclear "reaction." Although he was able to tolerate oral fluids and solids without any overt difficulty, he was quite anxious about taking any oral analgesics and requested that his medication be provided by the intravenous route, a dosing format in which he had great confidence. Because he was cared for by his daughter, who was able to learn the needed skills, it was possible to consider the use of parenteral analgesics. He had been started on intravenous hydromorphone in the hospital before coming home to the hospice program. The hospice nursing staff maintained intravenous access through his PIC line, and his daughter gave him doses of 5 or 6 mg hydromorphone every 3 hours, with good relief of his pain for the first week on the program. He was able to sleep well and developed a good appetite. By the second week, his pain was beginning to bother him much more. It was decided to add the anti-inflammatory choline magnesium trisalicylate, at 750 mg orally four times daily with food, and to maintain the intravenous hydromorphone at 6 mg every 3 hours. Throughout the next week he felt much better, but he developed the need for increasing doses given at decreasing intervals by the fourth week. When his intravenous hydromorphone reached 11 mg every 2.5 hours, he developed considerable nausea and vomiting, associated with anxiety about the ability to ever control his side effects and pain simultaneously. He was given 1 to 2 mg of sublingual haloperidol every 4 hours as needed, relieving his nausea and vomiting. In the fifth and final week on the program, he was switched to a continuous intravenous infusion of hydromorphone at 4 mg/hour with excellent pain relief. He remained alert, active, and involved with his family and care needs. His family was grateful that they could maintain meaningful dialogue with him and complete much of the anticipatory bereavement work. On the day before he died, he met with the funeral director to plan the details of his own funeral and met with a close friend to help prepare the eulogy that would be delivered.

Oxycodone and fentanyl are also commonly used medications and allow for good pain relief with relatively little toxicity. Both of these medications are available in oral formulations in the United States. Oral fentanyl is available in the United States as a branded transmucosal delivery system, Actiq®, with interesting pharmacodynamics and pharmacokinetics (25 to 50% bioavailability depending upon its method of use and ability of patients to swallow their own saliva). In the chronic steady-state condition, a 25 µg/hour transdermal fentanyl patch is almost equianalgesic to 10 mg oral morphine sulfate every 4 hours or 30 mg every 12 hours when given as sustained-release tablets (Emanuel et al., 1999). Fentanyl patches may improve medication compliance because patients only have to change them every 3 days, and they are generally well tolerated (Nugent et al., 2001). Patients and health care staff, however, sometimes report that patches are difficult to titrate, require the use of a second medication for breakthrough pain, may cause skin irritation, do not always adhere well in hot and humid environments, may show erratic blood levels due to nonstandard thermal conditions or low bodyweight (less than 110 pounds), and have significant cost. During episodes of fever (temperature >104°F), exertion combined with sunny and warm environments, and exposure to high external temperature sources (heating pad, heated water beds, electric blankets, and car seats in the summer), the actual dose of fentanyl delivered may exceed the dose printed on the patch and lead to potential increases in serum fentanyl levels (Newshan, 1998). Dosing tables for fentanyl transdermal patches suggest that 45 to 60 mg per day of morphine is equivalent to 25 µg per hour of transdermal fentanyl, although inter- and intraindividual variability requires cautious dosing and titrating to effect (Pereira et al., 2001).

Controlled-release oxycodone has been designed to provide sustained delivery of oxycodone over 12 hours, with an oral bioavailability of 60 to 87% (MEC, 2000). With repeated dosing, steady-state levels are achieved in 24 to 36 hours; however, controlled-release oxycodone exhibits a unique biphasic absorption pattern with two apparent absorption half-times of 0.6 and 6.9 hours (describing the initial release of oxycodone from the outer layer of the tablet, followed by prolonged release from the core of the tablet through the use of a patented technology). This unusual release system allows for prompt establishment of stable blood levels of oxycodone with the first dose and little need to overlap parenteral medications with controlled-release oxycodone. Oxycodone is metabolized primarily to noroxycodone (a considerably weaker opioid than oxycodone) and minimally to oxymorphone (a potent analgesic mediated by the CYP2D6 P450 system). Similar to other controlled-release medications, controlled-release

oxycodone must be swallowed whole and never broken, chewed, or crushed, which could lead to rapid release and absorption of a potentially toxic dose of medication. With hepatic failure, initial doses are one third to one half of the usual doses; however, oxycodone is not often associated with myoclonus or significant CNS toxicity due to its metabolites (MEC, 2000).

Despite appropriate use of opioids, some patients continue to have poorly controlled pain due to changing nociception related to disease progression, drug side effects, tolerance, and opioid metabolites among others (Mercadante & Portenoy, 2001a). These poorly controlled pain states frequently have a neuropathic quality (Mercadante & Portenoy, 2001b), and in an effort to better comfort these patients, basic and clinical research in recent years has focused frequently on the *N*-methyl-D-aspartate (NMDA) receptor. The NMDA receptors frequently play a role in opioid tolerance, neuropathic pain, and hyperalgesic states, and blockade of these receptors can help to attenuate certain NMDA-mediated pain conditions. Two NMDA-receptor blockers that have proved clinically useful are methadone and ketamine. Lack of well-controlled trials has probably restricted their recognition and use, and they frequently receive little mention in reviews on treatment of neuropathic pain (Dworkin et al., 2003; Mendell & Sahenk, 2003). Many palliative care and hospice teams, however, can readily attest to their efficacy.

Methadone is a synthetic opioid, which is a mu and delta opioid receptor agonist, an NMDA receptor antagonist, and an inhibitor of the reuptake of norepinephrine and serotonin. This would allow it to be useful in treating both nociceptive and neuropathic pain. Its use in addiction medicine creates a barrier in the minds of some physicians and patients to its use in pain control. Also, its long and variable half-life (12 to 120 hours) can cause its clinical dosing to be somewhat challenging with the main concern being gradual drug accumulation and toxicity.

Another challenge in prescribing methadone is that equianalgesic dosing conversions to methadone show large interindividual variability and are somewhat unpredictable. This may perhaps be in part due to its multiple modes of action, decreased cross-tolerance of opioid receptors, or elimination of active opioid metabolites (Bruera & Sweeney, 2002). Many older conversion tables are based on single dose studies and are inaccurate for converting to chronic dosing with methadone (Pereira et al., 2001). Table 89.3 shows one possible method for converting an opioid regimen to an estimated total daily dose of methadone.

Several methods have been recommended for initiating dosing with methadone. One of the more commonly employed methods is referred to as the United Kingdom or Morley–Makin model (Morley & Mekin, 1998), and this has also been described elsewhere (Wheeler & Dickerson, 2000). This model recommends using as-needed doses of methadone for the initial 5 days with patients

TABLE 89.3
Methadone Conversion Table for Long-Term Dosing

Equivalent Oral Daily Morphine Dose	Oral Morphine: Oral Methadone Conversion Ratio
<100 mg	3–5:1
100–300 mg	6–8:1
301–500 mg	8–10:1
501–800 mg	12–14:1
801–1,000 mg	16–18:1
>1,000 mg	18–?:1

guiding their analgesic dosing. Scheduled doses would be started on day 6. Because steady-state drug levels are not achieved until five half-lives have elapsed, and because methadone may have a 2- or 3-day half-life in some patients, this method might still result in drug accumulation and toxicity. A modification of this regimen is presented in Figure 89.1, and this dosing scheme allows for a more conservative titration.

Methadone can exhibit all of the same toxicities as other opioids. Constipation tends to be less of a problem, and this can be a reason to consider rotating to methadone (Daeninck & Bruera, 1999). Use of high doses of methadone has been associated with the cardiac problem of torsades de pointes (Krantz et al., 2002). Also, methadone is primarily metabolized by CYP450 3A4 and to a lesser extent by CYP450 1A2 and 2D6. This creates an obvious opportunity for significant drug–drug interactions to occur (Layson-Wolf, 2002). Methadone can be administered orally, rectally, or intravenously. Subcutaneous administration can result in localized erythema and induration, but site rotation and adding 1 to 2 mg dexamethasone per

1. Calculate the 24 h oral morphine equivalent.
2. The methadone dose for the patient will be 1/20th (mild to moderate pain) to 1/10th (severe pain) of the 24 hour oral morphine dose to a maximum of 20 mg methadone. Round dose to the nearest 2.5 mg increment. With severe pain not responding to an initial 20-mg maximum dose, consider using 25–30 mg as your maximum dose.
3. Stop the current opioid.
4. Start the fixed, calculated methadone dose every 3 h as needed. Continue to assess pain every 3 h. Hold methadone dose if the patient is comfortable or sedated.
5. The total daily dose of methadone is recorded each day, and the patient is observed for possible side effects.
6. On day 10 the average of the amount used on day 8 and day 9 will be calculated. One half of this dose will then be prescribed on a q12-hours dosing schedule. The breakthrough methadone dose will be approximately 10% of the 24-hour dose (rounding to the nearest 2.5 mg increment) given q6 hours as needed.

FIGURE 89.1 Method for converting opioids to oral methadone.

day to the infusion can ameliorate these side effects (Mathew & Storey, 1999).

CASE EXAMPLE

Mr. T N was a 63-year-old man with non-small cell lung cancer involving his right apex. He initially received radiation with good results and two courses of chemotherapy that he did not tolerate well. At 14 months after initial treatment, he had a relapse in his right apex with gradually increasing pain in his right shoulder and arm. He also developed a new pain in his midback with radiation around his chest to his left lower anterior ribs. A subsequent thoracic MRI (magnetic resonance imaging) scan showed a mass in his sixth thoracic vertebra with no spinal cord compression. He was given increasing doses of various pain medications and adjuvants without significant relief. At the time of his referral for palliative care consultation, he was already on OxyContin 120 mg every 12 hours, about 80 mg per day of liquid oxycodone for breakthrough pain, nortriptyline 75 mg at bedtime, gabapentin 600 mg three times daily, and 2 weeks of dexamethasone 4 mg twice daily. He had sharp burning pain in his right arm, midback, and left ribs, and his pain fluctuated in the 8 to 10 range on a 0 to 10 numerical scale. A decision was made to convert him to methadone to treat his mixed nociceptive/neuropathic pain syndrome. If oxycodone is considered to be 25 to 50% stronger than morphine, then 320 mg of oxycodone is equivalent to about 400 to 480 mg of morphine per day. Taking the midpoint of 440 mg as our equivalent dose, our conversion table would estimate that this patient may eventually require in the neighborhood of 44 to 55 mg of methadone per day (morphine in the 301 to 500 mg range has a morphine:methadone equivalency ratio of about 8:1 to 10:1). Because his total daily morphine equivalent dose is greater than 300 mg, he was started on 20 mg every 3 hours as needed.

Because 2 weeks of dexamethasone was not helping and because of concerns over the long-term use of steroids, this medication was tapered off over the next week and he was started on magnesium choline trisalicylate 750 mg three times daily for his bone involvement. Nortriptyline was continued for its antidepressant effect. Within 2 days of starting methadone his pain had subsided to the 4 to 5 range and it was in the 1 to 2 range by the fifth day. At this point his gabapentin was stopped with no increase in his pain level. Review of his methadone dosing over 9 days showed the following total daily doses: 80, 80, 40, 60, 50, 60, 55, 40, and 45 mg. His pain continued to be well controlled, and he was subsequently given a scheduled methadone dose of 20 mg every 12 hours with 5 mg every 4 hours as needed.

Ketamine is a surgical anesthetic agent that is also an NMDA receptor antagonist, and it is used in subanesthetic doses to relieve pain. It is usually reserved for patients with severe pain despite high opioid dosing or patients with intolerable opioid side effects. Ketamine is usually given as a constant infusion, and it does not depress the respiratory or cardiovascular systems. It can be administered orally 0.5 mg/kg every 12 hours (Furuhashi-Yonaha, 2002), but more often is given by either the intravenous or subcutaneous route. Excessive salivation can be managed by glycopyrrolate, and psychotomimetic effects (dysphoria, vivid dreams, hallucinations, delirium) often respond to small doses of a benzodiazepine given around the clock. Sedation can be expected when higher doses of ketamine are employed. Initial bolusing is done with 0.1 to 0.2 mg/kg intravenously or 0.5 mg/kg subcutaneously, and this is accompanied by a 50% decrease in the opioid dose. A subsequent infusion is started at 2 to 20 mg/hour depending on patient response. A recent review concluded that ketamine can be cautiously recommended as having potential efficacy as an opioid adjuvant (Bell et al., 2003).

The practice of combining opioid analgesics to provide better patient comfort is confusing for patients, their caregivers, and even the prescribing physicians. It is not justified under most circumstances, and there may be misuse of multiple opioid medications because few appreciate that titration and monitoring of a single opioid may require several days or longer. Also, sustained-release tablets do not adequately control pain until proper titration has occurred over 2 to 4 days. When two different medications are given simultaneously, it is usually because the base medication is not available in more than one or two routes of administration, the base medication has not been titrated to full effect, or there is some toxicity being experienced.

It is routinely necessary to provide additional immediate-release opioid medication for breakthrough pain occurring at certain times (incident pain, movement related pain), especially when the base opioid analgesic is a sustained-release preparation.

Unanticipated changes in pain can thus be effectively managed on an immediate basis, with day-to-day tailoring of the overall opioid medication by observing the use of these additional doses. Monitoring the 24-hour total usage of medication, and readjusting the daily scheduled dosage, is essential for keeping up with the analgesic needs of the patient. It is generally good practice to use the immediate-release form of the same opioid for breakthrough dosing as is used in the sustained-release preparation. The approximate dose of additional medication providing good control of breakthrough pain is 10 to 15% of the total daily amount of base medication (Emanuel et al., 1999). Using 10% is the easier method, allowing the prescriber to simply move the decimal point one digit to the left (avoiding the need for calculators) to determine the breakthrough dosage and then rounding up or down

depending on the formulations available. This 10% method of calculating the breakthrough dose assumes that the same route of administration is used for the immediate-release medication as for the base controlled-release medication. Frequent use of breakthrough medication indicates that the patient's pain management must be reassessed and that the dose of the scheduled controlled-release medication must be increased.

Oral transmucosal fentanyl citrate is a solid form of fentanyl incorporated into a sweetened lozenge on a handle, and it is sometimes used for breakthrough pain when using transdermal fentanyl. It is partially absorbed rapidly through the oral mucosa, and it is subsequently more slowly absorbed in the gastrointestinal tract (APS, 1999). The blood levels achieved will vary, depending on the fraction of the dose that is absorbed through the oral mucosa and the fraction swallowed and absorbed from the gastrointestinal tract (MEC, 2000). Normally, about 25% of the total dose of oral transmucosal fentanyl citrate is rapidly absorbed from the buccal mucosa, and the remaining 75% is swallowed with the saliva and slowly absorbed; the generally observed 50% bioavailability is divided equally between rapid transmucosal and slower gastrointestinal absorption (MEC, 2000). Because only about one third of the swallowed medication escapes first-pass liver metabolism to become systemically available, patients with impaired swallowing (or those incapable of swallowing) receive only half of the potential analgesic efficacy of oral transmucosal fentanyl citrate. Its use is limited because of its expense and limited duration of action.

The major side effect of all opioid therapy is constipation, regardless of the route of administration. Constipation must be vigorously managed and prevented from the initiation of treatment. Unrelieved constipation adversely affects the quality of life and must not be ignored. Failure to correct opioid-induced constipation leads to intractable nausea, vomiting, abdominal discomfort, and possible bowel perforation, as well as emotional distress. Options for treating constipation include stimulant laxatives, combination stimulant/stool softeners, prokinetic agents, osmotic agents, lubricants, and enemas. Dietary interventions alone or the use of bulk-forming agents is often inadequate and not recommended for those with advanced disease and poor mobility (Emanuel et al., 1999). Recalling that dirt and water alone produce mud, a viscous material, but the combination of dirt, water, and fiber (straw, grass) produces brick (as in adobe), should clarify the admonition to avoid bulk-forming agents. Opioid antagonists that act peripherally but not centrally are currently in clinical trials. Such medications would counteract the constipating effects of opioids without interfering with the centrally mediated analgesic effects.

CASE EXAMPLE

Mr. F was sent home from the hospital with advanced prostate cancer and widespread bone metastases, with no bowel movement for 1 week prior to entering the hospice program. He was fairly comfortable from a pain perspective, although he experienced increasing abdominal fullness and discomfort thought to be due to opioid-induced constipation. Digital examination of the rectum found significant hard, impacted stool that was manually decompressed. Once free of the impaction, he was started on an oral laxative and stool softener combination, and he developed bowel regularity within 2 days.

Although nausea and vomiting are initially common with opioids, once acclimated to these medications (in a matter of days for most patients), nausea and vomiting developing later more often result from unrecognized and ineffectively treated constipation. Early in the use of opioids, nausea and vomiting are usually controlled with dopamine-blocking agents (e.g., haloperidol, metoclopramide, prochlorperazine), antihistamines (diphenhydramine, hydroxyzine, or meclizine), or anticholinergics (scopolamine) (Emanuel et al., 1999). Respiratory depression, significant CNS dysfunction, allergic reactions, pruritus, and diaphoresis are much less significant in comparison with constipation or nausea and vomiting.

When opioid analgesics fail to provide relief of significant pain despite clear toxicity (respiratory or CNS depression), it is necessary to remember that these agents are not always effective as sole agents for neuropathic pain due to nerve involvement, viscus or muscle spasm, or significant psychological distress. The use of the adjunctive medications — with or without further opioid analgesics — may be warranted.

Adjuvant medications include antidepressants, antipsychotics, anticonvulsants, anxiolytics, and psychostimulants. These useful agents can be added at any step in the continuum of cancer pain management and often save patients from unnecessary progression to high-potency opioids or complex analgesic technologies. The adjuvant medications manipulate the neurochemistry of the nervous system and augment the overall effectiveness of both NSAID and opioid combinations.

The antidepressants are remarkable agents, with the ability to block the presynaptic reuptake of norepinephrine and serotonin, resulting in elevated levels of these important neurotransmitters in the brain (Botney & Fields, 1982; Hendler, 1982). The benefit of enhanced serotonin centrally is the consequent periaquaductal release of endogenous opioid peptides with a dampening effect on pain perception (Frier, 1985). These agents correct the depression (which is so common with persistent pain), stabilize sleep, and improve appetite, energy level, concentration, and the ability to experience pleasure. The

ability of antidepressants to relieve pain is independent of the antidepressant effect (Feinmann, 1985). Tricyclic antidepressants are recommended as one of the first-choice medications for painful polyneuropathy (Sindrup & Jensen, 2000) and especially for patients experiencing burning and tingling neuropathic pain (Emanuel et al., 1999). Although the antidepressants most traditionally used for neuropathic pain management are generally the serotonin-enhancing tricyclic agents (amitriptyline and imipramine), their more norepinephrine-enhancing tricyclic metabolites (nortriptyline and desipramine, respectively) are often particularly useful when patients are intolerant to the serotonin-enhancing effects or when psychomotor-retarded depression is present. Antidepressants are not habit forming and have little effect on respiration when used in therapeutic doses. Serotonin-enhancing tricyclic antidepressants are associated with a number of annoying anticholinergic side effects that limit their usefulness unless patients can tolerate them. The newer SSRIs, such as citalopram, fluoxetine, fluvoxamine, escitalopram, paroxetine, and sertraline, are generally free of the anticholinergic adverse effects (having unique side effects of their own), but are disappointing as co-analgesics (Emanuel et al., 1999). Atypical antidepressants (bupropion, mirtazapine, nefazodone, trazodone, and venlafaxine) are being evaluated for their analgesic usefulness and may provide benefit with less potential toxicity (Emanuel et al., 1999). Full effects of the antidepressants may not be seen for 4 to 6 weeks. It is also important to remember that the antidepressants are dissimilar enough that one should consider more than one trial with these agents.

Case Example

Mr. D, a 75-year-old gentleman, had severe lability of affect, impaired sleep, and advanced pulmonary cancer, leaving him short of breath and in need of continuous oxygen therapy. He had used diazepam for many years as a bedtime hypnotic, but the hospice staff was concerned about the CNS depressant effects of diazepam and sustained-release morphine. Rather than administer diazepam with the sustained-release morphine at 60 mg twice daily, he was started on 10 mg of doxepin hydrochloride at bedtime. This was eventually adjusted upward to 20 mg the next week with subsequent gradual improvement in sleep, stabilization of his mood, loss of affective lability, and better management of his chest wall pain.

Antipsychotic medications, still commonly referred to as neuroleptics or major tranquilizers, block the postsynaptic dopamine receptors and prevent the transmission of neuronal information. The consequence of the use of these agents is the functional disconnection of the limbic system (the modern-day equivalent of a noninva-

sive frontal lobotomy), with the patient relatively less concerned about the pain problem. This effect often permits the rapid tapering of high-dose opioid analgesic medication, especially intravenous, when a patient is trying to leave the hospital to return to the home setting. With antipsychotic medications, it is possible to significantly decrease the opioid dosage and maintain the patient in a relaxed state. Antipsychotic agents are also powerful antiemetics and control nausea and vomiting (Hanks, 1984; Johanson, 1988). The high-potency medications droperidol and haloperidol are particularly noteworthy because they work with minimal effect on the cardiovascular system. Droperidol is available only as a parenteral agent, but haloperidol is available as oral tablets and an oral concentrate (2 mg/ml) that can be used sublingually (Johanson, 1988). The low-potency medication thioridazine can be relatively toxic for the cardiovascular system and is best avoided in the seriously ill patient. Chlorpromazine is usually more sedating than haloperidol, but it also is an excellent antiemetic. Extrapyramidal reactions do occur with the high-potency medications, but they can be easily managed with the anticholinergic agents benztropine and diphenhydramine when necessary.

Case Example

Ms. M was a 45-year-old woman with end-stage human immunodeficiency virus (HIV) infection. She was experiencing only mild pain, but she suffered from intractable nausea and vomiting that were not relieved with standard antiemetics used orally or rectally. She was given 1 mg of sublingual haloperidol every 4 hours, with good control of her symptoms, and was eventually maintained well on haldol 2 mg twice daily.

In general, the anticonvulsants are frequently effective oral medications for deafferentation (neuropathic) pain, nerve injuries, and pain characterized by burning, tingling, or paroxysms (Swerdlow, 1986). Anticonvulsants stabilize nerve cell membranes and inhibit spontaneous discharge by blocking sodium channels nonspecifically, resulting in the control of seizures centrally or neuropathic pain peripherally (Sindrup & Jensen, 2000; WHO, 1986). The most commonly used agents (carbamazepine, clonazepam, gabapentin, phenytoin, and valproic acid) have been employed in the management of lancinating or stabbing dysesthetic pain (Emanuel et al., 1999; Hardy et al., 2001; Lack, 1984; Sindrup & Jensen, 2000). Bruera, Walker, and Lawlor (1999) reported that most patients with neuropathic pain do improve on opioid analgesics. Based on a prospective open-label study in which more than two thirds of patients with neuropathic pain achieved good analgesia with opioids alone, coupled with the expected effectiveness of adjuvants rarely exceeding 30%,

they recommended opioids as the first-line treatment for these patients. They advised using the adjuvants when patients reached dose-limiting toxicity. The use of methadone, discussed earlier in this chapter, is consistent with this concept. Also, another study has shown that levorphanol is useful for neuropathic pain in a dose-dependent manner (Rowbotham et al., 2003).

Clonazepam is a potent benzodiazepine with a relatively greater anticonvulsant effect than its congeners (Hanks, 1984). Clonazepam is one of the least difficult anticonvulsants to use in the home hospice setting because it can be used without the need for blood-level monitoring. Because it does tend to accumulate and may cause a moderate degree of sedation, clonazepam is often avoided in severely ill patients. However, the long half-life of clonazepam allows for effective once-daily dosing for many patients.

Gabapentin has become the more typically utilized oral anticonvulsant for neuropathic pain management (Emanuel et al., 1999). Gabapentin is generally started in low doses (100 mg, one to three times daily) and titrated upward to clinical effect (the reduction of pain) or the manifestation of dose-limiting toxicity (sedation and ataxia). There are no specific blood levels correlating to pain relief, and patients may require 3,600 mg per day or more to obtain pain relief. As it is renally excreted, dose reduction is necessary in those with renal insufficiency. Based on various studies addressing the treatment of neuropathic pain, gabapentin is considered to be one of the medications of first choice for the treatment of painful polyneuropathy (Sindrup & Jensen, 2000). Gabapentin is also better tolerated than amitriptyline as shown in a recent study treating diabetic neuropathy (Dallocchio et al., 2000).

Carbamazepine (with the relative risk of bone marrow suppression) and valproic acid (with the relative risk of gastric upset), coupled with the need for blood level monitoring, are generally less attractive as anticonvulsants for the home hospice patient. Carbamazepine is one of the medications of first choice for the treatment of painful polyneuropathy (Sindrup & Jensen, 2000). Carbamazepine is traditionally a preferred medication for trigeminal neuralgia and for other supraclavicular pain problems (phenytoin having the historical reputation for being the anticonvulsant to treat infraclavicular pain), but carbamazepine and valproic acid have the distinct disadvantage of requiring several days of oral titration before therapeutic improvement is noted. Both blood-level monitoring and complete blood counts are recommended with the use of carbamazepine.

Lidocaine has also been used for treatment of poorly controlled neuropathic pain. Lidocaine is a sodium channel-blocking agent, a mode of action it holds in common with mexiletene and carbamazepine. Inhibition or modulation of sodium channels appears to suppress neural pain transmission. Continuous subcutaneous lidocaine infu-

sions at rates between 10 to 80 mg/hour have been reported to relieve intractable pain with few significant side effects (Ferrini, 2000). Similar to when adding NSAIDs to an opioid regime, vigilance must be maintained in watching for rapid significant pain relief, which may necessitate an opioid dose reduction. Lidocaine has also been used topically for relief of neuropathic pain. A 5% lidocaine patch was effective in a placebo-controlled, two-way, crossover clinical trial with patients with peripheral neuropathic pain syndromes (Meier et al., 2003). Lidocaine-induced side effects can occur regardless of the route of administration, and such side effects usually correlate with serum levels. Lightheadedness, tongue numbness, blood pressure changes, muscle twitching, and visual or auditory disturbances are associated with lower lidocaine concentrations. The occurrence of such symptoms usually alerts one to lower the infusion rate before more toxic levels can be achieved, which are associated with seizures, coma, and respiratory arrest. Patches, up to three at one time, are usually applied for only 12 hours per day and can cause localized rashes.

Anxiety, depression, fear, sleeplessness, and restlessness may all lower a patient's pain tolerance (Emanuel et al., 1999; Hanks, 1984). Benzodiazepines, although not thought of as analgesics, have a limited role in the management of cancer pain. Most hospice patients sleep fairly well; but as some of them near the end of their lives, they may have disturbing dreams and recurrent nightmares interfering with the restful quality of their sleep for which benzodiazepines may prove helpful. Additionally, when pain interferes with the normal sleep pattern such that little or no stage four delta-wave sleep occurs, the addition of a short-acting sedative hypnotic agent (estazolam, triazolam, or zolpidem) may be beneficial. It appears that without the deepest stage of sleep, muscles do not completely relax, and muscular pain may spontaneously develop, causing the patient widespread discomfort. By improving deep stage four sleep, this diffuse muscular ache that many patients with cancer experience, which is also a consequence of their debilitation and malnutrition, can be lessened. When patients are morbidly anxious about their condition, the addition of a benzodiazepine medication may significantly allay their anxiety. For this indication, the long half-life benzodiazepine medications are preferable to the short half-life medications, which are more likely to produce wide swings in blood levels and consequent rebound anxiety.

Psychostimulants, such as dextroamphetamine and methylphenidate, are useful for the relief of depression, diminishing excessive sedation due to opioids, potentiating the analgesic effect of opioids in patients with postoperative and cancer pain, promoting a sense of wellbeing, and lessening feelings of weakness and fatigue (Breitbart et al., 1998; Homsi et al., 2000). Doses commonly used are 5 to 10 mg once or twice daily (breakfast

and lunch), with few patients requiring more than 30 mg per day (Emanuel et al., 1999). Compared with traditional antidepressants, the psychostimulants can show beneficial effects within several days rather than several weeks. Appetite can be enhanced (if significant depression is relieved) or suppressed, which can be a problem in patients with cancer. Pemoline, a unique alternative to the amphetamine-like medications, lacks abuse potential, has mild sympathomimetic effects, has low DEA scheduling permitting telephone orders, and comes in a chewable tablet form that can be absorbed through the buccal mucosa. It is not established, however, that it potentiates opioids, although it counters the sedation of opioids and relieves depression (Breitbart et al., 1998). Pemoline should be used with caution in patients having underlying liver disease.

ANESTHETIC TECHNIQUES

Certain anesthetic techniques are occasionally needed for the hospice patient. Some of the more useful procedures include the celiac plexus block for abdominal pain, the stellate ganglion block for upper quarter pain, the lumbar sympathetic block for lower extremity pain, the intraspinal neurolytic block for bilateral lower body pain, and the epidural use of opioid analgesics (Cousins & Mather, 1984; Foley, 1985).

The celiac plexus block can provide abdominal analgesia for several months and is an acceptable management approach for pancreatic (Parris, 1985), hepatic, and intestinal cancer and abdominal carcinomatosis from ovarian malignancy. A significant reduction in pain after this block is reported by 60 to 90% of patients (Foley, 1985; Verrill, 1989). If survival extends beyond several months, the block can be repeated, although frequently with a less successful outcome.

The stellate ganglion block is useful for sympathetically mediated pain involving the scalp, face, neck, arm, and upper chest (Campbell, 1989). This technique is frequently used in the management of upper quarter pain related to brachial plexus involvement by lung cancer or highly invasive breast cancer. Often, a single block is useful, but commonly, a series of these blocks is performed to modify the discomfort. When effective, the results of this block can be quite impressive and startling.

Intraspinal neurolysis is a highly destructive technique used for intractable pain when lower-body motor function, along with bowel and bladder control, is lost, usually due to a spinal cord tumor or invasion of the spine by metastatic lesions. It involves the deliberate chemical coagulation of the remaining cord structures by placing alcohol or phenol in the subdural space (Ferrer-Brechner, 1989). The end result is absolute anesthesia below the level of the completed cord destruction.

CASE EXAMPLE

Mr. A, a 65-year-old gentleman, had a widely metastatic prostate cancer that had invaded his lumbar spine anteriorly and left him paralyzed below the level of the lesion, without bowel or bladder control, but in constant excruciating pain in his lower body. Despite adequate trials of NSAID medication, low- and high-potency opioid analgesics, and transcutaneous electrical nerve stimulation, nothing seemed to relieve his suffering. After consultation with an anesthesiologist, it was decided to complete his cord lesion with intraspinal alcohol. This was done with the patient's informed consent and quickly produced complete resolution of his lower body pain. He still required some anti-inflammatory and opioid analgesic medication for his upper body pain, but was much improved and relatively comfortable after the spinal neurolysis.

Epidural and spinal administration of opioid analgesics is quite effective when the pain is fairly localized, especially if it is entirely below the level of the nipples. Long-term use of intraspinal opioids can be recommended for patients with cancer with regionalized pain below T1 failing to achieve pain control after adequate trials of several different systemic opioids (APS, 1999). By placing the opioid analgesic into the epidural space or intraspinally, the patient experiences relatively little cognitive impairment, and while the pain is significantly relieved, normal sensation is preserved. Once the catheter is in place, the opioid (usually fentanyl, hydromorphone, or morphine) is administered by continuous infusion or by bolus injections. The availability of small, lightweight, battery-powered portable infusion pumps allows the hospice nursing staff to provide a 24- to 48-hour supply of medication to the patient without the risk of catheter infection due to poor injection technique by the nonprofessional caregiver. Contraindications (absolute and relative) for epidural and spinal opioids with or without anesthetic agents include bleeding diathesis, septicemia, local cutaneous infection at the site of catheter insertion, known immune suppression, insulin-dependent diabetes, and lack of appropriate support for the ongoing management of the catheter (Swarm & Cousins, 1998).

SPECIAL CONSIDERATIONS FOR PARENTERAL THERAPIES

Parenteral opioid infusions are used much more frequently than anesthetic procedures, but less frequently than oral medications. They can be extremely beneficial for those patients who have patent intravenous access, swallowing difficulties that prevent the use of oral medications, the need for large dosages of medication, and the lack of other routes of administration of opioids. The common technique for the administration of parenteral opioids is via a portable infusion pump delivering high-potency opioid

analgesics through a small needle inserted into the subcutaneous tissue.

Ms. T was a 60-year-old woman with advanced hepatic cancer with pelvic metastases. She had delayed chemotherapy to allow for a long-hoped-for trip to Europe. When she first presented to the hospice program, she was experiencing severe bilateral hip pain with radiation into her thighs. Bothersome muscle spasms complicated her pain problem. She was a suspicious, guarded woman who did not have much faith in her physicians. She did not want to take any medication and desperately wanted to avoid being hospitalized. She was initially treated for her pain with intravenous morphine titrated eventually to 12 mg/hour, and was successfully converted to oral morphine in sustained-release form at 400 mg every 12 hours. Once she went home, she began to need more morphine and was quickly using 150 to 180 mg of immediate-release morphine every day in addition to the sustained-release morphine. The hospice staff observed that she used more morphine when her family members were present. Due to the wide fluctuations in her comfort level, and her increasing belief that the oral medications would never entirely control her discomfort, she was started on a subcutaneous hydromorphone infusion at 2 mg/hour, with satisfactory pain control within 1 day.

For cancer pain that becomes "out of control," Berger et al. (2000) have described a technique using intravenous ketamine (2 mg/ml), fentanyl (5 mg/ml), and midazolam (0.1 mg/ml) to control pain after traditional analgesics were unsuccessful. They felt that ketamine, an NMDA receptor antagonist, and midazolam, a benzodiazepine useful for myoclonus, nausea, and cognitive disturbances associated with opioid therapy, would enhance the overall analgesic effect of fentanyl. The use of several medications to treat intractable pain and suffering or to relieve terminal restlessness is often referred to as "total sedation" or "palliative sedation." Most often a parenteral benzodiazepine or barbiturate is employed, although antipsychotic and anesthetic agents can also be used (Rousseau, 2002). It is common to continue an opioid because many patients are continuing to experience pain. Efforts have been made to establish guidelines to help hospice teams and families as they approach these difficult clinical and ethical decisions (Braun et al., 2003).

NONPHARMACOLOGIC APPROACHES

Pain is also managed by a number of nonpharmacologic methods, including cognitive therapy, hypnosis, relaxation and imagery, distraction, reframing, patient education, peer support groups, transcutaneous electrical nerve stimulation (TENS), radiation therapy, surgery, and physical,

occupational, massage, music, art, and aroma therapy services (AHCPR, 1994; Emanuel et al., 1999). For prominent muscle spasm, predictably painful procedures, depression, and anxiety, the cognitive techniques are useful (Cleeland, 1987). Hypnosis can augment pain control but rarely relieves the pain completely. Providing orthotics or prosthetics, assistive devices, range-of-motion exercises, and bedside stretching can keep the remaining activities of daily living accessible for the patient. Radiation therapy and TENS are often effective management for bone metastases and pathologic fractures (Bosch, 1984; Howard-Ruben et al., 1987). TENS requires the participation of the patient. While a meta-analysis of studies of TENS therapy in postoperative patients found that both TENS and sham TENS significantly reduced pain intensity, suggesting that part of the efficacy of TENS could be attributed to placebo effect, patients with mild pain may benefit from a trial of TENS (AHCPR, 1994).

Surgical interventions in hospice patients are infrequent but can be quite appropriate to relieve bowel obstruction or to remove a gangrenous leg. Also, in patients with certain gastrointestinal tract cancers, one can consider biliary, esophageal, and intracolonic stenting.

RADIOTHERAPY

Radiation therapy can be a very effective form of treatment for local metastatic bone pain, spinal cord and cauda equina compression, brain metastases, mediastinal compression, superior vena cava obstruction, lung collapse due to bronchial obstruction, urinary tract obstruction, and limb edema (Hoskin, 1998). The strategy for palliative radiation therapy differs from the techniques used for active cancer treatment. Protracted regimens of more than 10 treatments may be more appropriate for patients with life expectancy longer than 6 months to reduce potential late radiation effects or acute effects such as nausea if critical structures such as the stomach have to be included in the radiation field. However, for patients with a more limited life expectancy, radiation can be administered in fewer fractions (Anderson & Coia, 2000; Lawton & Maher, 1991; Maher et al., 1992). In the hospice setting, a single high dose of radiation is generally as effective as multiple smaller doses for the control of pain from bone metastases (Jeremic, 2001). Serious late radiation damage (unlikely when life expectancy is short) is related to both high total doses and the delivery of radiation in large fractions over a relatively short period (Hoskin, 1998). Most retrospective and prospective studies report that 75% or more of patients obtain relief from pain and about half of those who achieve relief become pain free (Nielsen et al., 1991).

Radiopharmaceuticals are used therapeutically for the relief of pain in patients with cancer (AHCPR, 1994). Iodine-131 results in bone scan evidence of response in

53% of patients with bone metastases from thyroid cancer (Maxon & Smith, 1990). Strontium-89 is the most extensively evaluated as a treatment for bone pain and compares favorably with hemibody irradition in randomized trials, but it is potentially effective only in the treatment of pain due to osteoblastic bone lesions or lesions with an osteoblastic component (Silberstein, 2000). Strontium-89 is reported to provide partial pain relief in 65 to 80% of patients and complete pain relief for 10% of patients (AHCPR, 1994; Hoskin, 1998). Rhenium-186 and samarium-153 phosphonate chelates have demonstrated 65 to 80% efficacy in international trials (Maxon, et al., 1990; Turner, Claringbold, Hetherington, Sorby, & Martindale, 1989). These beta-emitting radiopharmaceuticals, requiring only a single intravenous injection, are used to relieve pain from widespread osteoblastic skeletal metastases visualized with bone scintigraphy. Approximately 50% of patients will respond to a second administration if pain recurs (AHCPR, 1994). The radiopharmaceuticals are most often used when patients fail to improve with NSAIDs, opioids, and external beam radiation.

Bisphosphonates (previously called diphosphonates) inhibit osteoclast activity and reduce bone resorption. Pamidronate and clodronate produce pain relief and reduce other skeletal morbidity (Hoskin, 1998). Placebo-controlled studies with oral clodronate in women with metastatic breast cancer demonstrated lower numbers of hypercalcemic events, vertebral fractures, rates of vertebral deformity, and combined rates of all morbid skeletal events. Zoledronic acid, a newer bisphosphonate, appears to be equally as effective as pamidronate, and it can be infused over 5 minutes rather than several hours (Berenson, 2001). Because analgesia often begins weeks after treatment is initiated, the late use of bisphosphonates in hospice patients may not produce significant pain improvement if they are being used only during a patient's final days (Hoskin, 1998).

Final Comments about Pain Control

To successfully manage the patient with terminal cancer pain, all of the underlying issues must be globally addressed. The etiology of the pain must be accurately defined to direct the appropriate therapy. The analgesics may progress from nonsteroidals to opioids and adjuvants, but with the clear understanding that the medications are titrated and used for sufficient time to adequately assess their efficacy. Realistic goals about pain and its management must be set and clear communication maintained with all of the parties involved. Education of the patient and the family regarding the use of resources and decision making for the various types of therapy are part of the process (Ferrer-Brechner, 1984). Education about the ability to control pain effectively and correction of myths about the use of opioids must be included as part of the

treatment plan (AHCPR, 1994; Emanuel et al., 1999). The emotional and spiritual needs of the patient are as important, and as aggressively managed, as the somatic needs (Emanuel et al., 1999). Psychosocial interventions should be introduced early in the course of illness so that patients can learn and practice these strategies while they have sufficient strength and energy (AHCPR, 1994).

SYMPTOM MANAGEMENT

In addition to pain, hospice patients, especially those with cancer, can be bothered by constipation, nausea and vomiting, poor appetite and weight loss, dyspnea, seizures, difficulties with oral care, hydration, skin integrity, and itching. These symptoms are bothersome, steal quality and comfort from the patient, and must be as aggressively managed as pain.

Constipation

As noted earlier, constipation is the expected consequence of opioid analgesic management and must be anticipated and preventively controlled from the moment opioids are used. Most patients can be given a high-fiber diet or a bulk laxative early on in their illness to prevent constipation. If ineffective, or if the patients are taking opioids, additional laxative strategies are needed (Emanuel et al., 1999; Portenoy, 1987). Bowel care products are available in a variety of groups, including stool softeners, which prevent excessive drying; stimulants, which increase mucosal secretion and peristalsis, causing movement of fecal material; and combination products. Osmotic wetting agents, lubricants, and prokinetic medications are also available. The goal of therapy for the prevention of constipation is to maintain bowel regularity and keep the stool texture similar to that of toothpaste. In that way, even the weakest patient remains able to expel stool with little straining or effort. Most patients respond well to a combination of a stool softener and a laxative.

Nausea and Vomiting

Nausea and resulting vomiting may initially be due to opioid analgesics, but over time may result from metastases, unrelieved constipation, meningeal irritation, metabolic abnormalities, medications, mucosal irritation, infections, or bowel obstruction (Emanuel et al., 1999; Rhodes & McDaniel, 2001). If a correctable process is the cause, it is best to manage the symptom by focusing on the pathology. When this is not possible, then the routine use of antiemetics is justified. Metoclopramide improves gastric emptying and affects the CNS vomiting center at higher doses (Ventafridda & Caraceni, 1994). The high-potency antipsychotic medications droperidol and haloperidol, oral, sublingual, or parenteral, are effective for

nausea and vomiting (Johanson, 1988). The lower-potency antipsychotic medications, such as the typical antiemetics, are generally more sedating than the high-potency agents and are more likely to produce unpleasant side effects such as dry mouth, constipation, urinary hesitancy, and hypotension. Despite this, chlorpromazine can still be quite helpful in patients with difficult-to-control vomiting. Nausea may also respond to serotonin antagonists that are able to suppress the serious chemotherapy-induced nausea associated with even Cisplatin (Johanson, 1993). Olanzapine, an atypical antipsychotic, is an antagonist at dopamine, histamine, acetylcholine, and serotonin receptors, and has been shown to be effective with intractable nausea and vomiting (Srivastava et al., 2003). Until vomiting is well controlled, most patients and their family members experience high levels of discomfort.

Loss of Appetite and Cachexia

Appetite loss, declining weight, and the underlying disease process leave most hospice patients weak, listless, and susceptible to skin breakdown. As a result of chemotherapy, radiation therapy, surgery, and the overall debilitation of chronic illness, many patients experience a reduced level of pleasure associated with eating. Some patients may even become anxious about eating due to swallowing difficulties, the risk of choking, or aspiration. The review of food preferences may be quite useful. Small, frequent portions of favorite foods are better tolerated than large, traditional meals (Lang & Patt, 1994). If chemotherapy has left the patient with little sense of taste, altering the diet to include highly seasoned or spicy foods or serving meals as colorfully as possible may help to stimulate the appetite (Kaye, 1989). Education for caregivers about loss of appetite as part of the dying process is critical because these caregivers may view the patients' loss of interest in food, and resulting cachexia, as therapeutic failure on their part (Emanuel et al., 1999). Ultimately, hospice patients should be permitted to eat whatever might give them enjoyment, not what the caregivers think is best for them to eat.

Case Example

Ms. A was a severely emaciated woman with advanced ovarian and abdominal carcinomatosis. She had undergone extensive surgical resection of her tumor, radiation therapy, and several courses of chemotherapy. She had lost most of her appreciation for taste and consequently found all food to have the taste and texture of oatmeal. It was hard for her to maintain her weight without motivation to eat. She began to experiment with different foods and found that spicy Mexican and Chinese meals were satisfying and helped her remain motivated to eat, whereas the more traditional oral nutritional supplements were refused. She enjoyed the cold and creamy quality of vanilla ice cream over any other dessert-type food.

Pharmacologic strategies for stimulating appetite include the use of alcohol, corticosteroids, megestrol, androgens, and the marijuana derivative dronabinol (Emanuel et al., 1999). Preliminary research suggests that treatment with medications may stimulate appetite with relatively low risk of serious side effects (Lang & Patt, 1994), but there is little evidence that such interventions in hospice patients can increase lean body mass or improve their performance scores.

Dyspnea

Dyspnea, an uncomfortable sensation or awareness of breathing, can be a mild or extremely distressing symptom at the end of life. It will occur in 21 to 90% of patients with cancer, and almost one fourth of hospice patients with dyspnea have no known cardiopulmonary pathology (Thomas & von Gunten, 2002). It does not always correlate with hypoxemia in that some hypoxic patients report no dyspnea and some patients with normal blood gases can be very dyspneic. Sometimes simple maneuvers such as keeping the room temperature cool or using a room fan can be very effective. If the patient is hypoxic and dyspneic, then supplemental oxygen is indicated. One would also want to consider bronchodilators and steroids if there is an underlying reversible obstructive process causing dyspnea.

One of our most effective interventions for dyspnea that persists despite our usual interventions is the use of opioids. Many physicians and patients have been reluctant to use opioids for this symptom because of the common belief that opioids suppress the respiratory drive too greatly. Use of oral morphine (0.8 mg/kg) in patients with COPD (chronic obstructive pulmonary disorder) was shown to increase exercise tolerance and decrease dyspnea with only a slight decrease in PaO_2 (from 71.9 to 65.8 mm Hg) and mild increase in $PaCO_2$ (from 38.3 to 43.5 mm Hg) (Light et al., 1989). Starting with low doses of oral morphine (5 to 10 mg q 4 hours as needed) or other short-acting opioids usually allows one to palliate patients with dyspnea without concern for respiratory suppression. If the shortness of breath is accompanied by significant anxiety, the clinician can also consider using benzodiazepines or phenothiazines.

Seizures

Seizures occur in 35 to 60% of patients with primary brain cancer and in 25 to 30% of patients with metastatic brain lesions (Krouwer et al., 2000). Seizure frequency tends to increase with the number of brain lesions. Also, seizures associated with primary brain cancers or with cancer in the temporal and frontal lobes are often more difficult to

treat. Although fairly easy to control with oral anticonvulsants and steroids, seizures occurring near the end of life are problematic because the patients often are no longer able to swallow effectively and often choose not to return to the hospital. Intravenous administration of lorazepam 2 mg and diazepam 5 mg in an outpatient setting effectively treated status epilepticus in 50 and 42%, respectively (Alldredge et al., 2001). Many patients with cancer, however, do not have easy venous access and resist returning to a clinic or hospital. An alternative to the use of crushed tablets or liquid suspensions via a feeding tube is the rectal or sublingual administration of benzodiapezines. Rectal administration of diazepam in a gel form or a solution is the optimal treatment when using the rectal route. Dosages can range from 10 to 20 mg depending on the patient's weight. The same dose of diazepam can be repeated every 15 to 20 minutes for an additional two doses when necessary (Krouwe et al., 2000). An alternative would be the rectal administration of 2 to 4 mg of lorazepam at similar intervals. Sublingual lorazepam or intranasal benzodiazepines in pediatric populations have also been described but standard dosing has not been established. Seizure prophylaxis can be accomplished with rectal dosing with valproic acid, carbamazepine, or benzodiazepines. Lorazepam provides seizure control for 3 to 4 hours (Leppik, 1983), does not significantly accumulate because it has no active metabolites, and is rapidly absorbed. As seizures are often an agonal event, giving a few intramuscular injections is another option for experienced caregivers once they understand that patients are not going to experience significant pain. Other possible seizure management alternatives include valproate sodium injection (if intravenous access is present), given at less than 20 mg per minute and over 60 minutes per dose; diazepam, 20 mg per rectum once or twice daily; midazolam, 30 to 60 mg per day by continuous infusion; and phenobarbital, 200 to 600 mg per day by continuous infusion (Twycross & Lichter, 1998).

Case Example

Ms. H was a 65-year-old woman with ovarian cancer that had metastasized to her right brain, producing a left hemiplegia and motor seizures. She was a remarkably angry woman who, while mildly dysphasic in her speech, was actually electively mute at times. Initially, 300 mg phenytoin at bedtime controlled her seizures. Later, 1 mg clonazepam was added at bedtime to control sleep and reported spasm, along with 30 mg sustained-release morphine twice daily for abdominal pain. This produced marked daytime agitation, which was felt to be due to the benzodiazepine, and it was replaced by 2 mg oral haloperidol every 2 hours as needed. She lost control of swallowing and stopped taking any oral medications, fluids, or foods in the last week of her life. This resulted in more frequent and severe motor sei-

zures that resulted in secondary generalization. Diazepam was given rectally in a 10 mg dose with good results, and she was subsequently maintained on diazepam 5 mg per rectum every 12 hours. Although she steadily deteriorated, she did not appear to experience significant pain and was able to remain seizure-free with the diazepam.

Skin Care

Skin care is vitally important for hospice patients, especially those who are bed bound. Minor and usually reversible skin disorders may become a major problem in the chronically sick patient, where healing powers are limited (Mortimer, 1993). Changes in body position, with frequent turning, proper padding with heel and ankle protectors, and a thick foam mattress cover should be used to prevent decubitus ulceration. There must always be 1 inch of foam between the lowest point of the patient and the surface of the bed (Emanuel et al., 1999). Once ulcers are established, they are difficult to treat due to the poor wound healing found in malnourished and debilitated patients. Bowel and bladder incontinence will produce skin breakdown if the patient is not kept relatively clean and dry. While powders and absorbent surfaces are helpful in keeping the patient dry, the use of urinary catheters and rectal tubes may be of assistance if soiling is constant and/or the patient is highly debilitated. The application of a "barrier" ointment can be quite effective once the skin is irritated. Metronidazole applied topically or given orally in doses of 250 to 500 mg three times per day can be helpful when skin lesions become malodorous.

Case Example

Ms. K, an 80-year-old woman with pancreatic cancer and secondary liver failure, had developed skin breakdown of her buttocks due to frequent diarrhea. Cleansing of her buttocks and perineum was associated with burning pain due to extensive irritation. She became progressively more fearful of any type of bowel activity and would allow herself to remain in a fecal- and urine-soaked bed rather than request appropriate care. To relieve her condition, and her resulting anxiety about hygiene, she was given a topical material made from equal parts of zinc oxide ointment, vitamin A and D ointment, and 1% dibucaine, to be applied to the involved area every 4 to 6 hours. Within the first few applications, immediate comfort was obtained, and significant healing occurred over the next 3 weeks.

Pruritus

Itching can be quite serious for patients with extremely dry skin and is often a complication of systemic conditions such as renal failure, cholestasis, and various cancers including lymphoma. Some of the more common chemi-

cal mediators of itching include histamine, serotonin, dopamine, prostaglandins, cytokines, and opioids (Krajnik & Zylicz, 2001). Applying topical moisturizers may be helpful for skin dryness, but for protracted itching, use of the antihistamines diphenhydramine and hydroxyzine or low-dose antidepressants may provide relief (Johanson, 1988; Kaye, 1989). One particularly useful agent for itching is the antidepressant doxepin hydrochloride, a potent antihistamine about 800 times more antihistaminic than diphenhydramine (Richelson, 1979). Serotonin-mediated pruritus is more often associated with renal and hepatic failure and can be treated with paroxetine or mirtazapine (Davis et al., 2003).

Mouth Care

Oral care is routinely performed by healthy individuals and sadly forgotten in some terminal patients. With dehydration due to decreased oral intake, coupled with mouth breathing as death approaches, it is common for the oral membranes to become dry and irritated. Cleansing the mouth with small quantities of water, giving ice chips, wiping the mouth with a lemon-flavored glycerine swab, and applying a lip balm are soothing for the dying patient (Kaye, 1989) and also help to relieve the sensation of thirst. Xerostomia can be treated by removing offending agents, frequent sips of liquids, salivary stimulants such as pilocarpine and sugarless gum or lozenges, and by use of saliva substitutes (Sweeney & Bagg, 2000). Oral mucositis can also accompany the use of chemotherapy and radiotherapy. Patients with mucositis frequently experience increased depression, anger, fatigue, and anxiety with an overall decrease in quality of life (Dodd et al., 2001). Many single and combination agents and modalities have been used to prevent and treat oral mucositis with varying degrees or success and without establishing one standard of care (Köstle et al., 2001).

CONCLUSION

Palliative and hospice care should be a choice for every person coping with the end of life. It requires a special commitment on the part of the caregiver and the support of a skilled interdisciplinary team. Hospice and palliative care work with pain and symptom management is enriched by the patients who believe in the hospice philosophy and provide the opportunity to participate in their living and in their deaths. There is no single or best way to control any particular symptom, but the coordinated efforts of the interdisciplinary team bring effective relief for physical, emotional, and spiritual discomfort. Although the team members are important for a successful outcome, the patients remind us that palliative care is not finite. It is evolving, and individualized care is absolutely necessary.

Only the patients and their families are able to judge the effectiveness of the palliative care team.

Ethics: History and Theory

Frank Chessa, PhD

INTRODUCTION

Many health care providers are familiar with the basic concepts of health care ethics — surrogate decision-making, advance directives, do not resuscitate (DNR), withdrawal of treatment, confidentiality, and informed consent have become need-to-know terms in the practice of medicine and nursing. Likewise, I expect many health care providers are familiar with the basic principles of health care ethics, including nonmaleficence, beneficence, respect for autonomy, veracity, and justice. What is perhaps more rare among practitioners is an awareness of how health care ethics is connected to the history of ethics and ethical theories more generally. Yet knowledge of the ethical traditions that have influenced health care ethics may help practitioners in a number of ways: (1) it may help practitioners extend well-known principles to novel cases; (2) it may help practitioners articulate why they have reached a conclusion about the ethics of a particular case; and (3) it may deepen practitioners' commitment to ethical values of their profession. This chapter seeks to bridge the gap between health care ethics and the traditions from which these ethics emerge.

This chapter also briefly surveys some ethical issues that are especially relevant to palliative care. Other chapters in this volume treat these issues in more detail. Here, the focus is on showing how the history of ethics is relevant to the ethical issues that arise with particular acuity in palliative care. It is not under the purview of this chapter to expand the discussion beyond Western ethical traditions, although non-Western traditions are increasingly important as more persons from various world cultures are served by, and practice within, health care institutions in the United States and Britain.

There is also a good deal in the history of Western ethics that could not be covered in this chapter. In part this is because many great minds have written about ethics — including just a paragraph on each would have made this chapter too long. I have instead chosen to focus on six philosophers: Plato, Aristotle, Augustine, Thomas Aquinas, Immanuel Kant, and John Stuart Mill. Of these six, Aristotle, Kant, and Mill are given the most attention because their theories are the most relevant to health care ethics. I should also note that it is not possible to consider every facet of the theories of these philosophers. Indeed, not only have these philosophers each written thousands of pages, but each is the subject of countless books and articles. In my inevitable narrowing of this material, I have selected topics that either have had a direct influence on health care ethics or raise issues that may be of interest to health care practitioners. My hope is that this will serve to make the current chapter different from other surveys of the history of ethics in a way that will prove useful to the health care providers likely to read this volume.

The first section of this chapter, by far the largest, is a chronological survey of the views of the ethical theorists. For each philosopher, I have provided biographical information, a sketch of his theory, prominent criticisms of the theory, and a discussion of the ways in which the philosopher's ideas emerge in current debates in health care ethics. The second section discusses how the historical theories relate to various methodologies in contemporary health care ethics (e.g., the ethics of care, casuistry). The second section also draws some parallels between three ethical issues in palliative care and the history of ethics.

ETHICAL TRADITIONS

SOCRATES AND PLATO

It is appropriate to begin a discussion about the history of Western ethics with Socrates and Plato. Socrates was born in Athens around 469 B.C., and famously, he died in 399 B.C. by drinking hemlock under order of the Athenian court. Plato (428–347 B.C.) immortalized his teacher in a series of dialogues that portray Socrates as a martyr for his ethical beliefs. Among Plato's 26 surviving dialogues are some of the first examples of extended ethical reasoning in the Western tradition. Plato's dialogues explore a range of moral (and nonmoral) issues, from the proper way to be religious (*Euthyphro*), to suicide (*Phaedo*), to civil disobedience (*Crito*), to political organization (*Republic*), to love (*Symposium*).

A good example of a Platonic dialogue that focuses on a moral issue is *Crito*. In *Crito*, Socrates faces the question of whether to accept death as punishment for corrupting the youth of Athens or whether to escape into exile. Escape was probably the outcome expected by Socrates's accusers, as this was a common practice and Socrates had the means to accomplish it. Socrates argues (to his friend Crito, who wishes him to escape) that although he is innocent of wrongdoing, and although the state is acting unjustly in prohibiting him from teaching philosophy, he nonetheless owes Athens a debt for raising and protecting him, and thus he should not escape (Hamilton & Cairns, 1961, 51d).* To escape would be to weaken the state, while all of his prior activities were aimed at strengthening Athens. Socrates does not escape and soon after this dialogue takes place, he is executed, with all of his friends present and weeping openly for the loss of their great friend and philosopher (*Phaedo*, 115b–118a). Plato's *Crito* presages modern views about civil disobedience: civilly disobedient actions are morally permissible if their intention is to reform unjust laws, if the actions are performed openly, and if the actors are willing to accept punishment. What emerges in *Crito* is the idea that the aim of civil disobedience is to reform a state, not to overturn it, and that those who are civilly disobedient are among the heroes of society because they are willing to sacrifice their well-being for the good of the state. The Reverend Martin Luther King Jr., certainly fits this model.

Plato's moral reasoning sometimes relies on the conviction that there is an afterlife. In particular, Plato is explicit that how a person lives on Earth will influence his or her afterlife, so he posits "a much better future [after death] for the good than for the wicked" (*Phaedo* 63c). Plato is often interpreted as dividing the world into the realm of appearance (the world as we experience it embodied on Earth) and the realm of reality (the world as it really

is, which is accessible to us, if at all, only after we die). However, even while Plato's thought has these religious dimensions, his conclusions about particular issues rely on an astute reading of human nature as much as on theological reasoning. In *Euthyphro*, Socrates questions Euthyphro about his attempt to prosecute his father for murder. The primary moral failing of Euthyphro is not that he is attempting to prosecute his father for murder. Rather, this potentially immoral action is a symptom of a character flaw, namely, that while Euthyphro is good-hearted, he has a wildly over-inflated confidence about his knowledge of theology. Plato thus depicts the type of moral failing likely to arise from a lack of humility in otherwise praiseworthy persons.

One of the lasting legacies of Plato's thought is the idea that living ethically should be the primary goal of human life. We will also find this idea in the writings of Plato's greatest student, Aristotle, and it is to his thought that we will now turn.

ARISTOTLE (384–322 B.C.)

Arguably, until relatively recently, the focus of modern ethics has been on the evaluation of actions. In contrast, Aristotle focused on the moral evaluation of a person's character, that is, on whether a person is virtuous or vicious. The focus on character evaluation is responsible for the popularity of virtue theory among contemporary ethical theorists (French, Uehling, & Wettstein, 1988; Sherman, 1989). In particular, focusing on character has three advantages. First, action-centered theories seem not to account for the emotional dimension of our moral lives (Stocker & Hegeman, 1991). Aristotle held that feeling the correct emotion and being motivated by it are important components of having a virtuous character. Second, virtue theory is at home with particularism about right action (Dancy, 1993; McNaughton, 1991). Particularism holds that rules and general principles are not much help in determining the morally correct action because real-life situations are simply too rich to be codified by general rules. Aristotle stresses correct perception of the features of a situation and wise judgment in figuring out what to do, rather than dependence on a set of rules. Finally, the focus on character has implications for how one learns to be moral. Modern advocates of Aristotle often view morality as a type of skill that is developed in the same manner as other skills (Little, 1995). Learning a skill primarily requires practice, although it may also involve emulation of experts, expert critique of one's performance, and reflection on theoretical issues. So Aristotle was the first in the Western tradition to deny that there is a book of rules that can teach one how to be moral. In other realms, this view is familiar. Many of us think that there is no book that can teach even a physically talented individual to play basketball like Michael Jordan — his

split-second judgments are too rich and varied to be codified. Why then do many of us nevertheless assume that there is a book on ethics that can teach us to be moral experts in the absence of practicing ethics in the rich context of everyday life?

Aristotle was born in 384 B.C. His father was a physician at the Macedonian court. Aristotle had a lifelong association with Philip of Macedonia and his son Alexander the Great. Aristotle studied with Plato for approximately 20 years at Plato's Academy in Athens. After Plato's death in 343, Aristotle moved to Macedonia to tutor the young Alexander before returning to Athens to found his own school, the Lyceum, in 336. After the death of Alexander the Great, Aristotle left Athens to avoid the political fallout from his association with the emperor. Aristotle died in 322 at the age of 62. Aristotle's writings were extensive, and although we have perhaps lost most of his published works, we are left with thousands of pages of carefully prepared lecture notes. His writings on ethics are contained primarily in the *Nicomachean Ethics*, on which we focus.

However, our discussion of Aristotle can begin not with ethics, but by sketching the theory of causal explanation that he outline in *Physics* (McKeon, 1941, 194b 20).* Aristotle believed that understanding how any object came to be required referring to four factors: the material cause, the efficient cause, the formal cause, and the final cause. The material cause is the raw matter that makes up an object. For example, the bronze is, in this sense, the material cause of the statue. The efficient cause is the energy that has molded the matter into a certain shape. So we say that the sculptor is also the cause of the statue. The formal cause can be understood as either the blueprint for the object before it is made, or the shape and organization of the finished object. For the statue, the blueprint may exist only in the sculptor's mind, but it nonetheless lays out the shape of the object to be created. The final cause is the purpose of the object. It is the reason for which the object is created or the action is done. So we say that the woman walks in order to improve her health and that is the final cause of her walking. For another example, consider a pitcher for holding and pouring liquid. Its material cause might be clay. The efficient cause is the potter's spinning of the wheel and movement of her hands. The formal cause, blueprint (which may only exist in the potter's mind), lays out the shape of the pitcher. The final cause of the pitcher is its purpose of holding and pouring liquid. An important aspect of this theory is that the formal cause answers to the final cause — that is, the shape of the object fits the purpose for which the object was

designed. Note also that there is interplay between separate causes. In designing an object to fulfill a purpose, we need to consider whether the material has the properties that will allow it to be fashioned into the shape needed and whether the energy is available to accomplish the change. Aristotle's theory is a good fit for explaining how human-made objects came into existence. But Aristotle did not limit the theory to artifacts. Aristotle also believed that this theory of causal explanation held true for natural objects, in particular, plants, animals, and humans.

The key to Aristotle's ethics is that humans, as do all things in nature, have a final cause or purpose. He felt that careful observation of humans, including their physical bodies, their culture, and social behaviors, would yield information about humans' purpose. Living an ethical life, Aristotle then reasoned, would be living a life that achieved this purpose to the greatest extent possible. Aristotle identified the purpose or function of humans as "an active life of the element that has a rational principle" (*NE* 1098a 1). What Aristotle meant by this enigmatic phrase is much debated, but a fair interpretation is that the purpose of human life was to use reason to think about oneself and one's place in the world and to perform actions as directed by the results of this reasoning — in short, to live an active life under the direction of reason. Aristotle felt that a virtuous person would be a person who did an excellent job performing the specialized human function. In fact, the word for virtue in Greek is *arête*, and this word can be translated equally well as excellence. An often-quoted illustration used by Aristotle to explain these concepts involves a knife: Aristotle says that the purpose of a knife is to cut, and an excellent knife is one that cuts excellently. So, too, with humans: an excellent or virtuous human is one that performs the function of humans excellently.

Aristotle believed that the result of a person performing the human function excellently is that the person will flourish. (The Greek word is *eudaimonia*, which can be translated as flourishing, happiness, well-being, or good spirits.) Aristotle's idea was that one would reap rewards from living a virtuous life. These rewards would be both internal and external. The virtuous person would be happy, that is, she would have an internal feeling of well-being. But the virtuous person would also have some of the external trappings of success — she would be respected in her trade or craft, have true friendships based on mutual admiration and respect, have a loving family, and be viewed as an upstanding member of the civic community whose counsel would be sought and trusted. These external trappings would include enough wealth to be secure and comfortable, but excessive wealth might be a sign that all is not as it should be. The virtuous person lives a well-rounded life, according to Aristotle. She enjoys good food and fine wine, but not to the detriment of her health. She enjoys poetry and drama, but does not live in a fantasy

world. She works hard at a successful career, but also has ample time for family, friends, and fun. She is concerned with and will work to enhance the well-being of others in society, but she will not impoverish herself in the process. Finally, she is emotionally and psychologically healthy, as a result of her good relationships with others and as a result of the proper cultivation of her emotions and the appropriate expression of them at the appropriate times. Balancing these various areas of one's life, or living in the mean between excess and deficiency in each of the areas, is one of the primary skills of the virtuous person.

So, as I have reconstructed Aristotle's ethical theory, there are four primary ideas: humans have a specialized function or purpose; those who perform this function excellently are virtuous; a virtuous person flourishes in her life; and finally, a flourishing life is lived in the mean between extremes. It is worth asking why, on Aristotle's account, a person should be virtuous? The answer is that one should be moral because it is in one's self-interest, very broadly construed. Virtuous persons flourish. This is not to say that one will always make decisions based on self-interested considerations. Indeed, Aristotle would say that sometimes the motivation to sacrifice a portion of one's own immediate well-being for the good of someone else is just what is required to make oneself happy. Conversely, aiming at one's own happiness in all the picky, little decisions of everyday life will have the effect of undercutting one's happiness. Nonetheless, the overarching motivation for becoming an excellent human is that benefits will rebound to oneself. As Aristotle says, the highest good is happiness (*eudaimonia*). Put differently, Aristotle was convinced that the best life for humans was the life that included moral virtue as a significant part.

This sketch of Aristotle fails to explore many of the specific topics that give his theory power and scope, for example, his account of how to deliberate about a decision, his enumeration and description of individual virtues (e.g., courage, temperance, generosity, honesty), and his discussion of the nature of friendship. However, a topic I consider in more depth is his account of how one becomes virtuous, and in this context, I also present Aristotle's definition of virtue.

Aristotle says that humans are not by nature virtuous, for if they were it would not be possible for a human to be vicious, but we know that some persons are vicious. Instead, Aristotle says that humans have the potential to become virtuous, and this potential is realized by habituation. He writes: "Neither by nature or contrary to nature do the virtues arise in us; rather we are adapted by nature to receive them, and are made perfect by habit" (*NE* 1103a 25). Habituation is a matter of practicing virtuous behavior.

> The virtues we get first by exercising them.… For the things we have to learn before we can do them, we learn by doing them, e.g., men become builders by building and lyre-players by playing the lyre; so too we become just by doing just acts, temperate by doing temperate acts, brave by doing brave acts. (*NE* 1103b 1)

The purpose of practicing to be virtuous by performing virtuous actions is to train our emotions and desires. By performing temperate actions, one both gets used to and begins to enjoy the emotions that accompany the actions. From this enjoyment, one begins to desire to be temperate. The opposite sort of habituation can occur as well: performing intemperate actions tends to create intemperate desires and thereby an intemperate character (Sherman, 1989).

Why is it that one should train oneself to enjoy being temperate, one might ask, if one can equally well train oneself to enjoy being intemperate? A useful, if somewhat fanciful, analogy helps to answer this question. Let us say that the human body functions best on a diet of vegetables, meats, and grains. Nonetheless, a child experiences pleasure on first tasting candy. The child's untutored tastes can lead him astray. In fact, the child can eat so much candy that he no longer finds unsweetened foods at all palatable. Now, in the long term, the health of the child will suffer. So, too, the child's taste will never progress beyond the unremarkable pleasure of tasting fat and sugar. This child has not learned to love the good. Aristotle would say that it takes real effort to learn to love that which one can love most fully. So, it takes effort to forgo candy in order to eat spinach, broccoli, rice, beans, etc. One will not immediately love the taste of these foods. But over time, one's palate will be sensitized to the varied and subtle flavors of these foods. The enjoyment experienced by this trained palate will far outstrip the enjoyment of the palate desensitized by fat and sugar. Further, of course, the health of the person will benefit from eating this natural diet. Aristotle would see both the potential for the enjoyment of natural foods and the health that results from natural foods to be directly related to the biological characteristics of the body — human biology is such that it gets maximum benefit from natural foods. Once one is sensitized to the tastes of natural foods, staying on the diet of natural foods is effortless. In fact, any other diet tastes bad. But, it takes effort to get to this stage, and indeed it may not be possible to get to this stage if one starts down the wrong path and incorrectly trains one's sensibilities from an early age.

We should note at this point the importance of emotion to Aristotle's ethical theory. Aristotle is clear that virtue is not an emotion, but is instead a state of character (*NE* 1105b 30). Nonetheless, a virtuous character is a stable set of dispositions to have appropriate emotions and to perform right actions. A person is not virtuous until she feels the appropriate emotions when performing the right action. Further, emotions are a guide to right action. While rational deliberation plays some role, in large part one is

moved to a certain action because one feels a certain emotion. Aristotle's emphasis on the importance of emotion is one reason that his "virtue theory" experienced a resurgence in the 1980s. Historically, all moral theorists have recognized that humans are emotional creatures, but more often than not emotions were seen as a hindrance to morally correct action. Emotions were not viewed as being under the control of reason — anger, love, jealousy, even sympathy, could move one to act in ways that would be regretted later. Aristotle admitted that emotions, in the moment of their occurring, were often beyond human control. But, by beginning early to train oneself to have the appropriate emotion relative to the situation one is experiencing, it does not matter if the emotion is "out of our control" in the moment of its occurring, for it is the appropriate emotion to have, and it will move one to perform the right action.

Thus, virtue in Aristotle's view is concerned with both emotions *and* actions. One mark of a virtuous person is that she takes appropriate pleasure in doing the right actions. And a mark of someone who fails to be virtuous is that, though she may do the right action, she may not feel the right emotions. So on the battlefield (one of Aristotle's favorite examples) where standing and fighting is appropriate, a virtuous person will courageously stand and fight and feel a kind of confident pleasure in doing so, while one kind of nonvirtuous person — what Aristotle calls a continent or strong-willed person — will stand and fight but feel terrible pain and fear as he does so. Aristotle also tells us that virtue is typically destroyed by excess and defect, and preserved by the mean. To explain this he says that:

> … the man who flies from and fears everything and does not stand his ground against anything becomes a coward, and the man who fears nothing at all but goes to meet every danger becomes rash. (*NE* 1104a21)

Extremes do not typically preserve or habituate virtue. The virtuous person is the one who rushes into battle where this is appropriate and similarly flees where this is appropriate. And the virtuous person is also the one who feels fear where appropriate and confidence where appropriate. So virtue is concerned both with passions and actions and the virtuous person is the one who finds the mean, or appropriate point, for both, feeling the right emotion and doing the right action as they are called for in particular situations. Again, Aristotle explains:

> … both fear and confidence and appetite and anger and pity and in general pleasure and pain may be felt both too much and too little, and in both cases not well; but to feel them at the right times, with reference to the right objects, towards the right people, with the right motive, and in the right way, is what is both intermediate and best and this is characteristic of virtue. Similarly

with regard to actions also there is excess, defect and the intermediate. (*NE* 1106b17)

We now have all the components in place to understand Aristotle's definition of virtue. He says that:

> Virtue … is a state of character concerned with choice, lying in a mean, i.e. the mean relative to us, this being determined by a rational principle, and by that principle by which the man of practical wisdom would determine it. (*NE* 1106b36)

Virtue is a state of character that individuals cultivate through practicing virtuous actions and emotions. Both virtuous actions and emotions must find the mean between the extremes, and this is relative both to the specific circumstances the person is in (so, how much fear an individual should feel in battle depends on how well-prepared for battle one is, how strong one's army is, how well-suited one's army is to the terrain, etc.) and to the person herself. So if a person is attempting to cultivate the emotion anger (associated with the virtue of good temper) and she finds that she often gets too angry, she should strive to feel too little anger in this situation. That is the way in which the virtue is relative to the individual herself. And finally, the mean is determined by reason, by thinking about and assessing the practical nature of the situation. It is also determined by the moral experts, what Aristotle calls persons of practical wisdom, because moral virtue is a kind of wisdom or as we saw earlier, a kind of skill-based knowledge.

Criticisms and Evaluation

Aristotle's claim that there are purposes in nature is at odds with the scientific world view. Aristotle did not believe that living organisms were designed with a purpose in mind in any obvious sense — for example, he did not believe that organisms were created by an intelligent God. Aristotle simply thought it was the case that things in nature had purposes because, as he saw it from his extensive botanical and zoological studies, it was obvious that living things had complex and purposeful bodily structures. However, since the publication of Darwin's *Origin of Species*, there has been an alternative explanation of how such organs, for example, the human eye, came into existence. In addition, after Darwin, surviving to reproduce was recognized as the goal of living organisms — whatever worked to pass on one's genes was, from the perspective of nature, good. In Aristotle's view, an organism has a potentiality that is implicit in it and waiting to be realized. With natural selection, there is no one right way to develop, as long as one's genes are passed on. Most contemporary philosophers of biology seek to describe the world without the teleological language of "purpose" or

"goal" (or they seek to redefine these terms appealing only to concepts in the theory of evolution).

A second criticism of Aristotle is that he provides few rules that set out specific moral obligations and thus little practical advice about how to act. Instead, his most tangible advice is to act in the mean between excess and deficiency, (he does mention that committing adultery, for example, is never in the mean). Aristotle also appeals to the "man of practical wisdom" and suggests that one should act as the person of practical wisdom would act. Nevertheless, Aristotle does not provide general rules that specify our moral obligations. This can leave the novice with little guidance about how to resolve specific issues. It also tends to invest a good deal of authority in the person of practical wisdom, a "moral expert." Novices emulate moral experts as part of the process of learning to be virtuous. Moral experts, in turn, have a good deal of discretion about how to resolve ethical questions. The moral expert is supposed to be sensitized to the moral landscape such that she discerns the right action where others see only an irresolvable dispute (or worse, overconfidently insist on a vicious action) (McNaughton, 1991). Perhaps everyone has known someone he considers to be morally wise, but there may be little agreement about who such people are. Further, it seems somewhat dangerous to invest so much authority in a single person's power of discernment.

But what is a weakness to some, is a strength to others (Hursthouse, 1995). Aristotle is relevant to contemporary accounts of health care ethics because he viewed moral goodness as a skill that must be mastered rather than a set of rules that must be followed. This approach fits with the type of training received by physicians and some other health care professionals. The training of physicians in residency programs often involves mentorship by older, more experienced physicians. The training includes not only information, but also close observation and emulation of the skills involved in medicine, from communication with patients, to physician interactions with nonphysician colleagues, to skills with a scalpel. The well-respected attending physician is viewed as passing the "art of medicine" to younger colleagues. This art cannot be codified, but rather is embodied in an expert. One suggestion regarding health care ethics is to make sure that the physician (and other) leaders in an institution are not only experts in the technical side of medicine, but are also moral experts as well (Pellegrino & Thomasma, 1993). An institution with wise moral leadership would, in theory, need very few specific rules to govern the ethical conduct of its members (Beecher, 1966; Kass, 1980).

Augustine (a.d. 354–430)

Augustine is an influential figure in the consolidation of early Christian thought. Aurelious Augustinus was born to Roman parents in Roman-controlled North Africa. Augustine described himself as living a "lustful" and "wicked" life until about the age of 30. In *The Confessions*, he writes to God about his struggle with lust:

> I in my great worthlessness had begged you for chastity, saying: "Grant me chastity and continence, but not yet." For I was afraid that you would hear my prayers too soon, and too soon would heal me from the disease of lust which I wanted satisfied rather than extinguished.

Augustine had always been a searcher for religious truth and was for a time a member of the Manichean sect, which held that good and evil were eternal and equally powerful forces in the world. However, Augustine was profoundly influenced by the sermons of the Catholic Bishop Ambrose, who over time convinced Augustine of the intellectual merit of Catholicism. After being baptized a Catholic by Ambrose in 387, Augustine never strayed from his faith. Augustine is responsible for quite a number of works, of which the best known are *The City of God* and his autobiography, *Confessions*.

Augustine was one of the first to systematize answers to the problem of evil, which is essentially the question of why an all-good, all-knowing, and all-powerful God would allow suffering and evil to exist. Augustine advanced a number of answers, but a prominent one is that, in sin, humans freely turn away from eternal goods in order to seek inferior, temporary goods. Augustine argued that evil is simply the absence of good, so that, strictly speaking, evil is not a thing that can be said to exist. Humans' free choice of sin results in suffering and a diminishing of the good because sin is the pursuit of inferior goods. The four cardinal virtues for Augustine are prudence, fortitude, temperance, and justice — each of these, except perhaps justice, is explained as helping humans to desire eternal goods and suppress desire for earthly goods. Augustine says that the person who desires the correct goods has "good will," and he takes this to be the most valuable possession a person can have. Augustine's ethical theory contains many prohibitions on action. Notably, Augustine presents a carefully argued, absolute prohibition of suicide in *The City of God* (the only possible exception is martyrdom at the direct command of God). Augustine also considers every lie to be sin, but his nuanced view of deception holds that some lies are clearly worse than others. (Readers familiar with the ethics of Immanuel Kant will notice some similarities between Kant and Augustine. However, it should be noted that the thinkers understand the good will in a fundamentally different way: Augustine explained it in terms of having the proper desires, while Kant felt that the good will did not depend on desires at all.)

Thomas Aquinas (1224–1274)

A second great religious thinker was Thomas Aquinas, who lived approximately 800 years after Augustine. Aquinas was born to a wealthy family in southern Italy near Naples. Aquinas received religious training early, and at 20 years old, he joined the Dominican Order. His family was disappointed that he joined the newly formed order, so much so that they held him hostage for about a year in the hope he would renounce the Dominicans. He served the Dominican Order with distinction throughout his life, spending the majority of his time as a professor of theology at the University of Paris. Aquinas's writings are extensive: the best known is *Summa Theologica*, which he probably wrote while at the residence of Pope Clement IV between the years 1265 and 1268. An interesting coda to the life of Aquinas is that soon after his death many of his writings were condemned by Church officials: studying the works of Aquinas was only fully sanctioned by the Catholic Church under Pope Leo XIII around the year 1900.

The thought of Aquinas is sometimes presented with the formula: Aristotle + God = Aquinas. While Aquinas's rich and extensive writings cannot be reduced to this formula, the formula does point to an organizing theme in Aquinas's thought. Aristotle held that everything in nature was imbued with a purpose (the final cause, in Aristotle's terminology). Aquinas identified God as the source of these purposes. Simply put, God designed everything in the world with a purpose in mind. With Aristotle, one can learn about an object's purpose by examining the form or organization of the object. So too for Aquinas — the study of humans and nature reveals natural laws, and these natural laws provide insight into God and God's "eternal law." One learns about the creator by studying creation. Sins are actions that conflict with natural law (and therefore also eternal law). From this guiding idea, Aquinas develops a complex taxonomy of immoral actions.

Among his specific prohibitions, Aquinas says suicide is wrong because (1) it violates the natural law of self-preservation, (2) it harms one's community, and (3) the power of life and death rightly belongs to God. Like Augustine, Aquinas holds that every lie is a sin, although some lies are relatively minor infractions. In this context, Aquinas defends what is known as the Pauline principle, namely, that it is not permissible to achieve a good end (no matter how great) by an evil means (no matter how minor).

Aquinas also had a good deal to say about sex and reproduction. Aquinas holds that procreation is the natural purpose of the sex act. Thus, a sexual act that does not allow for procreation conflicts with natural law. Thus, homosexuality and masturbation are sins for Aquinas. So, too, is heterosexual sex outside of marriage because Aquinas holds that the natural order is such that human offspring should be raised by two parents (if possible). Aquinas does not pull his punches here: any sexual act in or outside of marriage that does not allow for procreation and the proper raising of children is a mortal sin. That is, it is a sin that will result in one's damnation, unless this sin is absolved by God's grace. (Being sorry or doing penance can absolve one from venial sins, but they are powerless against mortal sins.)

The doctrine of double effect was developed by Aquinas (and others), and this doctrine plays an important role in some contemporary writings on medical ethics. The doctrine of double effect is a way to determine the moral permissibility of actions that have both good and bad effects. In essence, the doctrine holds that an action that causes a bad effect is permissible if and only if the following five criteria are met:

1. Only the good effect is intended; the bad effect may be foreseen, as long as it is not intended.
2. The action cannot be intrinsically wrong (such as lying).
3. The causal chain that leads to the good effect cannot contain the bad effect; that is, the good effect cannot be the causal result of the bad effect.
4. There are no ways to achieve the good effect without causing the bad effect (or a worse one).
5. The good effects of the action outweigh the bad effects of the action.

For example, routine surgery to remove a diseased appendix meets all of the criteria: bad effects (e.g., soreness, risks associated with anesthesia) are foreseen but not intended; removing the appendix is not intrinsically wrong; the good effect is not caused by any bad effects; there is no way to prevent a burst appendix except surgery; the badness of a burst appendix outweighs the risks and costs of surgery. A second application of the doctrine of double effect involves narcotics to relieve suffering in a terminally ill patient: the intent must be to relieve pain (this is the good effect), not cause death (this is the bad effect); providing narcotics in normal doses is not intrinsically wrong (i.e., normal doses are not tantamount to providing a deadly poison); pain relief is not achieved by death; there are no other means to relieve suffering; the good of pain relief outweighs the increased risk of premature death.

Criticism and Evaluation

While a few isolated arguments from Aquinas and Augustine are persuasive in secular contexts, their theories as a whole are plausible only within a religious context. This is because each of the thinkers derives ethical commitments from his theological views about the nature of God. And, of course, there are a variety of theological perspectives even within Christianity, so one cannot assume that ethical commitments of Aquinas and Augustine fit well

with all Christian faiths. Nonetheless, ideas from the thinkers, especially Aquinas's view that one can use "natural law" to derive ethical rules, continue to be influential among many in society.

The doctrine of double effect has been discussed, defended, and criticized since Aquinas's time. Major criticisms include the following. Some have argued that it is impossible to foresee the bad outcome of one's action and not also intend the outcome when performing the action; that is, there is no such thing as a foreseen but unintended effect. A second criticism holds that the notion of an intrinsically wrong action is incoherent: if this is so, then one must give up criterion 2 (and maybe criterion 3), in which case the doctrine is nothing more than a form of consequentialism. (See the section on Mill for a discussion of consequentialism.) Finally, one might argue that judgments made about balancing good and bad effects (in criterion 5) are necessarily subjective. Indeed, some would argue that death is actually a good for the suffering patient for whom no relief is possible. The doctrine of double effect seems to assume that there is some noncontroversial way of identifying effects as good or bad. These criticisms are powerful when the doctrine of double effect is used in a secular context. However, the doctrine of double effect was never meant to be divorced from a religious context, which would include a substantive account of which types of actions are intrinsically wrong and a substantive account of human goods. Further, a secular theory that identified intrinsically wrong actions and which provided a substantive account of human goods could also use the doctrine.

IMMANUEL KANT (1724–1804)

Kant invented one of the most influential deontological theories of ethics. A deontological theory takes some actions to be morally wrong regardless of their consequences. The clearest example in Kant's writing is lying. According to Kant, it is not permissible to lie even if the lie is about a relatively unimportant matter and yet would prevent great evils from occurring. Simply put, whether a lie has good or bad effects is irrelevant to whether the lie is permissible. Kant's theory is largely secular in its grounding. Nonetheless, Kantian ethics has strong affinities with religious ethics because religious ethics also tends to identify some actions as impermissible regardless of their consequences (as our discussion of the doctrine of double effect has just illustrated). A second important aspect of Kant's ethical theory is its emphasis on autonomy. Kant suggests that persons' capacity for reason gives persons both freedom and responsibility. As beings with the capacity to reason, persons can rise above the instinctual, animal aspects of their natures to make informed choices about the proper course of action. The ability to make informed choices forms the basis of one's freedom.

However, one is not free to make these choices willy-nilly. Rather, one has the responsibility to reason correctly about morality. This means that the choices ones makes for oneself — about lying, for example — have a measure of universality, that is, all persons who reason correctly will necessarily reach the same conclusion.

Immanuel Kant was born in 1724 and he died in 1804. He lived his whole life in Konigsburg, as a professor at the University of Konigsburg. Kant lived the life of a quiet and not very productive professor until about the year 1776, when he read David Hume's *Enquiry Concerning Human Nature*. Kant said that Hume's book woke him from his "dogmatic slumber," meaning that Hume's work showed him that there were deep flaws in his own understanding of the world. It was quite an awakening. At the age of 56, Kant embarked on one of the most ambitious and most successful research programs in the history of philosophy. Kant published the *Critique of Pure Reason* in 1781, and followed this work with books on practical reason, aesthetics, religion, and ethics. Kant not only made original contributions in each area, but his works fit together to form a philosophical system unmatched for its subtlety and sophistication.

Kant begins the first section of the *Groundwork for the Metaphysics of Morals* with a bold statement about moral value:

> There is no possibility of thinking of anything at all in the world, or even out of it, which can be regarded as good without qualification, except a good will. (*GW* 393)*

Kant contrasts a good will with talents such as intelligence and wit, with virtues such as courage and perseverance, and with calm deliberation and self-control. In contrast to Aristotle, Kant argues that none of these character traits has intrinsic value because each can be put to evil uses. What then is a good will, and why is it so valuable? Kant is clear that a good will is not good because it brings about good consequences. He writes: "a good will is good not because of what it effects or accomplishes, nor because of its fitness to attain some proposed end; it is good only through its willing, i.e., it is good in itself" (*GW* 494). Indeed, Kant says that the good will "shines like a jewel" with its full value even in a person who lacks all talent and skill, and thus never succeeds in accomplishing any of his aims. Kant rules out one potential reason why a good will might be thought valuable. So, again, what is a good will and why is it valuable? Kant explicates the concept of a good will in terms of a person's motivation to perform an action. A person with a good will has the

intention to do a morally correct action *because* the action is morally correct. That is, the person does the correct action out of respect for the moral law.

Kant uses a number of cases to illustrate the point. Adapting one of his cases, consider someone who goes out of her way to help an infirm person to board a bus. We can imagine any number of motivations for this kind stranger's action: she might want to impress someone she knows is watching her; she might feel guilty for snapping at a co-worker earlier in the day; she might want the satisfaction that comes from performing a good deed; the infirm person might remind her of her father, for whom she has kind feelings; she might even simply have found herself overcome by sympathetic emotions. Kant argues that none of these potential motivations for the action has any moral worth. What gives the stranger's action moral worth, if it has moral worth, is that the action is performed out of respect for the moral law. That is, the stranger intends to perform the action because the action is the right thing to do. Kant's terminology contrasts *acting from duty* with *acting according to duty*. Because this action is morally required, one acts *according to duty* no matter one's motivation. But only the correct motivation for the action yields an action *from duty*. In part, the distinction is easily understood — everyone recognizes that sometimes the morally correct action is performed for morally neutral or morally bad reasons. What is interesting is Kant's formulation of morally correct motivation: one does what is right because it is right.

It is possible to clarify what Kant means by acting from duty by considering motivations that do not count as being morally worthy. Kant's general term for such motivations is "inclination." An inclination is either a particular desire or an emotional disposition. So, one is motivated by an inclination if one helps because one *desires* to impress a potential romantic partner. Further, one is motivated by an inclination if one helps because one *desires* to feel satisfied for performing a good deed. One also is motivated by an inclination if one's emotional dispositions simply move one to act. The sympathetic person may act not because she desires something, but simply because she has a sympathetic character. (Note the contrast to Aristotle here, who would consider the sympathetically inclined person to be acting virtuously.) Kant does not view inclinations as chosen by the agent. Rather, he thinks that one finds oneself with inclinations; the inclinations arise in humans because humans are instinctual creatures with bodily needs. In an important sense, when a person lets these inclinations cause his actions, then he is not free or autonomous. An autonomous choice for Kant is one that is made on the basis of reason, not on the basis of desires or emotions. Of course, Kant thinks it is often appropriate to act to fulfill one's desires — the point is that one is not demonstrating one's highest potential except when one's action is motivated by reason, in particular, when one does the morally right thing because reason shows him that it is the right thing. Kant says that we are "self-legislating." This means that we each use our reason to determine what is morally right, and we bind ourselves to doing what is right because we see that it is dictated by reason. It is in that sense that we are free — the moral rules that bind one are self-imposed.

The rules of reason are universal, according to Kant. Two people who are not making any mistakes in their reasoning will reach the same conclusion. Thus, moral rules are universal, even though each of us must reach these laws using our own reason. This allows Kant to talk about the specific moral obligations that everyone must follow, even though each person is responsible for imposing these rules on herself. Kant's core moral principle is called the categorical imperative. The categorical imperative has a number of different formulations, but the first and third are the most influential.

Categorical Imperative, Universal Law Formulation: Act only according to that maxim whereby you can at the same time will that it should become a universal law. (421)

Categorical Imperative, End-in-Itself Formulation: Act in such a way that you treat humanity, whether in your own person or in that of another, always at the same time as an end and never simply as a means. (429)

Intuitively, the universal law formulation gets at the idea that people have a tendency to make exceptions for themselves: that is, a person might rationalize that it is permissible for him to perform an action, even though he would have to admit that it would be bad if everyone acted in the same way. Kant cannot appeal to bad consequences and remain consistent with his remarks about the good will. So, Kant explains that in performing an action one is, in effect, agreeing to the principle that it is permissible for everyone to act in the same way, and reason will show one whether it is possible to embrace this principle. Kant's clearest example involves keeping promises. Kant reasons that one cannot both expect to reap the reward of breaking a promise and yet assert that it is fine for everyone to break promises: this is because in a world in which everyone breaks promises, there will be no trust, and if there is no trust, then there will be no rewards to reap from breaking a promise because no one will believe the promise in the first place. Whether the categorical imperative "test" for the morality of actions works for all cases has been the subject of debate since Kant's time.

The end-in-itself formulation of the categorical imperative is more straightforward. The idea is that one must respect other people as decision makers in their own right — that is to say, that one must act to respect and support other people's autonomy. One can use other people as

means to fulfill one's own needs (e.g., as happens in all commercial transactions), but this use of others as a means must be consistent with respecting others as persons. Note that Kant is also clear that one has to respect oneself as an autonomous being. That is, one has an obligation to respect and support one's own autonomy.

Kant offers the following four examples to highlight the four categories of moral obligations.

	Perfect duties	Imperfect duties
Duties to others	Do not break promises	Help others in need
Duties to self	Do not commit suicide	Cultivate your own talents

Perfect duties require a person to always refrain from performing an action. They are required at all times. Imperfect duties require performing an action. Because performing an action requires time and effort and the effort one expends performing one imperfect duty must be balanced against one's obligation to perform other imperfect duties, any particular imperfect duty is not required of a person at all times. One needs to perform an imperfect duty when the opportunity arises and such that one is not favoring one imperfect duty to the detriment of others. (This raises the interesting practical question of how to balance imperfect duties to self with imperfect duties to others.)

Criticisms and Evaluation

Kant's theory is not immune to a type of criticism that can be made against all deontological theories, namely, that some instance of an action-type identified as impermissible by the theory is considered to be permissible or even obligatory on independent grounds. Consider the following example:

> You are hiding innocent people from the soldiers of a repressive regime. Soldiers knock on your door and ask you if you are hiding anyone. You know that the soldiers will torture and kill the people if you give them up. You know that the soldiers will search your house and find the people if you say nothing. You also know that if you lie convincingly the soldiers will go away. But you feel that it is wrong to lie. What should you do?

Many people have the intuition that in this case it is permissible or even morally obligatory to lie. Some will attempt to justify the lie by saying that the soldiers do not have a right to the truth. Kant would disagree. His view is that you should tell the soldiers the truth, no matter the consequence to the innocent people. In commenting on a similar case, Kant writes: "To be truthful in all declarations is … a sacred and unconditionally commanding law of reason that admits of no expediency whatsoever." Kant's view is that there are no exceptions to the prohi-

bition on lying. Many people find this sort of inflexibility untenable, especially given that it will more than likely result in the death of innocents.

A second criticism of Kant involves his attitude to the emotions. Kant is clear that an action motivated by an emotion such as sympathy has no moral worth. Rather, only actions done from duty have moral worth. Kant would say that a person who performs a compassionate act because she sees it as her duty is acting morally, and this is true whether or not the person also feels the emotion of compassion. However, a person who is motivated by the emotion, and not by duty, has not acted morally. This has led Michael Stocker to focus on the example of a person who is motivated by duty and not emotion. Here is an adaptation of his example.

> Sheila is ill and has been hospitalized. Her co-worker Bob comes to visit her. Sheila is immediately cheered: she didn't know that Bob cared about her; she is moved by Bob's compassion and friendship. She brings this up: "Bob, how nice of you to visit; it is so caring of you to go out of your way to cheer me; I am moved to have a friend such as you." Bob, ever the honest one, sets Sheila straight: "I consider it my duty to visit a co-worker who is ill, and so here I am. I would rather be at home, you know, but duty calls."

Few would think that Bob is a morally praiseworthy person, even if he refrained from telling Sheila his real motivation for the visit. Rather, we generally expect morally good persons to have morally good emotional dispositions, and indeed we evaluate people based on their emotional dispositions. Sometimes we do admire people because of their strong sense of duty, but other times we admire people for their kind, compassionate, or generous emotions. Kant seems to be missing this aspect of morality.

This criticism has prompted contemporary defenders of Kant to investigate more closely his view on the moral value of emotions. Some of these defenders have suggested that focusing on Kant's *Groundwork for the Metaphysics of Morals,* while ignoring his other works, results in a lopsided view of Kantian ethics. Kant's *Groundwork,* it is argued, defends his conception of right action. Kant's *Doctrine of Virtue*, on the other hand, presents his conception of a virtuous person. So *The Doctrine of Virtue* may be important to balancing the overall picture of Kantian ethics.

In *The Doctrine of Virtue* Kant argues that character traits and emotional dispositions provide important support to the good will. For instance, he argues that:

> … it is a duty to sympathize actively in the fate [of others]; and to this end it is therefore a duty to cultivate the compassionate natural feelings in us, and to make use of them as so many means to sympathy based on moral principles.… For this is still one of the impulses

that nature has implanted in us to do what the representation of duty alone would not accomplish. (*DV* 457)

In this passage, Kant argues that human imperfection and weakness often prevent us from acting on duty alone. Thus, we must cultivate our natural compassion, to bring it in line with the requirements of moral duty. Kant further thought that when we perform beneficent actions from duty we would "eventually come to actually love the person [we] have helped" (*DV* 402). Dutiful beneficent acts will produce the emotion of sympathy in us, but it is a kind of sympathy that is obedient to and consequent upon moral duty.

But even given this defense of Kant, many non-Kantians remain unsatisfied with the Kantian view of emotions. In particular, some critics have argued that Kant's ethical theory, at best, values emotions merely as instruments to doing one's moral duty. Kantians cannot see the simple experience of an emotion as morally valuable in itself. Thus, a Kantian cannot hold that simply feeling sympathy for a friend in distress has moral significance, apart from the emotion's ability to support an agent's good will. So for those moral theorists convinced that emotions have moral value apart from their role in morally good action, the Kantian position on emotions remains inadequate even with these important defenses of Kant's view (Stark, in press).

Kant is relevant to contemporary health care ethics for a number of reasons. First, Kant was perhaps the first to develop a well-supported secular deontological theory. This makes it possible to claim in pluralistic settings that some actions are just wrong, no matter their good consequences, and to formulate public policy around the sorts of actions that are considered to be intrinsically wrong. Second, Kant championed autonomy. His view is one of the primary motivations for the Principle of Respect for Autonomy, which is discussed in the second section of this chapter. Finally, Kant's views do much to influence theories of informed consent. Notably, informed consent procedures are designed not just to protect patients' freedom to choose, but also to support patients in making good decisions. Kant, as we saw, connects the freedom to choose with choosing for the right reasons: a person makes a genuinely free choice if and only if a person makes a choice based on reason. This issue is also discussed in the second section.

John Stuart Mill (1806–1873)

John Stuart Mill (with Jeremy Bentham) developed consequentialism, one of the most influential modern theories of ethics. Mill's version of consequentialism is called utilitarianism, and the great virtue of this theory is that it cuts away the complex and (Mill would say arcane) trappings of earlier ethical theories, and seeks to explain

ethics in a way that is simple and direct, and that appeals to common sense. Mill's guiding insight, which was exquisitely simple, was that those actions that cause good consequences are ethically good and those that cause bad consequences are ethically bad. Despite its apparent common sense, the theory stands in stark contrast to earlier ethical theories. In part, this is because Mill defined good consequences as pleasure and the absence of pain, and other ethical theories posited loftier goals for humans' lives. But an even more direct point of contrast, especially to Kant, is that Mill denied that any action is wrong in and of itself, regardless of its consequences. This means, for example, that telling a lie is not necessarily wrong; whether a particular lie is morally right or morally wrong depends on the consequences of telling it. For Mill, many of the reasons why we might be tempted to say that an action is wrong "in-itself" are based on outdated traditions or suspect religious reasoning. In both cases, the moral rules that result will tend to favor the already well off in society at the expense of the common folks working in fields and factories. Mill argued that human suffering is bad wherever it is found, and that society ought to be arranged so that such suffering is minimized — if a traditional right (say, one granted to the nobility) stands in the way of minimizing suffering, so much the worse for this right. Lest Mill seem too much of a radical, it should be noted that he found that many (but not all) of the institutions of the British Empire did serve to promote the general well-being.

John Stuart Mill was born on May 20, 1806, in London. His father was James Mill, a prominent intellectual and reformer and a close associate of Jeremy Bentham. James Mill pushed John in his studies from an early age — it was said that John was reading Plato in the original Greek at age 7. John began publishing his own work at age 16. He became the editor of the *Westminister Review* and founder of the Utilitarian Society. In 1826, at age 20, Mill underwent a mental crisis, entering a 4-year period of depression the cause of which he took to be the lack of "cultivation of the feelings" in his early upbringing. The end of Mill's depression coincided with meeting his life's partner, Harriet Hardy Taylor, who was at the time married to someone else. Mill and Taylor remained close friends and collaborators for the next 20 years, until the death of John Taylor allowed Mill and Harriet Taylor to be married. (See the dedication of *On Liberty* for insight into Taylor's contributions to Mill's thought and writings.) Mill was elected a member of the British Parliament in 1865, although he was defeated at the next election. Mill died on May 7, 1873, in Avignon, France, apparently as the result of the exertion of a 15-mile hike he had taken 2 days previously. Throughout his life, Mill maintained his father's commitment to reforming society, particularly the sort of evils brought on common people by industrialization and urbanization. Mill was also an early defender

of equality for women, publishing *The Subjugation of Women* in 1869 — which was most likely co-written with Harriet Taylor. (An interesting anecdote in this regard was that Mill was arrested and briefly jailed for obscenity in 1823, the result of distributing birth control literature in a working-class neighborhood of London.) Mill published widely in areas beyond moral philosophy, including logic (*A System of Logic*, 1843), political theory (*On Liberty,* 1859), and economics (*Principles of Political Economy*, 1848). Those interested in Mill's views on religion, God, and immortality will find his *Three Essays on Religion* (1874) to be helpful. Mill's *Autobiography* (1873) also makes fascinating reading.

Mill's moral theory is outlined in his short book *Utilitarianism* (1863). The primary idea behind the theory is that the morality of an action ought to be measured solely by the consequences, good and bad, that are produced by the action. We are obligated to perform the action that produces the most good, that is, the action that has the consequences with the highest net value. To complete the theory, Mill specifies what counts as good and bad consequences. Mill argues that the value of an action is measured by the pleasure and pain that it produces in humans. This leads to Mill's central principle, the Greatest Happiness Principle (GHP): "Actions are right in proportion as they tend to promote happiness; wrong as they produce the reverse of happiness." Mill leaves no doubt as to what he means by happiness: "By happiness is intended pleasure and the absence of pain; by unhappiness, pain and the privation of pleasure" (Mill, 1966, p. 157).

Three possible misinterpretations should be headed off at the outset. First, Mill is not an egoist. That is, he is not claiming that an action is morally right for me to perform if it produces the best consequences *for me*. Rather, he is claiming that an action is morally right for me to perform if it produces the best consequences for everyone. I am allowed to consider my own well-being in calculating which action is morally right, but my well-being counts no more than the well-being of anyone else who would be affected by the action. Indeed, because my action may affect the well-being of persons yet to be born, I should also consider their well-being in my calculations. Second, Mill is concerned with both short- and long-term consequences. Thus, the GHP does not require that I perform actions with immediately pleasurable consequences, if later consequences will cause enough pain to outweigh immediate pleasures. Finally, Mill seems only concerned with the pleasure and pain felt by humans. However, Jeremy Bentham, in developing an earlier version of utilitarianism, argued that the pleasure and pain of animals ought to be considered in the calculations. (Bentham's point is echoed by contemporary animal rights activists, notably Peter Singer [1990], who argues that if pain is bad in humans, then it is bad in animals too.)

In refining his basic theory, Mill anticipates and answers several objections. An initial objection is that utilitarianism does not encourage what is truly valuable in human nature. So, his imagined critic might point out: "Is it not beneath the dignity of humans to chase after pleasure? We think that gluttons, drunkards, and those preoccupied with sex are morally depraved — we certainly do not hold them up as models of right action" (Mill, 1966, p. 160). One component of Mill's answer is merely to note that some of these lifestyles will lead to painful consequences in the long term. But this answer leaves the basic thrust of the objection intact: Isn't it beneath the dignity of humans to chase after pleasure? Mill answers with a distinction between higher and lower pleasures. Lower pleasures are things such as sex, drink, food, and laziness. Higher pleasures include reading literature, writing, viewing art, listening to music, contemplating philosophy, etc. Even performing moral actions can be a higher pleasure for certain individuals. A strict reading of the GHP implies that the only moral reason to prefer higher pleasures to lower pleasures is that higher pleasures are more pleasurable. Mill embraces this statement, claiming that the higher pleasures of the mind are indeed more pleasurable than the lower pleasures. As evidence for this, he claims that people who have been lucky enough to have experienced both sorts of pleasures almost invariably choose higher pleasures as the more desirable. So Mill says famously: "It is better to be a human being dissatisfied than a pig satisfied; better to be Socrates dissatisfied than a fool satisfied" (Mill, 1966, p. 161). Mill's claim has fueled much debate about human nature: Is it true that people of sufficient means gravitate toward intellectual pleasure, and even if true, does this imply anything about the lesser value of lower pleasures — is reading Shakespeare really better than watching the World Wrestling Federation? At any rate, if we accept Mill's argument, then following the GHP will not require the pursuit of "swinely" pleasures, but rather the pursuit of the higher intellectual pleasures. In this sense, the GHP will promote what is dignified in human nature.

A second objection that Mill considered involves the time and effort that following the GHP would require. Mill seems to suggest that at any particular time a person should consider all of the alternative actions that are available, evaluate the short- and long-term consequences of these actions, and finally choose the action that has the highest net value. Even if we artificially limit the alternative actions available to three options, calculating the long-term consequences of these actions is a formidable task. Of course, there will be a good deal of uncertainty about what the likely consequences of the actions will be, but there will also be a good deal of information to sort through to attempt to trace out all the consequences of the three options. Utilitarianism, then, threatens to paralyze action in an endless fit of calculation. Mill offers a number

of answers. He points out, first, that following the GHP does not require intricate calculations. Rather, most decisions about which actions will produce the best consequences involve only common sense. Second, echoing a theme from Aristotle, Mill argues that training the appropriate dispositions (such as the disposition to answer honestly when asked a question) is an important aspect of his theory. Once one has decided that being honest usually promotes the best consequences, then one trains oneself to be spontaneously honest (that is, without calculating consequences every time one is asked a question). Mill points out that most ethical theories could be interpreted in such a way that they paralyze action by requiring too much reflection — so he points out that Christians are not required to reread the Bible every time they face a decision (Mill, 1966, p. 178). Finally, Mill suggests that our actions will have most of their consequences close to home. Theoretically, a decision I make today might have consequences for people in future generations and might have consequences for people I am unaware of on the other side of the world. But, generally, my decisions will have the most effect on myself, my family, my friends, and my colleagues. Also, generally, it will be easier to trace out the effects of my actions for this smaller group of people. Some of these decisions may require the careful balancing of potential good and bad consequences for this group of people, but the decisions do not require that the agent devote an extraordinary amount of time and effort to calculating how the action will affect persons in distant times and places.

Before turning to modern criticisms of Mill's *Utilitarianism*, it is important to introduce Mill's ideas from *On Liberty* because these, too, have had a huge impact on political philosophy in the United States. Mill was concerned not only that a monarch would have too much power, but also that in the "democratic republic" of America the danger exists of a tyranny of the majority (to use de Tocqueville's term). In order to guard against this, Mill proposed his harm principle: "That the only purpose for which power can be rightfully exercised over any member of a civilized community, against his will, is to prevent harm to others." Mill immediately clarifies the harm principle with an injunction against paternalism: A mature and competent person "cannot rightfully be compelled to do or forbear [any action] because it will be better for him to do so, because it will make him happier, because, in the opinions of others, to do so would be wise, or even right." Mill defends these principles based on the recognition that institutions within society can be quite powerful, and that the only way to guard against inappropriate paternalism is to completely rule out all paternalism (although there is debate on this interpretation). Mill continues in *On Liberty* to further specify the types of liberties that are important to protect. There are three main categories: (1) "the inward domain of consciousness," which includes the "absolute" freedom to think, feel, and formulate opinions; (2) "liberty of tastes and pursuits," which is freedom in choice of personal lifestyles and practices as long as these do not harm anyone else; and (3) freedom of association "for any purpose not involving harm to others." This "liberal argument" has been influential across the political spectrum in the United States. It also forms the core of many well-known Supreme Court decisions, including *Griswold v. Connecticut* (1965, birth control), *Roe v. Wade* (1973, abortion), and the dissent in *Bowers v. Hardwick* (1986, homosexuality).

Criticisms and Evaluations

Despite its commonsensical nature, utilitarianism is open to a wide variety of criticism. First and most prominently, utilitarianism does not give a special status to categories of moral value that many people take to be of central moral importance. For example, utilitarianism does not seem to grant a special status to promises, to ownership rights, to obligations arising from close relationships to family or friends, or to obligations relating to justice. For each and every category, it seems possible to imagine a situation in which utilitarianism would require that the moral value in question be overridden in the name of the common good. Consider the following example relating to justice:

> A mob is chasing a man through town. They blame him for a murder, and they plan to brutally execute him if they capture him. The man happens to be innocent, as you know. However, you also know that if the mob does not capture and kill the man, then a riot will ensue in which many persons will be harmed and killed (some of those harmed and killed will be innocent, having nothing at all to do with the situation). It is in your power to save the innocent man from being stoned. Should you do it?

The gut reaction of many people to this case is that the innocent person should be saved regardless of the bad consequences — justice simply requires it. But utilitarianism seems to require that one allow the innocent person to be killed. Utilitarians may attempt to answer the criticism by resisting the conclusion that utilitarianism requires allowing the innocent man to be killed. So, a utilitarian might argue that while the short-term consequences suggest that the innocent man should be killed, the long-term consequences of this decision include eroding society's commitment to the rule of law, which will in turn cause an increase in suffering, and these bad long-term consequences outweigh any short-term benefits of allowing the man to be killed. While this response is plausible enough, it is possible to manipulate the details of the example to exclude the possibility that the long-term bad effect of eroding the rule of law will occur — thus, in essence, painting the utilitarian into a corner in

which she must admit that killing the innocent is justified by her theory. The utilitarian might then be forced to accept the troubling result. Because it is possible to construct equally plausible counterexamples to utilitarianism about promise-keeping, truth-telling, ownership rights, obligations to family, etc., this manner of argument represents a strong challenge to utilitarianism. How persuasive such counterexamples should be is an interesting philosophical question because the evidential authority of the counterexample ultimately relies only on the strength of one's gut reaction to the story and, one might argue, gut reactions are not to be universally trusted.

A second prominent criticism of utilitarianism is that it is too demanding. For example, utilitarianism seems to require too much personal sacrifice in order to promote the interests of other people. Consider that I have $10 in my pocket that is uncommitted as far as my budget is concerned. I consider using the money to go to the movies tonight — I certainly would get pleasure from this, and there are no relevant constraints on my time. But, I reason, this money could also be used to benefit other people — it might even save lives if contributed to Oxfam or some other worthwhile charity. Utilitarianism seems to require that I give the money to Oxfam. Now perhaps this particular sacrifice is morally obligatory, but notice that if tomorrow I again find myself with an unencumbered $10, I would again be obligated to donate the money, and so on, and so on. I would only be entitled to use the money for myself (or my family and friends) when it becomes the case that the happiness I can create close to home is greater than (or equal to) the happiness I can create by donating the money. Even if we lived in a world in which the inequities between rich and poor were much less pronounced, one might wonder whether a person is morally required always to spend his money (and his time) in a way that produces the most good, regardless of how it affects himself and his loved ones. These issues have led to a spirited debate about the level of self-sacrifice that can legitimately be required by an ethical theory. Notice that even minimalist ethical theories, such as libertarianism, require some self-sacrifice in the name of morality, since libertarians hold that one must refrain from harming others even if harming another would benefit oneself. Peter Singer (1977), inspired by utilitarianism, is at the other extreme, arguing that people in wealthy Western countries have an absolute obligation to dramatically lower their standards of living in order to benefit people in developing nations. Mill attempted to ameliorate the concern that utilitarianism demands too much personal sacrifice both by noting that one's resources are more efficiently used close to home (perhaps that was true in his day), as well as by pointing to the hedonist's paradox, which is the view that a person cannot obtain happiness by aiming directly at it, but rather truly happy people have as their goal something outside of themselves (Mill, 1966,

p. 172). So it is likely that some self-sacrifice will indeed make us happier.

A third criticism of utilitarianism is that it requires a person to sacrifice his or her integrity. This criticism has been developed by Bernard Williams. Williams asks us to consider the following case, which I paraphrase:

> George, a chemist, has been offered a job in a research facility for chemical and biological weapons. Despite his best efforts, George has been out of work for some time, and his young children have suffered greatly under the strain placed on the family. George does not feel he can take the job, however, given that he is a committed pacifist who has always been against chemical and biological weapons. The person offering George the job says that she, too, is against such weapons: in fact, she has offered George the job in part because of his beliefs; other candidates for the job will enthusiastically push the work along at a faster pace, while George will likely drag his feet. Should George take the job? (Williams, 1977, pp. 97–98)

Utilitarianism would seem to require that George take the job. The point of Williams' story is not merely that George is being required by utilitarianism to do something that most of us would agree is wrong. Rather, Williams is trying to show that utilitarianism is incompatible with having integrity. George has identified himself with pacifism — it is part of his self-image. Maybe George initially embraced pacifism for utilitarian reasons — because he felt it brought about the most good — but being a pacifist is now George's central project; it is who he is. But whether pacifism actually causes the best consequences depends not on George, but on facts in the world, and depending on how these facts change, George at any moment could be required to act contrary to his central, defining project. At any moment, he could be required to live a lie. Williams explains:

> The point is that [George] is identified with his actions as flowing from projects and attitudes which in some cases he takes seriously at the deepest level, as what his life is about.... It is absurd to demand of such a man, when the sums come in from the utility network which the projects of others have in part determined, that he should just step aside from his own project and decision and acknowledge the decision which utilitarian calculation requires. It is to alienate him in a real sense from his actions and the source of his action in his own convictions.... It is thus, in the most literal sense, an attack on his integrity. (Williams, 1977, 132)

According to Williams, the only project that a utilitarian can be fully committed to without putting his integrity at risk is the project of being a utilitarian. But, Williams argues, this project is too thin, too formalistic, to be a central commitment or life's project. To use another of

Williams' well-known examples, one should perform acts that demonstrate love for one's romantic partner out of a genuine love for one's partner, not because demonstrating love for one's partner creates, in the long run, the best consequences for all of humanity.*

One strategy utilitarians have adopted in response to all of the criticisms mentioned is to move from act utilitarianism to some type of indirect utilitarianism. Act utilitarianism says that one should evaluate which act brings about the best consequences. Indirect utilitarianism is still interested in the best consequences, but it focuses on other mechanisms for bringing them about. For example, rule utilitarianism says that an action is morally right if and only if that action is required by a *set of rules,* the adoption of which would produce the best consequences. The rule utilitarian advises that one should follow the set of rules identified, even though in isolated instances following a rule will not bring about the best consequences. Rule utilitarians think that the benefit (in good consequences) of having a stable set of rules outweighs the cost (in bad consequences) of occasionally performing non-optimal actions. Another form of indirect utilitarianism is character utilitarianism, which holds that performing an action is morally right if and only if that action promotes or is promoted by a *set of character dispositions,* the inculcation of which would produce the most good or value for the members of a society. Once again, character utilitarianism identifies the occasional non-optimal action as morally good in order to gain the benefit of allowing persons to internalize content-rich dispositions and commitments (such as George's commitment to pacifism). As a final example, rights utilitarianism holds that performing an action is morally correct if it is in accord with a scheme of *individual rights and liberties,* the adoption of which would produce the most good for society. The distinction between direct and indirect utilitarianism post-dates Mill, but passages in Mill's *Utilitarianism* have been interpreted as advocating forms of indirect utilitarianism.

A second strategy for meeting the criticisms involves modifying the definition of good consequences. Utilitarianism is the name for the view that seeks to maximize pleasurable feelings and minimize painful feelings. Consequentialism is a broader category that recognizes that there are many different accounts of what "good consequences" are. So, preference satisfaction consequentialism states that one should maximize the satisfaction of preferences (whether or not such satisfaction also maximizes pleasurable feelings). A second example is objective list consequentialism, which identifies a list of goods (such as friendship, knowledge, veracity) such that persons should seek to maximize the obtaining of goods on the list (such a view requires a scheme for trading-off between the goods, as when a gain in friendship requires a loss of veracity). At the center of Mill's utilitarianism is the claim that only consequences matter in moral evaluation. It is possible to hold firm to this central claim, and yet modify significant aspects of the theory. This means that consequentialist theories of ethics may have the resources, despite first appearances, to answer the sorts of criticisms that have been leveled at them.

Many of Mill's ideas are directly relevant to health care ethics. Although Kant is more often seen as the champion of autonomy and informed consent, Mill's arguments in *On Liberty* also provide justification for these ideals. In addition, consequentialism is the method presupposed in cost–benefit analysis, and thus is at the heart of many policy decisions. Indeed in some ways consequentialism seems more appropriate for policy decisions made at an institutional level than it does for guiding individuals in their personal decisions.

But perhaps Mill's ideas have been most influential in debates about care at the end-of-life. Mill believed that no category of action is intrinsically morally good or bad — the morality of an action depends on its consequences, not on the type of action that it is. This has important implications for end-of-life decisions. For example, in the early 1980s a not uncommon view was that withholding treatment is permissible in certain circumstances, but withdrawing treatment is never permissible (Cugliari & Miller, 1994). The idea was that withdrawing life-sustaining treatment is a category of action that is tantamount to killing. Consequentialists, on the other hand, were less concerned about the category (withholding or withdrawing) and more concerned with the consequences of doing either in a particular situation. They argued that the categories themselves have no moral relevance: only the consequences of individual actions (or omissions) have moral relevance. As we know, the utilitarian position on this issue has been adopted in current medical practice (although there are dissents; Sulmasy & Sugarman, 1994). A very similar debate occurred around withdrawing medical nutrition and hydration in the late 1980s, prompted primarily by the Nancy Cruzan case (Lynn & Childress, 1983). Some argued that providing food and water is a special category of action required by morality (Callahan, 1983). Others argued that if the best thing for someone is that she be allowed to die, then it did not matter whether this occurs because food and fluid is withdrawn or because another intervention such as a ventilator

---

* Mill considers and responds to a very similar criticism. He considers the criticism that "It is often affirmed that utilitarianism renders men cold and unsympathizing; that it chills their moral feelings towards individuals; that it makes them regard only the dry and hard consideration of the consequences of actions" (1966, p. 174). Mill argues that all moral theories sometimes require one to ignore bonds of love, and thus utilitarianism is no better or worse in this regard than other theories. Mill also draws a distinction between a standard of right action and the motivations for pursuing right action. He claims that his theory is meant to address only the former issue.

is withdrawn. Here, again, the position consistent with utilitarianism has been adopted.

The reader will have already surmised that the story is not over yet. Consequentialism tends to undermine the moral relevance of the distinction between killing and allowing to die. But this distinction is very important in current law and medical practice. In every jurisdiction in the United States, practitioners may allow a patient to die by withholding or withdrawing treatment. But in every jurisdiction in the United States, except Oregon, practitioners cannot kill their patients or assist patients in killing themselves. This means that extubating a terminally ill patient who is in great pain and has requested to be allowed to die is permissible, even if one knows that death will occur with extubation. But it is not permissible to kill a patient who is in identical circumstances except that he has no respirator to remove. Imagine that the consequences for the patients (and others) in each case are identical: the consequentialist would argue that if it is good to omit treatment in the first case, then it is also good to kill the patient in the second case (Rachels, 1975, 1986). But this consequentialist viewpoint has yet to be adopted, and it looks as if popular opinion is moving in the opposite direction (Emmanuel 2002). One note of caution, here, is that there are also consequentialist arguments against active euthanasia and physician-assisted suicide, most prominently the concern that the long-term effects of legalizing active euthanasia and physician-assisted suicide will include eroding society's respect for human life in general.

HEALTH CARE ETHICS

PRINCIPLES IN HEALTH CARE ETHICS

The most prominent way of organizing consensus on ethical issues in health care into a usable methodology is the principles method. The principles method identifies a small number of general rules, and subsumes more particular and concrete obligations under the general rules. A number of authors use principles to develop a methodology for identifying and resolving ethical conflicts that arise in clinical settings (Veatch, 1981). The best-known principles method is that of Tom Beauchamp and James Childress, *Principles of Biomedical Ethics* (2003), now in its fifth edition. Beauchamp and Childress identify four principles:

1. *Beneficence*: *One's actions ought to benefit the patient*. Health care providers perform actions in order to improve a patient's health, prevent disease, or generally enhance a patient's welfare. This is a positive duty, that is, a duty to perform actions. Under this principle, Beauchamp and Childress discuss paternalism, sui-

cide prevention, futility, risk–benefit assessments, quality of life, and other topics.

2. *Nonmaleficence: One's actions ought not to harm the patient*, inspired by *Primum non nocere* (First, do no harm) from the Hippocratic oath. This is a negative duty, that is, a duty to refrain from certain actions. Under this principle, Beauchamp and Childress discuss withholding and withdrawing life-sustaining treatments, physician-assisted suicide, double effect, surrogate decision making, and other topics.

3. *Respect for Autonomy*: *One should respect a patient's authority to make decisions about his or her health care.* Persons have a basic right to make decisions about their lives and bodies. This is both a negative and positive duty. One should refrain from actions that diminish a patient's autonomy. One should perform actions that enhance a patient's autonomy; in particular, one should provide a patient the tools and support necessary to make good decisions. Under this principle, Beauchamp and Childress discuss informed consent, competency, disclosure, coercion, and other topics.

4. *Justice*: *One must fairly balance the interests of all the parties affected by a decision.* Under this principle, Beauchamp and Childress discuss resource allocation, rationing, rights to health care, ageism, racism, sexism, and other topics.

A common misperception about Beauchamp and Childress's method is that they offer only general principles as guidelines for resolving clinical disputes. These general principles are viewed as being not very helpful in resolving concrete and particular disputes. In fact, Beauchamp and Childress present general principles, such as respect for autonomy, and then use the principles to derive more specific rules that provide concrete recommendations. For example, Beauchamp and Childress present a detailed set of guidelines regarding procedures for obtaining informed consent under the category of Respect for Autonomy.

A close look at the principles reveals that they are grounded in some of the ethical theories that we have discussed. Respect for autonomy has a decidedly Kantian flavor, particularly because Beauchamp and Childress understand respect for autonomy as requiring both negative and positive duties, which correspond roughly to what Kant called perfect and imperfect duties. For Kant, autonomy did not mean the mere freedom to do as one wishes, but rather the capacity to use one's reason to make good decisions. This can be seen in Kant's explanation of both perfect and imperfect duties. Kant held that we have a perfect duty to refrain from certain actions because these actions interfere with the exercise of a person's autonomy. For example, lying to an individual robs her of the oppor-

tunity to make the best decision possible by keeping relevant information from her. Kant also held that we have an imperfect duty to help individuals make good decisions. Thus, Kant explains that the reason we must help someone in need is not only to make the person happier, but also to help support the ability of the individual to make autonomous decisions (O'Neill, 1977). Likewise, for Beauchamp and Childress the purpose of the procedures for obtaining informed consent are not meant merely to protect the freedom of the patient, but also to help the patient make the decision that is best for him or her.

Beneficence is grounded in utilitarian ethics. The idea is simply that health care providers should have the best interest of the patient at heart. Indeed, this may be one of the primary reasons that people go into health care ethics, the desire to help others. Beneficence has been associated with paternalism, the view that one should do what is good for the patient regardless of whether the patient is aware of what is being done and regardless of whether the patient desires what is being done. While Mill is himself decidedly antipaternalistic, utilitarianism, theoretically at least, could justify overriding rules meant to protect patient self-determination in the name the patient's best interest. While this may make beneficence seem like a sinister principle, one should also recognize that the desire to do good for others has motivated many noble actions.

The most important criticism of Beauchamp and Childress's methodology involves the balancing of principles in cases of conflict between principles. Beauchamp and Childress say that their principles are *prima facie* binding (2003, pp. 19–24). This means that following each principle is a moral requirement unless two or more principles are in conflict. Of course, in almost all difficult cases there are at least two principles that conflict with each other — that is primarily what makes a difficult ethical decision difficult. When two principles conflict with each other, Beauchamp and Childress say that one must balance the principles. This means, in effect, that one must decide which principle is the most important in this case and resolve the dispute in favor of this principle. Unlike some authors who adopt a principles approach (e.g., Veatch, 1981), Beauchamp and Childress do not set up the principles in a hierarchy such that one principle always "trumps" another principle. Rather, any of the four principles could be the most important principle in any particular case — it is up to clinicians to use their judgment to make a decision about which principle "wins" in the case.

In their treatment of many issues, Beauchamp and Childress try to do this balancing in advance. That is, they consider potential conflicts between principles, raise arguments on both sides, and then specify which principle ought to be considered most important in that case. To take a simple example, if a person shows up at an emergency room in need of medical attention, but is not competent to express a preference about receiving treatment and no other information about the person's desires are available, then the ER staff is authorized to provide medical treatment even if the treatment carries some risks with it. In this case, the principle of beneficence (to act in the patient's best interest) is more important than the principle of respecting autonomy (to not treat a patient unless she consents). A second example involves telling a patient the truth about his cancer diagnosis. A clinician might feel that telling the patient the truth will increase his depression and perhaps accelerate the disease process. Beauchamp and Childress suggest that the patient needs to know the truth to freely choose a treatment and to plan for the next period of his life, and this is more important than the likely worsening of depression. Respect for autonomy is more important in this situation than beneficence (and perhaps also nonmaleficence). Just because a principle is deemed of secondary importance, however, does not mean that the principle lacks all importance and that steps cannot be taken to ameliorate any problems arising from the partial disregard of that principle. In the last example, the practitioner should be careful to provide the diagnosis in as gentle and reassuring a manner as possible, as well as being vigilant to treat the depression as medically indicated.

In many situations of conflict, however, it is impossible to do the balancing of principles in advance. This has led to the criticism, made primarily by K. D. Clouser and Bernard Gert, that Beauchamp and Childress do not provide any real help in resolving situations of conflict (Clouser & Gert, 1990; Clouser, Gert, & Culver, 1997). In essence, the criticism is that all that Beauchamp and Childress have done is provide some very general labels for moral values that everyone accepts. In difficult cases these labels do little good. Rather, in difficult cases it is up to the clinician to decide which values are most important, and it is in coming to this decision that all of the substantive ethical reasoning is performed. Thus, so the criticism alleges, the Beauchamp and Childress method for identifying the correct action in difficult cases fails to achieve its goal, for in these cases it offers no answer at all.

Beauchamp and Childress defend themselves not by backing away from the *prima facie* nature of their principles, but by offering criteria to make balancing less "intuitive and open-ended":

1. Better reasons must be given in favor of the overriding principle.
2. The moral objective for infringing a principle must have a realistic prospect of achievement.
3. The infringement of a principle must be the least possible commensurate with achieving the primary goal.
4. The negative effects of the infringement should be minimized.
5. The decision must be made in an impartial manner. (Beauchamp & Childress, 2003, pp. 19–20)

Whether these steps are enough to answer the criticism raised by Clouser and Gert, their criticisms have highlighted an alternative set of methodologies for resolving ethical disputes in clinical settings.*

OTHER METHODOLOGIES IN HEALTH CARE ETHICS

The alternatives to principles that I discuss are virtue theory, casuistry, and the ethics of care. Interestingly, these approaches to clinical decision making do not identify moral duties that are uncontroversial in their application and thus are less open to interpretation than is Beauchamp and Childress's method of balancing. Rather, these alternatives embrace discretion and very open-ended methodologies in ethical decision making. Their common theme is that if discretion cannot be eliminated from ethical decisions, then methods for decision making ought to admit to this, rather than offering principles that promise but do not deliver definite answers. I should be clear, however, that these alternatives are not thereby accepting ethical relativism — the view that a person's belief that an action is morally correct is sufficient for the action to be morally correct. Rather, the alternative theories hold that morality is objective, that is, there is a correct answer to a moral question that arises in a particular situation. The alternatives simply hold that principles are not the best way to identify this answer; rather, individuals should trust in other means to arrive at the objectively correct answer.

Virtue Theory

In Aristotle's ethics we have already examined some of the central themes of contemporary virtue theory. Virtue theorists emphasize the importance of moral experts to discern the morally relevant features of a situation. Further, such experts use judgment and skill to respond to the moral problem, rather than reaching decisions based on rigid and overly simple sets of rules. The best-known advocates of virtue theory in health care ethics are Pellegrino and Thomasma (1988, 1993). Using a decidedly Aristotlean methodology, Pellegrino and Thomasma argue that medicine is a distinct human activity that has its own ends, goals, and purposes. From the purposes of medicine, Pellegrino and Thomasma derive the virtues required of those who would practice medicine: fidelity to trust, compassion, *phronesis* (practical wisdom), justice, fortitude, temperance, integrity, and self-effacement. The physician who embodies these character traits to a high degree is an exemplary physician, and these traits will guide him or her in her moral decisions. Again borrowing a page from Aristotle, Pellegrino and Thomasma downplay the importance of formal education in ethics, citing instead the importance of developing a virtuous character in the actual practice of medicine as a result of working "in the

---

* For an overview of the debate, see Davis (1995).

trenches" with senior members of the profession who are role models for virtue. Pellegrino recently appealed to some of these themes in an editorial on Iraqi physicians' complicity in torture. Criticizing the claim that education in ethics would have helped Iraqi physicians resist complicity, Pellegrino writes:

> This tendency to see education as a panacea is a common misconception. Rarely do courses in ethics make one virtuous. Nor does extensive familiarity with the intricacies of moral discourse guarantee moral wisdom.… More than education is needed. Character formation is, in the end, the surest way to inculcate the virtues. This cannot occur unless the culture of the profession is itself ethically rigorous. Even the most virtuous physicians need a supportive culture to remain virtuous (2004, pp. 1505–1506).

While virtue theory as developed by Pellegrino and Thomasma may rely on the judgment of moral experts, virtue theory in their interpretation does not deny that there are objective moral truths by which practitioners must abide. In fact, in their emphasis on beneficence at the expense of respect for autonomy, their theory tends to underwrite a fairly conservative position on substantive moral issues such as active euthanasia and physician-assisted suicide. Simply put, Pellegrino and Thomasma argue that these actions are contrary to the ends, goals, and purposes of medicine.

Casuistry

Casuistry is the method embraced by some leaders in the field of health care ethics, particularly Albert Jonsen (Arras, 1991; Jonsen & Toulmin, 1988; Jonsen, Siegler, & Winslade, 1998). Casuistry is the view that past cases are the repository of ethical knowledge. One decides a current case by judging that it is similar in all relevant respects to an earlier case and applying the decision from the earlier case to the current case. This is essentially the system of identifying precedents used by judges in the legal system. This type of ethical reasoning requires careful analysis of the similarities and differences between cases, and judgments about which similarities and differences are ethically relevant and which are not. Casuistry has a number of features to recommend it. First, health care providers may already use this form of reasoning in their clinical practice, comparing a current patient with earlier ones. Second, case presentation is typically an interesting and effective type of learning. Third, it is *de facto* the way in which much of health care ethics is taught. Consider Tarasoff, Quinan, Cruzan, Donald "Dax" Cowart, Timothy Quill's patient Diane, Barney Clark, Kimberly Bergalis: each name brings to mind a set of issues and lessons learned. Casuistry has a number of limitations, however. First, knowledge of a wide range of cases in health care ethics takes some time to acquire. Second, casuistry is somewhat conservative

(i.e., resistant to change and reform), since it relies on the assumption that past cases were decided correctly. Third, federal, state, and institutional policies cannot merely reference past cases, but must be written in the form of rules, thus reintroducing principles into health care ethics. Nevertheless, casuistry may be an important supplement to a methodology that also includes ethical principles (Toulmin, 1981).

The Ethics of Care

The ethics of care is an important strand of the vibrant and growing field of feminist ethics. The term *ethics of care* was first coined in 1982 by Carol Gilligan (a clinical psychologist) in her book, *In a Different Voice*, where she argues that many women frame moral issues and problems "in a different voice" from many men (Gilligan, 1982). According to past research in moral development, many men frame moral issues as matters of conflicting rights and obligations, and questions of justice and fairness. Gilligan found, however, that many of the women she studied resisted understanding moral problems this way. Instead, the women focused on issues of caring and relationships: whether a relationship should be continued, and if it should, how best to care for and meet the needs of the members of the relationship. While Gilligan's empirical findings and their connection with gender have been the subject of much controversy, it is clear that her articulation of a care-based moral outlook as an alternative to the predominant justice-based moral outlook has struck a chord with many contemporary writers on ethics (Carse, 1991; Little, 1998). Gilligan and subsequent writers on the ethics of care have argued that the justice-based view overlooks many important facets of the moral life. The care ethic, on the other hand, brings these features sharply into focus. For example, whereas the justice ethic assumes that moral situations involve free, equal, autonomous, and independent individuals, the care ethic emphasizes that in many cases these features of a relationship are not present. Individuals often find themselves embedded in relationships in which the members are unequal, where some of them are not fully autonomous, or fully free, or fully independent of the other members. Surely, the care ethicist argues, morality pertains to the parent–child relationship, where the individuals are not equals, not fully independent or free of one another, and moreover, one of the members of the relationship may not be autonomous. Similarly, many feminists have argued that the abortion debate has become intractable precisely because the two "individuals" involved (mother and fetus) are viewed as free, equal, autonomous, and independent individuals. Whatever position one takes on abortion, it is argued, one should not understand the involved parties as the justice framework does: the fetus is metaphysically a *relational* being — it

simply cannot survive (prior to 22 weeks of age) outside of a woman's body.

The ethics of care has made important contributions to health care ethics. For example, some ethicists of care have emphasized that the patient–provider relationship may not be best understood on the consumer model, where the consumer is a free and equal member of the relationship, contracting for a certain service in exchange for a monetary fee. Instead, some ethicists of care have reminded us that serious illness causes fear, anxiety, and some dependency, even in otherwise autonomous adults. Moreover, the relationship between patient and health care provider is necessarily a relationship among unequals: the health care provider is far more knowledgeable about medicine and disease than the patient, while the patient is far more knowledgeable about her life as a whole and the values she holds. Pointing all this out also makes it clear that the members of this relationship have special responsibilities to one another. The health care provider ought to acknowledge and respond with caring to the vulnerability and anxiety of her patient. The patient on the other hand ought to be open and honest with her care provider.

There are some limitations to the ethics of care. For one, some defenders of the justice perspective have wondered whether the care ethic represents a distinct moral perspective or simply an addition to the justice perspective. For another, it is clear that some moral problems, even ones in relationships of unequals (e.g., child abuse) are better viewed in the justice perspective. Other moral situations are better viewed through the lens of care. However, it is not always — or even often — clear which lens to use. Indeed, as I pointed out above, some feminists think that abortion should only be viewed through the lens of care. But this point is contentious, and as of the moment, there appears to be no clear way to determine which framework to use to grapple with a particular moral problem. Nevertheless, the choice of one framework over another will often point toward one resolution or another. So the choice is a deeply normative one, but one without clear criteria to guide it.

Issues in Palliative Care

Some ethical issues tend to arise more frequently in the context of providing palliative care. These issues include (1) the moral status of the decision to forgo life-prolonging treatment, (2) informed consent and truth-telling, and (3) the interplay of curing and caring as the goals of medicine. I want here to sketch how some of the authors we have discussed would respond to these issues, although I would also caution that my sketch is brief and programmatic, and that there is significant room for disagreement in the interpretation of the historical figures on these issues.

The Moral Status of Decisions at the End-of-Life

Laws, codes of professional ethics, and public opinion generally draw a distinction between withholding/withdrawing life-sustaining treatment and "active" means of ending life such as physician-assisted suicide or the administration of large quantities of opiates with the intention of ending life. We have seen that a consequentialist approach to ethics would tend to undermine the moral relevance of this distinction between what has been called passive and active euthanasia. For example, Mill holds that only the consequences of an action (or omission) matter to the moral goodness of the action. As long as there were no long-term bad consequences for society, Mill might favor having the legal option of ending a terminally ill patient's suffering more quickly than merely withdrawing life-sustaining treatment would allow. This position would also be supported by Mill's arguments against paternalism, as expressed in *On Liberty*. Nevertheless, there are limitations to how far Mill might be willing to take this position. For example, if adequate pain management is available, it is a least theoretically possible for him to argue that the long-term costs to society (in the erosion of an ethic of respect for life) would outweigh any benefits to the particular patient. However, while this type of slippery slope argument is often mentioned in contemporary debates, I think it is unlikely that Mill would avail himself of it.

Deontologists, such as Augustine, Kant, and Aquinas, are much more likely to hold that the distinction between passive and active euthanasia is morally relevant, in part, because the distinction between intrinsically wrong and permissible types of actions is central to their theories. Each theorist also holds that suicide is intrinsically wrong. Kant seems to hold that one cannot protect autonomy by ending human life — if life is over, there is no chance to be autonomous. It is unclear whether Kant would also hold that withdrawals of treatment that result in death also are inconsistent with protecting autonomy. Augustine and Aquinas, however, would recognize that withdrawing treatment in some circumstances is consistent with the good of the patient because it is merely allowing the natural process of death to occur. Aquinas would invoke the principle of double effect to show that it is permissible to give pain medications, even with the risk of hastening death. The limit on this practice would be when the pain medication is given at such a dose that it constitutes a poison such that death is intended and/or the relief of pain is accomplished only by the death of the patient.

Informed Consent and Truth-Telling

Kant is often taken to be the inspiration for the modern doctrine of informed consent. Indeed, Kant not only believed that there is strict requirement not to lie to patients about their prognosis, but he also held that health care providers have an obligation to fully and truthfully provide information to patients to allow them to make decisions about care at the end of life — not to do so is to fail to respect the patient as a person. Kant would deny that a health care provider is required to follow every instruction given to her by a patient — a health care provider is not compelled to act contrary to the categorical imperative. But if a health care provider refuses to follow patient instructions as a matter of conscience, this too must be fully and truthfully disclosed to the patient. It is fair to say that Kant would require a good deal more transparency in communication between patients and care providers than is now the case in many institutions.

Theoretically, it is possible that Mill might think it best to lie to a patient to alleviate the patient's suffering. However, given Mill's extremely negative assessment of paternalism, it is more likely that Mill would see the potential for harm in lying to outweigh values from ameliorating depression. Indeed, Mill might worry that deceit would be likely to increase suffering as patients began to recognize inconsistency in their health care providers' behaviors regarding their care.

Curing and Caring

Health care professionals have obligations to attempt to *cure* patients of disease (and repair their injuries), as well as to *care* for patients who are experiencing pain and suffering. Mill is the only philosopher we have discussed who emphasizes the badness of physical pain. Indeed, rather than starting with the idea that some pain is useful (e.g., to keep us from danger, to teach us fortitude) as some philosophers do, Mill is clear that pain is always bad. For Mill, an episode of avoidable pain is to be tolerated only if (1) it prevents worse pain in the future or (2) it will produce or allow for a stronger feeling of pleasure. In this sense, Mill's philosophy fits well with the goals of palliative care, which recognizes that most if not all of a patient's pain should be ameliorated in the context of caring for those with life-threatening illnesses.

Last, Aristotle's ethics complements palliative care's emphasis on caring for the emotional needs of the patient. As we have seen, Aristotle holds that an essential part of being morally good is experiencing the appropriate emotion in response to a situation. This might mean that a care provider's laugh at a patient's joke is genuine, allowing the patient a moment of respite in an otherwise difficult day. It might mean that a care provider knows how to comfort a patient, even in the midst of a very quick and efficient visit. Aristotle is clear that feeling the appropriate emotion is important to discerning the appropriate action: unless one feels compassion, one cannot "see" the right way to be compassionate in a situation. One need not think of this as some magic new ability to see occult objects. It

might only mean that one has a subtle understanding of a patient's fears, so that one is sensitive to language that might raise these fears. This sensitivity may be physical rather than intellectual. To change examples for a moment, think of one's response to an offensive, racist joke — the first reaction is in the body, a cringing, a clenching of the stomach, and only then does one consciously think of the words of the joke and explain to oneself why it is offensive. Likewise, one might be so "tuned-in" to one's patient that the knowledge that he needs some particular object is simply felt, rather than resulting from a minute of problem-solving deliberation. Feeling (rather than feigning) emotions is important for another reason as well. Persons with life-threatening illnesses, like the rest of us, are very good at picking up subtle inconsistencies between affects, behaviors, and spoken words. Telling a patient one thing, while believing another, is likely to raise the anxiety level of the patient as he picks up on these inconsistencies. The patient may not be able to recognize that the care provider is lying, but he will nonetheless be left with the vague feeling that "something is not right."

CONCLUSION ON THE PERSONAL IMPORTANCE OF ETHICAL THEORY

Too many people associate ethics with a code of conduct that necessarily involves the significant sacrifice of one's own well-being in order to benefit others. People with negative views about ethics then tend to view ethics as a cage: the bars of the cage are the ethical rules that keep one from acting in one's own self-interest. I believe this view of ethics is dangerous and inaccurate. It is dangerous because it tends to drive people away from ethics. It is dangerous because even for those who would embrace ethics, it is an ethics of self-denial and martyrdom, an ethics that encourages guilt and moralism. The ethics-as-self-sacrifice view is inaccurate because most ethical theories identify moral obligations to enhance one's own well-being, and some moral theories (such as Aristotle's and Kant's) take the enhancement of one's own well-being to be the central ethical project. A better way to understand ethics is as a tool that helps one create the sort of life of which one can be proud. Every day each of us makes decisions that constitute who we are now and that influence what sort of person we will become. While we do not often think of decisions in these terms, it would be a tragedy to come to the end of a long life and be unable to look back with pride and pleasure at the life we have created with these decisions. And it is a rare person who would not wish to see kindness, compassion, generosity, trustworthiness, and integrity as parts of this life. A better metaphor might be that ethical theories are maps that identify desirable locations to visit and that show the best paths to these destinations. To that end, we should view Aristotle, Mill, and Kant not as providing theories that

narrowly tailor our actions in the name of the rights and interests of others, but as providing theories that describe ways of life that are worth living.

Bioethics and Pain

John Peppin, DO, FACP

"We must all die. But that I can save him from days of torture, that is what I feel as my great and ever new privilege. Pain is a more terrible lord of mankind than even death itself." (Schweitzer, 1948, p. 95)

INTRODUCTION

As medicine has progressed over the past century the problem of treating pain, both acute and chronic, has become a serious concern. Media attention to the problem has been impressive (Springen, Raymong, & Underwood, 2003). The U.S. Senate recently voted this decade 2001–2010 to be the "Decade of Pain Control and Research" and has pledged to support research and education in this critically important area (Nelson, 2003). Unfortunately, the reality of the treatment of pain and of patients with pain does not reflect the attention this problem has received. More than 75 million Americans still suffer chronic handicapping and persistent pain (Gureje, Von Korff, Simon, & Gater, 1998). Over 50% of home hospice patients feel their pain is moderate to severe in spite of the impressive onslaught of professional attention (Crane, Wilson, & Behrens, 1990). The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) study found that more than 50% of patients did not have their pain well controlled in the 2 weeks preceding their deaths (Desbiens et al., 1996). At the two extremes of life our outcomes have been abysmal. Bernabei in 1998 found that over 50% of elderly patients with cancer in the nursing home received absolutely nothing for their pain, not even acetaminophen (Bernabei et al., 1998). Data from this study show that a minority woman patient over 85 years of age was the least likely to receive pain medications, regardless of the cause of her

pain. Wolfe et al. (2000) in their study on children with cancer found that 89% suffered "a lot or a great deal" with pain, dyspnea, and fatigue. Further, chronic pain is very expensive, costing the U.S. economy in excess of $200 billion in 2000 (including lost days from work, lost productivity, lost ability to earn a wage, individual suffering, and the impact of pain on families, e.g., divorce and lost self-esteem) (U.S. Dept. of Health and Human Services, 2000; Walter et al., 2003). This figure is staggering especially when it is compared with more familiar societal expenditures such as alcoholism which cost $148 billion during the same period of time (National Institute on Drug Abuse, 2004). This is not just an American phenomenon. In a World Health Organization (WHO) survey involving patients from five continents, over 22% suffered persistent chronic pain (Gurege et al., 1998). Ferrell (1997) has described the current status of pain management as "the moral outrage of unrelieved pain" (p. 11).

The preceding discussion illustrates the poor performance of health care professionals in treating acute and chronic pain and the marginalization of the pain and palliative medicine patients. Interestingly, this poor performance occurs in the presence of an extensive and expanding literature of the science and practice of pain medicine (and palliative medicine) over the last 30 years. Although there is a time lag time between literature support and use in actual practice for other types of medical knowledge (approximately 8 years), pain management suffers from continued lack of inculcation of literature and research that defies understanding, i.e., more than 30 years.

Although there have been attempts to explain why we treat pain so poorly, these attempts have been unsophisticated and less than explanative. We must explain not only why we treat pain so poorly, but also why patients with

pain are marginalized compared with other types of patients. The purpose of this chapter is to investigate and discuss some of the philosophical, sociological, and bioethical issues involved in pain management. The presentation in this chapter will be controversial and from the perspective of a physician. However, the goal here is to engage the academy (I use the term *academy* in its broadest academic sense and not to refer to any specific professional organization) in a deeper discussion of the reasons why pain management remains little changed even after extensive media, professional, and legislative efforts. It may even be that patients are worse off today. The recent media frenzy with opiate medication misuse, abuse, and diversion is causing even more physicians to refuse to treat patients with chronic pain. As the author of this chapter I come at this problem from the perspective of a physician because this is my profession, training, and occupation. Additionally, my medical worldview is largely Western, and this will be the focus of this chapter; medical philosophies from other perspectives, i.e., Eastern, could have a very different approach to pain and patients with pain.

The concepts that follow may be applicable to other health care professionals, such as nurses and pharmacists as well as to alternative health care professionals such as those from an Eastern perspective (Broekmans, Vanderschueren, Morlion, Kuman, & Evers, 2004). I use the term *health care professional* or *HCP* to indicate physicians, nurses, and pharmacists and to indicate a Western perspective in those professionals' understanding of health, pain, and disease. When the term *physician* is used, it refers specifically to medical doctors and doctors of osteopathy. A review of how health care professionals with an Eastern medical philosophy or "alternative" HCPs, e.g., chiropractors or massage therapists, would be a very helpful as well, but beyond the goals of this chapter. (I agree with Wardwell [1994] that the term *alternative medicine,* as currently construed, has little value in investigations of bioethics, health, or disease. However, the use of medications specifically may place the physician into a situation that predisposes marginalization of patients. This view needs to be explicated elsewhere.)

This chapter covers a number of diverse topics and presents many controversial concepts. It is important to understand that I am not suggesting that this chapter describes actual attitudes and mechanisms leading to marginalizing behaviors in clinical practice. Rather, it is a presentation defining real problems and possible mechanisms that explain behaviors that hinder appropriate pain medicine and patient care. Additionally this chapter is a passionate challenge to the academy to evaluate these concepts comprehensively and seriously and to act upon them. The time has come for dramatic change in how we care for vulnerable patients in pain. Action needs to be substantive and to date the academy has been less than proactive. There is a schizophrenic character to our society

that worries about using the pronoun *he* in scholarly writings so as not to offend, yet allows pain and suffering to continue. How we treat the weak and suffering is a powerful statement about our very social being.

THE MARGINALIZATION OF PAIN

Patients in pain and those receiving palliative care are marginalized in our society. Admittedly this is a deliberately provocative statement requiring explication and examples. At a recent bioethics conference the following case was presented (University of Notre Dame, 2004):

> An elderly and frail 80-year-old man with do-not-resuscitate (DNR) status due to metastatic cancer was having a second intravenous port placed (as the first had ceased functioning). The port, needed for "pain control," had to be placed under general anesthesia. The patient underwent the procedure, but developed respiratory arrest after the surgery and died despite resuscitation efforts that were specifically not requested.

Most attendees at the conference found the violation of this patient's DNR the most distressing issue in this case. When it was pointed out that this patient's pain could have been treated less invasively and more safely by other means, i.e., subcutaneous infusion (as this patient had problems with oral and rectal administrations), the comment was made that this patient was terminal and "would die anyway." There were clearly other routes of administration to approach this patient's need for pain medications that would not have ended this patient's life prematurely and unnecessarily. To suggest that this patient's life was not important because he would "die anyway" is a dramatic example of the marginalization that is inherent in the current system of health care. This is not a case of violation of DNR orders, but one of marginalization of a terminally ill patient in pain.

Some insurance companies have refused to pay for medications to treat pain in the name of "reducing diversion" or because medications are not prescribed according to the "FDA label" (i.e., "off-label" usages). Interestingly, there are few insurance companies limiting hydrocodone combination preparations containing acetaminophen, still one of the most-abused controlled substance prescription medications in the United States. Neither does there seem to be any concern with multiple less expensive medications used off label. For example, amitriptyline does not have an FDA indication for neuropathic pain or fibromyalgia, yet it is used frequently in these disorders, again without comment from most insurance companies. Multiple other medications are used off label without apparent concern. FDA indications and secondary concerns about potential for diversion are disingenuous. More often than not the "issue" has less to do with diversion per se or

quality of care but rather with the cost of branded patented medications. Even this, however, is a concern that seems to lead some insurance companies to reject only certain kinds of expensive medications but then pay for other more expensive invasive procedures. The use of spinal surgery for pain has never been shown conclusively to have long-term efficacy nor good outcome studies, and yet it is routinely paid for by many insurance companies (Devo, Nachemson, & Mirza, 2004). Part of the reason for denying coverage for pain medications may be societal and individual attitudes toward pain. Examples commonly seen include "pain patients" being accused of "drug seeking," patients being told that opiates will make them addicts, and patients being told "it's all in your head." Patients are frequently told they need to "learn to live with their pain" without being told specifically how to do this or that they are only asking for surgery or medications to "get attention" or a bigger settlement in their lawsuit. It is almost universally assumed that patients with chronic pain have psychiatric illness that partially causes them to have chronic pain. These are further examples of marginalization of patients with pain.

How physicians and health care professionals relate to those who are in pain and those who are weak and vulnerable is where our examination should first be focused. It may be that marginalizing behaviors have, at their roots, deeper visceral, and perhaps even instinctual, responses that must be explained before we can understand why we treat physical pain, weakness, and suffering so poorly. As Rousseau states, "Human society contemplated with a tranquil and disinterested eye appears at first to display only the violence of powerful men and the oppression of the weak; the mind is revolted by the harshness of the strong; one is impelled to deplore the blindness of the weak, and as nothing is less stable among men than these exterior relationships which are produced more often by chance than by thought, and since weakness or strength go by the names of poverty or riches, human institutions seem at first sight to be founded on piles of shifting sands" (1984, p. 71). Therefore our *prima facie* intuitions about how the weak or those in pain are treated may or may not be accurate, and we should explore these notions in more depth. This exploration should have as its goal the changing of attitudes and behaviors that marginalize patients with pain.

The barriers to good pain management have been accepted. These barriers include (1) fear of addiction when using opiates (Ferrell, Cronin Nash, & Warfield, 1992); (2) legal obstacles and fear of regulatory agency sanctions (especially when using opiates) (Hoffmann, 1998); (3) fear of side effects of medications (Cleeland, 1993); (4) ignorance of proper assessment of pain (Grossman, Sheidler, Swedeen, Mucenski, & Piantadosi, 1991); (5) lack of appropriate education in pain management (Hoffmann, 1998); (6) beliefs in how "proper" patients should

respond, i.e., the "good patient" (Proulx & Jacelon, 2004); (7) ignorance of pain physiology (Moseley, 2003); (8) failure to identify pain relief as a priority (Ferrell, 1997); (9) failure of the health care system to hold clinicians, physicians and others, accountable for pain relief (Ferrell, 1997); (10) cost constraints and inadequate insurance coverage (Hoffmann, 1998); and (11) patient reluctance to take medications, specifically opioids (Dar, Beach, Barden, & Cleeland, 1992). However, to date there has been little criticism or in depth evaluation of these barriers.

Prima facie these barriers seem to explain why health care professionals so poorly manage pain. However, upon further reflection these barriers are simplistic and without rigor. As Rich (2000) states, "The criticism of the 'barriers' literature that is the focus of this article is its consistent failure to analyze these barriers from an ethical perspective.… [T]he barriers, and the unnecessary pain and suffering that they engender, are treated as merely clinical failures, free of significant moral implications" (pp. 54, 55). Rich is correct in his criticism; however, he does not go far enough. There are deeper, more robust reasons for the inappropriate treatment of pain, which may include (1) visceral and deeper responses, evolutionary if you will, toward the disabled and sick; (2) the position and ego of physicians; (3) notions of eugenics, perhaps based on evolutionary drives; (4) the deconstruction of the patient–physician relationship and emergence of institution–physician relationships; and (5) lack of physician trust toward patients. Again, as Rich states, "the barriers are not simply artifacts of our healthcare system, they relate directly and immediately to aspects of our American culture and society"; however, they may also relate on deeper and more profound levels (p. 55).

The treatment of chronic pain is often palliative. We rarely find a painful condition that when treated alleviates the pain completely. We "palliate" the pain with medications, surgeries, and procedures. Pain medicine is similar in many ways to hospice care and palliative medicine (there are obvious and apparent overlaps). Both fields allow the health care provider the privilege of helping with a patient's suffering and both are symptom focused. (I use *pain medicine* throughout this chapter to refer to both groups, pain and palliative medicine, and patients in these groups because I believe both groups are significantly marginalized for similar reasons. Therefore, the discussion that follows should apply to both groups.) Practicing good pain medicine allows the practitioner to regain the "art," "heart," and "soul" of medicine. To do this one must develop deeper more substantial relationships with patients. To date, however, patients are kept at a distance and their suffering is not engaged by practitioners. The question that has yet to be answered to date, in any depth, is why health care professionals do not take suffering and pain seriously and why we treat weak, vulnerable, suffering patients so poorly.

PAIN AND SUFFERING

Emanuel states, "one of the universally acknowledged fundamental goals of medical care is to provide palliative care to relieve patients' pain, suffering, and other symptoms" (1996, p. 42). Interestingly, this has been a fundamental goal from the birth of medicine (Pellegrino, 1980). Professional organizations recognize this goal and publish statements to this effect. The American College of Physicians *Ad Hoc* Committee on Medical Ethics statement of 1984 is an example: "The primary goals of the physician are to relieve suffering, prevent untimely death, and to improve the health of the patient while maintaining the dignity of the person" (p. 130). Although patients obviously wish their suffering to be addressed, HCPs have done a poor job in approaching suffering patients. "The relief of suffering, it would appear, is considered one of the primary ends of medicine by patients and the general public, but not by the medical profession, judging by medical education and the responses of students and colleagues" (Cassell, 1991, p. 32). It is this disconnect between what is declared as the "fundamental goal" of health care and actual clinical practice that concerns us in this chapter. "Consequently, the widespread failure of physicians to make effective pain management and palliative medicine a priority in patient care denotes an alarming departure of the profession from its deepest ethical roots, and the collective failure of the profession to recognize the ethical implications of under treated pain and the unnecessary suffering that it engenders calls into question whether a majority of its practitioners continue to acknowledge that health care is a moral enterprise" (Rich, 2000, p. 55). Rich has emphasized the focus of the chapter, the marginalization of pain patients. He also has shown the weaknesses of the "barriers" approach to explaining this marginalization. However, he has not elucidated clearly why this marginalization occurs. In the following pages we provide a more thorough explanation than has been given to date for pain patient treatment.

Pain is defined by the International Association for the Study of Pain as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey & Bogduk, 1994, p. 210). Although this definition has been discussed in other chapters of this text, it deserves a further comment. Pain has both a physiological and an emotional component. The emotional component is part of what makes chronic pain management so interesting and at the same time so frustrating to HCPs. The components of emotional and physical suffering make pain unique, ontologically different from other human experiences in that it involves the entire person. Because of this difference, it presents unique problems both clinically and ethically. It attacks who we are, our dreams, our goals and abilities. It attacks at a visceral basic level and challenges every-thing about our being and existence. "Bodily pain affects man as a whole, down to the deepest layers of his moral being. It forces him to face again the fundamental questions of his fate, of his attitude toward God and fellow man, of his individual and collective responsibility, and of the sense of his pilgrimage on earth" (Pope Pius XII, 1956). From an ethical perspective the treatment of chronic pain involves issues that are distinctly different from other areas of medicine and medical care. Others cannot feel the pain an individual feels; it is intimate and personal regardless of what a previous president may claim (Clinton, 2004). We must ask the patient whether or not he or she is in pain.

Pain is described in terms of narratives. This is not all that dissimilar from other medical symptoms and problems; when we collect the medical history information, we are collecting a narrative (Hunter, 1996). "In medicine, practical reason manifests itself as clinical judgment, and narrative is an essential part of it" (Hunter, 1996, p. 308). When patients are asked about their pain, they will describe the pain in clinical terms, but will place these terms into the context of a story of how their pain started, how it has affected their lives, and (frequently) how the health care professions have not believed them and/or treated them poorly.

Pain is clearly subjective, which has been a stumbling block and excuse for poor pain management for many HCPs. However, pain is no different from dyspnea or depression in this regard (Aronowitz, 2000). These are also "symptoms" that require us to believe the patient, rather than tests or laboratories. One can have absolutely normal laboratories, yet still be short of breath. Further, we do not have a laboratory or radiologic procedure to measure depression (there may be new evidence from fMRI, SPECT, and PET scans to suggest certain types of depression, which may help direct treatment [Amen, 2004]). We must obtain information about both the symptoms and their severity directly from the patient. Unfortunately, HCPs routinely underestimate and disbelieve patient's pain reports. This further marginalizes pain patients: "Questions about the authenticity of the pain experience, especially when raised by medical professionals, represent yet another ontological challenge to the integrity of the self" (Garro, 1992, p. 104).

Suffering is frequently viewed by HCPs only as a physical experience. However, suffering involves the entire person. Although this chapter is not a place for a complete exploration of suffering and personhood, it is fair to say that to suffer one must be a person and to understand suffering one must understand the person (Cassell, 1991). Each person has a physical dimension, a body that is unique and yet has important features in common with the bodies of other people. Persons exist in time, possess beliefs, do things, and identify with those things. Certain dimensions of the person, such as their

profession, are very apparent. Additionally, each person has a transcendent dimension (regardless of their metaphysics) (Byock, 1966; Cassell, 1991). Persons are complex and the experience of suffering is personal, existential, and subjective. Unfortunately, once beyond the experience of physical pain, HCPs are lost. They are not trained to deal with pain much less other aspects of suffering; neither are they trained to view patients as persons. If an HCP asks a patient, "where does it hurt?" and the patient responds, "I have a pain in my soul," the HCP is helpless to proceed. Although these phenomenologic distinctions are beyond the scope of this chapter, still it is important to realize medicine's significant limitations. The physician steeped in the medical philosophy of positivism does not possess the tools to treat the whole person. It should be obvious that this can lead to a further marginalization of pain patients.

HCPs tend to approach patients' suffering from a positivistic, scientific, and mechanistic perspective. This view can produce a nihilistic attitude on the part of the HCP. "Subtle manifestations of therapeutic nihilism exist in current clinical practice, being revealed by the language we choose. The tendency to label difficult symptoms, such as neuropathic pain or nausea, as 'intractable,' or to refer to a person's suffering as 'uncontrollable,' can prove self-fulfilling" (Byock, 1996, p. 242). Further the logical positivistic scientific approach to suffering patients taken by many HCPs has contributed to what Robert Veatch and others (Schultz & Carnevale, 1996) call, "a crisis in which care is often disengaged and in which interminable bioethical problems are endemic" (Veatch, 1991, p. 278). Issues that are difficult to quantitate, such as pain and suffering, do not fit in this positivistic paradigmal medicine.

It is important to understand that suffering is not something health care professionals understand or that they have been trained to treat and alleviate (Rawlinson, 1986). The science of medicine tells us nothing about the person and the person's suffering. Neither is the thin bioethics that imbues our secular society able to understand or deal with a patient's suffering. HCP education must be restructured to take into account the nature of suffering and the patient as a whole person.

PAIN AND MEANING

Unfortunately, most individuals in our current multicultural society find little meaning in their suffering and pain. Suffering is to be avoided; especially in our Western culture, suffering is a negative experience. However, one wonders if, without suffering, our society would not be akin to Huxley's *Brave New World* (1998) or Woody Allen's movie, *Sleeper* (1973) Both of these renditions of a futuristic society actively avoid any suffering or discomfort. They use drugs and other conveniences to be oblivious to pain and suffering in order to achieve "happiness."

In these conceptions of the future, suffering is always negative and always to be avoided. This is very similar to our current societal view.

Many robust religious traditions see suffering in a very different light. For both the Buddhist and the Christian, suffering is seen as an inevitable component of human life. The Buddhist believes suffering arises from a person's attachments to the world while the Christian sees relief of suffering as a laudable and spiritually redeeming exercise. The Christian may also see suffering as a way toward a deeper understanding and relationship with God although it should not be sought; Judaism has similar views of suffering (Byock, 1996). What all these robust religious traditions have in common is a sense of meaning from suffering, something lacking in current society. As Frankl suggests, "pain and privation are insufficient to explain suffering. Privation can be endured if there is a purpose in the suffering experience.... Suffering ceases to be suffering … at the moment it finds meaning" (1963, p. 115).

We do not share a common moral vision; neither can we refer to any commonly held understanding of pain and its role in our culture and lives. Pain is unavoidable and will be experienced by all of us. Acute pain comes and goes. It has a clear ending and, therefore, is much easier for us to tolerate within our lives and worldview. However, chronic pain needs to be examined in a broader moral context to derive any meaning from the experience. Lacking this moral framework, existential angst can further exacerbate the patient's suffering. Delivering a baby certainly has a component of physical suffering. However, it is placed in a broader view of accomplishment and a known goal, i.e., bringing a child into the world. Patients with chronic pain usually do not have access to such a perspective, and current medicine is incapable of providing this. Finding meaning in pain and suffering is something that is missing from current pain management treatments and programs and is rarely addressed seriously in the pain literature. Patients' mistakenly seek meaning in physician's recommendations and treatments. However, as has been shown, physicians are neither trained nor are they in a position to deal with meaning in patients' lives. Meaning is suggested in studies measuring levels of sensory pain and pain unpleasantness. *Prima facie* one would think sensory pain and unpleasantness to be very similar, yet there can be a wide disparity between the two.

In previous societies and cultures, the priest was the one who helped guide individuals through chronic pain and suffering. However, those rich moral traditions that gave meaning to pain and suffering no longer exist for a vast majority of individuals in Western culture. "The meaning of pain seems a non-issue as long as medicine can provide its reassuring explanation and magical cures. When cures repeatedly fail, however, or when the explanations patently fall flat, we must confront once again — with renewed seriousness, even desperation — the ever-

implicit question of meaning" (Morris, 1991, pp. 31–32). In previous cultures with strong moral traditions, pain maps onto a broader foundational view of life. Although treatments may still be necessary, patients are able to deal with their pain more effectively; i.e., the unpleasantness is reduced. We lack this mapping in our current fragmented and thinly construed social and moral framework.

PAIN MANAGEMENT AND BIOETHICS

Although there are a number of different ways to approach bioethics and moral theory, for our discussion here principlism, liberal political theory, and Engelhardtian libertarianism are the most important to discuss. Attempts to reduce bioethical issues to a clear and simple set of principles began during the 1960s and 1970s. The theory of principlism emerged from the work of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research in 1974 (Federal Registry, 1979). Beauchamp and Childress (1994) further describe principlism as a set of four principles with which they claim most, if not all, bioethical controversies can be resolved. These principles are beneficence, nonmaleficence, justice, and autonomy. They are felt to be common threads for HCPs interactions with patients regardless of foundational philosophy or strong moral traditions.

The principle of beneficence is to act in the patient's best interest for the good of the patient. Intuitively, treating pain is in the patient's best interest. Interestingly, when the principle of beneficence is evoked in support of pain management, it is represented as a *prima facie* principle, and "clearly includes the effective treatment of pain and other symptoms" (Cherny & Coyle, 1998, p. 643). For secular society, however, these notions hold no authority. Doing good takes on a different meaning in secular society. For example, in a given religious tradition, a monk, when queried about pain, might respond that pain could bring a seeker to a richer prayer life and closer to God. Therefore, the pain should not be treated or at least not treated completely. However, the secular priest, i.e., the modern-day physician, could make no such claims, and in fact, such claims would be considered nonsensical. The goal would not be a richer spiritual life but something much more practical: the relief of pain. The secular priest could only hope to maintain a state from which an individual could seek his or her own view of the good. In this postmodern age this is where liberal political philosophy fills the gap left by religious traditions, *vide infra*. Beneficence then can only be construed as maximizing a patient's autonomy. Notions of beneficence beyond this cannot be established in secular society in any broad sense. To do this requires a richer robust foundation, which is inconsistent with liberal political philosophy.

The principle of nonmaleficence prohibits HCPs from harming or inflicting evil on patients. Pain places patients at risk for further harm because pain is not a benign physiologic process. Physiologically, patients in pain have poorer outcomes postoperatively. Acutely, pain causes sympathetic nervous system activation, increases fibrinolysis, heart rate, and blood pressure. There are other side effects of pain such as inhibition of the immune system and effects on respiration. Nonmaleficence requires not causing pain or not allowing patients to be harmed by pain. Again, this view of pain is epistemologically different from those of certain religious traditions, *vide supra*. Therefore, unilateral notions of nonmaleficence are also limited by our multicultural social structure (Engelhardt, 1996). One must have a robust moral foundation to apply nonmaleficence in any rigorous way.

Justice deals with the fair distribution of resources and requires an ability to rank-order different resources. However a just distribution must, of necessity, have a moral foundation from which to make judgments concerning various resource choices. Ranking *cannot* occur without such a foundation and such a foundation belies any pretense of neutrality, an important concept in liberal political theory. Justice, nonmaleficence, and beneficence are all dependent on "canonical" understandings of bioethics and morality. As mentioned, there cannot be any canonical understanding of these concepts; they are culturally dependent.

The one principle we are left with is autonomy, to allow patients to seek their own notion of the good. To establish a "right" to pain management autonomy can provide a central principle. An individual's autonomy is sacred in our society. Autonomy for patients was an even later development in the ethics of medicine and society than political autonomy, one born from philosophical, political, and religious reflection. "[T]he belief that persons have a right to individual self-determination has captured the imagination of the Western World," and "the idea that a similar right should be accorded to patients has surfaced largely, and surely more insistently, during the last few decades" (Katz, 1984, p. 104). To be autonomous is to be self-governing, and autonomy is a form of personal liberty. "Autonomy is one of those widely applauded concepts which, on closer inspection, turns out to be difficult to define with precision.… What is common to most definitions is the notion that an autonomous person is one who, in his thoughts, words, and actions, is able to follow those norms he chooses as his own without external constraints or coercion by others" (Pellegrino, 1994, p. 48). To be self-governing, one must be a person and able to deliberate and choose from various options. In addition, that person must be capable of acting on those deliberations. There must be no hindrances to free and autonomous decision making, i.e., "without constraints either by another's action or by psychological or physical limitation" (Beauchamp & Childress, 1994, pp. 56–57). Free decisions require a competent person, enough and

appropriate information, and freedom from coercion. Whether a person could ever have free and unhindered decisions is problematic; yet such hindrances would clearly include pain.

For individuals to manifest their own view of the good, they must be autonomous. However, autonomy presents real and significant difficulties for bioethics and specifically for pain management. Pain can reduce a patient's decision-making capacity and make it difficult for an individual to make autonomous decisions. It can prevent an individual from achieving his or her concept of the good. If pain limits a person's ability to be autonomous or a patient cannot make autonomous decisions if he or she is in pain, then does this require us to treat a patient's pain against the person's will? Is the patient then incompetent in this regard? "Bioethicists, who are so preoccupied with the ethnocentric principle of personal autonomy as to regard it as the only solid ground of ethical choices in the hospital, do not know what to make of chronic pain" (Kleinman, 1992, p. 169).

THE "RIGHT" TO PAIN TREATMENT

Our secular culture is founded on liberal political philosophy. And such a philosophy, as defined by Rawls, Dworkin, and others, revolves around the liberal state (Dworkin, 1989; Rawls, 1989). Because it is claimed, this form of liberalism rejects any substantive theory of the good, it must, at least theoretically, be neutral to any form of the good. The state is justified because diversity is a basic fact of modern life and it would be a breach of individual freedom for the state to impose any predetermined set of values. Because it cannot be shown that some individuals should be treated unequally, all should be treated as equals. Treating an individual as an equal requires that individuals be allowed to seek life opportunities. This, it is claimed, is one major reason why a state should not proclaim any notion of the good because it could coerce or manipulate an individual away from his or her own life opportunities. The public square should be without any general notion of the good and should be "neutral" to avoid any undue influence or potential coercion toward a specific view of what constitutes the good by the state. Although there are justified critics of this form of the liberal state, it nevertheless has been a powerful force in the development of bioethics (Galston, 1991). Further, it has permeated our social programs including health care. How can an individual seek his or her notion of the good without being in good health and, certainly from the perspective of this chapter, free of pain? Therefore, the state has an obligation to foster health and alleviate pain to allow individuals all the tools and resources to achieve their own life opportunities.

The former Agency for Health Care Policy and Research (AHCPR) stated that pain management "begins with the affirmation that patients should have access to the best level of pain relief that may safely be provided" (U.S. Dept. of Health and Human Services, 1992). The World Health Organization (1990) claims that for patients with advanced and terminal cancer, relief of pain is a "right." The American Pain Foundation (2004) has had similar set of "rights" for patients with chronic pain. *Prima facie* it seems to many that the treatment of pain is a "right" for all patients in the United States. As Somerville states, "to leave a person in avoidable pain is a fundamental breach of human rights" (1994, p. 42). Although obligations to relieve patients' suffering have been discussed, these obligations are derived from the historical and bioethical foundations of the medical profession. However, these obligations do not require any concept of rights. The foundations for a "right" to pain management have rarely been explicated in the literature. Unfortunately, it has never been apparent from a secular perspective that patients have a right to treatment or alleviation of their pain.

Neither principlism nor liberal Western political philosophy can give a single way of understanding the obligations to relieve pain or the right to pain relief. Each of these views is subject to different understandings and to the weaknesses described above. We need an approach that might tie together those aspects of principlism and liberal Western political philosophy that can give us a "right" to pain management. Rights require not only bioethical principles but also grounding in political philosophy. Principlism, although claimed to be universal, does not apply to all cultures and individuals. It would be very difficult, if not impossible, to establish a *robust* "right" to pain management apart from a specific cultural and moral construct. As has been pointed out by Engelhardt, "the impossibility of establishing the concrete vision of the good life, proper deportment, health care policy, or bioethics by an appeal to general rational secular arguments leads to the development of two divergent understandings of bioethics: secular bioethics and the bioethics of content-full moral commitment" (1996, pp. 16–17). Although Engelhardt would take umbrage at any mention of rights in secular society, he adds the third component to our building of a "right" to pain management. To Engelhardt the principles of beneficence, nonmaleficence, and justice all require a content-full moral vision. There is no way for multicultural society with a multitude of moral visions to establish one vision of the good. Therefore, all we have left is the notion of autonomy. We allow individuals the option to engage in their own vision of the good and to seek their own opportunities. We allow individuals to have the option of good pain management or to refuse such an option. To Engelhardt notions of "rights" or "morality" have no real place as these concepts also require a content-full vision of the good. Only a thin vision of bioethical understanding is possible. All we are

left with is our agreement to disagree amicably without violence or coercion. Autonomy or allowing individuals their own view of the good must be, by default, our overriding principle.

Cherny and Coyle state that a right to pain relief "is derived from the universal concept of respect for all persons and is inextricably linked to the concept of human ethics" (1998, p. 644). However, as the previous discussion has shown, there can be no robust "universal" right to relief of pain without a cultural context. That context, at least in secular United States, comes from liberal political philosophy. Engelhardt and the notions of principlism all have as a central foundation the notion of autonomy or permission. Autonomy is the key to a "right" to pain management and treatment, albeit thin. As discussed, to be autonomous a person must be free from outside coercion and influence. The impact of pain significantly reduces a patient's ability to make decisions and achieve his or her notions of life opportunities and the good. Their pain should be treated to allow the patient autonomous choice. Therefore, the state should recognize a right to pain treatment. This is admittedly somewhat thin logically, but all we can achieve in this multicultural liberal polity.

PHYSICIANS, HEALTH CARE PROFESSIONALS, AND PAIN

The title of physician is one of the few non-egalitarian titles in society. President, congressman, senator, governor, and professor are also such titles. Physicians are called "doctor," an honorific title that establishes their place in society with each utterance. We do not call plumbers, "Plumber Smith," yet physicians are called "Doctor" and if this honorific is not used there is a feeling of insult. Humanitarians can give millions of dollars to the poor and they will still be called Mr. or Ms.; yet physicians regardless of their morality or philanthropic inclinations are still called "Doctor." This elevated societal position of physicians can be traced through history. It may be that maintaining trust in individuals who are responsible for lives represents part of this societal position. Other professional groups may have average IQ scores that are much higher than physicians; yet these individuals do not hold the societal position held by physicians. I was recently at the back of a hospital elevator with three hospital employees in front of me. When the door opened they insisted that I leave first, even though I was at the back. The only reason was obvious; I was a physician. So the title alone carries with it a tremendous amount of societal respect and position, not necessarily earned. Ivan Illich explores this notion when he pejoratively states, "Societal acceptance of the illusion of professional omniscience and omnipotence may result either in compulsory political creeds (with their accompanying versions of a new fascism), or

in yet another historical emergence of neo-Promethean but essentially ephemeral follies" (Illich, 2000, pp. 11–12). The position of "physician" may be necessary to some extent, since there may be some therapeutic benefit to the position. However, this societal position can become expected by the physician, which could lead to feelings of superiority, resulting in low regard for and poor treatment of patients in pain. This combined with other more instinctual notions can result in the barriers to effective pain management we currently observe.

Evolutionary psychology is a relatively new field. It brings into the discussion the notion of "instincts," which are "domain-specific, information-processing modules" that are behaviors in response to external and internal stimuli (Charlton, 1997a). Most evolutionary psychologists would agree that animals are mostly solitary and the ability to live in social groups depends on "psychological specializations" (Charlton, 1997a). Charlton discusses a categorization of social instincts into "dominant and counter-dominant." Among the human species is the counter-dominance instinct, which leads to egalitarianism, unique in the animal kingdom. Most important of these counter-dominant instincts is sharing. However, "dominance is indeed phylogenetically older than counter-dominance and these instincts are more powerful in delayer-return economies" (Charlton, 1997a, p. 425). Before one dismisses this discussion as irrelevant to our current society, Charlton continues, a "dominance hierarchy is one in which the high status individuals who have access to a larger than equal share of sexual activity also get a larger than equal share of desired resources such as food" (Charlton, 1997a, p. 425). In other words, in a dominance hierarchy, prestige and power go together and reinforce one another. Modern humans live in a "dominance hierarchy." So we have some evidence for a more visceral or "phylogenetically older" response of dominant individuals to those who are weaker, suffering, or in pain. Physicians clearly have a dominant role in society and a much higher share of resources. They also hold tremendous power as the "gatekeepers" to medical care. To receive many treatments for pain, or medications, one must see a physician (this may be part of the reason why patients seek "alternative" medical care). If these dominant roles are tied to bias and prejudice, perhaps based on instinctual racial and other notions, marginalization of certain groups of patients with pain, such as the elderly, the infirm, racial minorities, and females with chronic pain, may be the result. Notions of racial superiority are not unique to one specific culture, but have been seen throughout history and in numerous cultures regardless or color or creed. One way to view these notions can be as basic visceral human responses to different cultures and peoples. It may be that "a little" racism was important to survival in the distant past, but these leftover visceral responses to different cultures and races are now destruc-

tive. (I am clearly not supporting any notion of racial purity or eugenics, which this author finds repulsive. Morality and ethics begin when we say no to our baser responses; see Burnham and Phelan, 2000.)

These are feelings that must be overcome, but can be insidious and may play a role in physicians' response to patients with chronic pain. Lasch may be correct when he writes, "men have always been selfish, groups have always been ethnocentric; nothing is gained by giving these qualities a psychiatric label" (1979, p. 32). However, he is incorrect in his unwillingness to explore these selfish instinctual behaviors because only by "labeling" these behaviors can we begin to know how to correct them. This instinctual response combined with physicians' hierarchal position could have a powerful impact on patient's treatment. (This is a problem not only with physicians, but nurses who take on the role of "nurse pain clinician." The training for such a title has little consistency, yet these individuals take on a powerful role in the hospital. Because of their lack of credentials and education they can be a barrier to creative and new ideas in pain medicine and treatment.)

"Even in areas where we feel that we act purely of our own free will, our dramas are played out on a genetic stage" (Burnham & Phelan, 2000, p. 3). Whether we fully "buy in" to their claim that genes play such a dominant role, his writings are intriguing. "What is useful in small quantities often becomes destructive in excess, so instinctual desires in a new environment lead us straight to a problem" (Burnham & Phelan, 2000, p. 244). The previous discussion of racial biases and dominance may be examples of what Burnham and Phelan are discussing, i.e., instinctual "genetic" responses that have become "destructive in excess." The notion that a group maintains its gene pool may have had some evolutionary advantage in the past, but in excess has caused untold suffering and death in modern society. So, too, with the social instincts of dominance and counterdominance, in excess at a different time in history, marginalization of the weak and those in pain is the result.

It is interesting that beauty and deformity also have a tremendous impact on our responses to individuals with whom we interact. This is again a deeply visceral basic response. As Hume (1739) states, "beauty is such an order and construction of parts, as either by the primary constitution of our nature, by custom, or by caprice is fitted to give a pleasure and satisfaction to the soul. This is the distinguishing character of beauty" (p. 350). Hume is speaking of a deeply visceral response to what is considered "beautiful." As we view chronically sick and weak patients do we consider them "beautiful"? If they are not, then our behaviors can belie our true feelings and continue the further marginalization of patients with chronic pain. Additionally, feminist theory may add to our explication of poor pain management behaviors. Certain groups,

women, the aged, minorities, and persons with chronic pain are viewed as less trustworthy, both epistemically and morally (Code, 1991). There is clinical support for such a view, e.g., Bernabei in his study of elderly nursing home patients with cancer (*vide supra*) (Bernabei et al., 1998). Young goes further, "judgments of beauty or ugliness, attraction or aversion, cleverness or stupidity, competence or ineptness, and so on are made unconsciously in interactive contexts and in generalized media culture and these judgments often mark, stereotype, devalue or degrade some groups" (1990, p. 133). Young echoes Hume's discussion of beauty and ugliness and gives a further potential rationale for how pain patients are regularly treated.

Another aspect of our society is its loss of a moral foundation and a move to a more individual narcissistic social structure. "The weakening of social ties, which originates in the prevailing state of social welfare, at the same time reflects a narcissistic defense against dependence. A warlike society tends to produce men and women who are at heart antisocial. It should therefore not surprise us to find that although the narcissist conforms to social norms for fear of external retribution, he often thinks of himself as an outlaw and sees others in the same way, as basically dishonest and unreliable, or only reliable because of external pressures" (Kernberg, 1985, p. 238). William Osler (1932), in his work *Equanimitas*, suggests that HCPs should distance themselves from their patients in the belief they are protecting themselves emotionally and improving diagnosis and treatment. This view of "equanimity" has been perpetuated from medical school through residency. Emotional distance must be maintained to allow the freedom to diagnose and treat. It is claimed that getting emotionally involved with patients hinders this process. This view never has been tested in any scientific sense and why it continues to be perpetuated may relate to the discussion we have been having concerning the instinctual responses to those in distress and pain. However, once we distance ourselves from a patient's pain, that pain becomes "objectified" (Madjar, 1999). What is meant by this "objectification" is that the physical component of pain is separated from the patient's suffering. This is what HCPs are trained to do, distance themselves from the patient as person, separate out the problem and deal with one physical problem, at a time. The HCP no longer engages the patient as person; the patient is now a disease, an abstraction. HCPs are much better trained to deal with a clear disease, such as a coronary artery blockage: easily seen on angiogram and repaired through surgery. Unfortunately, pain does not fit our disease-based paradigm. Therefore, not only do HCPs have instinctual genetic drives that may influence their behaviors toward patients in pain, they also further exacerbate these behaviors by distancing themselves from the patient and objectifying patient narratives.

Clinicians admire the patient who "suffers with dignity," quietly, and with a minimum of pain behaviors. When physicians' diagnostic and interventional procedures have failed in finding an organic cause, they may feel there is no objective basis for a patient's pain. HCPs then, based on their professional training, "will be forced to conclude he [or she] has some sort of mental problem" (Black, 1979, p. 40). Additionally, when HCPs suggest that patients' pain is "in their head," this implies that the patient has a moral responsibility for bringing on suffering to the patient, family, and society. As has been shown, physicians, through their dominant position in our society, their visceral evolutionary responses to those who are weak, elderly, and "less beautiful," and their equanimity combined with societal narcissism, could contribute to the marginalization of patients with pain that we have been discussing.

INSTITUTION–PATIENT RELATIONSHIP

One of the profound changes associated with modern health care is the reemergence of an institution–patient relationship. An investigation of these institutional changes and their impact on pain management has not been provided previously. As managed care becomes more prominent and prevalent, the institution–patient relationship is itself reemerging as prominent. The previous oaths, creeds, and professional "professions" of obligations toward patients have less and less authority. As mentioned, all we have left as a secular society is the notion of autonomy. We no longer have the background of the religious norms that initially governed relationships with patients. When institutions such as insurance companies, hospitals, and clinics take over the roles previously held by physicians, it is now business ethics and economic theory, rather than a traditional medical or theological ethic, that provide the guiding norms. However, business ethics does not provide the needed foundation for protecting patients or guiding health care. *Caveat emptor* is still the overriding value in such an ethic. This is a further barrier not heretofore discussed in the pain management literature. Business has as a core goal the accrual of wealth and profits. This is not inherently bad or evil as profits can be tempered with social conscience. Patients with chronic pain or those who are chronically ill cost money and reduce profits. Therefore, there is a built-in incentive to limit the care for these patients or eliminate them, e.g., from an insurance pool. If patients with chronic pain are at risk for poor pain treatment and management from HCPs, the transfer of relationships to an institution with little or no ethical foundation should be very concerning.

In today's health care environment shared discussions and decision making by the physician–patient dyad is increasingly "being supplanted by the rules, standards, traditions and collective decision process of organizations,

which instruct and construct institutional actions in shaping health care choice" (Reiser, 1994, p. 28). Toulmin in his 1990 article states, "to the extent that, in the operation of a modern hospital, the claims of budgetary survival tend to outweigh those of a moral calling, the institution vergers on the condition of a tyrant.… [M]edical practitioners collectively cease to be a profession, and the individual doctor's work, circumscribed by institutional imperatives, is removed from the sphere of moral commitment and placed within the realm of social necessity. To that extent … the physician's work is de-moral-ized" (p. 25). Reiser's and Toulmin's articles support the notion that in a very real sense the institution–patient relationship is increasingly eliminating the middleman, i.e., the physician and other HCPs; and this will further marginalize the patient in pain.

Often, managed care is criticized because it allows monetary considerations to play a role in health care although this is not a new development. Even in the fourth century, Saint John Chrysostom was well aware of economic influences in health care: "[I]n the reception of strangers, and the care of the sick, consider how great an expenditure of money is needed, and how much exactness and discernment on the part of those who preside over these matters. For it is often necessary that this expenditure should be even larger than that of which I spoke just now, and that he who presides over it should combine prudence and wisdom with skill in the art of supply, so as to dispose the affluent to be emulous and ungrudging in their gifts" (Chrysostom, 1998). While Chrysostom sought to expand the financial base of hospitals, he simultaneously recognized that care may take place in a context of constrained resources, and that prudence would be needed in making decisions about allocating these resources. A concern with money and its role has thus been present from the beginning of organized health care.

Money has been an essential part of health care for centuries. Today it is assumed that "money distorts, as well as corrupts, distracts, and vulgarizes the professional relationship" (May, 1997, p. 10). Why do we see it as having such a negative role in the 21st century? To answer this, we must consider the basic moral foundation upon which the hospitals in Chrysostom's time were based. Chrysostom had a robust moral tradition in which to place those monetary constraints. Care of the sick and suffering took precedence over profits. That Christian Orthodox religious community shared a common vision and conception of theological truth that enabled him to address the questions of human finitude and societal responsibility associated with financial considerations, and as previously discussed, gave a framework from which patients could find meaning in their pain. Hospitals, during the Enlightenment and under the banner of "scientific medicine," began to pull away from their religious underpinnings and detach themselves from "superstition" (Reiser, 1994). With the loss of

religious foundations there was a concomitant degradation in the previously strong concept of the institution–patient relationship. Not only did the moral foundation of the institution–patient relationship change drastically but the moral foundations for health care professional's obligations also changed. This is part of the reason the other aspects of the HCP–patient interaction, those negative behaviors, can play a more important role. Into this void came medical professionalism with its distinct ethos.

Physicians sustained an understanding of their role and obligations, an understanding that was originally steeped in religious commitment (the idea of "profession"), but increasingly ignored that grounding tradition. The patient, rather than the religious community, became the central focus. With the modern discipline of bioethics, these traditional obligations were fully reconstructed in a philosophical idiom, with the language of "autonomy" and "beneficence" providing the means for rationalizing the role and obligations of physicians. However, without these rarefied moral notions, these principles, except autonomy, lack sufficient political force. The protection and advocacy that physicians or patients should be trying to provide and that were part of a previous age's moral framework is no longer available. So it is not at all surprising, in this current age of the primacy of business, erosion of moral foundations, and the previously discussed rationales for poor pain management behavior, that patients in pain are marginalized.

Currently, the focus of the institution–patient relationship is "business," and its ethical foundation is at best thin and lacks substantive power to protect patients. Because health care institutions have tremendous financial and political power, an ethos that considers patients' welfare as primary is critical. However, this power base, with the *current* minimalist business ethos, is dangerous to patients and their care. The push to save money and the pressure to limit care as financial constraints continue (especially for those who cost the system the most money, i.e., the elderly, the chronically ill, the weak, and those with chronic pain) will be overwhelming. (Although beyond the scope of this chapter, it is concerning that the ethical issues that seem such conundrums in our secular society all have the potential of saving the health care system substantial amounts of money. Euthanasia, physician-assisted suicide, abortion, and substandard care may all become attractive cost-saving options.)

A criticism of the role of business in medicine is illustrated by the Emanuels' article (1996), which can be taken as typical of the literature critical of business ethics in health care. To the Emanuels, the risk that the economic model will take precedence involves "a ruse portraying physicians as caring professionals while forcing them to act like economic producers [which] will ultimately discredit the entire practice of medicine and sow distrust and cynicism that cannot easily be overcome" (p. 238). They

further decry the economic model and suggest that physicians "must resist the tremendous tendency within U.S. society to believe that the ideal solution for every complex social problem is the market and economic accountability" (p. 238). To the Emanuels the economic model views patients as "consumers" and physicians and other HCPs as "providers." Just like buying a dishwasher, consumers are encouraged in this model to compare the costs of different providers. Successful providers will, it is said, attract more consumers and make higher profits. This view of the health care market assumes that the market is free; yet the reality is that the health care market has become more and more constrained. Implicit in the criticisms of this model is a dread of the emerging institution–patient relationship and the fear of patient vulnerability. The Emanuels' criticisms should be taken seriously, but this does not take the discussion far enough. If we were just buying dishwashers, there would be less need to worry about *caveat emptor*. A bad dishwasher will very rarely put our lives at risk. However, when patients' lives hang in the balance and their classical ethical protections have been eroded, the need for concern becomes obvious.

Morreim (1997) sees health care institutions as having important and critical obligations to patients. She comments, "there is good reason to regard managed care organizations as fiduciaries of patients" (p. 36). The term *fiduciary* was once reserved only for individual professionals, e.g., physicians and attorneys, and only rarely applied to institutions. However, Morreim feels health care institutions (specifically managed care organizations) have fiduciary obligations that are little different from those of physicians. This is a unique view, and one that takes into consideration the evolving institution–patient relationship. Morreim's article gives import to the view that business ethics is not currently in a position to provide adequate protection to patients. Nevertheless, while Morreim broaches the issue of fiduciary obligations for health care institutions, she does not address the question of the ethical foundation for these obligations; how are they to be built? A medical ethic cannot merely be transposed onto a business ethical paradigm. Business ethics is not prepared to assume the roles previously held by physicians. Therefore, patients are increasingly vulnerable as business becomes more and more the driving, albeit *thin*, ethos in health care.

The advent of liberal political philosophy has further marginalized the role of physicians as well as patients in the physician–patient relationship and helped bolster the emerging institution–patient paradigm. As discussed previously, liberal political theory suggests that the state must be neutral with respect to its constituents, a philosophy that has been co-opted as a foundation for the physician–patient relationship, a view critiqued elsewhere (Peppin & Beckwith, 2000). Health care institutions are also to be value neutral, and this approach complicates

attempts to develop any robust conceptions of the institution–patient relationship (Emanuel, 1991). Can a theoretical foundation that is "value neutral" develop the ethical robustness needed for patient protection? Suffice it to say that political systems nor physicians nor health care institutions can be value neutral (Galston, 1991; Peppin & Beckwith, 2000). As Starr (1982) comments, "the organization of medical care cannot be understood with reference solely to medicine, the relationships between doctors and patients, or even all the various forces internal to the health care sector. The development of medical care, like other institutions, takes place within larger fields of power and social structure" (p. 8). Starr sees clearly that medicine in general has a number of different non-value-neutral layers, if you will, each with its own set of values, the health care institution no less than the physician.

Unfortunately, attempts at a resurrected classical formulation of the physician–patient relationship combined with a business ethos also cannot provide any patient protections, as previously described. Although Emanuel and others continue to suggest that physicians are the buffer, the intermediary between the patient and institution, institutions are increasingly inserting themselves between the physician and patient. Morreim and others would do well to take the analysis of Sen (1988) seriously. "It is arguable that the importance of the ethical approach has rather substantially weakened as modern economics has evolved.... If one examines the balance of emphases in the publications in modern economics, it is hard not to notice the eschewal of deep normative analysis, and the neglect of the influence of ethical considerations in the characterization of actual human behavior" (p. 7). Economic theory and business ethics, as currently described, are too thinly construed to be of help in our current ethical crisis in health care, or in understanding the implications of the reemerging institution–patient relationship.

The marginalization of physicians' ability to act on patients' behalf and our previous discussion concerning patients with pain make deeper investigation into how to change the state of the weak, elderly, and those in pain imperative. Patients are not able to secure the protections they may have in other markets as "consumers." A consumerist ethos "cannot operate effectively in health care because of the asymmetry of information between supplier (doctor) and consumer (patient) and the special agency relationship which subsequently must exist between the two. The uncertainty of illness also makes it difficult for patients to adopt consumerist behavior" (Lupton, Donaldson, & Lloyd, 1991, p. 560). The other issues discussed in the previous part of this chapter also bring the "consumerist ethos" into question. Patients thus do not have even the consumerist ideal to provide them protection from *caveat emptor*. The problem does not lie in health care as a business or the managing of costs *per se*, but rather in the lack of a robust business ethos that will regulate and limit the impact of financial considerations on patients.

CONCLUSION

It should not be construed that this author is suggesting physicians purposefully take a dominant role or purposefully try to marginalize patients with pain. Peters and Watt-Watson (2002) suggest, "[a] lack of trust in patient subjectivity reveals an epistemic bias that privileges objectivity in a positivistic sense.... It would be wrong, however, to hold individual clinicians entirely accountable for these moral and epistemological failings, for such failings have deep cultural and historical roots" (p. 75). HCPs generally are generous and empathetic professionals. They do not knowingly, generally, cause harm or purposefully marginalize the sick and weak. However, the behaviors we have been discussing may be instinctual rather than conscious. Also the lack of substantial and content-full moral foundation does not provide the framework necessary for interactions with patients. This absence could allow these instinctual behaviors more outlet for expression than when constrained by a content-full moral view of the good.

Current bioethics has not been able to provide the robust moral foundations that previously formed the fundamental protection against the marginalization of patients that we have discussed above. Now, in our multicultural society, no one view of the good can be determined to be "canonical." Therefore, the only reliable principle a secular society and health care system have left is autonomy. We may be able to acknowledge, however, that through liberal political theories, a "right" to pain management based on maximizing a patient's autonomy could be developed. However, other aspects of liberal political theory would be inconsistent with the foundation I am suggesting. For example, the Christian monk discussed previously, who might feel that pain brings one closer to God, would find an ethic based on liberal political theory very unfriendly. There is no room for those who have robust religious or moral traditions in such a philosophy. Here we turn to Engelhardt's work and his *Foundations of Bioethics* (1996). To Engelhardt there is no way to discern a canonical view of the moral and good life in a secular society. All we have left is to agree to disagree agreeably, i.e., to allow individuals autonomy. Engelhardt does not use the term *autonomy* to describe interactions between persons, only "permission." We give or withhold permission in all our interactions. Permission is the "foundational principle." Individuals are allowed to seek their own notions of the good life. Engelhardt does not consider permission a "right," just all that is left to our multicultural society.

Health care institutions occupy a middle ground between individual, privatized beliefs, and a broad social political ethos. Individual health care institutions, at the

organizational level, may recover a rich theological ethos from which they can develop concrete guidelines for the institution–patient relationship. Efforts to enrich business ethics to provide patient protection should work toward enhanced safeguards for institutions with rich value structures, so that their development is not hampered by governmental coercion. These institutions can provide rich moral foundations, if allowed, and individual patients can choose which institutions would best fit with their own worldviews. It will be up to patients to seek those health care institutions that adhere to a rich conception of ethics and values, or not. This requires a departure from traditional Rawlsian political philosophies. Unfortunately, those patients who are in lower socioeconomic classes, the weak, the infirm, the disabled, and those in chronic pain will be the ones least likely to have the skills to seek such institutions. Regardless, in all discussions concerning the role of business ethics in health care we should consider that "the real business of health care is not about the mergers and acquisitions, financing mechanisms, or structural reforms that have occupied center stage on the public agenda for much of the past decade. It is about preventing ill health, caring for people who are sick, and meeting the needs of people who must live their lives with disabilities or chronic disease" (Edgman-Levitan, 1998, p. 1). Unfortunately, the thin structure of business ethical theory that currently supports most of our health care institutions is not strong enough to protect patients, especially those at greatest risk such as patients with chronic pain. Without a clear and robust ethic, patients will continue to be at risk from the health care institution of sacrifice for the sake of cost constraints. Can a business ethic protect patients with chronic pain within the institution–patient relationship? Currently, the answer is a resounding *no.* Developing a robust moral foundation for companies has not been a focus in the business or economics literature.

Medical education needs a modern-day Flexenerian revolution (although I focus on medical education, the criticisms described here may also apply to pharmacy, nursing, and other HCP educational institutions and universities). During the early 1900s medical education underwent a tremendous evolution through the efforts of Flexner (1910) and subsequent legislation. The way medicine was taught changed dramatically and this approach has continued little changed until today. Unfortunately, the current system, although successful in many ways, has failed substantially in other areas such as pain management. In order to successfully treat the chronically sick patients that currently fill our clinics, we need a different perspective, one that focuses on patients and their suffering, their quality of life, and a better approach to symptom management. The current approach is disease centered. Perhaps the greatest barrier will be that the disease model is so entrenched that most clinicians and patients are unaware of its existence. What was once itself a new

model, developed as a means of translating emerging scientific knowledge into better medical care, is now accepted as "truth." A move to a more symptom-based approach, as outlined by Tinnetti and Fried (2004), would be a positive step in improving the care of patients with chronic pain and would at least provide a framework for pain and symptom management. "Notwithstanding these structural difficulties and philosophical barriers, medical care must evolve once again to a more individually tailored, integrated model based on the health care needs of patients in the 21st century" (Tinetti & Fried, 2004, p. 183). Although Tinetti's article may be a radical approach to the changes in medical education that need to occur, it illustrates some very important issues (Tinetti & Fried, 2004).

Pain and palliative medicine are good examples of such a failure of medical education to meet the needs of patients in American society. Few medical schools have even a few hours of lecture in these critical topics; fewer still have organized courses for pain, symptom management, and palliative care. (I know of no published surveys of medical schools concerning the amount of time spent on pain and symptom management. However, our group looked at this, peripherally, for osteopathic medical schools. Only one school of 19 had an elective in pain and one other had an hour lecture on pain. There was none in palliative medicine [Peppin, Leeper, & Garloff, 2002]). This is not just of academic concern, but is obviously critical to the care we provide our patients; we all have pain, we will all suffer both physically and emotionally, and we all will die. The dominance assumed by physicians in society, their visceral "evolutionary" instinctive behaviors toward the weak and the patient with chronic pain, the preeminence of business ethics in the moral framework of health care, and the failure of liberal political theories to protect patients in pain must be a primary focus of the academic efforts and thought.

There is no question that our current model of medical education is archaic, self-perpetuating, and a barrier to appropriate pain and palliative medicine; it needs a complete overhaul. Unfortunately, the medical educational system has not voluntarily made the changes that need to occur. It needs to refocus and restructure its basic science and clinical curriculum. Fortunately, education can be changed to make a difference. Weinstein in her 2000 article found that a course in pain management could have a profound impact on students during the 4 years of medical school. These students had a better understanding of pain, were more open to the patient with chronic pain, and were less anxious concerning pain medications (Weinstein et al., 2000). The rationale for the changes in medical education comes from the preceding discussion. Changing medical education might change the instinctual foundation for the poor behaviors in pain management. Further, medical education can strengthen the notions of autonomy through a thorough explanation of HCP behaviors.

Having shown that a "right" to pain management might be developed, it should be pointed out that this is not what drives this author to practice pain medicine. It is not to a secular bioethics but toward "the bioethics of content-full moral commitment" that this author looks for moral direction (Engelhardt, 1996). I agree with Engelhardt that the preceding section "surely has not sustained all the moral propositions that this author knows are necessary for the good life. It is simply that this is all that secular moral reasoning can provide" (Engelhardt, 1996, p. 421). It is the freedom to seek each individual's own notion of the good, whether content-full or not, that is important to maintain.

The disturbing, potentially destructive notions held by HCPs need more and deeper reflection. If we can show that these behaviors do have rationales along the lines I have been discussing, then we can work on changing those behaviors. The HCP educational system can provide the enlightenment that students need to place their own biases and prejudices in context, deal with them, and thereby improve the care of patients in pain. We will unfortunately not find support or help in business ethics as it is currently formulated to protect or give us a foundation to properly care for patients in pain. Further, we should always be suspicious when such institutions claim they are working in the patient's best interest. However, those hospitals, insurance companies, and other health care institutions that choose to have a "content-full moral commitment" should be allowed to do so. There should be no coercion by the central government, and those patients who so choose can use those institutions. HCPs should be aware that relationships with patients have dramatically changed and that our ability to protect patients, especially the weak and those in chronic pain, has been dramatically reduced. Patients should be made aware of this as well. Ground-level patient action groups are the power that is most likely to make substantive changes when it comes to governmental and legislative action.

This is the obvious goal of this chapter and text: improving the care of patients with chronic pain. Our focus should always be the patient and, for our purposes in this chapter, reducing the marginalization that is so inherent in the current health care system for these patients. Interestingly, those health care professionals who treat chronic pain are also marginalized both professionally and financially. This has been a somewhat bleak view of current health care; however, I believe it is accurate. There is also significant potential for change. That change is only going to come from the academy and the specialists contained within. We must be forceful and proactive in our attempts to change the current system. The treatment of the weak, the suffering, and those in chronic pain must be a passion for those health care professionals who specialize in this area. This passion must extend beyond the walls of individual clinics and into legislative bodies, hospitals, and other institutions.

Legal Considerations in Pain Management

James S. Lapcevic, DO, PhD, JD, FCLM

INTRODUCTION

Pain, an important and serious symptom, is one of the most compelling reasons for seeking medical care (Weiner, 1993). Nine of ten Americans age 18 years or older report suffering pain at least once a month, and 42% of adults report experiencing pain every day, with more than 70% surveyed expressing the fear of dying in pain or alone without an opportunity to say good-bye to loved ones (Gallup, Inc., 1999). Chronic pain is an estimated daily experience of 75 million people in the United States (Bostrom, Ramberg, Davis, & Fridlund, 1997). In the last decade interest in pain and management of pain has risen, largely due to the revelation that inadequate pain control is a norm under traditional clinical management (Rorarius & Baer, 1994). Surveys over the past decade have shown as many as 75% of postoperative patients unnecessarily suffer unrelieved pain (Shapiro, 1994). A survey was conducted in an attempt to identify medical personnel and patient attitudes toward the use of opioids in postoperative analgesia with the finding that 82% of surveyed physicians responded that they had not been adequately educated in pain management, while patients indicated more than half wanted decision capacity on when more analgesia should be given them for pain relief (Lavies, Hart, Rounsefell, & Runciman, 1992).

In 1990, a conducted survey of physicians through the Eastern Cooperative Oncology Group (ECOG) found virtually 90% of the physician respondents felt they had received inadequate training in medical school regarding pain management, in particular, cancer pain management, and many were reluctant to prescribe opioids to relieve pain (Von Roenn, Cleeland, Gonin, Hartfield, & Pandya, 1993). In recent years, medical practitioners have gained a new and emerging awareness of pain, its effects on quality of life, and the evaluation and issues involved in its treatment. Although the relief of pain has not always been a priority for medical practitioners, the increasing number of those experiencing pain coupled with other chronic medical conditions now places extreme urgency on physicians to stay abreast of the most current and effective options for pain assessment, evaluation, and management. Much pain remains underreported as well as undertreated (Dahlman, Dykes, & Elander, 1999). Good clinical practice of medicine requires an ongoing effort to access and treat pain with appropriate analgesic therapy (Foley, 2000). Varying patient populations have been found to receive less than quality treatment of their pain if indeed they received any treatment at all (Bernabei, Gambassi, Lapane et al., 1998; Cleeland, Gonin, Baez, Loehrer, & Pandya, 1997; Foley, 1997). Within the last decade it has been reported that a significant percentage of ambulatory patients with cancer have received inadequate pain treatment (Cheville, 2001), with significant percentages of ambulatory patients with AIDS (84%) receiving inadequate pain relief (Portenoy, 2000). Inadequate pain relief particularly has been ascribed to women, elderly nursing home patients, and ethnic minorities.

GUIDELINES FOR PAIN MANAGEMENT

In the past decade, societal and governmental needs have molded medical practice into a less variable, more standardized activity (Hill, 1996a). Guidelines for pain management have been issued by such diverse groups as the WHO, the APS, the American Society of Anesthesiologists, the American Academy of Pediatrics, the Interna-

tional Association for the Study of Pain, and the U.S. Agency for Health Care Policy and Research (AHCPR) (Hill, 1995). Federal oversight of controlled substances extends into community standards of care.

According to the 1992 AHCPR guidelines, opioids may be prescribed to treat acute and chronic pain, but the prescribing physician assumes the burden of proving that the prescription falls within normal clinical procedures for pain management. This burden remains in effect to this day. A physician prescriber of a controlled substance is obligated to demonstrate both the medical necessity and adherence to law of such a choice. Many health care practice acts do not provide for the interpretation of phrases such as "practicing medicine in a manner inconsistent with public health and welfare" (Hill, 1996b). It is often the legal process that later defines concepts of "reasonably necessary" and "good faith" among others that are critical to the justification, and even legal defense, of controlled substance prescribing in any individual case. Allegations of prescribing too much or too little, or not prescribing a controlled substance that was needed according to the definition outlined in federal or state guidelines may be open to court interpretation through expert witnesses brought in by medical boards, plaintiffs, or the Drug Enforcement Agency (DEA). Allegations that prescribing behavior is not in good faith or not reasonably necessary, requirements designed to establish medical necessity, which may be redefined ad hoc, can make it difficult for physicians to justify their treatment decisions. To avoid running an unwitting collision course with these complex issues, better training in proper pain management procedures is necessary for physicians (Carr, 1998). Generally, physicians prescribing scheduled or nonscheduled analgesic medications do so believing patients need them. Physicians must be aware of the immediate medicolegal ramification, including the burden of proof that must be considered when analgesic medications are prescribed (Clark, 1998). It has been suggested that treatment guidelines should ideally be based on data from the medical literature, case law, and clinical experience.

THE PHENOMENON OF UNDERTREATED PAIN

- A standard of care for pain management can be established medically and legally.
- Health care professionals and organizations that fail to meet the standard will be held morally, legally, and monetarily accountable.
- Laypersons take the duty to relieve pain and suffering seriously.
- A painful death is now considered to be a presumptively mismanaged death. (Rich, 2004)

The boards that administer and interpret health care practice acts comprise state government officials' appointees whose members' biases may be reflected in the guidelines (Hill, 1996b). While not all state medical boards hit the mark, many experts favor state medical policy, issuing from the medical boards rather that from elected officials, directly addressing physicians concerns through medical guidelines. In 1999, The Ohio State Medical Association, in cooperation with the state legislature, distributed a new clinical handbook titled, *The Fifth Vital Sign*. Distributed to all physicians, but directed at primary care physicians, the booklet encouraged better pain management including a step-by-step guide to documentation requirement compliance.

AHCPR (1992) issued recommended guidelines for effective pain relief, which promise patients attentive and effective analgesic care as well as quantification in the medical chart of pain assessment and pain relief. The earliest recommendation to establish the basic principles of use of medications for management of pain in adults was formulated after extensive literature review and evaluation of data. Among these basic principles were specialized technology and nonpharmacologic approaches to pain management (AHCPR, 1992). A systematic review of the literature was used to compile evidence for each mode of pain relief (Carr et al., 1992) (Table 92.1):

- *Type I* evidence comes from large trials.
- *Type Ia* evidence is derived from multiple, randomized, controlled trials that may be consolidated utilizing meta-analysis.
- *Type Ib* data originate from at least one large, randomized, controlled study with statistically significant results.
- *Type II* studies involve well-designed but nonrandomized comparisons.
- *Type III* evidence is from descriptive studies.
- *Type IV* evidence is expert consensus, based on the opinions of prominent practitioners.

Organizations and publications have also developed evidence-grading scales. The diversity of these scales can be confusing. Formation of a unified taxonomy has been proposed and is under development to evaluate the strength of recommendations based on a body of evidence (Figure 92.1). The new taxonomy is recommended to (Ebell, Siwek et al., 2004)

1. Be uniform in most medicine journals and electronic databases
2. Allow evaluation of the strength of recommendation of a body of evidence
3. Be comprehensive and allow evaluation studies of screening, diagnosis, therapy, prevention, and prognosis

TABLE 92.1
Pain Management Guidelines: Medication for Management of Pain in Adults

Medication	Evidence*	Comments	Precautions
Oral NSAIDs	Ib, IV	Effective for mild-to-moderate pain; begin preoperatively; relatively contraindicated in patients with renal disease and risk of or actual coagulopathy	May mask fever
Oral NSAIDs in conjunction with opioids	Ia, IV	Potentially effect resulting in opioid sparing; begin preoperatively	As above
Parenteral	Ib, IV	Effective for moderate-to-severe pain; expensive; useful if opioids contraindicated, especially to avoid respiratory depression and sedation	As above
Oral opioids	IV	Route of choice; as effective as parenteral in appropriate doses	Use as oral medication tolerated
Intramuscular	Ib, IV	The standard parenteral in appropriate doses	Hence, avoid this route when possible
Subcutaneous	Ib, IV	Preferable to intramuscular route when low-volume continuous infusion is needed and intravenous access is difficult to maintain; injections painful and absorption unreliable	Avoid this route for long-term repetitive treatment
Intravenous	Ib, IV	Parenteral route of choice after major surgery; suitable for titrated bolus or continuous administration but requires special monitoring	Significant risk of respiratory depression with inappropriate dosing
PCA (systemic)	Ia, IV	When suitable, provides good analgesia	Significant risk of respiratory depression with inappropriate dosing
Epidural and intrathecal opioids	Ia, IV	When suitable, provides good analgesia; use of infusion pumps requires additional equipment and staff education; expensive if infusion pumps are used	Significant risk of respiratory depression; sometimes delayed in onset; requires careful monitoring

Note: Ia = evidence obtained from meta-analysis of randomized controlled trials. Ib = evidence obtained from at least one randomized controlled trial. II = well-designed nonrandomized studies. III = descriptive studies. IV = expert consensus based on the opinions and/or clinical experiences of respected authorities. NSAID = nonsteroidal anti-inflammatory drug. PCA = patient-controlled analgesia.

The newfound appreciation for aggressive action in treating acute pain resulted in the Federation of State Medical Boards of the United States, Inc. (1998) promulgating model guidelines for pain management strategies and objectives. Clinicians will be potentially held to these guidelines, and the quality of medical practice will be judged in part by the ability to meet these criteria. Some states have adopted even more stringent guidelines for pain treatment: at present, certain barriers to delivery of adequate analgesia and pain management exist. Members of the health care team, patients, and the health care system continue impeding the delivery of proper analgesia (Jacox et al., 1994) (Table 92.2).

FOCUS ON PAIN

In 40 states, a variety of efforts have been made to improve pain management. Individual state laws have tended recently to follow the recommendations made by the Federation of State Medical Boards. Most state laws regarding the management of pain are still evolving. Some of these efforts have been undertaken by *lawmakers* through specific *legislation*, or by *regulators* through new *regulations*; others are a result of revised or newly adopted guidelines and policy statements on pain treatment from state medical boards. Aimed at making standards uniform across the nation and encouraging better pain management, physicians who prescribe a controlled substance "for a legitimate medical purpose" are reassured not to worry about medical board, state regulatory, or enforcement agency actions. The Federation initiative was endorsed by the DEA and by advocates for better pain management. The medical use of controlled substances has gained a new legitimacy, but physician fears of regulatory scrutiny continue to linger. The careful physician, in attempting to steer a course clear of regulators, must be prepared to prescribe opioid analgesics utilizing a consistent methodology. This consistent methodology is analogous to the checklist pilots use, no matter their experience, preparing for take off, landings, and other aircraft performance standards on which safe pilotage is based. Tips for prescribing opioids under a consistent methodology are as follows:

TABLE 92.2
Barriers to Delivery of Adequate Analgesia

Health Care Professionals	Reasons for Patient Reluctance to Report Pain	Health Care System
Inadequate knowledge of pain management (especially clinical pharmacology)	Fear of patient addiction	Concerned about adverse reactions and development of tolerance
Poor assessment of pain	Fear that pain means progression of disease	Low priority given to pain management
	Want to be a "good" patient	Inadequate reimbursement
Concern about:		
Regulation of controlled substances	Do not want to distract physician from treating underlying disease	Limits availability of treatment
Side effects of pain management	Reluctant to take pain medication	Limits access to treatment
Development of tolerance	Fear of addiction or of being classified as an addict	Restrictive regulation of controlled substances

Note: Modified from *Management of Cancer Pain. Clinical Guideline,* by A. Jacox et al., 1994, Rockville, MD: U.S. Department of Health and Human Services.

- Obtain a thorough history and perform a first rate physical examination (sound familiar?).
- Chart everything you see, think, feel, and hear about the patient.
- Obtain informed consent for long-term opioid therapy.
- Obtain a second opinion from a colleague to verify the plan of care if you are not a pain practitioner.
- Convince the patient to agree to use only one pharmacy and to obtain opioids only from you.
- See the patient regularly (at least every 30 to 90 days); prescribe controlled-release medications to stabilize the blood levels to limit the "buzz" associated with immediate release medications.
- Keep the dosages controlled to the amount necessary to provide comfort.
- Check the urine drug screen to make certain what you are prescribing is being taken and that illicit substances are not being used.
- Obtain more education about the use of opioid analgesics.

Does it seem likely that you would ever be accused of improper behavior if all of these steps were followed (Cole, 1998)?

Historically, from the advent of the Victorian era until after World War I, doctors were held largely responsible for the heroin, morphine, opiate, and cocaine problems that swept the United States. The Harrison Narcotic Act of 1914 began the heavy-handed crackdown on narcotics that narrowed the scope of medical practice and interfered with their legitimate medical use, especially in pain management (Guglielmo, 2000). A short decade ago, conven-

tional wisdom in the medical establishment was that a physician treating chronic pain with opioids was at substantial risk of sanction by state medical regulatory boards for overprescribing (Hill, 1993; Joranson, 1992; Portenoy, 1996). A review of state medical board actions from 1990 to 1996 reveals that the perception of regulatory risk far exceeded the reality (Martino, 1998). A California study concluded that most offenses of disciplined physicians involved some aspect of patient care (e.g., inappropriate prescribing) (Morrison & Wickersham, 1998). Regulatory risks associated with overprescribing are still perceived as real and far greater than those associated with underprescribing despite regulatory relief efforts (Glanelli, 1999). The premise of the regulatory relief efforts was the undertreatment of pain is a public health problem. Regulatory relief has seemed to fail to alter significantly the perception of risk associated with the physicians prescribing opioids for the treatment of chronic pain. Ann M. Martino, Ph.D., while executive director of Iowa's Board of Medical Examiners, recommended that new laws be written to discipline physicians who prescribed too little pain medication. Ironically, she wrote that the most immediate means of achieving good pain management may not be regulatory relief, but more regulation (Martino, 1998).

It has been recommended that physician education is key to better pain management. Knowledge of the best pharmaceutical and nonpharmaceutical methods for controlling pain and of the federal and state laws that apply to medical practice is recommended at "should know" levels. State medical boards or medical societies are good resources for current laws that apply to medical practice. Caveat: A potent reminder finds that knowledge alone is insufficient to promote behavioral change (King, Bungard, McAlister et al., 2000); in the absence of other actions, such as steps toward disseminating a medical guideline or

providing continuing medical education, it is unlikely that significant, or even measurable, improvement in the effectiveness of an intervention might occur (Goff, Canely, & Gu, 2000).

For decades, improving the quality of health care delivery relied on changing physician behavior. Experience has shown that quality improvement is better achieved through systems solutions that *support clinicians* in providing quality care (Calonge, 2000). The imperative to measure, promote, and improve the quality of medical care continues to be an essential, if not daunting, endeavor. The quality of health care is, in the opinion of many, a serious problem. Research demonstrates that physicians overuse health care services by ordering unnecessary interventions, underuse services by failing to provide a standard of care that would produce favorable outcomes, and *devise* an *incorrect* treatment plan or improperly execute the correct plan (Chasin & Galvin, 1998; Leape, 1992, 1994; Nyquist, Gonzales, Steiner, & Sande, 1998). Quality assurance in the health care system is an important public health objective (Lohr, 1990). The lessons of history confirm that the medical factors that have prompted medical malpractice litigation still continue as advocated in the public interest: scientific innovation, uniform standards, and liability insurance (Gostin, 2000).

From a legal perspective, government directly and indirectly (through tort law) regulates the health care system. Medical malpractice litigation ostensibly seeks higher-quality care. Tort law, on the other hand, functions to deter substandard medical conduct, to avoid unnecessary injury, and as a fair method of compensation. Several reform methods are currently under public debate; the most prominent among these proposals is capitation on damages. Although enacted in some states, this approach does not eliminate liability, it is proposed that such action would decrease fear of inordinate damage awards. It is commendable that the various medical organizations proceed with pressing for caps legislation, but at the same time, more of an effort should be made to press for court reform and legislative proposals possessing reasonable chance of successful passage in the next year (Post, Brady, McCaulley, & McGuire, 2004).

EMERGING STANDARD OF CARE IN PAIN MANAGEMENT AND LEGAL IMPLICATIONS

The rapidity of change in the clinical practice of medicine has brought frustration because of decreased autonomy, increased oversight, pressures on reimbursement, and allegations of fraud and abuse. Malpractice and legal complications of care have increased. Despite the widespread promulgation of the benefits of opioid analgesics in all types of pain states — acute, chronic, and malignant — fear and trepidation remain on the part of prescribing

TABLE 92.3
Key Points Included in the Controlled Substances Act

- Opioids are necessary to public health.
- A mechanism is devised for external medical input.
- Drug availability is guaranteed.
- The federal definition of an addict does not include the patient with chronic pain.
- Regulations specifically recognize the treatment of intractable pain with opioids.
- Prescription size is not restricted.
- Without a special license granted by the DEA, physicians may not provide methadone maintenance for patients with known addiction to controlled substances.

physicians. The Uniform Controlled Substance Act of 1970 provides for the registration of those handling controlled substances, as well as for labeling, order forms, record keeping, and reporting of substances or their use. Key points included in the Controlled Substances Act are listed in Table 92.3 (Clark, 1998).

The issues of safety, efficacy, and compliance associated with most statutes are based on the 1970 Model Uniform Controlled Substances Act. It is the intricacies and interrelationships between federal and state laws regulating the prescribing of opioid analgesics that have been repeatedly identified as one of the more significant barriers to the provision of effective pain management and palliative care. The barriers to pain management provide plausible reasons for so many patients to experience undertreated pain. Collectively, these barriers have either contributed to or caused an enduring epidemic of pain and suffering trailing in the wake of untreated pain (Rich, 2000). Patient-related barriers to good pain management also exist. The general public is ignorant and fearful of opioid analgesics, and reluctant to be viewed as too demanding of more in the way of care than has been proffered. Laypersons can hardly be more sophisticated and knowledgeable about an emerging aspect of clinical medical practice than health care professionals (Cleeland, 1992). In 1996, an international panel of distinguished health care professionals assembled by the Hastings Center (1996) identified the goals of medicine as follows:

- The prevention of disease and injury and promotion and maintenance of health
- The relief of pain and suffering caused by maladies
- The care and cure of those with a malady, and the care of those who cannot be cured
- The avoidance of premature death and the pursuit of a peaceful death

The stated goals strike a remarkable balance between the *curative* and the *palliative* approaches to patient care

and are the hegemony of the curative model that is the hallmark of modern medical education and practice reflects a medical ethos inconsistent with the core values of medicine (Rich, 2000).

EMERGING LIABILITY ISSUES IN THE MANAGEMENT OF PAIN

It is argued that there are three essential duties of a health care professional regarding pain management:

1. The first duty is to minimize iatrogenic (physician-induced) pain; no further pain and suffering are to be inflicted upon a patient beyond the unavoidable consequence of a reasonable effort to effect a cure (Edwards, 1984).
2. The second duty is to be a competent practitioner in pain management. Effective application of state-of-the-art pain relief techniques is required to relieve as much pain as possible without imposition of patient burden that exceeds benefits. This is a duty that can reasonably be placed on all physicians who care for patients in pain and not one reserved for pain or palliative care specialists only. It is time for those physicians who are most likely to see chronically ill patients in the first line of duty (general practitioners, oncologists) to make pain control and palliative care a part of routine clinical practice (Stjernsward et al., 1996)
3. The third duty is to adequately inform the patient of the risks and benefits of alternative pain management strategies, including that of not pursuing pain relief (Emanuel, 1996).

Additionally, physicians have a duty to continue their education throughout their professional lives to maintain their practices consistent with current advances in science and technology.

The issue of whether physicians should be insulated from ethical and legal responsibility for undertreating pain due to deficiency in this area of medical education was in seemingly direct contradiction to the AMA Principles of Medical Ethics and the current opinion of the AMA on Professional Rights and Responsibilities (AMA, 1996).

There is a developing health care professional consensus that failure either to manage effectively pain that can be managed or to refer the patient to a professional who can bring state-of-the-art techniques to bear on the problem constitutes a breach of professional ethics and a departure from an emerging standard of care (Oherney & Catane, 1995). The concept of the patient's legal right to effective pain management and the correlative duty on the part of physicians, because of their virtual monopoly on

TABLE 92.4
Liability Issues in Pain Management

Liability to Patients
- For cost-containment practices that affect pain management (Townsend, 1983)
- For inappropriate pain management (*Bergman v. Eden Med. Ctr. et al., No. H205732-1 Sup. Ct. Alameda Co., Cal. 2001*)

Liability to Third Parties
- For injury caused by patients treated for pain (Heller, 1992; Vainio, 1995; *Wilchinsky v. Medina*, 775 P.2d 713 [NM 1989])

the authority to prescribe narcotics to provide effective pain management to patients, has begun to emerge in the last decade (Table 92.4).

One of the first serious discussions on poor pain management as an example of medical malpractice was conducted by Margaret Sommerville, a Canadian legal scholar and bioethicist. With the prevailing standard of care, it is argued that, because it is abundantly clear that physicians traditionally fail to alleviate pain, a patient would find it difficult to establish undertreatment of pain as a departure from the applicable standard of care (Sommerville, 1986). The failure of the medical profession to adopt and consistently apply readily available therapeutic modalities that would improve patient care presents precisely a situational scenario ripe for judicial standard setting. With deficiencies in prevailing custom and practice of medicine so clearly inconsistent with the traditionally attributable goal, the medical profession appears negligent (The T.J. Hooper, 60 F.2d 737.740 [2d Circ. 1932]).

A primary impetus for the promulgation of clinical practice guidelines for pain assessment and management has been the demonstration, through recent studies, that many health care professionals lack, or fail to apply, basic knowledge and skills in this area. A declaration that "not relieving pain brushes dangerously close to the act of willfully inflicting it" has become one of the strongest statements recorded from an objective, nonclinician perspective (Morris, 1991, p. 134). The willful infliction of pain is torture, which is foreclosed to the government by the Eighth Amendment to the U.S. Constitution, as "cruel and unusual" even in punishment of convicted criminals.

TOWARD A NEWER MEDICAL MODEL

Inadequate pain control appears to be the spur for increased interest in physician-assisted suicide, but one reason for inadequate pain management is an unfounded concern of both patients and health care providers that pain control is a form of euthanasia. Euthanasia refers to the intentional act of painlessly putting to death persons with incurable and distressing disease as an act of mercy

(*Black's Law Dictionary*, 1979). Appropriate pain management aims to reduce suffering, not cause death.

In January 1998, Kirk Robinson, president, and Kathryn Tucker, director of legal affairs, for the Oregon-based organization Compassion in Dying Federation (CIDF) sent a memorandum to every medical board in the United States arguing that dying patients have a right to adequate pain medications. Although the focus of the memorandum was end-of-life care, it outlined a series of steps for each state board to follow in addressing the perceived risks for overprescribing controlled substances and the absence of any risk real or imagined for underprescribing medications to any patient experiencing pain. The idea that state medical boards should take on the responsibility of scrutinizing licensees for inadequate pain care was urged, as well as the adoption of underprescribing as a ground for discipline. Additionally, the CIDF put all boards on public notice that it was willing to assist patients suffering chronic pain and their families in making complaints and/or in filing suits against practitioners who failed to provide adequate pain relief through underprescribing.

In July 1994, the California Medical Board (1994a) issued a formal statement on "Prescribing Controlled Substances for Pain Management." The board stated that "principles of quality medical practice dictate that citizens of California who suffer from pain should be able to obtain the relief that is currently available" and that "pain management should be a high priority in California." Concomitantly, the board issued "Guidelines for Prescribing Controlled Substances for Intractable Pain," which included the following admonition: "The Board strongly urges physicians to view pain management as a priority in all patients. Pain should be assessed and treated promptly, effectively and for as long as the pain persists. The medical management of pain should be based on up-to-date knowledge about pain, pain assessment, and pain treatment" (Medical Board of California, 1994a).

The legal theory of negligence in medication error lawsuits can be applied to cases claiming inappropriate management of pain (Frank-Stromborg and Christiansen, 2000). In any allegation of inappropriate pain management, the patient (plaintiff) must prove:

- That a duty of care was owed to the patient by the defendant (health care professional),
- That duty owed was breached with conduct that violated a standard of care recognized in the profession,
- That breach of the duty owed was the cause of injury or the suffering, and
- The patient (plaintiff) suffered damages as a result (Keeton, Dobbs, Keeton, & Owen, 1984).

In cases involving pain control, the professional will be judged according to the expectation of what a reasonable practitioner would have done in similar circumstances (Willis, 1998). In general, the standard of medical care a physician may with reason and fairness be expected to possess is that commonly possessed or reasonably available to minimally competent physicians in the same specialty or general field of practice throughout the United States. A physician should have a realistic understanding of the limitations of his or her knowledge or competence and, in general, exercise minimally adequate medical judgment (*Hall v. Hilbun,* 466 So. 856, 871 [Miss. 1985]). In litigation, the appropriate specialist is located to provide information through testimony about the standard of care and any deviation from such standard. A minority of jurisdictions take the position that adherence to customary practice should not insulate a physician from malpractice liability if the patient (plaintiff) can provide persuasive evidence that the physician failed or refused to apply readily available measures that would have prevented harm to the patient. The Wisconsin Supreme Court stated that should customary medical practice fail to keep pace with developments and advances in medical science, adherence to custom might constitute a failure to exercise ordinary care (*Nowatske v. Osterlok,* 543 N.W. 2d 254 [Wis. 1996]). Adherence to custom is not the sole test of professional malpractice (*Toth v. Cmty. Hosp.,* At Glen Cove, 239 N.E. 2d 368,373 [N.Y. 1968]). The notion that an entire medical specialty (*Helling v. Carey,* 519 P.2d 981 [Washington, 1974]), or at least all the members of a particular locale, would never be guilty of negligence by adhering to a substandard of care fell to a Louisiana appellate court statement: "We are firm in the opinion that it is patently absurd, unreasonable, and arbitrary to hold that immunity from tort liability may be predicated upon a degree of care or procedure amounting to negligence, notwithstanding such procedure is generally followed by other members of the profession in good standing in the same community" (*Favalora v. Aetna Cas. & Sur. Co.* 144 So.2d 544, 551 [La. Ct. App. 1962]).

Most lawsuits brought by patients against health care providers are for medical malpractice, which is defined as a breach of accepted medical practice resulting in injury and legally recognized damage to the patient. Courts are now willing to hold physicians liable for allowing a patient to suffer because of a failure to provide appropriate pain relief under the recognition of improper pain management as a breach of good and acceptable practice. A medical malpractice judgment exceeding $1 million against the Veterans Administration included an award of $125,000 for pain and suffering predicated largely upon the defendants' failure to provide sufficient pain medication in the final days of the patient's life (*Gaddis v. United States,* 7F. Supp. 2d 709 [D.SC. 1997]). The primary claim and bulk of the total award for damages in this South Carolina case were based on a failure to timely and properly diagnose and treat the patient's throat cancer.

In California, William Bergman, a man in his early 80s, wrenched his back pulling a battery out of a car. Over the next few days he developed more and more back pain, which was originally thought to be a strain-sprain until the patient became immobilized due to the pain (Tucker, 2000). He was taken to the emergency room of a northern California hospital whereupon he was hospitalized for severe pain in his back with a diagnostic finding of metastatic lung cancer. The patient indicated he wished no treatment for his cancer but wished only to receive pain medication that would allow him to return to his home and functionality for what time he had left. Dr. Wing Chin became Mr. Bergman's assigned physician for his hospitalization. The patient was reported by nursing staff to have increasing VAS ratings despite receiving meperidine on an as-needed (prn) order for pain relief based on patient request. Bergman was subsequently discharged to his home with the oral pain medication, hydrocodone and acetaminophen (APAP). Meperidine is inadequate for cancer pain relief and is inappropriate for use in the aged due to nervous system toxicity that may develop as a side effect of metabolite formulation. Morphine agents are appropriate for cancer pain relief. Oral hydrocodone and APAP are indicated for moderate to moderately severe pain. Pain medication for cancer pain relief should be give at specific times, not on an as-needed (prn) basis. Dr. Chin was called regarding Mr. Bergman's pain after discharge from the hospital and when asked about morphine agents for pain relief, the family was told that he (Dr. Chin) did not possess the required multiple prescription form pad to order these pharmaceuticals for patient use. After 2 days at home in what was described as "agonizing pain," a hospice nurse succeeded in contacting William Bergman's regular physician, who immediately administered oral morphine achieving pain relief. Mr. Bergman died comfortably the next day.

Mr. Bergman's daughter (Beverly Bergman) was so disturbed by her father's suffering that she made formal complaint, supported by independent expert opinion, to the Medical Board of California (MBC), that the pain care provided to an elderly, terminally ill patient with cancer was inadequate. California is among the most progressive states in attempting to improve pain care. In 1994, the MBC (1994b) adopted official guidelines on pain management, which specifically identifies failure to adequate, manage pain as "inappropriate prescribing." The MBC expressly recognized that this is a form of professional misconduct, subject to the full range of sanctions.

The MBC agreed with Beverly Bergman that the physician had failed to provide adequate pain care but declined to take any action against the physician (MBC Letter, 1998). It was not until after the MBC conclusion that a formal complaint was filed.

In February 1999, what appears to be the first suit filed against a physician, grounded primarily on failure to prop-erly manage a patient's pain, was filed in Superior Court of California (*Bergman v. Eden Med. Ctr. et al., No. H205732-1* [*Sup. Ct. Alameda Co., Cal. 2001*]). Cases of inadequate pain treatment may result in civil liability (tort cases) with significant financial implications. The unusual aspect of the *Bergman* case was that a cause of action under the California Elder Abuse Statute was included, which provided for heightened remedies to what would not be available under a medical malpractice claim, including awarding punitive damages, no cap on damages, and paying attorney's fees. The defendant physician and hospital agreed that the family was entitled only to the limited remedies available in a malpractice claim and repeatedly disputed the elder abuse cause of action, and petitioned for it to be dismissed. In January 2000, the court ruled against dismissal of the elder abuse claims, recognizing that inadequate pain care can constitute elder abuse. In 2001, the case was tried before a state court jury in California where the sole claim was failure of the physician to adequately treat the pain of an elderly main dying of a painful form of lung cancer. The plaintiff's lawyers succeeded in demonstrating that the physician had little concept of the body of authoritative literature governing pain management, and had not stayed current with the many developments in the field since graduation from medical school some 30 years prior to the time of this trial and treatment of the patient. It was further shown that he had used outmoded and discredited strategies and the patient suffered unnecessarily during his final week of life as a result. The jury hearing the case determined that the physician's conduct was reckless. Under the elder abuse cause of action, plaintiffs were required to prove reckless, as apposed to simply negligent, conduct. This heavy burden was apparently carried successfully and the family of the deceased, Mr. Bergman, was awarded $1.5 million for the patient's pain and suffering under the State Elder Abuse Statute (*Bergman v. Eden Med. Ctr. et al., No. H205732-1* [*Sup. Ct. Alameda Co., Cal. 2001*]). Kathryn Tucker, Esq., director of legal affairs for the Compassion in Dying Federation, explained that a successful trial meant the Bergman family would be able to recover significant damages and as exposure for inadequate pain care becomes more significant, providers will be more motivated to attend and treat pain properly under exposure to significantly greater financial risk (Albert, 2001).

Dying patients clearly have the right to adequate pain medication; this was recently recognized by the Supreme Court of the United States (Burt, 1997; *Vacco v. Quill,* 521 U.S. 793 [1997]; *Washington v. Glucksberg,* 521 U.S. 702 [1997]). The duty of a physician when treating a patient experiencing pain associated with a terminal illness is to inform the patient of the possible treatment options from management of the pain and the anticipated side effects of any such treatment including having no treatment at all, and to permit the patient to make an informed choice

about the treatment. Increasing dosage of strong pain medication such as morphine may have a foreseeable but unintended consequence of suppressing respiration and possibly advancing time of death. The "double effect" is accepted in medical ethics and practice and has been endorsed by the U.S. Supreme Court. Whether to accept the double effect risk of medication must be the patient's choice, not an imposition by a paternalistic physician (*Washington v. Glucksberg*, 521 U.S. 702 [1997]). A second recent case resulted in a negotiated out-of-court settlement of damages apparently using leverage from the *Bergman v. Eden Med. Ctr.* case.

Illustrative of the law's recognition that assurance of comfort and appropriate pain control are integral components of appropriate medical care is the case *State v. McAfee,* 385 S.E. 2d 651 (Ga. 1989). Mr. McAfee, a quadriplegic who was incapable of spontaneous respiration, sought court approval for discontinuation of his respirator. The Georgia Supreme Court affirmed the patient's right to refuse medical treatment and held that he was also entitled to have a sedative administered at the time of discontinuation of the respirator. That Mr. McAfee had the right to be free from pain at the time the ventilator is disconnected is inseparable from his right to refuse medical treatment. The record shows that Mr. McAfee had attempted, in the past, to discontinue his ventilator, but has been unable to do so due to the severe pain he suffered when deprived of oxygen. His right to have a sedative (a medication that in no way causes or accelerates death) administered before the ventilator was discontinued is a part of his right to control his medical treatment. The implication flowing from this court's ruling was that providers may be held accountable for not providing such measures (Shapiro, 1994).

In a North Carolina negligence lawsuit, a health care facility was held liable for the first time for failure to treat serious pain appropriately (*Estate of Henry James v. Hillhaven Corp.* No. 89 Civ. 65 [Hertford County Superior Ct. N.C. Nov. 20, 1990]). Henry James, 74 years of age, a retired house painter, was diagnosed with cancer of the prostate for which he was subjected to removal of his testicles. The cancer, however, was metastatic in nature, having spread to his leg and spine. His pain was severe and excruciating. He was place in a nursing home in February 1987. Almost at once, the nursing staff began cutting his prescription pain medications by giving him on some days mild headache-related medicines, placebo substituted for morphine, or nothing at all. The nursing supervisor explained to the family that Mr. James was in danger of becoming a drug addict and because Mr. James and his family were Medicare and Medicaid recipients, she did not like her tax dollars supporting his drug habit. Eventually, Mr. James became irritable, withdrawn, and bedfast, where he laid sweating and moaning in pain,

dying 4 months later. His family eventually filed a complaint with a state regulatory agency and went to court.

On November 20, 1990, the verdict was that the nursing home had been negligent in failing to provide Mr. James adequate pain relief. At the trial, Catherine Faison, James's great niece, explained that as far as the nursing home was concerned, when he died, it was a closed issue; it was over. "It's not over for me," Faison told the jury. "I can't sleep at night when I think about the fact that he had to lay over there and suffer.… I think about him laying there hurting, saying I want my medication, and not being able to get it. I don't want to suffer like that.… I don't think anybody would. Somebody needs to say you can't do it."

Safe harbor provisions in intractable pain legislation enacted in many states grant immunity from discipline to physicians who treat intractable pain. These enactments clarify the position that physicians shall not be disciplined for treating intractable pain with large doses of medication, even if such prescriptions hasten the moment of the patient's death, as long as the intent is simply to alleviate pain. Such provisions are designed to clear the confusion that may occur because of the similarity with prescribing medications to end a patient's life.

In 1999, the Oregon Board of Medical Examiners disciplined a physician for the undertreatment of a patient's intractable pain. Dr. Paul Bilder, an Oregon pulmonary specialist, was disciplined for a pattern of failing to treat pain adequately (Goodman, 1999). The physician was reported to have undertreated patients as follows (Mascheri, 1999):

1. Tylenol was used to treat the musculoskeletal pain of an elderly male patient with cancer, denying requests for stronger medications when pain increased. He also denied a nurse's request for catheterization, citing a risk of infection. The patient died the next day.
2. He removed a catheter from an 84-year-old man against the patient's and family's requests, directing that he instead use diapers. He further reduced a hospice nurse's requested dose of 5 to 20 mg of Roxanol every 4 hours to 0.25 cc and gave Tylenol to treat the patient's 102° temperature. The patient died that evening.
3. He refused a request for sedatives and pain control for a 35-year-old intubated, mechanically ventilated woman who became increasingly restless, had increased wheezing, and was fighting the ventilator. After the patient extubated herself, the doctor ordered a paralytic agent but no sedative following reintubation.
4. He used physical restraint to intubate a 33-year-old man without using anxiolytics or narcotics. The patient had been admitted with severe

pneumonia associated with hypoxemia. The physician, it is claimed by the board, engaged in "unprofessional or dishonorable conduct" and "gross negligence or repeated negligence," according to a stipulated order released by the board. While the physician will not lose his license, this is the first time a state board has taken this type of action.

Thus, in addition to potential liability to patients for inappropriate pain management, professional discipline of health care professionals also may ensue. As a result of development and growing acceptance of pain management guidelines, medical boards may be more inclined in the future to undertake disciplinary action for inadequate pain management.

Increased use of advanced directives resulting from passage of the Federal Patient Self-Determination Act (effective December 1, 1991) also may increase physicians' exposure to professional discipline for inappropriate pain management (Patient Self-Determination Act, 42 U.S.C. § 1395 cc [1990]).

In the interests of sustaining protection, physicians are advised to honor appropriate pain management instructions set forth in patients' advanced directives. Where questions or concerns arise about complying with such pain management instruction, ethics committees should be consulted (Shapiro, 1994).

Appropriate pain management aims to reduce suffering, not cause death. When physicians deliberately administer lethal doses of medications — even for reasons of compassion — they risk prosecution for homicide, and when lethal doses of medications are prescribed, they risk prosecution for assisting suicide.

Investigations of physicians for alleged excessive prescribing of pain medication reduce physician willingness to treat pain with strong pain medication prescriptions. This is one factor contributing to the problem of undertreatment of pain. During the past few years, aggressive educational efforts have begun to correct the undertreatment of pain and other physical suffering in dying patients — a major failing in medical care (Noble, 1999).

Historically, to date, only the state of Oregon has passed a law permitting physician-assisted dying (Or. Rev. Stat §§ 127.800 to 127.897, 1996). Opponents made many attempts to defeat the Oregon Death With Dignity Act (ODWDA). The same opponents then sought in two successive sessions of Congress to amend the Controlled Substances Act of 1970, ("CSA") 21 U.S.C. §§ 801–904 and expand the scope of it to reach the ODWDA to destroy it through the Lethal Drug Abuse Prevention Act of 1998 and the Pain Relief Promotion Act of 1999 (PRPA).

Both the proposed acts failed due to strong opposition from the medical community, based on the concern that the proposed measures would exacerbate physicians' fears regarding use of controlled substances for pain management (Orentlicher & Caplan, 2000). Under the Bush Administration, Attorney General John Ashcroft issued a directive on November 6, 2001 (*Ashcroft Directive* 66 Fed. Reg. 56.607 [Nov. 9, 2001]), the latest Federal government attempt to attack and destroy the Oregon Death With Dignity Act. The *Ashcroft Directive* was challenged in Federal Court by the State of Oregon, an Oregon physician and pharmacist, and a group of terminally ill Oregonians, who asserted that the Ashcroft Directive violates the CSA (Controlled Substances Act), the APA (Administrative Procedure Act), and the U.S. Constitution. *Oregon v. Ashcroft,* 368 F.3d 1118 (9th Cir. 2004), *aff'g.* 192 F. Supp. 2d 1077, 1092 (D.Or. 2002), *cert. granted sub nom. Gonzales v. Oregon, 73 U.S.L.W. 3298* (U.S. February 22, 2005) (No. 04-623). Among the most important findings emerging from the data from the Oregon Legalized Practice of Assisted Dying is the clear evidence that the availability of the option for assisted dying serves as a catalyst for improved end-of-life care and specifically for improved pain care. Some religious organizations and right-to-life activists continue to obstruct and seek to nullify legislative reform although even staunch opponents of the practice of assisted dying increasingly recognize that continued opposition cannot be justified in the light of Oregon experience (Tucker, 2004).

A significant opportunity exists for medical boards at the state level to take a leadership role in the proper treatment of pain and become a viable and reliable resource in both the legal and the medical communities. Instead of enacting more statutes, efforts should be directed toward adoption of "informed guidelines" or "policy statements" by medical boards to address the proper treatment of pain and legitimate use of opioids.

Physician fear of prosecution or investigation continues to be a barrier to pain relief in our present society even though social science literature indicates the likelihood and frequency of prosecution or investigation is extremely low with overall prosecution surrounding the prescription of opioids being found to be rare (Ziegler & Lovrich, 2003). The use of opioids in the management of pain is a legitimate and recognized protocol in medicine with a rate of addiction that is really quite low. Both law and medicine recognize that patients have a right to adequate pain care. Doctors who prescribe opioids for extended periods are acting well within the professional practice of medicine, and in fact, the frequency, amount, and chronicity of opioid prescriptions are not particularly indicative of inappropriate treatment protocols. Without considering the individual patient, the aspect of dispensing practice is not determinative of abuse or diversion.

Pain is one of the most common reasons for seeking medical care, yet it is often inadequately treated. Pain is dehumanizing, a destroyer of autonomy, and humiliating. In its extreme, pain has the capacity to destroy the soul

and all will to live (Post, Blustein, Gordon, & Dubler, 1996). Untreated, the pain accompanying illnesses slows recovery, severely impairs an individual's quality of life, and adds significantly to the health care system's financial burden. The Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards (the new evidence-based pain management standards introduced by JCAHO) (Phillips, 2000) assert that individuals seeking care at accredited hospitals, behavioral health facilities, and health care networks have the right to appropriate assessment and management of pain. All patients are to be screened to characterize their pain by location, intensity, and cause, including a detailed history, physical examination, psychosocial assessment, and diagnosis evaluation. The most reliable indicator of pain existence and intensity is the patient's self-report because it is more accurate than others' observations. These standards do not dictate specific pain management procedures nor advocate in any way the use of certain drugs (e.g., opioids).

Debilitating pain has reached epidemic proportions in the United States. Many physicians nevertheless fear that dispensing opioid medications for patients suffering from pain will result in negative patient outcomes; heightened scrutiny from medical licensing boards, county prosecutors, and federal government; or may promote iatrogenic addiction, despite the fact that the documented rate of addiction in patients using opioids is extremely low. Chronic pain is notably undertreated and the amount of opioids clinically indicated for each patient suffering from pain is highly individualistic. Dosage awarded for one patient suffering from chronic pain or for a patient in an end-of-life situation may be wholly inappropriate for another patient.

A discussion of the emerging standards and guidelines (Jacox, Carr, & Payne, 1994), coupled with developing disciplinary and legal consequences to mold physician action and "standardize" delivery of medical care utilizing the fulcrum of "inadequate pain management" as "inappropriate medical care," appears designed to move physicians into fungible units in need of surveillance to assure compliance with all controlling legal authority. During the past 30 years, the ethics of the medical care in the United States has changed radically from a traditional paradigm of the largely paternalistic doctor decision making of what is medically appropriate to a present form of governing ethic, which is totally anti-paternalistic in nature. Legal scholars, bioethicists, physicians, and judges have made a powerful case for patient autonomy and have objected to paternalistic medicine on the grounds that it supplants patient values and patient preferences with those of the provider. In the treatment of pain, a physician is not limited to prescribing levels that appear in the package insert or in the *Physician's Desk Reference,*

and a physician who is authorized to prescribe opioids may do so as long as they are for a legitimate medical purpose and the physician observes the procedures of good medical practice (Cole, 1998).

The key to distinguishing between aggressive palliative care and euthanasia remains one of intent. Intent often escapes exacting proof. Recent attempts at legislation in the area of opioid use in terminally ill patients have been unsuccessful in part because opponents to that legislation had extreme concerns regarding the difficulty in the determination of intent. Through all the sophisticated advances in medical technology and disease management, bioethical discourse is framed in terms of balancing the values and interests with the benefits and burdens that underpin principled decisions about how, when, and whether intervention should occur. Despite all these advances, one mandate remains constant and compelling for physicians, and that is the relief of pain.

When cure is impossible, the physicians' duty of care includes palliation with the centrality of this obligation being both unquestioned and universal, transcending time and cultural boundaries. Treatment of pain is supported by the ethical principle of "double effect." Under this principle a good effect, "relief of suffering," may overcome a foreseeable bad effect, "causing death," as long as the physician did not intend to accomplish the bad effect. It is fair to say that this ethic is now one of medical custom and standard practice. The U.S. Supreme Court has endorsed this ethical principle and may have even created a defense to prosecution should a terminally ill patient die during pain medication administration with palliative care. *Vacco v. Quill,* 521 U.S. 793, 1997.

The centrality, universality, and transcendent obligation of the physician is to adhere to the core values of medicine: (1) to cure if possible; (2) to relieve suffering always. This mandate to relieve pain is as compelling and constant today as it has been throughout history, despite dialectical transvaluation of values so prevalent today. Pain remains, even now, an untestable hypothesis (Rich, 2004).

Law Enforcement and Regulatory Issues

John Duncan, PhD

INTRODUCTION

The interface among physicians, regulatory boards, and law enforcement is a critical part of any practice; however, it takes on an added importance for practitioners working in the treatment of chronic pain. Specifically, many of the medications used to treat pain are also those most frequently abused and associated with drug addiction. Because of historical conflict between regulators and the practice of medicine, and the turn-of-the-century problems with iatrogenic addiction, careful consideration should be given to the role of developing shared understandings and overlapping consensus with regulators. In this chapter, the general features of this understanding are presented, as well as guidelines for both working with regulatory agencies and also staying out of trouble with them.

HISTORICAL CONSIDERATIONS

To understand the regulatory and legal landscape of opioid prescribing in the United States, it is important first to examine some of the more important historical occurrences that have led to and shaped current legal perspectives and attitudes, of both regulators and physicians. Against the backdrop of this historical context, it will become evident that the fear of iatrogenic addiction, a problem that was prevalent in the late 1800s in the United States, has been the chief inhibitory force in prescribing opioids for chronic pain. This stalwart attitude remains, however, even after years of research have shown that they can be used both effectively and without creating narcotic addicts. The law enforcement and regulatory challenge continues to address these concerns, with states enacting laws to protect physicians who use large amounts of opioids in their pain medicine practice.

Although evidence of opioid use can be traced back to prehistoric Neolithic sites in Switzerland, and its use has continued for medicinal, ritual, and recreational purposes from that time onward, the peculiar regulatory history within the United States with the most severe impact on the context for pain medicine in recent time goes back to the late 1800s (Booth, 1996). In the United States, it has been well documented that the leading cause of opioid addiction in the 19th century was the medical community itself (Courtwright, 2001a). Many people became addicted to opium, which was widely available from physicians and over the counter. While many of the addicts were soldiers who had been wounded in the Civil War, about two thirds of those addicted to opium were middle- to upper-class Caucasian women, between the ages of 25 and 45, and most were administered opiates by their physician (Courtwright, 2001a). Iatrogenic addiction to opium was rampant, but the reliance upon opium to treat a wide-range of disorders was based on the most valid medical theories of the time. Finding roots in the work of the Scottish physician John Brown, who categorized all disease as the result of either too much or too little *stimulus*, American medicine made liberal use of opium, which was the single most prescribed medication in the *pharmacopoeia* (Courtwright, 2001a; Janz, 1974). Opium addiction, particularly in light of the defeat of China by Great Britain in the "Opium Wars" (with China unable to field an army), became a major concern of the U.S. government (Booth, 1996). Widespread misuse of the drug revealed a landscape at the turn of the century within which addiction appeared to many as a looming threat to national security and the bane of the medical profession. While physicians

continued to prescribe opium, there were those in the government who strongly believed that there was little, if any, use for the drug.

It is not surprising that drastic action was taken, both within the medical community and from the government, emerging as a new domain of governmental regulation. On the medical side, physician attitudes, somewhat shaped by the failure of opioids to live up to their portrayal as a panacea, began to change into skepticism expressed as reluctance to prescribe various opioids. On the other hand, the government began involvement in ways that were yet uncharted and with the attitude that the medical community, left unchecked, might cause a cascade that would compromise the very ability of the United States to field an army in times of national threat.

Addiction, from the medical standpoint, was seen as a medical problem and, while the administration of opioids diminished, opioid "maintenance" clinics abounded. However, with the change in attitude within the medical community, bringing restrictions on the availability of opioids, more addicts turned to over-the-counter substances that contained opioids. These substances, often called "patent medicines," were marketed to "cure" a wide range of ailments, oftentimes addiction to the very ingredients contained in the preparation itself (Courtwright, 2001a). There was a move from viewing addiction as a medical problem to seeing it as a regulatory problem.

Along with the shift away from physicians as the source of opioids came the rise in popularity of opium smoking, a nonmedical practice that was introduced by Chinese immigrants. In the late 1800s, opium addicts began associating with the criminal element that frequented "opium dens." These secret locations were associated with immoral behavior and criminal activity, leading to the passage of a San Francisco municipal ordinance in 1875 that prohibited opium smoking (Courtwright, 2001a).* Other similar laws followed the San Francisco ordinance on the local and state levels, culminating in the passage of Federal Exclusion Act in 1904 that prohibited the importation of opium except for medicinal purposes (Courtwright, 2001a). Prices of opium increased as a result of this act, and many addicts turned to injecting morphine and heroin. There was an expansion of the illegal market, and criminal organizations began to control the importation and distribution of opioids.

The Exclusion Act of 1909 marked the first time in the United States that addiction was seen as a criminal problem instead of a medical or regulatory one. The move to criminal enforcement and prohibitive regulations continued in response to heroin, which became an inner-city drug abuse phenomenon. Despite criminal enforcement and import restrictions, the problem of opioid addiction in the United States continued to rise. This rise led to the

emergence of a regulatory backdrop that continues to inhibit the use, even legitimate use, of opioids well into the 21st century.

Hamilton Wright, as the U.S. delegate to The Hague Opium Convention of 1912, agreed to push for more restrictive domestic laws for opioids as a part of an international plan to curb the rise in addiction worldwide. Cast against the backdrop of the tensions that led to World War I, amid concerns about heroin use among draft-age youth, the Harrison Anti-Narcotic Act passed in 1915 (Courtwright, 2001a). Among other things, it required physicians to keep records of morphine and heroin prescriptions and placed great penalties on physicians who prescribed opioids indiscriminately. The U.S. Treasury Department, Internal Revenue Bureau, was charged with enforcing the narcotics laws.

There was ambiguity on the question of whether, subsequent to the Harrison Act, physicians could maintain addicts. After the Act, addicts had to get a prescription for their drugs — and there was a dramatic increase in "dope doctors" who would simply write narcotic prescriptions to addicts for a fee. While the Treasury Department went after these dope doctors, it took the U.S. Supreme Court to decide in 1919 (*U.S. v. Webb*) that these clinics and doctors were, in fact, subject to enforcement and disallowed by the Harrison Act (Courtwright, 2001a). After *U.S. v. Webb*, Treasury agents went after physicians who were prescribing for addicts. This marked the first time that law enforcement targeted physicians for criminal enforcement and set the stage for the relationship between physicians and law enforcement that continued until the last decade of the 20th century.

The illegal market for morphine and heroin continued to expand with the restrictions upon medical availability. Criminal groups continued to thrive on the importation and sale of these drugs, leading to the outlawing of the domestic use of heroin in 1924 (Courtwright, 2001a). Within this environment of criminal prosecution and overwhelming concern about the problem of addiction, medical professionals responded by advocating the use of opioids solely for the treatment of pain in terminally ill patients. The underlying thought was that only in terminally ill patents was the specter of addiction a moot point. Patients suffering from chronic pain who were not terminal were offered little relief. Enduring pain became a sign of stoic fortitude and complaining of pain that of weakness of character.

By 1940, addiction was viewed as a criminal problem, especially because the majority of addicts were obtaining their drugs from street sources rather than medical professionals (Courtwright, 2001a). Addicts were seen as criminals rather than, as 50 years earlier, as patients. Laws continued to restrict access to drugs and broaden enforcement authority. In 1951, the Boggs Act passed and was followed in 1956 by the Narcotic Control Act (Court-

---

* Laws first emerged in San Francisco and then Virginia City in 1876.

TABLE 93.1
Controlled Drug Schedules

Drug Schedule	Characteristics	Examples
Schedule I	Drug has no accepted medicinal use in United States	Heroin, LSD, marihuana, peyote
	Drug has high potential for abuse	
Schedule II	Drug has accepted medicinal use	Morphine, oxycodone, hydromorphone, amphetamine
	Drug has high potential for abuse	
Schedule III	Drug has accepted medicinal use	Hydrocodone
	Drug has medium potential for abuse	
Schedule IV	Drug has accepted medicinal use	Benzodiazapines
	Drug has low potential for abuse	
Schedule V	Drug has accepted medicinal use	Some codeine cough syrups
	Drug has lowest potential for abuse	

wright, 2001a). These Acts codified penalties for simple possession of certain drugs and mandated prison sentences for violators. The environment became one in which law enforcement raided and arrested those involved in the importation, distribution, or use of illegal drugs. Medical professionals who overprescribed opioids were seen as "dope dealers" and often arrested.

As the problem of illegal drug use in the United States continued to rise, in 1962 the Kennedy administration held a White House conference, called the Prettyman Convention, on narcotics and drug abuse (Courtwright, 2001a). This conference led to the formation of an advisory commission that, in 1963, recommended changing the focus on drug use from incarceration to treatment, the elimination of mandatory minimum sentences on small cases, and transferring the powers of enforcement from the Treasury Department to the Justice Department. Finally, in 1965, new laws controlled the manufacture, distribution, and sale of barbiturates, tranquilizers, and amphetamines and also established the Federal Bureau of Narcotics and Dangerous Drugs Control (BNDDC) and the Food and Drug Administration (FDA) (Courtwright, 2001a). The shift in dealing with drug use as a treatment issue continued and in 1966 Congress passed the Narcotic Addict Rehabilitation Act. This Act allowed the medical treatment of addiction under very strict regulation, leading to the establishment of methadone treatment facilities throughout the United States (Courtwright, 2001a, b).

Finally, in 1970, the Controlled Substances Act, Title II of the Comprehensive Drug Abuse Prevention and Control Act, was passed, becoming effective in 1971 (Courtwright, 2001a). Under this Act, a classification system for evaluating the abuse potential of various drugs was established. This system consists of five schedules. In Table 93.1 each classification is shown, with the criteria for inclusion and an example of drugs in that schedule. Drugs that have a high potential for abuse and no recognized medicinal use in the United States are in Schedule I and can only be used with a special registration by researchers. Schedule II drugs are those that have a high potential for abuse and have accepted medicinal use. Drugs in this schedule, which includes most of the strong opioids and their synthetic equivalents, are restricted to a 1-month supply and must be prescribed on a written script, signed by the doctor. Schedule III drugs have less potential for abuse and include, among other drugs, many hydrocodone preparations. These drugs can be called in by phone or ordered by prescription. The same holds for Schedule IV drugs, which have less potential for abuse. Schedule V drugs can be purchased by an individual from a pharmacist, but require identification and a signature (21 USCS Section 801, 1996).

The Controlled Substances Act contains the federal drug laws, specifies penalties, and sets up regulation of medical professionals. Changing little from 1970, prescribers and suppliers must obtain a registration from the U.S. Drug Enforcement Administration and receive a DEA number, which is used to index controlled substances prescriptions and to form a closed system within which the legitimate use of controlled drugs is monitored (21 USCS Section 821–830, 1996).

As Table 93.2 shows, the historical landscape in the United States began with no governmental involvement in either the practice of medicine or the importation of opium. However, because of the rising problem of addiction and its attendant fears, various steps were taken by the federal government (and followed by individual states) to control both the drugs and the medical community. The landmarks in this history are the Harrison Anti-Narcotic Act of 1915 and the Controlled Substances Act of 1970. Together, these laws have set the stage upon which prescribing of controlled drugs for pain must occur.

The medical community responded to the problem of addiction by closing the doors on opioid prescribing, except in the case of a terminally ill patient. It was common for doctors to see patients as unwilling to endure pain

TABLE 93.2
Major Drug Legislation in the United States

1875	San Francisco Municipal Ordinance	Made opium smoking illegal
1904	United States Federal Exclusion Act	Prohibited importation of opium except for medicinal purposes
1912	Hague Opium Convention	U.S. commitment to control opium
1915	Harrison Anti-Narcotic Act	Regulated physicians under U.S. Treasury enforcement
1919	*U.S. v. Webb*	Decision that physicians could be arrested for prescribing opioids for addicts
1951	Boggs Act	Imposed harsher penalties for narcotics violations
1956	Narcotic Control Act	Increased penalties and clearly stated antinarcotic commitment of government
1962	White House conference (Prettyman Convention)	Recommended dismantling Bureau of Narcotics and Dangerous Drugs and refocusing government on treatment and prevention
1966	Narcotic Addict Rehabilitation Act	Allowed medical treatment of addiction under strict control
1970	Controlled Substances Act	Created federal drug schedules and established drug violations
1990s	States began passing intractable pain laws	Allowed physicians latitude in using controlled drugs in the treatment of chronic pain

and weak in character. These attitudes were passed on through medical schools throughout the nation and only began to change after the Prettyman Convention renewed the idea of addicts as medical patients. Still, until pain management research found that opioids could be used effectively and without creating addiction, in the early 1990s, negative views of opioid prescribing continued (Courtwright, 2001b).

In the 1990s, various states, in response to new research in the management of chronic pain, began passing various forms of intractable pain legislation. These laws typically state the following: (1) recognition of chronic pain and the rights of patients to have relief from pain, (2) recognition of the value of large quantities of opioids in treating chronic pain, and (3) giving physicians the right to prescribe pain medications in such a treatment, providing that the drugs are not intended for euthanasia. This decade marks a radical break with previous attitudes, many of which are still held by both medical professionals and regulators. The challenge continues to be education of the medical and regulatory communities.

REGISTRATION REQUIREMENTS

According to the Federal Controlled Substances Act, "Every person who dispenses, or who proposes to dispense, any controlled substance, shall obtain from the Attorney General a registration issued in accordance with the rules and regulations promulgated by him" (21 USCS Section 822(A)2). The list of those who are allowed to prescribe controlled drugs has grown from only medical doctors to include other medical professionals, such as advanced practice nurses, physician assistants, and certified registered nurse anesthetists.

While every person who dispenses controlled drugs must obtain a DEA registration and number, many states have a "dual registration" requirement. This means that a dispenser must obtain state registration as a necessary prior condition for the DEA number. The forms taken by states vary, with some registrations through the medical board, pharmacy board, or state narcotics agency. In every case, dispensers must also be registered with their appropriate professional practice board. Registrants on both the state and federal levels must comply with a series of "Rules and Regulations" that vary somewhat on a state level. These rules spell out the requirements that must be followed by registrants.

Both state and federal rules allow the controlling agency to bring a registrant in for a "show cause" hearing. This is an administrative hearing designed to determine whether actions shall be taken against the license of a medical professional. In a show cause hearing, a "hearing officer" hears both sides of the case and then makes a determination. The standard of proof in most of these hearings is a "preponderance of the evidence," which is much less strict than the criminal court, in which "beyond a reasonable doubt" is the standard. The final ruling from an administrative hearing can be appealed in either state or federal court. Some of the actions taken by regulatory agencies include denial of registration, revocation, suspension, and modification of privileges (21 USCS Section 822(A)2; see also Title 21 CFR, Part 1300–1399). Punitive fines are also levied against those deemed guilty of violating the rules. Pain medicine practitioners should review their respective state regulations pertaining to controlled drugs.

Criminal action can also be taken against physicians who misuse or divert controlled drugs. Examples of criminal acts include trading controlled drugs for sex, selling controlled drugs illegally, selling prescriptions for controlled drugs, stealing controlled drugs, and illegally using controlled drugs. These actions are unambiguous

and criminal prosecution can result in imprisonment and/or fines.

CONCERNS ABOUT USING CONTROLLED DRUGS IN PAIN MANAGEMENT

Almost all legal and regulatory actions concerning the treatment of pain center on three features: (1) guarding against the diversion of controlled drugs, (2) effectively differentially diagnosing drug-seeking behavior, and (3) maintaining records that support the medical decision to use controlled substances to achieve pain relief and life maintenance. Physicians failing to meet basic standards in any of these categories place themselves at greater risk of disciplinary (or even criminal) actions. In fact, it is best to view these three areas as parts of a unified approach to achieving a practice that avoids pitfalls of regulatory mistakes.

GUARDING AGAINST DIVERSION

The standard established by the U.S. DEA and codified by all states for those who prescribe, administer, or distribute scheduled drugs is that they have an affirmative duty to "guard against diversion" (Title 21 CFR). What this means is nebulous and not well delineated by regulators. Consequently, law enforcement and regulatory agencies, both state and federal, have a wide range of possible areas in which they can regulate the activities of those involved in pain medicine. In the broadest sense, "diversion" is the use of controlled substances for any purpose other than their intended medical purpose; thus, "to guard against diversion" means to exercise reasonable care in the storage, handling, and dispensing of scheduled drugs, along with taking reasonable measures to see that, at any point in the medical practice, the possibility of drugs being used outside of their intended purpose is minimized (Gibbs & Haddox, 2003; see also Compton & Athanasos, 2003). To comply with this statutory and regulatory requirement, it is necessary to examine the various processes of a medical practice and make adjustments that will fulfill the DEA and state regulations.

To meet the requirement of guarding against diversion, a number of things should be examined. If drugs are stored at the practice, they must be kept in secure locations in compliance with the federal and state requirements. This usually means locked cabinets or safes with controlled and limited access. Furthermore, "readily retrievable" records must be maintained that reflect both the receipt of controlled drugs and their dispensation. When large quantities of controlled drugs are stored on premises, an alarm system is required. Next, one of the major sources of diversion is forged prescriptions. Prescription pads should be secured away from patient and non-essential personnel access. For example, the receptionist in a pain practice

has no business with access to prescription pads — only the physician or other authorized persons should have access to them. Fraudulent call-ins represent another vulnerable area for diversion control. Pain medicine practitioners should have strict records and guidelines for calling-in controlled drug prescriptions, including a logbook of call-ins, a reciprocal relationship with the pharmacies used to check and crosscheck call-ins, a designated person to call in scripts and another person to check the record, and a periodic overview of the record in comparison with patient charts.

SCREENING PATIENTS FOR ADDICTION

A very important part of guarding against diversion, as well as in the effective practice of pain medicine is to employ a series of "screening questions" to evaluate the risk of a patient for drug abuse. Included in this screening are questions about family history of drug and alcohol abuse, the patient's daily life, and whether the patient has abused drugs or alcohol in the past. If the patient appears at risk, more detailed information should be gathered. This screening interview should be followed by a physical exam, in which signs of drug abuse might be identified (Smith, 2000).

DIFFERENTIAL DIAGNOSIS OF DRUG-SEEKING BEHAVIOR

Another very important manner in which physicians can guard against diversion has to do with being able to differentially diagnose those legitimate patients from those seeking drugs. This is not always an easy task, especially because many patients with pain have comorbid disorders. Mostly, pain medicine specialists see patients who fall within the following categories: (1) patients with legitimate pain who have no comorbid disorders, (2) patients with legitimate pain who have a comorbid psychiatric disorder, (3) patients with legitimate pain who have a comorbid drug-seeking behavior problem, (4) patients with legitimate pain who have a comorbid addiction disorder, and (5) patients with nonlegitimate pain who are drug-seekers, addicts, or professional patients.

The first step in differentially diagnosing these kinds of patients and coming up with appropriate treatment is eliminating the drug-seekers and addicts who are not patients in legitimate pain. This can be very difficult, because many of the patterns of behavior associated with these patients also overlap with patients with pain and comorbidity. Consequently, physician judgment is critical in establishing patient legitimacy. Furthermore, drug seeking can either be a pattern of behavior that has already developed with other medical professionals, or it can be a pattern that begins within the realm of a current practice. It is useful, therefore, to catalog the classic phases of drug-seeking behavior. Table 93.3 shows the various phases, as

TABLE 93.3
Stages of Drug-Seeking Behavior

Level	Characteristics	Sign of
Phase 1	Unauthorized dose escalation	Undertreatment, drug diversion, drug abuse
Phase 2	Minor scams (e.g., excuses for needing more medication)	Undertreatment, drug diversion, drug abuse
Phase 3	Script forgery and fraud	Drug diversion, drug abuse
Phase 4	Injury to self or others	Drug diversion, drug abuse

well as the characteristics and possible reasons for the behavior (Longo, Parran, Johnson, & Kinsey, 2000; see also Parran, 1997).

The first phase of drug-seeking behavior is unauthorized dose escalation. If a patient exceeds the dosage prescribed on controlled medications, the physician should first evaluate the treatment to ensure that the patient is receiving enough pain medication. Many patients with pain may escalate dosage to meet the level of pain. In this case, it is a question of proper titration of pain medications and not drug-seeking. However, if a pattern of dose escalation emerges that is not indicative of undertreatment, it may suggest drug-seeking behavior. At this point, the physician should take action — either discontinue treating the patient or fix parameters on drug usage.

The second phase of drug-seeking behavior consists of different inventive "scams" that end up expressing a need for more of a controlled substance. These scams are as prolific as the minds of the patients and can be either elementary or sophisticated. Examples of the more elementary scams include losing the prescription, the script being eaten by the family dog, stolen medications, spilling the bottle into the toilet, and continue along these lines with the final request for more medication. As simple excuses fail, intelligent patients craft more elaborate excuses, such as the following: a patient receives a written script for 300 oxycodone 7.5 mg. tablets, makes a photocopy of it, fills the script at an out-of-the-way pharmacy and pays cash, puts the photocopy in his blue jeans, washes the pants, then comes back with an "accidentally washed' prescription, allegedly unfilled, to get another script. There is, of course, a limit to the number of excuses that any physician will buy. Consequently, this phase is short-lived and usually ends in increasing tension between the patient and prescriber over the medications.

The third phase of drug-seeking behavior reflects a greater level of despair by the patient. Characteristics of this phase occur when the patient (1) goes to multiple physicians to get drugs, (2) forges prescriptions or makes fraudulent call-in prescriptions, or (3) both. This represents a major step in the patient's willingness to take serious risks to obtain drugs because all of these actions are felonies and punishable by imprisonment. Typically, a drug-seeker at this level will first go to multiple physi-

cians without telling them about each other, present complaints of pain (or other disorders requiring controlled drugs), obtain prescriptions, and fill them at different pharmacies. Often, this kind of drug procurement can continue for years without being discovered, particularly if the drugs obtained are Schedule III or IV and not monitored as carefully as Schedule II controlled substances.*

More desperate is the drug-seeker who steals or has printed up prescription forms and writes bogus scripts that are filled at different pharmacies. Many of these are self-evident forgeries, such as the case in which a pediatrician received a call from a concerned pharmacist, who advised him that a person had attempted a forgery, which was clumsily written by the suspect for "mo-feen, 1 kilo, use as needed." Other forgeries are virtually indistinguishable from legitimate scripts and only communication with the prescriber can determine their bogus nature. Similarly with fraudulent call-in prescriptions, many more articulate and sophisticated drug-seekers can run this scam for years without detection.** Patients at this level are beyond simple intervention and should be brought within the criminal justice system for coercive treatment. For example, the drug court program requires such offenders to go through treatment and stay sober for a required period of time. Some pain medicine practitioners have strict procedures that involve working closely with pharmacists, to ensure that the script or call-in is legitimate. Examples include using caller ID to ensure that the phone call is from a legitimate medical practice, employing designated personnel in the medical practice who are authorized to call-in scripts, using only one pharmacy to fill scripts for a patient at risk, and physicians periodically reviewing the patients' pharmacy files and comparing them against the medical chart.

---

* Many states have Schedule II monitoring programs; fewer monitor other schedules. These programs usually track controlled dangerous substances prescribing in one of two ways: (1) triplicate prescriptions (doctor buys script pads from the government and keeps a copy for the chart, another copy goes to the pharmacy, another to the government agency in charge of the monitoring program), or (2) electronic capturing of prescription information as it is filled by the pharmacist.
** Professional diversion investigators routinely tell stories of patients who have scammed doctors in this manner for years — refer to National Association of Drug Diversion Investigators (NADDI).

TABLE 93.4
Illicit Equivalents for Controlled Drugs

Illicit Equivalent	Legitimate Drug(s)
Heroin	Opioid analgesics
Cocaine/methamphetamine	Stimulants
Alcohol	Sedative hypnotics

The fourth and final phase of drug-seeking behavior represents a much deeper level of despair in which the patient injures either herself or others to obtain drugs. One such drug-seeker would take pliers to his teeth, breaking one off, and then visiting all emergency rooms, several doctor's offices, dentists, and clinics — obtaining prescriptions of hydrocodone from each source, selling some of the drugs to pay for filling more prescriptions, until he finally had no teeth left. Eventually, this patient died from endocarditis. Other patients have injured their own children in order to get narcotics. Some threaten physicians at gunpoint, blackmail the doctor (usually over either sexual misconduct or drug abuse), or commit armed robberies and burglaries of pharmacies in order to get drugs. At this level, the patient becomes a major law enforcement problem and should be stopped as soon as possible.

Another area of concern for pain medicine physicians is the "professional patient," a scammer who may or may not be a drug user, but one who scams physicians out of large quantities of drugs that can be sold for profit on the street. These individuals can have many different scams, but all are actually trying to profit from illegal drug diversion. Many pharmaceutical drugs are the licit equivalents of illegal street drugs and, consequently, can have a high street value. Table 93.4 shows several common prescription drugs and their illicit equivalents. Examples of professional patients are groups that hire a patient with terminal cancer to travel from one city to another, going to various doctors and obtaining pain medications that are eventually sold on the street. Another example is a patient who steals a doctor's DEA number and has several prescription pads printed with a bogus name and address for a phony practice. Using the DEA number fraudulently, this individual hits city after city with prescriptions, often obtaining tens of thousands of dosage units before moving on.

In addition to the various phases of drug-seeking behavior, pain medicine practitioners must be able to spot and deal with comorbid patients. Of particular difficulty are two kinds of comorbid patient: those with (1) comorbid drug-seeking or addiction disorders, and (2) comorbid psychiatric disorders. The first category usually is either a patient who has a history of addiction disorder and also has chronic pain, or one who has been under treated for pain and developed drug-seeking patterns as a result. In either case, appropriate adjunct therapy, usually in the form of addiction treatment and/or cognitive behavioral therapy, in conjunction with careful monitoring of pain drugs and restricted access to quantities of drugs, is essential. Many times these patients remain untreated, because of the liability in working with them — however, with appropriate strategies and very careful documentation, they can be effectively treated. Likewise, when encountering a patient comorbid with a psychiatric condition, care should be taken to work closely with a psychiatrist in controlling the medication mix to allow for both therapies to work together. Both kinds of patients represent a great challenge to pain medicine practitioners.

MAINTAINING RECORDS

Keeping comprehensive charts is critical when prescribing controlled drugs. These are the documentation of the medical evaluation and the rationale for the use of certain drugs. Good charts are the best defense against allegations of overprescribing or misuse of controlled drugs; conversely, poor charts can result in disciplinary action against even the best doctor. Charts should contain at least five areas that correspond to good practice of pain medicine: (1) patient evaluation, (2) treatment plan and objectives, (3) periodic review, (4) consultation records, and (5) documentation of all prescriptions.

Particularly when prescribing dangerous drugs, the doctor should conduct a thorough evaluation of the patient. This evaluation should include a pain history, especially the impact of the pain on the ability of the patient to function occupationally and socially. Any preexisting diagnostic studies and medical records should be carefully reviewed, and if the studies are insufficient, new ones should be ordered. The patient should be evaluated for a history of drug-seeking behavior and substance abuse, along with any comorbid conditions. Finally, a physical examination of the patient should be documented in the chart. All of these categories should be summarized in the chart for every new patient with pain. From a regulator's standpoint, as well as a medical board expert review, this shows that care was taken to determine whether the patient was legitimately a pain sufferer and there was scientific basis for the prescription of pain medications.

Next, the chart should document the diagnosis of the patient's condition and outline the treatment plan. This plan should include measurable goals, such as being able to go to work or experience an increase in personal activities. Documentation of informed consent on using opioids to treat the pain should be included at this point as well as the parameters of using the drugs.

Many pain management physicians use a "medication agreement," a contract between provider and patient that specifies what is expected of the patient. The following are important points to include in such a document:

1. Patient agrees to take medications as prescribed.
2. Patient agrees to not request refills except as specified by the agreement.
3. Patient agrees to use a specific pharmacy (of the patient's choice) to fill the prescriptions and authorizes the physician to obtain medication records from the pharmacy.
4. Patient agrees not to go to other doctors for pain treatment and to advise of any other doctor visits.
5. Patient agrees to guard against theft or misuse of medications.
6. Patient agrees not to use street drugs.
7. Patient agrees to submit to random drug screening.
8. Patient agrees to provider having the right to contact state or federal narcotics agencies regarding the patient.

While these are just a few of the main tenets of a medication agreement, it is a good way to document the conditions existing between the provider and the patient regarding controlled drugs and shows that the provider is guarding against diversion.

A periodic review of the treatment plan is necessary with patients with pain. Every few months (no longer than 6 months), the physician should reassess the treatment and determine if the objectives are being met. Adjustments or notes about continuing the course of treatment should be documented at this point. An example of a rationale for continued treatment might read: "The patient continues to report that he is able to function at his workplace and also reports getting adequate sleep at night." Such annotations in the chart show that the provider is concerned with actual functioning of the patient and that continued therapy is warranted.

If patients are referred to outside physicians for consultation, this should also be documented in the chart — for example, referral to a psychiatrist for emotional issues should be noted, along with the diagnosis and treatment plan set up by the psychiatrist. The results of a consultation should be carefully reviewed for compatibility or incompatibility with the existing pain treatment and appropriate adjustments made.

Finally, all prescriptions should be documented and included in the chart. Many pain management physicians actually photocopy the prescriptions written and include them in the chart. Others have a log that can be easily reviewed that lists all controlled drug prescriptions given to the patient. It is critical, however, that the scripts for controlled substances be carefully charted and that these prescriptions match the course of therapy outlined in the treatment plan.

By using these guidelines for charting patients with pain, physicians can have an affirmative defense against allegations of indiscriminate prescribing of controlled drugs. The process that most medical boards follow in reviewing a complaint against a physician for overprescribing controlled drugs usually involves bringing in a board-certified expert to review a random sample of charts from the practice. Good charts can explain thought processes and scientific findings that support medical decisions to prescribe controlled drugs. Such documentation is critical to maintain in the practice of pain medicine.

CONCLUSION

The practice of pain management occurs within a regulatory environment that has a long history of preoccupation with the problem of addiction. Consequently, laws, rules, and regulations have been compiled that form the parameters within which a pain medicine practice must operate. Because pain medicine makes extensive use of opioids, it is imperative that those involved know the regulatory landscape. Furthermore, regulations require that prescribers have an affirmative duty to guard against diversion of controlled drugs. These drugs have a street value and are frequently diverted to illegal use. By exercising reasonable care in storing these drugs, limiting access, and understanding the differential diagnosis of drug-seeking behavior, physicians can demonstrate that they are prescribing the drugs for legitimate purposes and that they are conscientious about the problem of diversion. Furthermore, by comprehensively charting the patient evaluation, diagnosis, treatment plan, and other relevant information, pain management physicians are able to defend themselves against allegations of drug mismanagement. With the adoption of intractable pain laws, most states have officially recognized the value of using opioids and other controlled substances and also have recognized that patients have a right to expect relief from chronic pain. Yet this new philosophy is cast against the backdrop of a restrictive environment and those practicing on this medical frontier have to contend with working under regulatory scrutiny.

Controlled Substances and Risk Management

Hans Hansen, MD, Art Jordan, MD, and Jennifer Bolen, JD

INTRODUCTION

The role of the pain management specialist is to control pain, improve the quality of life, and reduce the suffering of those stricken with acute and chronic pain. Often the doctor of last resort, the pain practitioner is left with few options not previously attempted to treat patients, especially those with chronic pain. In fact, many of these patients are not difficult to manage, but they are lost between the kinetic interaction of families, care providers, and other parties. Subsequently, the patient becomes a fatigued and overwhelmed individual who may appear apprehensive and suspicious of the new treatment plan. Further straining the nurturing environment of the patient–practitioner relationship are the many payers and regulatory agencies that are increasingly insistent that the patient be managed in a cost-contained environment, free of potential adverse risk; in reality, this setting does not exist.

Risk is a part of medical care that is acknowledged in any treatment plan. Unfortunately, the current climate of regulatory and legal challenges demands that pain practitioners take steps to minimize the potential for risk while continuing to offer high-quality, effective treatment. Few professions are held to such demanding standards where the cost of adverse outcome is so high for patients, family, and care providers.

THE PERSONALITY OF PAIN

Controlled substances, particularly opioids, are an important component of a pain practitioner's treatment arsenal, and often provide a reasonable alternative to invasive procedures and costly therapies in some patient populations. As an example, surgery, although an important consider-

ation for certain diseases, is not always a curative approach for many patients with pain and may result in significant post-surgical morbidity, such as post-laminectomy syndrome. Patients frequently ask for back surgery to stop the pain when surgery may actually promote further disability. Well-controlled pain, in many cases, may decrease the perceived need for surgery. "Cutting nerves" or surgically removing pain seems reasonable to patients, but is rarely possible. Pain is, of course, a complex interaction of peripheral and central processing events evolving its own "personality" through the limbic system and central neurophysiologic interactions.

Most pain management practitioners agree that patients will, in many cases, develop this "personality of pain" that directs much of their behavior. Depression, anxiety, and aggressive characteristics are particularly troublesome when controlled substances become a patient's focus. These drugs must be managed carefully. The personality of pain often overwhelms the original pain complaint and interferes with a positive, productive outcome. There is no test to identify these subtle personality characteristics, but most practitioners would agree that certain pain diagnoses, such as complex regional pain syndrome and fibromyalgia, demonstrate subtle personality idiosyncrasies at presentation. Perhaps the personality factors exist that predict or measure these characteristics, but a test has not been developed to measure these personality traits. Standard Functional Capacity Exam testing routinely reports inconclusive results in fibromyalgia assessments, and no personality trait has been identified with standard psychological tests.

Pain does influence plasticity in central processing events, including affective and motivational centers. Controlled substances will further alter these behavioral cen-

ters, sometimes with deleterious effects. Exercise caution with controlled substances in those with psychiatric disease or labile personalities. The use of adjunctive medications, such as anxiolytics and antidepressants, may greatly enhance treatment of coexisting anxiety or depression, which accompanies chronic nonmalignant pain. The stair-step approach to substance use to control pain recommended by the World Health Organization (WHO) consistently improves outcomes and provides a rational and defensible approach to pain therapy.

Controlled substances may also help a patient's pain-related anxiety, and may positively improve function and interactive lifestyle. Controlled substances, such as opioids, are an option for those who cannot tolerate a particular restorative procedure or treatment, such as surgery, or who have not improved function or quality of life to the lower levels of the WHO model. Properly used, returning to work and involvement in interactive social activities decrease utilization of the medical system, and control of disease states related to pain and anxiety.

Controlled substances are known to be of high value to relieve cancer pain and other common degenerative diseases, such as low back pain and arthritis. Occasionally, controlled substances have limiting side effects that decrease utility at therapeutic dose, and other medications are superior choices. For example, opioid effect is resisted in certain disease states, such as neuropathic pain and fibromyalgia, suggesting non-opioid alternatives and adjuncts might be a better choice.

Another approach is enhancing the synergistic effect of combination therapy, noncontrolled agents and low-dose controlled substances, decreasing side effects, increasing compliance, and enhancing pain control. Occasionally, reinforcing the concept of off-label use, adjunctive therapy has allowed boutique combinations and altered doses of controlled and noncontrolled substances to improve outcome.

The pain management prescriber is best positioned to optimize controlled and noncontrolled substances to minimize side effects and improve the patient's life experience. The *personality of pain* will benefit from acknowledgment that treatment of anxiety, depression, or any number of subdiagnoses of chronic pain is recognized, accepted, and a predictable and compassionate understanding between patient and provider. Herein is the foundation of the provider–patient relationship built on trust.

DEA'S REGULATORY OVERSIGHT ROLE

The Drug Enforcement Agency (DEA) is responsible for monitoring the flow of controlled substances in the United States. The DEA has the authority to establish manufacturing quotas or drug supply, establish the framework for manufacturers and wholesale distributors, regulate retail matters, and register individuals and businesses for pur-

poses of monitoring the administering, dispensing, and prescribing of controlled substances. DEA uses two Websites to make relevant information available to the public and the body of registrants — www.dea.gov and www.deadiversion.usdoj.gov. Practitioners should consult these Websites regularly, or use one that links to the DEA Websites to provide updated information, such as ASSIPP.org or aapainmanage.org.

The DEA uses the Code of Federal Regulations and the Federal Register to establish and explain record-keeping requirements and abuse and diversion control mandates on controlled substances. The DEA cannot use its authority to tell practitioners "how to practice medicine." Consequently, the federal legal and regulatory framework does not define *legitimate medical purpose*, leaving this matter to state licensing boards and community standards on accepted medical practice.

Several professional organizations have also published materials related to the treatment of pain and to the risk management aspects of using controlled substances to treat pain, including the American Academy of Pain Medicine (AAPMedicine) and the American Pain Society (APS), the American Academy of Pain Management (AAPManagement), the American Society of Interventional Pain Physicians (ASIPP), the American Academy of Physical Medicine and Rehabilitation (AAPMR), the American Society of Regional Anesthesia and Pain Medicine (ASRA), the American Society of Addiction Medicine, and the American Academy of Family Practitioners (AAFP), among many others. All practitioners should become familiar with these organizations named above. In addition, all practitioners should use the Website, www.ngc.gov, to learn about current practice guidelines and standards used nationwide in the area of pain management.

PART ONE. RISK AND CONTROLLED SUBSTANCES

Risk is defined as a "chance of loss." Risks are part of everyday life and certainly a part of the daily practice of medicine. Before one can establish an effective risk management program, it is important to understand potential risk areas and consider how they factor into the clinical setting. Part One focuses on the identification of general practice risk areas and those risks specifically associated with the use of controlled substances to treat pain. After reviewing potential risk areas, practitioners should perform a self-audit to determine where they stand on identifying potential risks. After the self-audit, practitioners will be able to use Part Two to structure a basic risk management plan, focusing on issues relating to controlled substances and specific patient populations commonly presenting risks in this area. In all cases, the key components of effective risk management when using

controlled substances to treat pain are patient assessment, selection, and monitoring.

Controlled substances are a part of the necessary daily interactions of patient and practitioner in most pain management practices, and should be used according to accepted standards of care and applicable legal and regulatory guidelines. Most importantly, the practitioner's clinical decisions and supporting rationale for the initial selection and continued use of controlled substances must be documented accurately and completely, according to applicable federal and state guidelines, laws, and regulations on the use of controlled substances to treat pain. To meet these standards, it is incumbent upon the practitioner and medical staff to be aware of the intricate balance between clinical need and appropriate use, and the misuse and diversion potential of these substances. The practitioner and his or her staff must be familiar with the basic epidemiology behind a growing trend of drug abuse. Practitioners are advised to implement office policies that protect against "doctor shoppers," drug diverters, and other unscrupulous individuals who put an entire practice at risk for licensing board, insurance company, and law enforcement intervention. Practitioners should use patient assessment and selection tools that enable them to identify those patients who present with increased potential for substance abuse, so they can be cared for in a manner that addresses their substance abuse problems without ignoring co-existing pain problems. Finally, practitioners are advised to use patient monitoring tools that enable them to assess the patient's continued legitimate medical need for controlled substances, while minimizing the potential for adverse drug events, abuse, and diversion.

Controlled substance risk management is not a static form of quality assurance, because risk is an ever-changing threat to the livelihood and health delivery of physician, employee, patient, and staff. Risk management in daily practice activities improves the likelihood of providing quality care, and suggests to legal and regulatory authorities that the practice is designed to minimize the potential for the abuse and diversion of controlled substances, as required by an *Interim Policy Statement*, published by DEA in the Federal Register on November 16, 2004.

UNDERSTANDING RISK AND CONTROLLED SUBSTANCES

A variety of categories present the potential for risk to a medical practice. Prior to implementing risk control strategies in clinical practice, practitioners should attempt to identify their specific risk areas or categories.

- Unexpected. A regulatory or legal event arising from an adverse outcome experienced by patient or an organization, and culminating in dissatisfaction with the health care rendered by the targeted practitioner. Often, there is no prior warning or heralding event.
- Patient injury. A definable event, predictable or not, with unwanted outcome.
- Risk to staff and provider:
  - Regulatory. This includes professional licensing board investigations, state and local law enforcement investigations, and DEA law enforcement and regulatory actions.
  - Compliance. State and federal fraud/abuse allegation, procedural/responsibility or negligence, Occupational Safety and Health Administration (OSHA) violation, violation of institutional by-laws (such as hospital or surgery center).
  - Perception in the community as an outlier. The perception is often the result of health care benefit plan Drug Utilization Reviews (DURs) and related billing and coding analyses.
  - Loss of peer support and/or organizational sanction. HMO/PPO, managed care sanctions. Substance abuse, outlier activity, practice habits outside of community standard.
  - Natural disaster. Vulnerability or absence of a disaster recovery plan.
  - Emotional risk. Practitioner and staff are particularly vulnerable. Being a health care provider is stressful, and prescribing controlled substances adds a level of vigilance and responsibility that many individuals in the clinic are ill equipped to address. Specifically, aggressive or manipulative patient behavior is a difficult management scenario, and it is recommended that well-trained and appropriate individuals interface with patients seeking controlled substances and refills.
  - Physical plant. Environment of care. Is the office safe and meeting regulatory challenges? Not necessarily an OSHA issue. An example might include interstate variation of fluoroscopy requirements. Are samples and scheduled medications stored and distributed safely?
  - Financial. The practitioner and practice require a positive, rewarding monetary cash flow, as any business would expect. Costs of providing care are increasing, and reimbursements decreasing. Practitioners and patients often find themselves in a bad position because health care benefit plans do not cover needed drugs or procedures, mental health services, or an adequate number of follow-up visits. Overall, profit and loss are

tenuous and, in some cases, a practitioner's billing and prescribing patterns may imply an improper profit motive.

- Practitioner or "key-man." If one provider is extraordinarily productive, loss of that coverage and income may be devastating to the viability of the practice. Furthermore, will loss of a key prescriber disrupt patient care?
- Americans for Disability Act. Conforming to the ever-changing requirements of the disabled is mandated by law. A prescriber with a substance abuse history requires a risk management plan that minimizes the potential for a discrimination claim by those who have legitimate medical need for controlled substances.
- Licensing. Loss of privilege:
  1. State license. This may be the practitioner's greatest asset. Protection of this privilege cannot be stressed enough.
  2. Federal and State Controlled Substances Registrations: Particularly at risk when practitioners prescribe controlled substances without knowing the requirements of their state controlled substances acts and related guidelines, laws, and regulations on the use of controlled substances to treat pain. If a practitioner loses his or her medical license, he or she will lose their controlled substances registrations as well. Not all states require a separate registration from the federal registration to administer, dispense, or prescribe controlled substances.
  3. Local licensing requirements. Various tax and provider business licenses require ongoing vigilance. A designated credential officer avoids overlooking deadlines and renewals.
- Whistleblower:
  1. Employee retaliation. The practitioner is more likely to be sued from an employee than from a malpractice event (J.H. Holmes, J.D., personal communication). The practice and practitioner usually do not carry insurance for this type of exposure. Employees may even be rewarded for their report to a regulatory agency encouraging whistle-blowing "Qui Tam."
  2. DEA. Drug enforcement investigations are rare in routine practice, but disgruntled employees, pharmacists, and some patient groups may initiate an inquiry about a practitioner's prescribing habits.

Often, the originating complaint extends to topics beyond the DEA's investigative scope (such as those investigations involving community care standards). When this happens, many civil and state regulatory agencies, including professional licensing boards, get involved in additional investigative activities.

3. Medicare/Medicaid. Fraud/abuse. Financial incentives and antiretaliation protections place the practice at a disadvantage. A disgruntled employee may see an opportunity to retain information and expose the practitioner to an unforeseen or unexpected abuse investigation. An employee may allege misuse of these government programs to profit from controlled substance prescribing. Another example may include Office of Inspector General investigation. Usually initiated by disgruntled employees. Costly and lengthy.
4. Harassment. Sexual, or risk to harm. Again, antiretaliation laws and the usual lack of practice policy and education makes for a difficult defense, civil and governmental.
5. Employee violence. A prevalent and rising risk. The practice may be cited as culpable. An employee may allege the provider did not protect a prescription pad or samples of controlled substances, aiding in their addiction or legal troubles.
6. Improper employee background check. Theft, loss, harassment, violence. Each costly and difficult to avoid accepting responsibility without knowing the employee risk history.
7. Negligence of others. You are responsible for your employees' actions in the practice — "those that can pay, will pay." Practitioners are perceived as deep pockets.

- Opioid and controlled substance prescribing:
  - Prescribing without sufficient information about the patient's treatment history, drug history, including the patient's history of chemical and substance abuse and a proper family history of chemical/substance abuse.
  - Prescribing without the patient's informed consent as to (i) the risks of using controlled substances, including the potential for addiction, the concepts of physical dependence and tolerance, and potential for adverse effects, such as con-

stipation, sleepiness, and nausea, etc.; (ii) the benefits expected from the use of controlled substances in combination with the patient's participation in the treatment plan; and (iii) treatment alternatives.

- Prescribing without a proper follow-up and monitoring plan to ensure the patient's compliance with the overall treatment plan and to guard against potential problems sometimes associated with the long-term use of controlled substances.
- Risk to practitioner. This includes threat of personal injury, particularly from a seeker of drug, and/or a psychiatric patient, or a family member. Family members and close friends often "convince" patients of a practitioner's error, initialing legal action.

RISK-CONTROLLED SUBSTANCES

Opioid and controlled substances, sedatives and anxiolytics, are often chosen management strategies and arguably some of the most cost-effective approaches to treat pain. Controlled substances are a powerful and proven tool in the practitioner's pain management resources. Surgery, interventional procedures, and psychological adjuncts are effective, but not always indicated in many patient populations. A high level of accountability is necessary for both practitioner and patient to avoid improper use of these medications. Moreover, practitioner decision making may be affected by the fear of reprisal from regulatory agencies, patient drug abuse or diversion possibilities, and the perceived stigma of opioid and controlled substances used in community clinical practice. While prescription drug abuse and diversion are major concerns for the pain practitioner, one need not fear investigations and potential lawsuits if the practitioner implements and uses proper risk management tools regularly. Strategies to control risk — to patient, practitioner, and practice — increase both patient and practitioner acceptance of controlled substances, foster understanding, and ultimately benefit society by minimizing the potential for abuse and diversion. The current climate of the medicolegal system exposes prescribers to civil suits by plaintiff attorneys for the act of prescribing controlled substances, inferring *harm* and not aid to those suffering from pain. Access to care is close to many practitioners' souls, and may one day be denied for those suffering from pain. These lawsuits will result in prescriber fear and reduction of controlled substance availability for legitimate purposes. There is little doubt that drug abuse is increasingly prevalent, but the risk–reward benefit of controlled substances in the management of an appropriate pain diagnosis remains in the patient's favor.

WHAT ARE CONTROLLED SUBSTANCES?

Controlled substances are drugs or chemicals exerting bioactive effects, and are under federal and state regulation. Controlled substances are classified as opioids, stimulants, or hypnotic agents. The term *narcotic* is improperly used in the lay community, implying that any mind-altering or habit-forming bioactive substance is a narcotic. In typical medical usage, the "narcotic" often is used to mean an opioid analgesic, which is an opium-based or synthetic drug with specific opioid receptor activity. Opioids (true narcotics) are pharmacokinetically long, medium, or short acting and are used to control many painful conditions.

In the legal vernacular, narcotics may include barbiturates, stimulants, hypnotics, and opioids, although the federal statutory definition refers specifically to opium-like drugs and cocaine (http://www.dea.gov/pubs/csa/802.htm). Stimulants are a separate classification of controlled substance that may arouse and accelerate bodily and mental activity. Stimulants are used to control obesity, increase mental alertness, and treat distraction disorders, such as attention deficit disorder. Hypnotics are sedating, soothing, and exert a calming effect, often described as "tranquilizing." Many hypnotic agents reduce anxiety, stress, excitement, and induce sleep. Controlled substances are scheduled, based on the potential for risk of misuse or diversion, *not* by potency. See DEA Web site for list of drugs by schedule (http://www.dea.gov/pubs/scheduling.html).

Schedule I: No accepted medical use in the United States. Abuse potential is high. Examples include marijuana, heroin, hashish, and methaqualude.

Schedule II: High abuse potential. Accepted medical use is recognized, but complicated by the potential for severe psychological or physical dependence liability. Examples include oxycodone, morphine, cocaine, methadone, and hydromorphone.

Schedule III: Significant abuse potential, but less so than Schedule I or II. May involve combination preparations such as hydrocodone and acetaminophen (hydrocodone alone would be classified as Schedule II, but is Schedule III if mixed with acetaminophen). Further examples of Schedule III drugs include hydrocodeine and many synthetic preparations mixed with acetaminophen.

Schedule IV: Abuse potential less than Schedule III. Abuse and misuse is prevalent, and often underestimated. Typically these are inclusive of the benzodiazepines class, but may include some forms of codeine preparations.

Schedule V: Abuse potential less than Schedule IV. Practitioners tend to believe that lower risk accompanies lower scheduling. That is not a correct assumption, and Schedule V drugs may be trafficked and abused as easily as Schedule II drugs. The sanctions for misuse of *any* controlled substance are vigorously prosecuted and criminal in nature. Sedative hypnotics and mixed agonist antagonist drugs frequently are Schedule V preparations.

Schedule II prescriptions are often prescribed monthly, and currently not allowed to be "forward-dated." When a prescription is "forward-dated," the date the prescription is actually written must be on the prescription followed by "Do not fill until …." Schedule II prescriptions may not be written for renewal of the original prescription and must have an original prescription for presentation to the pharmacy. It is recommended from a risk perspective and medical necessity requirement that an actual physical assessment by the practitioner or practitioner extender occur monthly to warrant continued Schedule II use.

Schedule III, IV, and V medications may be no less habituating than Schedule II drugs, and street value remains high for most controlled substances. In fact, hydrocodone is among the most widely misused and illegally distributed medications in America (Federation of State Medical Boards [FSMB], 1998). Other highly habituating medications that are erroneously and commonly considered benign in many treatment arenas include benzodiazepines, particularly alprazolam (Xanax®), and muscle relaxants, such as carisoprodol (Soma®), to name two. Many other examples exist, and regional variations may be important. Caution should be exercised when prescribing these medications. Even Schedule IV drugs, such as butorphanol tartrate (Stadol®), may be highly sought after by the patient. Misuse and drug-seeking behavior should be documented in the medical record and acknowledged by the prescriber. The prescriber's decision to continue treatment in the face of misuse or abuse behavior is documented in the record as soon as this behavior becomes evident. If the prescriber chooses to continue prescribing controlled substances, the reason(s) must be clearly expressed, and a discussion of what safeguards and restrictions will be placed upon the prescriber–patient relationship is clearly documented. Initial encounters are recommended to document family or patient abuse/use history, including alcohol. Merely filling out a prescription each month without documenting functional indices, quality of life indices, pain scale, restorative sleep, and appropriateness to treatment should be avoided, and in state and federal cases this lack of documentation has been used as evidence of improper and/or illegal activity by prescribers.

KEY TERMS TO KNOW AND USE

Practitioners must know and use the following terms in daily medical practice. These terms, addiction, tolerance, pseudoaddiction, and physical dependence, factor into each of the five key documentation components for controlled substance prescribing and, consequently, risk management concerns.

Addiction: Addiction is an important clinical and legal term. In its 2004 revised *Model Policy for the Use of Controlled Substances for the Treatment of Pain*, the Federation of State Medical Boards defined addiction as "a primary, chronic, neurobiologic disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. It is characterized by behaviors that include the following: impaired control over drug use, craving, compulsive use, and continued use despite harm. Physical dependence and tolerance are normal physiological consequences of extended opioid therapy for pain and are not the same as addiction (Federation of State Medical Boards [FSMB], 2004).

Practitioners should consider addiction issues if a patient no longer has control over drug use and continues to use the drugs despite potential harm to self or others. Ronald Kanner, M.D. (2003) cites five main characteristics of addiction: chronic use, impaired control, compulsive use, continued use despite harm, and craving (the five Cs). These distinctions are in contrast to tolerance, pseudoaddiction, and physical dependence, in which continued use of the controlled substance does not place the patient at risk of harm (see Federation of State Medical Boards, http://www.fsmb.org).

Tolerance: Tolerance is a physiologic state resulting from regular use of a drug in which an increased dosage is needed to produce a specific effect, or a reduced effect is observed with a constant dose over time. Tolerance may or may not be evident during opioid treatment and does not equate with addiction (FSMB Model Policy, 2004).

Pseudoaddiction: The iatrogenic syndrome resulting from the misinterpretation of relief-seeking behaviors as though they are drug-seeking behaviors that are commonly seen with addiction. The relief-seeking behaviors resolve upon institution of effective analgesic therapy (FSMB Model Policy, 2004). Not grasping this phenomenon may lead the clinician to inappropriately label the patient as an addict due to unrelieved pain resulting in frequent requests for escalating

drug doses, requiring clinical reevaluation of need and of the risk-reward benefit. This is a controversial issue. Many pain physicians do not believe pseudoaddiction exists.

Pseudotolerance: Pseudotolerance is the need to increase dosage that is not due to tolerance, but due to other factors such as disease progression, new disease, increased physical activity, lack of compliance, change in medication, drug interaction, addiction, and deviant behavior. When a once-fixed opioid dose is no longer effective, these conditions should be reviewed to exclude pseudotolerance (FSMB, 1998).

Physical Dependence: Physical dependence is a state of adaptation that is manifested by drug class-specific signs and symptoms that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist. Physical dependence, by itself, does not equate with addiction. [FSMB *Model Policy* 2004]. Physical dependence may also occur if an opioid antagonist is administered to an individual exposed to a prolonged, regular course of opioids. Physical dependence ". . . is not a clinical problem if patients are weaned to avoid abrupt discontinuation of the drug, a tapering regimen is used (if treatment cessation is indicated), and opioid antagonist drugs (including agonist-antagonist analgesics) are avoided" (2).

PART TWO. CONTROLLED SUBSTANCES AND CHRONIC PAIN

RISK MANAGEMENT

Chronic pain treatment is often delegated, by default, to select individuals who have demonstrated an interest in dealing with some of the most difficult patient management issues in contemporary medicine. The pain management specialist is the tip of a funnel, and usually perceived as the last hope for many patients suffering from pain. Pain diagnoses are usually the product of a complex relationship of social, psychological, and physical factors, cultural and religious experiences and thus require a comprehensive environment of care and co-managing providers to afford the best outcome. The very complexity of pain and pain management demands a proactive approach to risk management overall, and specifically in the use of controlled substances to treat pain. Worse yet, few specialists face the problem presented by health care benefit plans that do not cover services, such as mental health referrals, the use of certain specialists, and drug control measures, thereby placing the practi-

tioner in a risk position. Practitioners must learn to respond to these issues and understand that they can achieve balance in their respective practices with proper risk management protocols.

Practitioners who prescribe controlled substances routinely *must take steps* to understand the legal and regulatory environment and to structure risk management protocols based on federal and state legal and regulatory standards and accepted standards of care. Our news media increasingly report stories about a small number of practitioners who have been charged with the illegal distribution of controlled substances (in lay terms referred to as "inappropriate prescribing"). These practitioners, often guilty of recklessly disregarding medical ethics and specific legal and regulatory standards relating to the use of controlled substances to treat pain, face financial ruin and leave dozens of improperly handled patients behind for the community of practitioners to absorb or channel through an already overstressed health care system. These very few "rogue" practitioners give a bad name to the whole process of treating pain and ethical and quality-minded practitioners *must take action* to ensure "dumped" patients are handled appropriately and turned into success stories, where possible. For all these reasons and more, today's pain treatment paradigm strives to find a treatment plan that provides a high level of satisfaction for all involved. Ultimately, this means every practice *must participate in* a proactive risk management program, especially when the practice uses controlled substances to treat pain.

The purpose of this chapter is to analyze risk in the context of a pain management practice, with a special emphasis on risks associated with the use of controlled substances to treat pain. After looking at the various risk areas, the chapter offers suggestions on how pain practitioners might minimize risk in their practices while still offering quality medical care. It is important for readers to remember that a risk management plan is only part of an ongoing process to identify and respond to risk factors in daily practice. Once risk management protocols are learned, the process becomes second nature to the practitioner and often results in better practitioner–patient relationships overall.

Legitimate medical purpose and use within the usual course of professional practice define, for legal/regulatory purposes, the validity of a controlled substance prescription. [21 CFR 1306.04(a)] Federal law does not provide a specific definition of legitimate medical purpose. However, there are many reported federal criminal cases and DEA registration revocation cases discussing what may or may not constitute a "legitimate medical purpose" in the context of a sufficiency of the evidence against the defendant argument. For example, here are a few criteria both DEA and the courts use to find a lack of legitimate medical purpose:

Patient demands take the place of a physician's medical judgment [(Revocation of Registration, *Robert L. Dougherty, Jr., M.D.*, DEA Docket No. 94-63, 60 Fed. Reg. 55047 (October 1995).]

Dispensing (or prescribing) controlled substances to a patient who has demonstrated actions consistent with being a substance abuser (or diverter) [*Dougherty*].

Dispensing (or prescribing) an excessive number of refills to a patient over time (e.g. six months) without requiring a clinical examination or visit. This demonstrates a *reckless disregard for medical standards in dispensing controlled substances*. [*Dougherty*].

Prescribing controlled substances to patients without conducting a proper physical examination or appropriate tests to determine if the patient's medical condition justified the prescribing of the controlled substances. [(Revocation of Registration, *Sajjan Gangappa Chikkannaiah, MD*, 55 Fed. Reg. 38174 (September 1990).]

Prescribing an enormous quantity of frequently abused controlled drugs to patients for patently inappropriate periods of time, sometimes for years. [*Chikkannaiah*].

Prescribing controlled substances to patients the provider knew, or should have known, were drug abusers or addicts. [*Chikkannaiah*].

Both DEA and state licensing boards are serious about monitoring complaints regarding a practitioner's prescribing practices. These entities expect practitioners to conform to clinical and community standards, and to comply with applicable federal and state legal/regulatory materials. The pain practitioner is a leader in the community, understanding the proper use of opioids and controlled substances and the best techniques for diversion avoidance. Likewise, the pain practitioner is positioned properly to assist others in developing appropriate community policy.

Overall, the legitimate medical purpose or need for controlled substance relates to the practitioner's documented assessment of the patient's medical condition and findings regarding his/her pain complaint. Moreover, the practitioner's documentation *must* include relevant diagnostic and lab studies to support the diagnosis and justification for the use of controlled substances. Documentation of legitimate medical purpose *should not* be accomplished as a reactive response to fear of federal or state scrutiny. Rather, documentation of legitimate medical purpose reflects quality medical care and practitioners *must* make this a habit. The DEA publishes a pharmacist's manual that contains a good overview of the DEA's perspective on controlled substances and documentation requirements. Every practitioner is encouraged to read this manual.

Obviously, many patients challenge the pain management practitioner, alleging lack of compassion and clinical competence when the dose is changed or the drug replaced with an alternative choice. The patient and referral source require open communication to ensure that the patient receives the treatment needed, not necessarily what the patient wants. The referral source is educated that a change in the patient course might be beneficial to avoid alienation or misunderstandings, and not enhancing the patient/referral interaction.

While it is true that most prescribers are well trained and will appropriately use controlled substances, unfortunately the doorsteps of pain practitioners' offices are littered with stories of less-enlightened practitioners (from all specialties) who are lulled into the belief that high-dose opioids are appropriate for certain painful disease entities, only to find that their primary care practices or nonpain specialty practices are ill equipped to manage these drugs over a prolonged period of time. Pain management practitioners are referred these complex patients, who are told that pain specialists are their "parachutes" and will be their sole prescribing entities; "Don't ask me for these medications anymore; the pain specialist will give them to you." Herein lies the problem: what is the best course of care with the least risk profile to the practitioner and patient? An alarming, increasingly popular, and "easy" course of action for many primary care practitioners is to initially prescribe habituating controlled substances, only to later find the patient increasingly demanding and time-consuming. Often, these primary care providers respond to complaints of "I hurt" without assessing function and risk. When their patients fall outside of a clinical comfort zone, a referral, or "risk-shift," is made to a pain management provider. The pain practitioner may then be exposed to a high-risk, demanding patient in the first encounter.

Few specialties commonly accept these high-risk individuals outside of pain management practices, which implies to the medical community pain practitioners are, indeed, their "parachutes."

Another group of patients frequently encountered in a typical pain management practice are those *undertreated* by community providers. Acknowledging pain undertreatment and the practitioner's fear of prescribing controlled substances, the FSMB adopted guidelines in the 1990s that aided the practitioner's comfort level for controlled substances, even in large doses, for those suffering from legitimate chronic nonmalignant pain. This problem, pseudoaddiction, is less common today, and the enlightenment of pain treatment as a disease state has lessened suffering in the community. Practitioners are not free of risk, however, and the variable levels of controlled substance use to control pain imply a lack of formal training available for community care providers and other specialty providers. Misinformation and the potential of profes-
FIGURE 94.1 Instances of nonmedical use of OxyContin among U.S. population. Adapted from A. Atluri et al., 2003, *Pain Physician, 6*, 233. With permission.

sional sanction impair appropriate prescribing-related decision making, but to a lesser degree than previously existed prior to the FSMB guidelines. The recently updated Model Policy for the Use of Controlled Substances for the Treatment of Pain by the FSMB is available at http://www.fsmb.org.

Abuse and misuse of controlled substances is rising, however, and prescribers occasionally feel they are caught in the middle (Figure 94.1). Is there risk of retaliation from the patient or regulatory agencies? Are my patients in pain adequately treated, and how can I reduce personal risk? To reduce risk and enhance patient care, it is in the prescriber's best interest to exhaust all nonhabituating and non-opioid approaches to pain control prior to introducing potentially habituating agents. Consider reviewing the World Health Organization's "WHO Ladder" and become familiar with a knowledge base of minimally invasive interventional and surgical options.

Non-opioid adjuvant medications are effective and readily available to decrease opioid pain medication, or in many cases to help us decrease habituating risk. The interventional pain procedures pain physicians perform are further witness to the usefulness of adjunctive approaches to treat pain.

Additionally, psychological enhancements may be extraordinarily helpful, but are not always readily available. Below are suggestions to assist the practitioner in decision making, reducing risk, and promoting the proper use of controlled substances.

1. **Be goal oriented with medication management.** The patient and practitioner mutually understand that there is not a single agent, a "magic bullet," or an interventional procedure that will rid a patient of all pain. Realistic expectations are discussed with the patient, family members, and other third-party individuals that are interactive with the individual in pain. The interventional procedures and medications are *tools*, and when used properly, an important asset to enhance patient function.
2. **Pain is not static, but dynamic.** Pain will change, the character of presentation will vary over time, and functional indices are many times determined by the "personality of the pain." No more so is this true than when controlled substances are used for pain relief. The bio/psycho/social/religious influences of pain disrupt mood, function, quality of life, and personal interactions with others. Patients want a return to premorbid function and a pill is the easiest and most available treatment to many. Use of medications and functional enhancements should be reassessed on a regular basis to drive appropriate clinical conclusions and rule out the negative or ill effects of any pain control strategy. A patient asking for escalating doses of opioid and controlled substance-based pain or habituating adjuncts should be assessed of need, and documentation should be appropriate to the patient's presentation. Patients ultimately are given what they *need*, not what they *want*. Beware of the "ask-for-it-by-name" patient.
3. **You cannot document enough.** A personalized medical necessity checklist is a good approach, particularly a tool that includes elements of the recommendations by the FSMB for documentation purposes. Controlled substances are a double-edged sword — they can help and harm patients. Is the patient enabling or disabling? Are the patient's function and quality of life indices improved, or do we even measure these? Is the risk–reward benefit clearly reviewed, and is the patient documented to be of *no risk to harm self or others*? Always record the family and patient substance abuse history.
4. **Understand pain control as it relates to adjunctive medications.** Many pain-producing entities are opioid resistant. With any disease entity, defining the diagnosis precedes therapy, and this is particularly true when we treat the patient in pain. Establishing the differential diagnoses of patients with pain deserves careful thought prior to reaching any diagnostic conclusion, but when pain becomes *the disease*, a clear single diagnosis may be elusive. With no diagnosis, the practitioner and patient become frustrated and the costly process of "chasing" the pain frequently ends without resolution.

The patient with acute pain should be approached differently from the chronic pain sufferer. Acute pain responds more predictably to medications. Barriers to therapy such as psychological and physiological disturbances rarely impair the patient.

Patients with chronic pain require thorough management. Due to the many providers they encounter, these

patients frequently feel the allopathic physician has lost interest in their complaint. It is not unusual that treatment is sought outside of traditional therapy, many times without the physician's knowledge. The physician's role remains to help the patient understand sensible treatment goals. It is unreasonable to expect complete pain relief in many situations, and expectations must be clearly explained to the patient. Establishing improvements in activities of daily living and functional lifestyle should be stressed. Very effective non-opioid, nonhabituating pain medications are currently available to improve perception of pain and well being with minimal risk of abuse. Adding these options or transitioning to these solutions is an important consideration, particularly if a habituating medication places the patient or prescriber at risk.

What Controlled Substances Do to Practice Dynamics

Practitioners use controlled substances to manage symptoms of disease, such as chronic painful entities, with a primary goal of improving the patient's function, quality of life, and restorative sleep. Prescribing controlled substances necessitates the prescriber's commitment to continuing education in pain management, setting and enforcing proper treatment boundaries with patients, and understanding the interplay between law and medicine in the use of controlled substances to treat pain. A compassionate understanding between patients, their unique social dynamics, and other important individuals that influence treatment often are time-consuming for practitioners and create added attention of staff resources and training. Prescribing these medications frequently requires the staff to respond to numerous office phone calls and requests for early visits. Considerations of overutilization are valid, but when properly used to treat pain, these medications can ultimately control cost, possibly controlling utilization issues. Further considerations for prescribers and staff are that controlled substances increase provider medicolegal risk exposure and increase the potential of regulatory and civil scrutiny. Last, increased documentation is required, adding further burden and cost to the practitioner and staff.

Risk Management and the Concept of Iatrogenic Addiction

Iatrogenic addiction describes what happens when a well-meaning prescriber, providing symptom management with controlled substances, consequently habituates the patient to these medications. Patients may report to the prescriber for the sole purpose of obtaining pain medication, irrespective of current pain perception. These patients may have multiple sources available to procure these substances, and are quite insistent about their medication

need. Frequently, more than one provider supplies these medications, so the patient does not "run out." In many states this is a violation of the law and is referred to as "doctor shopping." Poor vigilance places the prescriber in a potentially troublesome risk environment. Occasionally these patients believe it is their "right" to be treated with these substances, referring to Web sites, insisting that physicians undertreat pain. Patients may be convincing and unrelenting. A busy practitioner will often take the path of least resistance, write the prescription, or as mentioned, refer to the "parachute" provider in the community.

Controlled substances impose routine pharmacy checks and require that patients remain close to the guidelines that are developed by the practice to follow the use of the drug and its legitimate need. In cases of iatrogenic addiction, patients will expect a prescription to be written, and little deviation from their routine will be tolerated. Avoiding iatrogenic addiction is a key element when treating pain. Iatrogenic addiction, as the name implies, suggests that pain is no longer the primary reason for the visit. A careful history at each patient encounter will avoid this pitfall into which many providers fall. Pain may well become the disease of need, addiction an occurrence of the disease, and the practitioner should avoid facilitating both.

Controlled substances are not a patient retention or recruiting tool. Bad clinical outcomes and an increased risk of substance abuse are commonly encountered with a patient not closely scrutinized or followed with a high level of prescriber awareness. Furthermore, a subset of patients uses opioids for their euphoric effects, essentially initiating an antidepressant effect, inappropriately using controlled substances for mood alteration. Patients might also use controlled substances as an effective way to gain repeated access to the health care system for secondary gain purposes. The prescriber and the practice are accountable for the proper use of these medications despite external pressure, and the gatekeeper for proper prescription habitry.

Documentation

When using controlled substances to control pain and disease, documentation must be thorough, and the risk–reward benefit reviewed with the patient regularly. The following model guidelines for the use of controlled substances for the treatment of pain are authored by the FSMB (http://www.fsmb.org). Adopted May 2004, the FSMB strongly encourages the medical record to include the following components:

- Medical history
- Substance abuse/chemical dependence history
- Pain history
- Appropriate studies (labs, imaging, etc.)

- Working diagnosis
- Treatment plan
- Rationale for treatment selected
- Patient education
- Doctor and patient understanding methods and goals of treatment
- Follow-up protocol, which must be adhered to
- Regular assessment of treatment efficacy
- Consultation with pain specialists, when warranted
- Multidisciplinary approach, when indicated and approved by payers (sometimes difficult)

As previously mentioned, a medical necessity checklist is suggested to be placed in the chart when treating patients with controlled substances and opioids in the chronic nonmalignant pain arena. The FSMB recognized the need for provider guidelines, enhancing compassionate care for those suffering from pain, lowering prescribing reluctance and guiding legitimate use. The FSMB requests that each practitioner demonstrate knowledge of narcotic-based pain medication, especially in a chronic scenario, and recommends ongoing continuing education. Furthermore, the medical record reflects low risk and states the patient's risk to harm self or others is reviewed. Provider documentation also includes, as a routine part of the history, current or previous substance abuse, and family risk factors.

Medical Necessity and Agreements

Practitioners *must* document "medical necessity" or "one or more clinical indications" for the use of controlled substances to treat pain. Practitioners *must* properly assess the patient, which means that the practitioner document the patient's general medical history, specific medical history concerning the existing pain complaint, past medical treatments, including controlled substances for the existing pain complaint, a working diagnosis, and the patient's history of chemical/substance abuse. In many states, licensing board prescribing guidelines and regulations require a practitioner to document that non-addictive treatment modalities or adjunctive therapy have been tried and failed or ruled out in the patient's case. Once a practitioner starts a patient on controlled substance therapy, it is suggested that the practitioner periodically review the patient's care to determine whether there is an ongoing medical necessity or clinical indication for the continued use of the prescribed medications.

True medical necessity is more than a diagnosis — it considers the whole patient, and his or her willingness to (1) be proactive in his or her own health care, (2) participate in formalized or home-based therapy, physical and well-health behavior, and (3) demonstrate behavioral stability. Particularly in pain therapy, enhancing function and quality of life indices improves compliance. Many state licensing boards have documented investigations involving practitioners who fail to consider (or seriously consider) patient personality characteristics and history of chemical or substance abuse *prior to prescribing*. Practitioners are wise to consider these items in connection with a statement of medical necessity of clinical indication for the use of controlled substances. Remember, personality characteristics do vary among individuals, but aggressive personality characteristics are often the harbinger of a potentially problematic relationship with the patient.

To be complete in the medical necessity component of risk management, practitioners are urged to use medical history questions directed at gathering information about the patient's antisocial behavior, if any, including an assessment for personality disorders and violence. If unfavorable personality characteristics exist, a consultation with an addictionologist or psychiatrist is strongly urged, and may increase the likelihood of improved patient compliance and enhanced therapeutic decision making. Finally, consider further minimizing the potential for practitioner liability by having the patient sign a "No risk to harm self or others" form at each visit. Use this document along with a medical necessity checklist or another form of pain inventory (Figure 94.2).

A drug *contract* is less wordy than a "controlled substance *agreement*." The term *contract*, however, may imply legal obligations from both the patient's and the practitioner's perspective, and a *contract* may be used *against* a practitioner. An *agreement* between patient and practitioner is less legally intrusive. The drug agreement is signed with a witness present, and a copy is given to the patient with full explanation of the risks, complications, and options of habituating medication treatment. Consider having the patient initial each point of the agreement to acknowledge that the agreement was read and understood with no barriers to communication. It is strongly recommended that the patient's record reflect review of this controlled substance agreement at frequent intervals during the patient's subsequent visits.

Controlled Substances, the Controlled Substance Act, the Physician, and the Concept of Legitimate Medical Purpose

An important triangle of understanding exists between the DEA, pharmacist, and prescriber, each with a unique perspective of patient well-being and controlled substance management. First, the premise of the DEA is to ensure the health and safety of patients exposed to controlled substances, to safeguard society, and to provide guidelines and amendments to assure adherence to the law. The DEA, therefore, protects the public health and safety. Next, the pharmacist is the source of dispensing and distribution. Finally, the prescriber determines the need of a controlled

substance based on patient presentation. The prescriber alone is responsible for understanding, and ultimately defining, legitimate medical purpose at the patient level.

REDUCING RISK WITH POLICIES AND PROCEDURES

Policies and procedures are a roadmap for practices to determine course of care and direction of daily expected and unforeseen activities. Strong policy and procedures that are accessible to staff and providers remain a powerful risk reduction tool. Frequently, a heralding event initiates a policy *reactively* and is kept in a dynamic nature to be modified as the practice grows. The staff is invited to add to the policies and procedures, where appropriate, and feel compelled to become part of the process of relevant documentation. This active involvement improves not only employee–practitioner relations, but takes the employee to task as a solution provider and an involved individual

to assist in practice growth and protection. Policy and procedures are best developed *proactively* before reacting to a heralding event, but in both cases, demonstrate a high level of practice accountability.

Typical policy and procedures that address controlled substance use involve

- *Documentation*. Clear, concise history, physical, and diagnosis. The medical record is accessible and organized.
- *Medical necessity*. The risk is appropriate to the use.
- *Legitimate use*. The controlled substance is used within state, federal, and community standard. Currently, there is no designated *federal* community standard recommendation.
- *Credentialing*. The medical service provider is properly licensed by the state and registered with the DEA. Institutional affiliations and

medical organizations are important associations, and activity in local medical societies assists in community awareness of standards of care.

- *Standards of conduct of controlled substance use*. Standards of conduct are oftentimes defined by community and state recommendation. The provider is aware of the ethical and moral boundaries of controlled substance use.
- *Standards of prescribing practice*. Use, misuse, and expectations are understood by the patient, provider, and staff.
- *Continuing education*. Necessary to document awareness of legitimate use.
- *Emergency protocols*. Hospital affiliation and availability of services addressed, and protocol defined to assist in extreme care instances.
- *Call policies*. 24-hour availability for adverse event.
- *Operational and personnel responsibilities*. Each provider or staff member is aware of communication channels, when and whom to notify for a question or event, and providers or officers of concern are available when adverse event occurs.
- *Job descriptions and responsibilities*. No confusion should exist. Responsibility for controlled substance prescribing rests with the practitioner of record, or in the case of physician extender providers, the supervising physician is responsible for oversight.

Risk, as a form of loss, is reduced by developing policies and procedures that are understood and followed by the practice, and reflective of community standard. Continuing education of the staff and providers within a practice demonstrates responsibility to the patient and the regulatory system. Documentation of understanding and awareness of a diagnosis and plan are mandatory. A controlled substance agreement, signed, dated, and witnessed, and a signed informed consent are included in the chart.

As drugs with similar trade names, abbreviations, decimal points, and dose are common errors, both in and out of the hospital setting, prescriptions should be legible, and numbers of pills documented both numerically and then written out.

Altered prescriptions are becoming easier to pass for original, and computer software programs allow scanning of prescriptions generating look-alike prescriptions, further complicating issues of diversion. A novel tactic that might be used to avoid use of a fraudulent prescription is to apply a notary-like seal, unique to your practice, obtained at any local business shop. Local pharmacies can be made aware that controlled substance prescriptions are invalid without this notary seal. Of course, not all practices

will be able to inform each pharmacy, but demonstration of this high level of vigilance is in the prescriber's favor should the practice fall under scrutiny.

The practitioner should produce readable, organized, and accessible records. Within these records, documentation is thorough and recognizes drug interactions. Care is exercised to document alternative therapies considered, and a diagnosis matches the therapy offered. Considerable risk can be avoided if prescribers follow practice guidelines unique to community standards developed to address limits and expectations. All practitioners are compelled to remain within the scope of their practice defined by state law. Policies and procedures in the pain management office are often developed to assist in practitioner credentialing and monitoring of provider practices.

Another problem encountered with controlled substances is the availability of prescriber or staff to address adverse effects. A designated individual to follow patients and their needs decreases the confusion of perceived side effects, or outright complications from these medications. This response is particularly important in the elderly population, who are subject to multiple drug interactions. A designated and experienced person is often an important "go-between," connecting the prescriber and the patient to reduce misuse, confusion, or complications associated with controlled substance use. Documentation in the chart further reduces risk exposure when patients call, and a telephone log sheet is a necessary part of the formal medical record. In the next few years, we can envision the advantages of an electronic prescribing system that performs medication crosschecks and alerts misuse, incompatibility, and possible diversion. Although this technology is on the horizon, the electronic medical record still remains distant and not an easily available entity for many practices to acquire.

STANDARD OF CARE, INFORMED CONSENT, AND TREATMENT AGREEMENTS

Standard of care is a community effort, unique to an area's medical need, resource availability, and accessibility of practitioners. Relevant to the practitioner, standard of care acknowledges that education remains a key component to avoid risk of adverse event exposure. Standard of care also embraces informed consent as a foundation to develop understanding of the risks and benefits of treatments offered during the practitioner-patient relationship. In the use of controlled substances to treat pain, the development of a viable informed consent process is a critical component of the risk management process.

Informed consent has its origins in law. Historically, cases involving assault and battery involved touching without consent. Lack of informed consent frequently gives rise to a negligence or malpractice claim in the medical community. Informed consent is not limited to

medical procedures alone. Instead, providers must learn that informed consent applies equally to procedures and treatment plans involving the use of controlled substances to treat pain.

Some states have intractable pain treatment acts (laws) requiring practitioners to engage in an informed consent process with patients prior to prescribing controlled substances to treat intractable pain conditions. Likewise, most state guidelines and position statements on pain management and/or prescribing controlled substances to treat pain suggest that practitioners *should* engage in an informed consent process. The American Medical Association's (AMA) Code of Medical Ethics contains a discussion of informed consent and states that it is a process that involves the exchange of relevant information between the practitioner and the patient. The information must be sufficient to allow the patient to make an informed decision about accepting or rejecting the proposed medical treatment. Specifically, the AMA contemplates an informed consent process that explains to the patient the risks and anticipated benefits of the controlled substance therapy, scientifically available treatment alternatives, and an opportunity for a meaningful exchange of information between the practitioner and patient. Once again, the lack of informed consent might result in a negligence action against the practitioner. Combined with a pattern of reckless disregard for legal/regulatory materials, accepted clinical practice standards, and community standards, lack of informed consent may be used as evidence of a practitioner's criminal intent in a case charging the illegal distribution of controlled substances.

The process of informed consent does *not* guarantee immunity. Explaining the risks and benefits, and treatment alternatives is not enough to constitute foolproof informed consent. Rather, practitioners must ensure the patient has the capacity to give his/her consent, and to understand the importance of the information supplied during the informed consent process and what it means to act upon the information. For example, did the practitioner explain the risks, complications, and options of the procedure, and spend the time necessary to ensure that no barriers to communication were evident? Furthermore, was the patient aware of the importance of the practitioner's comments, understood culturally, and was there no evidence of language barrier present? The key issue here is "First do no harm."

ORAL OR WRITTEN INFORMED CONSENT?

Practitioners are clearly pressed for time during the practice day and thus likely to see an oral informed consent process as the most efficient way to handle this risk management measure. However, oral informed consent will always pit the practitioner's word against the patient's word in the courtroom and, in such cases, the practitioner is likely to be on the losing end of that battle. Practitioners should be proactive with informed consent and use a written informed consent document that explains the required information in simple fashion and contains a space for the practitioner, patient, and witness signatures.

CONTENTS OF THE INFORMED CONSENT

The key elements of a written informed consent (see Figure 94.3) are: (1) a list of the risks of using controlled substances to treat pain, including a discussion of addiction potentials, the concepts of physical dependence and tolerance, commonly experienced side-effects, and potential drug-drug interactions; (2) the expected benefits of using the recommended controlled substances; (3) scientifically available treatment alternatives (given without regard to a patient's financial condition); (4) specific issues of concern, such as driving or handling a weapon; (5) the opportunity for the patient to ask questions of and receive a response from the practitioner; and (6) signature space for the patient, a witness, and the practitioner. Practitioners may use a similar informed consent form when considering special procedures or general treatments. Finally, find a way to show that you have inquired about patient competency (or guardian competency) to provide informed consent. This may require you to obtain a power of attorney, or the signature of an immediate family member in the case of a minor, and possibly a third party appropriately designated. In all cases, practitioners should determine whether the consenting individual is able to provide consent legally.

CONNECTION TO THE TREATMENT PLAN

Informed consent relates directly to the development of a treatment *plan. Before entering into an informed consent*, the practitioner is encouraged to document a working diagnosis justifying the use of the controlled substance(s) covered by the informed consent. Simply placing the patient on an opioid or controlled substance for symptomatic analgesia is inappropriate when the diagnosis is poorly understood. Many times a correctable procedure or non-habituating medication profile is more appropriate for the patient. A practitioner's failure to consider these issues prior to prescribing controlled substances may expose him/her to greater risk and thus greater liability.

THE USE OF TREATMENT AGREEMENTS

Most state prescribing guidelines and regulations contain a sister-component to informed consent called *Treatment Agreement*. Many practitioners are familiar with the concept of a "narcotic contract." A *Treatment Agreement* is similar to a "narcotic contract," except the *Treatment Agreement* should cover office policy on prescribing controlled substances and patient promises to handle con-

Informed Consent for the Use of Controlled Substances to Treat Pain

Dear _____ (Patient Name)   Date: _____

This document is called an "Informed Consent" form. The purpose of the document is to explain important information about the controlled substances (medications) your doctor recommends that you use to control your pain. You are responsible for reading this document, asking your doctor questions about the medications, and signing this form if you decide to use the recommended medications to control your pain. You will be given a chance to talk to your doctor about this information. You will get a copy of this form and we will keep a copy of it in your patient file.

Based on your statements to your doctor, and his/her review of your pain history and relevant medical records and tests, your doctor believes you have a medical condition called _____ and this causes you [acute, chronic, intractable] pain.

Your doctor has recommended treating your pain with the following controlled substances:

Drug	Strength	Qty	Route of Administration	Delivery	Potential Drug — Drug Interactions; Special Instructions

Treatment Benefits, Goals and Alternatives
Your doctor believes these medications will benefit you in the following way(s), but only if you follow the complete treatment plan your doctor discussed with you during your office visit:

1.
2.
3.

Your goals from therapy are to reduce your pain to a level that will allow you to do the following:

1. [example, Garden 3 days a week]
2.
3.

Your doctor has advised you that the following alternative treatments to using controlled substances are available to you:

1. [example, Physical Therapy]
2. [example, ibuprophen]

MATERIAL RISK NOTICE – DRUG CLASS _____ (e.g., Narcotics/opiates)

In general, using the medications listed above may put you at risk for the items listed below. You should check with your pharmacist for additional information about the above-listed medications if you decide to take them:

1. **BRAIN**: Sleepiness, difficulty thinking, confusion. **It is important for you to consider how your use of the above-named medication might affect your ability to operate a motor vehicle or other heavy machinery. IT IS YOUR RESPONSIBILITY TO FOLLOW THE LAWS IN THIS STATE REGARDING THE OPERATION OF A MOTOR VEHICLE WHILE USING CONTROLLED SUBSTANCES. Likewise, for those licensed to carry weapons, you must consider whether you have an obligation to report your use of controlled substances to your employer. If you have a concern about these issues, consult your attorney or call the Department of Transportation, Driver's License Bureau, Weapons Licensing Bureau.**

2. **LUNG:** Difficulty breathing, shortness of breath, wheezing, slowing the breathing rate.

3. **STOMACH:** Nausea, vomiting and constipation can be severe.

4. **SKIN:** Itching, rash.

5. **URINARY:** Difficulty urinating.

6. **ALLERGY:** Potential for allergic reaction.

Continued

FIGURE 94.3 Informed consent form.

7. **DRUG INTERACTION(S):** Possibility of interaction with other medications. Can make the effect of both drugs stronger when taken together.

8. **TOLERANCE:** With long-term use, an increasing amount of the same drug may be needed to achieve the same pain-relieving effect.

9. **PHYSICAL DEPENDENCE/WITHDRAWAL:** Physical dependence may develop within 3–4 weeks when taking these drugs. If they are stopped abruptly, symptoms of withdrawal may occur. These include but are not limited to: abdominal cramps, abnormal heartbeat, nausea and vomiting, sweating, flu-like symptoms. These may be life threatening. All controlled substances need to be slowly tapered under the direction of your physician or facility.

10. **ADDICTION:** This refers to the abnormal behavior directed toward acquiring or using drugs in a non-medically necessary supervised manner. People with a history of alcohol or drug abuse are at increased risk of developing an addiction.

If you want to know more about these risks, ask your doctor after you finish reading this form.

Have you read and do you understand this document? (Initial one)

____ I was satisfied with the above description and did not want any more information, or

____ I requested and received further explanation about the treatment, alternatives, or risks.

I agree to follow the terms of this agreement and I understand the risks, alternatives, and additional therapy associated with the use of controlled substances to treat my pain. I understand this document will be maintained as a permanent component of my chart.

Patient Signature: _____ Date:

Witness Signature: _____ Date:

Provider Signature: _____ Date:

*Note to provider : Use the back of this form to document the patient's questions and your responses to them.

FIGURE 94.3 *Continued.*

trolled substances responsibly. It is imperative that practitioners understand that Informed Consent and Treatment Agreement ARE NOT THE SAME PROCESS. These processes require different forms and different language. It is legal in most states for a practitioner to combine the informed consent and treatment agreement processes into one document, but that document should discuss informed consent on the front of the document and the treatment agreement on the back. The concept of a Treatment Agreement originates from a need to set boundaries for patients in attempt to minimize the potential for abuse and diversion of controlled substances. A Treatment Agreement does not originate from the law of assault or battery and a failure to use a treatment agreement generally will not give rise to an action in negligence or malpractice. Thus, before discussing the elements of a *Treatment Agreement*, it is important to review information relating to the extent of the controlled substance abuse and diversion problem in the United States.

EXTENT OF CONTROLLED SUBSTANCE ABUSE AND DIVERSION IN THE UNITED STATES

Erroneously assuming the patient is safe using an FDA-approved drug is not borne out by recent Drug Abuse Warning Network (DAWN) reports (Figure 94.4). Hydrocodone, oxycodone, and methadone preparations are rising in use and abuse. Emergency departments are docu-
FIGURE 94.4 Estimated number of hydrocodone emergency department (DAWN ED) mentions for total coterminous United States from 1996 through 2001. Adapted from A. Atluri et al., 2003, *Pain Physician, 6*, 233. With permission.

menting increases in substance abuse admissions (see Figure 94.4 and Figure 94.5). The estimated cost of this misuse has continued to rise every year since 1992.

Patients using controlled substances may suffer from psychiatric disorders. Personality disorders, bipolar diseases, psychosis, and depression add a level of instability and risk to controlled substance management (Atluri et al., 2003). Informed consent must be understood by patients who are challenged by their psychiatric disease. Documentation requires support of clarity in mental status and no barriers to understanding.

The manifestation of pain is complex and multifactorial, and coexisting disease is common. Risk to harm self
FIGURE 94.5 Percent increase of opioid abuse from 1994 to 2000. Adapted from A. Atluri et al., 2003, *Pain Physician, 6*, 233. With permission.

or others is an important documentation point, especially in the psychologically impaired individual. Substance abuse and misuse are common in this patient population, even those complaining of legitimate pain. Multiple illicit drugs may be combined with controlled substances, including marijuana. The patient with psychiatric disease requires frequent assessments, pill counts, drug screening, and occasionally, a responsible individual to assist with drug dispensing. Despite close control, abuse and misuse of any controlled substance are difficult for the provider to eliminate. Policies in the practice include proactive identification and an action plan for diversion control. Patient selection and a close patient–practitioner relationship are important, but Manchikanti (2002) reveals substance abuse is common in random screening (14 to 16%), and 34% with controlled substance abuse.

The most commonly abused drugs in the United States are opioids, and the principal drugs of abuse for almost 10% of the U.S. population are prescription preparations (Atluri et al., 2003). Even "good" patients are a potential source of risk, reinforcing the need for vigilance when adding controlled substances. Consider these points as a start for policy development to avoid diversion and misuse of controlled substances:

- **The patient must have a diagnosis.** Not understanding a diagnosis is fraught with complications when treating patients in pain. Simply placing the patient on an opioid or controlled substance for symptomatic analgesia is inappropriate when the diagnosis is poorly understood. Many times a correctable procedure or nonhabituating medication profile is more appropriate, and a wide differential diagnosis should be explored prior to moving forward into the narcotic arena.
- **The patient should be accountable.** We do not live in a perfect world, and some patients are going to be more successful at understanding directions than others. However, the staff should be readily available and the practitioner

should be involved in helping the patient understand, to the patient's cognitive capacity, the implications of controlled substance accountability and treatment. An agreement is reached between the patient and prescriber, and it is advisable that *a patient care agreement* (formally referred to as a "contract") be signed by the patient, preferably line item initiated, and each feature of the agreement explained. The agreement should state that controlled substances will be prescribed only at prearranged times, and that visits to the practitioner's office are mandatory to identify successful therapy. An opioid or controlled substance must be followed within the context of appropriate usage. Pill counts are common practice, random drug screens are recommended, and full informed consent should be in writing. At no time should the practitioner be a victim of "TWOG" (tail wags the dog) where the patient self directs care. The prescriber will document the name of the dispensing pharmacy and communicate when necessary with this pharmacy, and the patient consents to this in written form prior to adding controlled substances to a treatment profile. This informed consent protects patient confidentiality and the patient–practitioner relationship. The patient–practitioner relationship is based on trust, and should be inviolate. The patient knows that this is a two-way street, that these drugs have risks, and agrees to the guidelines laid forth by the practitioner.

- **A zero tolerance policy should be in place.** If an illicit drug, typically THC, is found in the medical drug screen, or if pill sharing occurs, the patient is unsuitable for controlled substance therapy. Abrupt withdrawal should be avoided, but frequent visits and tapering of the drug might be implemented. A potential exception occurs with the use of methadone. Utilizing methadone to withdraw from controlled substances requires a special attachment to the DEA certificate. Methadone is used for pain control, where appropriately documented, without added credentialing. Other medications are more appropriate to wean, and the practitioner remembers that he or she has no absolute/legal obligation to provide controlled substances to any inappropriate patient who has violated the patient–practitioner relationship. The practice may offer a strategy for the patient to be given a "second chance." The risk–reward benefit of controlled substance use is carefully considered in this situation.

- **If the patient seeks medication from someone other than the prescriber of record, and it was clearly outlined in the patient care agreement that this behavior is inappropriate, the patient will be taken off the controlled substance therapy.** The patient care agreement is not a contract, but an understanding of the practice's policy when using controlled substances. A contract implies legal obligations from the patient, and the practitioner as well. It is recommended that the patient care agreement be reviewed by a health law attorney and, of course, follow state guidelines.

- **A cautionary word about medical drug screens**. Many commonly prescribed medications, such as fentanyl, oxycodone, and methadone, are not revealed in routine medical drug screens. It is imperative that the practitioner utilizes one laboratory, clearly understands what this laboratory tests, and communicates often with this laboratory. The laboratory will understand the concept of informed consent and not obtain tissue, blood, or a urine sample for drug screening purposes unless informed consent is given. The patient is also made aware that when the drug screen is requested, the patient must report immediately to be tested. The patient may not report the following day, and again, this policy of compliance is specified in the patient care agreement.

- **An accountability system must be in place for writing and dispensing controlled substance prescriptions.** It is inappropriate to regularly call controlled substances to the pharmacy. Documentation of a prescription is placed in the medical record, and it is discouraged for opioids or controlled substances to be called in on weekends, holidays, and after hours, if at all. Phone-in prescriptions are not recommended to be a common practice, but used as a rescue only. The patient understands that *rescue* is for extraordinary purposes, and the patient care agreement states that if the patient loses his or her medication, or if it is stolen or misplaced, the prescription will not be replaced under any circumstances. Patients who obtain a police report stating that their medication was stolen simply fill out brief paperwork. This is not acceptable, and a lost prescription should not be replaced. A close patient–practitioner relationship may yield some latitude in this regard, but is a rare occurrence.

- **Strategies to avoid diversion would include keeping copies of prescriptions, not faxing duplicating prescriptions, and using unique prescription pads.** We recommend the use of a seal, much like a notary public would use, and that the prescriber communicate this to the pharmacy by having prescription forms declaring, "Do not fill without seal." Furthermore, altered or forged prescriptions can be rapidly identified by a copy retained in the chart. In the near future, computer-based prescriptions and online communication with pharmacies will make it much easier to avoid diversion. The DEA is currently developing electronic prescription guidelines.

- **A proper prescription designates the name of the medications, dosage, the number of units dispensed, and instructions for use.** The number of units should generally be handwritten as numbers (example: #50 fifty tablets) and by spelling out the number of doses as well. It is recommended that only one controlled substance be placed on a single prescription, although state laws vary in this regard.

- **The patient is regularly assessed for cognitive decline**. A brief mental status exam is recommended to be performed at each visit, as well as a functional assessment. Frequent communication with a family member documents subtle changes in mental awareness, and at least every 4 to 6 months a reassessment of functional parameters, pain relief, and elements of legitimate medical purpose will be repeated as continued justification of controlled substance use. At each visit the patient acknowledges and signs a medical necessity checklist, including the declarative statement "no wish to harm self or others." Any evidence of suicidal ideation is referred to appropriate practitioners, and narcotics and controlled substances withheld in a risk environment. It is proper to provide relief with controlled substances in a compassionate care arena, and family members or other reliable individuals may aid in dispensing to the patient at risk. If this is not possible, the practitioner determines if the risk exceeds the potential benefit of opioid or controlled substances and acts accordingly. Side effects from these medications are clearly elaborated to the patient, and changes in treatment strategy are adjusted promptly. Most commonly, constipation or other side effects are easily treated, which enhances compliance.

- **The patient should not be allowed to self-direct care while using controlled substances.** If the patient feels undertreated, this must be discussed with the practitioner. The concept of *pseudoaddiction* (where a patient seeks increas-

ing analgesic doses to treat increasing pain), although controversial and often misquoted, should not be confused with drug-seeking behavior. Pseudoaddiction is easily identified, and should be documented in the medical record. However, the possibility of addiction should also be addressed. To simply increase the dosage when a patient says, "I hurt," is inappropriate. Again, a tool to assess functional capacity may reduce misunderstandings.

- **The practitioner should demonstrate a clear understanding of the pharmacokinetics of the drug prescribed, and the pathophysiology of the pain entity being treating.** Recognizing that pain does change and that the pain diagnosis is not necessarily permanent should alter prescription habitry. Finally, documenting continuing medical education is mandatory with any controlled substance use.

Risks, complications, and options of treatment are explained with each encounter that controlled substances are considered, including the risk of habituation; and definitions such as addiction, pseudoaddiction, and tolerance, with their implications, are communicated to the patient. Risks of driving, operating machinery, and making important cognitive personal or legal decisions are further divulged to the patient. Ironically, it is unclear at this time whether driving a vehicle and the use of a controlled substance are quantified within the arena of risk, but it stands to reason that the patient should be informed that impairment is possible to avoid retaliation should an adverse event occur.

As previously stated, a patient care agreement is also offered to the patient, and *not* referred to as a "contract." A contract infers certain legal obligation to the patient and of the prescriber. The patient care agreement is not a legal document; however, the patient care agreement is best reviewed periodically. An example of an agreement for controlled substances prescriptions is shown in Figure 94.6.

COMPLIANCE

REVIEW OF PERSONNEL AND PRACTICE OPERATION

Ongoing dynamic assessment of risk includes review of insurance, internal and external issues, controlled substance practice, and other liability areas, as well as confidentiality of records and patient information.

Internal issues to a practice include appropriate provider coverage, 24 hours 7 days a week, and avoidance of call coverage gaps. A provider is responsive to an adverse event, and provider performance should be reviewed randomly for competency of care. Deficiencies

require employee education and retraining where necessary. Competency exams for employees will assure that policies and procedures are met with the appropriate response. Controlled substances used in the office require a secured and locked environment, and familiarity with federal DEA regulations.

External risks include environmental OSHA scrutiny; regulatory agency investigation, such as the DEA or state board; fraud and abuse action procedures; and other barriers to care. Particularly important is addressing the Americans with Disabilities Act. Should an employee be found using controlled substances obtained from a prescriber, policies and procedures should clearly spell out the practice liability and offer rehabilitation if indicated.

Background checks are a useful approach to dealing with new patients, but do carry risk. The patient or employee is best informed of issues where violations of personal medical information might be breached. The patient receiving controlled substances agrees that the chosen pharmacy can be referenced and also defines who picks up medications. Other prescribers are not allowed to prescribe controlled substances by agreement, and appointment follow-up is necessary to monitor prescription habitry.

OUTCOME ASSESSMENT PRACTICE GUIDELINES

Outcome assessment requires three inputs to create an output: (1) the patient's perceived complaint matching the diagnosis, (2) the active participation of a medically challenging treatment profile, and (3) inclusion of a plan and appropriate follow-up, biostatistically active measures, and a bioappropriate outcome. The outcome tool recognizes the patient's self-report as the most valuable subjective tool a practitioner uses to assess complaints of pain. Based on the prescriber's practice habits, specialty, and experience, a diagnosis reflecting a broad differential diagnosis and plan are presented to patients in their best interest. This is proactive participation involving both prescriber and patients. Outcome will be adversely affected if the patient is noncompliant, and treatment hurdles identify reasons for failure. For example, did the patient not understand the opioid or controlled substance patient care agreement, or ignore it? Finally, the tools necessary to treat specific pain disorders should be traditionally accepted in general/clinical practice and within community standard. The medical record will document effectiveness of treatment progress, good or bad. This task should not be as challenging as it sounds. For example, an antibiotic given for strep throat may be considered effective when the fever is resolved and the patient is able to return to work and maintain adequate oral intake. These are measurable entities and are easily included in the medical record. The pain management practitioner might document improved func-

Agreement for Controlled Substance Prescriptions

Controlled substance medications (i.e., narcotics, tranquilizers,and barbiturates) are very useful but have a high potential for misuse and are, therefore, closely controlled by the local, state, and federal government. They are intended to relieve pain, to improve function, and/or ability to work, not simply to feel good. Because my physician is prescribing such medication for me to help manage my condition, I agree to the following conditions:

1)_____
    <u>initial</u>

I am responsible for my controlled substance medications. If the prescription of medication is lost, misplaced, or stolen, or if I use it up sooner than prescribed, I understand that it <u>will not be</u> replaced.

2)_____
    <u>initial</u>

I will not request or accept controlled substance medication from any other physician or individual while I am receiving such medication from the pain center. In addition being illegal to do so, it may endanger my health. The only exception is if it is prescribed while I am admitted in a hospital. If necessary to go to an Emergency Room for an emergency, I will notify the Pain Center within 48 hours.

3)_____
    <u>initial</u>

<u>Refills</u> of controlled substance medication:
<u>Will be made only during regular office hours,</u> in person, once each month (or as arranged by the practitioner) during a scheduled office visit.
a) <u>Will not be made if I "run out early".</u> I am responsible for taking the medication in the dose prescribed and for keeping track of the amount remaining.
b) <u>Will not be made as an "emergency",</u> such as Friday afternoon because I suddenly realize I will "run out tomorrow." <u>I will call at least seventy-two (72) hours ahead if I need assistance with a controlled substance medication prescription.</u>

4)_____
    <u>initial</u>

I will bring in the containers of all medications prescribed by the pain center each time I see the practitioner, even if there is no medication remaining. These will be in the <u>original</u> containers from the pharmacy for each medication.

5)_____
    <u>initial</u>

I understand that if <u>I violate any of the above conditions,</u> my controlled substances prescription and/or treatment with the pain center may be terminated immediately. If the violation involves obtaining controlled substances from another individual, as described above, I may also bereported to my physician, medical facilities, and other authorities.

6)_____
    <u>initial</u>

I understand that the <u>main treatment goal is to improve my ability to function and/or work.</u> In consideration of that goal and the fact that I am being given potent medication to help me reach that goal, I <u>agree to help myself by the following better health habits:</u> exercise, weight control, and the nonuse of tobacco and alcohol. I understand that only through following a healthier lifestyle can I hope to have the most successful outcome to my treatment.

7)_____
    <u>initial</u>

No wish to harm self or others.

8)_____
    <u>initial</u>

I agree, with full informed consent, to provide tissue or body fluid for drug analysis when requested for initial routine screening purposes.

9)_____
    <u>initial</u>

I agree to allow the pain center to talk with my other treating practitioners, obtain records as needed, and obtain information from my pharmacy when needed.

I have been fully informed by the pain center and the staff regarding psychological dependence and physical dependence, addiction, and other unsuspected consequences of a controlled substance, whichI understand is rare. I know that some persons may develop a tolerance, which is the need to increase the dose of the medication to achieve the same effect of pain control, and I do know that I will become physically dependent on some medications. Should this occur I will stop the medication only under medical supervision or I may have withdrawal symptoms.

I have read this contract and it has been explained to me by the pain center and/or their staff. In addition, I fully understand the consequences of violating said contract.

Patient's Signature _____   Date _____

Doctor's Signature _____   Date_____

FIGURE 94.6 Example of controlled substance prescription agreement.

tional indices, better restorative sleep and endurance, and less pain medication usage. Validating medical necessity for procedures and pain treatment in general requires verification that the community standard is met, a diagnosis fits the presentation, and a plan of care ensures compliance and continuity of care. Experimental treatment falling under the category "I think it, therefore it is" does not meet these criteria.

DISPOSAL OR LOSS OF CONTROLLED SUBSTANCES

Theft and Loss

- When theft or loss is discovered, it is the responsibility of the prescriber or the entity responsible for the substance in question to fol-

low best judgment and take appropriate action. Based on volume, a significant loss for one institution may be insignificant to another.

- Controlled substances that are lost, even in small quantity, over a period of time can be problematic to the prescriber's practice. Repetitive, unexplained losses are considered suspicious. Furthermore, any break-in or robbery must be reported.
- If, by best judgment, the office notes the loss to be determined as significant, the DEA suggests the following documentation:
  1. Identification of quantity missing
  2. Name and schedule of the missing medication
  3. Abuse potential of missing substance
  4. Documentation of first loss occurrence, or a repetitive problem
  5. State where the loss was reported to state/local law enforcement authorities

The DEA requires practitioners to use Form-106 to report theft or loss of controlled substances. Report Form-106 may be obtained from the DEA Diversion field office to document the circumstances of this loss. Practitioners also may obtain this form at www.deadiversion.usdoj.gov. If you have to destroy a controlled substance, it is best to contact the nearest DEA Diversion Field Office for guidance. In addition, some states have more stringent guidelines, laws, and regulations on the destruction of controlled substances. Practitioners should endeavor to learn both federal and state requirements.

Practitioners should keep records of this event for at least a year. Patient names do not have to be used, but unique identification numbers must be attached to a particular patient to reference the medical record.

DEA Investigation and Accountability

The DEA may initiate an investigation, unannounced, and records must be supplied upon request. The DEA agents must present their credentials, state the purpose of the visit, and present a written notice of inspection. Once the investigation has been initiated, documentation of amount of medication lost, type and amount of spill, or return to manufacturer and transfer of drugs should be provided. Maintaining complete and accurate records ensures that these requirements are met. The DEA recommends that employees understand how to operate relevant equipment and computers, maintain appropriate records (with backup), and understand shutdown/lockup procedures.

Should a DEA investigation occur, the following is a list of documentation that is required to facilitate a review. These documented entities were derived from recommen-

dations of opioid treatment programs and include the following:

1. A list of individuals having access to controlled substances, including full name, date of birth, and social security number.
2. A list of those involved in medication shipment, including licenses and permits of the practitioners involved.
3. DEA-222 order forms, and supplier.
4. Dispensing records, including patient identification and references. This would also include incident reports of drug loss.

Dispensing

The dispensing record will include name of substance, dosage form, and date dispensed. A signature encounter on the form is unique to the drug disposal and will also include the amount and dosage utilized, and whether any wastage was necessary.

Prevention of Diversion, Abuse, and Dependence: Review and Reduce Risk

Pain is a difficult entity to measure. We cannot see, touch, feel, or measure pain, and the patient's self-report of pain, coupled with functional assessment, may be the most useful measurement of relief cycling available to the physician. It is incumbent upon the pain management practitioner to offer and document compassionate relief, quality of life enhancement, review of functional indices, and improvement in activities of daily living when possible. These attempts are made within the patient's best interest, "to first do no harm."

Realizing this goal, opioids and controlled substances are frequently prescribed to control pain and symptoms secondary to pain. Prevention of diversion, abuse, and dependence is an issue that is paramount to the prescriber's best practice. Documenting patients' well-health behaviors and characteristically proactive contributions to their health care in most cases leads to best predicted outcome. Pain relief is sometimes a best estimate as to these functional enhancements, as are subjective reports, and are reported to the medical record understanding the nature of the complaint as related to the diagnosis. The American Pain Society (APS), The American Academy of Pain Management (AAPM), The American Academy of Pain Medicine (AAPM), and The American Society of Interventional Pain Physicians (ASIPP) have all issued guidelines relating to avoidance of abuse and/or diversion.

The core points of these guidelines may be summarized as follows:

1. *Recognizing pain as a critical point of care.* The helping professionals, their extenders, and associated personnel, residing in either hospital or office-based practices, should provide a compassionate care arena to understand the patient's pain within the context of the patient's normal life's activities. When controlled substances or opioids for chronic nonmalignant pain are utilized, steps to ensure adequate dosing, minimization of side effects, and avoidance of adverse reactions are important to ensure compliance, social integration, and improvement of activities of daily living. Documentation to the medical record will include such descriptive entities as subjective complaints of pain, functional decline, or enhancement of normal activities, medication usage patterns, and documentation of adherence to a treatment plan. A *diagnosis* is followed by the carefully designed treatment plan that is understood by the patient, with no barriers to communication. The diagnosis should match medical necessity for controlled substance use. It is also required that the patient bring medication in for pill checks and agree to sign a *patient care agreement*. A patient care "contract" implies certain legal considerations, and *agreement* is a more suitable term. This agreement would likely require random drug screening, and the patient should be informed (full informed consent) prior to undertaking a random medical drug screen. The prescriber will also understand the implications of the drug screen, its necessary confidentiality, and what the drug screen actually measures, including sensitivity to adulterants and false positives.

2. *Prevention of diversion.* Prevention of diversion requires the prescriber and the staff to be vigilant of patient usage patterns and factors of outside individuals that influence the patient's behavior. If the pill count is off on more than one occasion, diversion is suspected, and the patient's explanation for abnormal pill count is inappropriate, reevaluation of controlled substance use should follow. Is the patient improving functional indices and quality of life indices, or just asking for medication every month? Has the patient attempted physical therapy, cigarette cessation, etc., and taken active participation in his or her own health care, or is preoccupation with the medication the paramount reason for the prescriber visit?

If diversion is suspected, the prescriber bears the responsibility of documenting the suspicion, finding a remedy to avoid further diversion, or making plans to discontinue these medications. The practitioner has no implied responsibility to "taper" the patient, especially if a *risk to harm* environment is present. This must be carefully weighed against potential for withdrawal complications, particularly evident with benzodiazepines. It is recommended that an addictionologist also be involved in this particular event, ultimately hospitalizing the patient if necessary. If the patient is suspected of obtaining medications from multiple prescribers, every effort should be made to eliminate this behavior and assure that controlled substances are obtained from only one source. Furthermore, a small group of patients with a known addiction history or substance abuse disorder requires narcotic-based medications to control legitimate pain complaints. A high level of vigilance and documentation ensures availability and access to care. The patient's medication for relief of symptoms should not be withheld simply because of previous history of abuse. The patient, however, does remain accountable, is aware of the clinic's agreement for use of controlled substances, and is regularly assessed. A caveat to this statement is the requirement of the practitioner to obtain a special attachment to the DEA certificate for the treatment of addiction with ongoing opioid usage (maintaining known opioid addicts with opioids). Pain practitioners treat pain, not addiction. Prescribing opioids solely to maintain an opioid addiction is inappropriate without the DEA attachment, and violates controlled substance guidelines. Treating pain with opioids, even for someone with opioid addiction, is lawful if the purpose of the treatment is for the control of pain.

SUMMARY

There are risks in any medical practice. When controlled substances are used in medical treatment, the prescribing practitioner *must* use risk management tools to help minimize the potential for abuse and diversion of controlled substances. The cornerstones of risk management related to the use of controlled substances to treat pain are patient assessment, selection, and monitoring. Practitioners are encouraged to become familiar with and use federal and state legal/regulatory materials on prescribing controlled substances and pain management as a basis for medical record documentation and office policies and procedures. All prescribing *must* be based on a *documented legitimate medical purpose* and be issued *within the usual course of professional practice*. When practitioners follow these risk management principles, pain management can be rewarding for all involved.

The use of controlled substances to treat pain is not an easy component of a pain practice, yet the use of these drugs is an important piece of pain control and access to care. Patients in pain are like any other a practitioner may encounter; empathy and responsiveness to individual need enhance clinical outcome. The pain management special-

ist is uniquely considered the community expert, engaged and interactive with his or her peers to develop standards, and ultimately define legitimate purpose. It is the practitioner's responsibility to minimize the potential for abuse and diversion of controlled substances in the medical practice. Risk management allows you to balance your legal/regulatory obligations with your ethical obligation to provide quality medical care to your patients.

APPENDIX: CONTROLLED SUBSTANCE PRACTICE GUIDELINES AND COMPLIANCE REVIEW*

Scope of need, first steps

- The patient–practitioner relationship is established and documented.
- The nature and intensity of pain have been recognized and the current past medical history and coexisting disease are verified as justifying a controlled substance plan. There is a cause-and-effect relationship of pain on physical and psychological well-being, as well as function, and is contributory to a therapeutic plan. If present, documentation is completed to reflect the need for controlled substance use.
- History of a substance abuse has been asked. ☐ Yes ☐ No

Documentation of Legitimate Medical Need

- Legitimate medical need is defined by our pain management clinic as an understanding that pain and suffering are treatable and are met in a compassionate care arena. This sometimes requires the use of controlled substances or other adjunctive technology or medications. Legitimate medical need is an ongoing and dynamic process that is reevaluated regularly and not considered a stable entity. In fact, pain changes regularly, and the characteristics of its presentation are frequently transformed. Psychological and physical changes that accompany a patient's original chief complaint and coexisting disease states are not static and require frequent reevaluation. Therefore, legitimate medical need for controlled substance use is evaluated by measuring subjective and objective complaints and weighing the risk-reward benefit against enhancement of function, quality of life, restorative sleep and the potential complications of these drugs.

* Adapted from the J. Bolen Group, LLC.

Background

Education

- Ongoing education requires review of literature, peer interaction, and attending appropriate specialty-specific meetings that address the controlled substance issues contemporary to current pain practice.
- The care provider is aware of the Federation of State Medical Board Guidelines, other guidelines, and principles of legitimate medical need. Furthermore, this clinic treats pain and not addiction. Controlled substances are offered to improve quality of life and not maintain an opioid or controlled substance addiction.

Considerations That May Indicate Drug Misuse or Diversion

- Distance from clinic. A high level of suspicion and vigilance is in order when a patient travels past other care providers that might provide the same level of care or offer services similar to the pain management clinic. This includes, but is not exclusive to, prescribing controlled substances.
- Referral source. A referral source is an important, and many times pivotal, acknowledgment that the patient is entrusted to a specialist that manages a controlled substance. Understanding the referral source, and that the referral source is relinquishing controlled substance management to the clinic expertise, is established in the medical record. Special attention will be attributed to patients referred by a "friend" or acquaintance with little medical history available. Records should be requested and reviewed, and where appropriate, contact should be made with the primary care/specialist familiar with the patient. These risk reduction exercises should occur prior to prescribing controlled substances.
- Behavioral issues. Patients who experience particularly risky behavior or have underlying psychiatric disease are at higher risk for controlled substance diversion and misuse. This includes bipolar disease, risk takers, and those who have depressive disorder, among others. These behavioral issues are associated with patients at risk for misuse and overdose of these medications.
- Specific request. A specific request for a medication by name, or an unusual knowledge base demonstrated by the patient, about a particular medication is a point of question that requires further investigation.

- There will be no weekend or off-hours controlled substance call-ins unless the patient is well known, and a legitimate reason exists for this deviation from the patient care agreement. There is no black-and-white presentation of chronic pain, and there are times when a prescription will need to be called in on the weekends, but should be recorded in their medical record as to need for this drug.
- Exaggerated behavior. The symptoms must match the complaint, with no evidence of exaggerated behavior. It is uncommon that a patient with legitimate medical need for controlled substances will need to "prove" his or her pain, and a painful disorder should be self-evident by physical examination and historical features in the medical record, either past or present. The patient who "symptom exaggerates" may be exhibiting seeking behavior, and care should be given to prescribing controlled substances.
- Reluctance to change certain medications. Clearly, brand names, as well as scheduled drugs, have different street value, and a reluctance to change from a certain delivery system, or name of drug, should be considered of significant risk value to reexamine diversion or misuse. An exception may be the individual who is less sophisticated or has a fear of change. This individual should be separated from those who are either new to the practice or have a poor historical background of controlled substance usage patterns documented by other physicians, pharmacy checks, or demonstrated adulterated drug screens.
- Screens and controls. Drug screens have their limitations. The U.S. Department of Transportation does not require the DS-9, but in fact utilizes the National Institute of Drug Abuse 5. Some authorities have suggested that cutoff levels for positive tests may be too high in many situations. Furthermore, we acknowledge the fact that drug screens do not always identify the drug of interest, and a quantitative specimen must be sent. We also are at disadvantage with certain labs that do not test specific gravity or temperature, or identify chain of custody. We will do what we can to ensure chain of custody and proper testing, but we will not be able to obtain this ideal at all locations. Therefore, we will acknowledge this and use the drug screen as a tool and not an absolute. Consider the screen as a reference that we might use with a positive value, but not necessarily determine course of care based on this singular test. This piece of data may also be ambiguous with one positive result followed by a negative repeat

value, but it is the clinician's best judgment that will determine the appropriate use of controlled substances. Where a positive result is found, as in any medical test, we must acknowledge this as practitioners, regardless of follow-up testing, which may be negative. It is inappropriate to prescribe controlled substances when a risk environment may exist, and a consultation with peers may be in order. The ultimate decision to prescribe controlled substances still remains with the moment, the available data, the patient's behavior, and the training that we necessitate within the clinic directed by its guidelines.

WHEN THE PRACTITIONER–PATIENT RELATIONSHIP IS CHALLENGED OR TERMINATED

Discharge Guidelines

- Discharge guidelines are defined by the local professional societies, as well as the professional licensure boards and others. The issue of "Thirty-day Emergency Evaluation" should be only that, an emergency evaluation. The emergency department is certainly available to patients and should be a first source of true emergency care, and utilizing the pain center for "emergency chronic pain" may be inappropriate. A long-standing pain problem that has occasional exacerbations might be construed by the patient as an emergency and should be handled on an individual basis. This does not necessarily mean a controlled substance will be prescribed. If the patient has demonstrated a risk environment, where risk to harm is possible, either to self or others, or has demonstrated a lack of accountability to controlled substances, the pain center is under no obligation to provide the patient a prescription. Alternatives should be offered to the patient such as a detoxification center, and in certain situations where necessary, utilizing a family member or trusted friend to dispense very small amounts of medication. We would even consider a weaning protocol, with frequent visits to the clinic to obtain medication. Some states may consider this detoxification and, therefore, not legal without appropriate attachments to the DEA certificate. Rarely, if ever, will a 30-day prescription be offered when discharged from the clinic. The pain center will provide a maximum of only 7 days of drug to those discharged from the clinic without reevaluation, and the patient will be made aware of this policy at the time of

discharge. Furthermore, it will be documented in the medical record that the patient was *offered detoxification* if such can be legally provided by the pain prescriber consistent with licensure and privileges where appropriate.

PRESCRIBING GUIDELINES*

- Proper use. Proper use of medications is an important consideration for those who may be visually, mentally, or structurally challenged, and should be acknowledged when a chosen delivery system is provided. For example, a fentanyl patch may be an excellent delivery system for those who have difficulty taking pills, or a suspension may be compounded for those who cannot swallow pills. The pain center considers the *fewer pills* available the better, and breakthrough medications will be used with caution, demonstrating to the record clear medical need. The proper use of all these medications is discussed, as an as needed (PRN) medication does not necessarily mean that the patient takes the medication every 4 hours regardless of level of function or pain. It is also inappropriate to use medications for purposes other than pain control, or as they are deemed in the controlled substance justified diagnosis. An example might include benzodiazepines used for anxiety because "I have nerves." The diagnosis must match the need for controlled substances.

- Side effects. Side effects are documented in the chart. The patient should not drive, make important decisions, or perform activities that could be injurious while using these medications. However, numerous studies have shown that patients on stable doses of opioids or controlled substances do not have a significant decline in their ability to operate a motor vehicle. Although this policy may be restrictive, controlled substances, such as pharmacokinetically long-acting opioids, may compound the synergistic effect of benzodiazepines and adjunctive medications. Informed consent and risk must be understood by the patient that any treatment, especially controlled substances, has risk, and be acknowledged in the record. Some latitude may be exercised by the patient and the clinician's best judgment, as there are no specific guidelines regarding driving a vehicle while using controlled substances, but care should be exercised with the elderly or physically challenged patients to reinforce this understanding. Studies have repeatedly shown that the incidence of clinically significant cognitive dysfunction is much higher with benzodiazepines than with opioids or controlled substances.

- Adverse effects. Adverse effects require notification to the pain center, and a response to these adverse effects is dictated by descriptions of the problem relayed through the nurses and discussed with the providers. Adverse effects may be mild, moderate, or severe, and might require evaluation of the patient as a work-in or a referral to an emergency department. Many times adverse effects are short term, short lived, and self-limiting. In many cases, reassurance many be all that is necessary, and the provider will be aware of the side effects and complications of medications provided, and understand the appropriate response to these side effects. All *Black Box* warnings will be noted. A Black Box is a Food and Drug Administration warning that is prominently displayed in the *Physician's Desk Reference* (PDR). If medications are used off-label, which the CSA of 1962 allows, there will be documentation in the medical record that there was an efficacious response and a justification in this regard. Off-label uses of medications are valuable aids in pain management and should not be discouraged, but encouraged as adjuncts if they decrease the opioid or controlled substance requirement. For example, amitriptyline (Elavil®) may be used to control sleep, and an antiepileptic agent such as gabapentin (Neurontin®) may decrease the required narcotic load in an opioid-resistant pain complaint or in neuropathic pain. Valproate (Depakote®) may be used for mood stabilization.

- Document discussions. Patients have many questions, and concerns should be documented to the medical record so that we can demonstrate a response to their understanding or misunderstanding. If a patient has a discussion with the pain provider off-hours, or on a weekend, it is necessary to document this encounter into the chart. (*Note:* It is not always necessary if very little action is taken or if the call responds to a routine question, but a high level of vigilance to documentation is our best position.)

- There is no one drug cocktail. As we have choices, the practitioner understands the individual variation and response to medications. Morphine and codeine have different side effects in different individuals, and synthetic compounds do as well. Therefore, it is not advised that a single drug be considered stan-

---

* A suggested practice inventory.

dard for an individual prescriber, and that variation matches the diagnosis and the patient diagnosis defined by presentation.

TREATMENT EFFICACY

- Policy for breakthrough medications, "rescue" medications. Policy for breakthrough medications is based on *medical necessity*. A breakthrough medication is considered an adjunct and should also be a starting point for advancing opioid- or controlled substance–based pain medication to a higher level. It is acknowledged that a pharmacokinetically long-acting drug does not always have steady serum concentrations, and occasional breakthrough medication is warranted. It is not clearly appropriate, however, to offer breakthrough medication as just routine two, three, or four times daily dosing response to a patient's complaint "I hurt." Many instances respond to readjustment of a pharmacokinetically long-acting drug, and decreases the rollercoaster effect of the short acting drug, which might adversely affect cognitive function and place the patient at risk. Furthermore, resistance to the underlying parent drug, the long-acting drug, may develop more quickly, when breakthrough drugs are added, and defeat functional enhancement. Finally, breakthrough medications should be demonstrated to improve function, quality of life, or restorative sleep, and the patient must use these medications correctly. Pill counts, as with other medication counts, should be appropriate.
- When a certain medication fails, it is documented to the medical record. It is inappropriate for a patient to call 2 or 3 days after an initial change in medication, stating that "it doesn't work," and the patient should be informed that "stabilization" may take longer. Of course, these medications have pharmacologic activity, and bioavailability is rarely an issue. In fact, some patients prefer certain medications and request them by name. As previously noted, this is not always appropriate, even when discussing generics and brand name medications. A medication must be tried for at least 2 to 4 weeks (there may be some individual patient variation), and no immediate changes are made without appropriate pill count and accountability to the original medication. If intolerance to a side effect is noted, where appropriate, a change may be made. The patient must present the remaining drug prior to a change in agent. If a

medication is "lost," flushed down the toilet, or "thrown out" because it did not work, a second prescription will not be given. There may be some flexibility if appropriate pharmacy checks are made, the patient is well known to the clinic, and a clear adverse reaction was documented. Not every patient is a drug seeker or manipulator, and not every "good patient" is a good patient. Three studies have documented the "good patient" with an adulterant present in the urine drug screen occurring in the 14 to 30% range (Manchikanti, 2002). This is a heralding mark for us to understand; the "good patient" may get used to taking medication and see very little risk in mixing or even borrowing. It is incumbent upon the practitioner to be aware of this, and even "good patients" should receive drug screens. Use common sense, of course. We will not ask infirm or elderly patients for a screen unless a clear reason exists.

- The medical record will reflect correlation of treatment efficacy and medication need. It was previously noted that improved functional indices and quality of life indices should be self-evident, but not always reflected by subjective complaints. Do not hesitate to exercise a high level of vigilance (2-week prescriptions, checking transdermal fentanyl [Duragesic®] patches for intrusion, etc.) if the treatment plan shows significant failure and the medications that we believe should be "working" produce no therapeutic benefit. A second opinion is recommended, and of course, pharmacy check and drug screens quantitated as well.
- Patients with drug abuse histories and diversion histories do have pain. It is a difficult but important concept to grasp that we do have to acknowledge these patients without preconceived assumptions or prejudice. This is where the difficulty in our profession arises, as these patients are of the riskiest nature. A sickle cell patient may have, from time to time, abuse, diversion, or seeking tendencies, but the fact remains that sickle cell is a punishing disease. Pain relief *ethically* should be provided. It is recommended that consultation with a colleague is documented to the medical record, and these patients are treated with frequent office visits, pill checks, drug screens, etc. Common sense weighs heavily here. Furthermore, the medical record should routinely document that we have asked the patient if there is abuse or drug diversion history.

Documentation/Follow-Up Guidelines

- It is a struggle to determine overutilization versus appropriate medical care when we use controlled substances to control pain. These drugs require a high level of respect and are not simply "pills" such as an antibiotic. It *is* appropriate for monthly visits, most notably with Schedule II prescriptions. Overutilization is a concern for everybody, but pain control complaints and side effects are common, especially in the early phases of treatment, requiring a special development of the patient–physician relationship and realization of improved function and quality of life indices through our treatment plan. The pain center recommends monthly visits unless the patient is a well-understood patient, with a well-understood indication for chronic controlled substance use, and is individualized. The patient's convenience, usage history, and medical indication are not static and will be reassessed, and many patients originally seen at monthly intervals may be allowed to visit us every other month, or every few months depending on their presentation. If the patient is not seen and examined every month, the reason for this should be documented in the record.

- Records from other treatment sources, pharmacies, and pain clinics will be sought from referred patients and will regularly be reviewed.

- An action plan for treatment failure will be addressed and discussed with peers if necessary. A treatment failure does not necessarily mean a drug failure. Many times a treatment failure represents the need for adjunctive care, such as an interventional technique or an adjunctive medication. It is not necessary just to increase the opioid without understanding this risk–reward benefit, and many times pain presentations are complex requiring both non-opioid or controlled substance medication adjuncts and adjusted opioid treatment strategy. There is no "one right course." Patients are individualized, and it is the expert opinion of the trained pain practitioner with the eyes and hands on the patient that wins out in this important cornerstone of decision. Issues of *pseudoaddiction* may be addressed, although the concept of pseudoaddiction many times falls to the side of a poorly diagnosed or undertreated individual.

- Detoxification will be offered for those who are in violation of guidelines or who want to be removed from narcotics. Methadone, in particular, will not be detoxified in the pain management center, and in fact, methadone will *only*

be used to treat pain, and *never* to treat an addiction or to "wean." This requires a special attachment of the DEA certificate, which we will not seek. An addictionologist may be a useful consultant, from time to time, to enhance therapy. A psychiatrist will be a useful alternative, if that psychiatrist is known to have substance abuse training.

- The State Board Guidelines and the Federation of State Medical Board Guidelines will be understood by the provider, and occasionally elements of this will be revealed to the patient, and definitions revealed to the patient through the medical necessity checklist.

Discharge Plan and Documentation

- The patient will be required at all times to maintain contact with a primary care practitioner, and this will be documented to the chart.

- Withdrawal from opioids or controlled substances is problematic in many situations, but in those with preexisting disease such as heart disease or tenuous medical history, the medical record will reflect that this was acknowledged and precautions were taken in this regard to avoid adverse event. Again, in-house detoxification, if allowed by state law, or utilizing the primary care practitioner as a co-managing provider should be entertained early for patients who are to be weaned from narcotics or controlled substances.

- The controlled substances we use in the pain center are important treatment entities. The Pain Relief Centers is not, however, a substance abuse clinic or a drug maintenance clinic. Ongoing assessment as to need, legitimate medical use, and appropriateness to diagnosis is paramount. If controlled substances can be eliminated from the list of medications used to control pain, they will be, and done so compassionately, with the patient's understanding.

- Patients understand that detoxification always requires medical assistance and should not be done by themselves or at home.

- Staff training should be ongoing, and if the provider notices a deficit in a colleague or staff member, this will be brought to the attention of appropriate individuals who can correct this deficiency through an action and remedy plan. Competency tests will be asked of any practitioner identified as having knowledge weakness, and we will do what we can to be very proactive in an ongoing, collegial understand-

ing of these controlled substances and their
proper use.

Take Action: Be a Pain Management Advocate — A Quick How-to Guide for Healthcare Professionals

Lenore B. Duensing, MEd

Advocate — A believer, a supporter, a defender, a champion, an activist

It is now the Decade of Pain Control and Research, and all of us working in pain management have a not-to-be-missed opportunity to work as advocates for people with pain and to make *pain* a national healthcare priority. This chapter is a call to action from the American Academy of Pain Management (the Academy).

As a healthcare professional treating people with pain, you are in an ideal position to serve as an advocate. You are an expert on pain management; you know how pain devastates the lives of so many people; and you have the credentials it takes to make yourself heard. In other words, you have the power to effect a positive change in pain management on the local, state, and national levels. That is why we are calling on you to become a pain management advocate.

WHERE WE ARE RIGHT NOW: FACING-UP TO A NATIONAL HEALTHCARE CRISIS

Chronic pain is arguably the nation's number one public health problem. More than 50 million Americans live with serious chronic pain that affects almost every aspect of their personal, social, and work lives (Louis Harris and Associates, 1999). Chronic pain also takes an enormous toll on the U.S. economy. The findings of a study reported in the November 12, 2003, issue of *The Journal of the American Medical Association* showed that lost productive time from common pain conditions among active workers costs an estimated $61.2 billion per year (Stewart et al., 2003). The tragedy is that although the medical technology is available to reduce most chronic pain, most pain goes untreated or undertreated. This is particularly true for minorities, elderly patients, children, and other medically underserved groups.

In spite of the staggering toll pain takes on the nation and on the lives of the individuals who suffer with it, pain management is not a public healthcare priority, and millions of people continue to suffer needlessly. Why? Because there has been neither the will nor the commitment required to change the pain management environment, a central part of the Academy's mission is advocacy — reaching out, empowering, and organizing other healthcare professionals, people affected by pain, policymakers, and others to make this commitment and take the actions needed to put pain on the national healthcare agenda.

IDENTIFYING AND REFRAMING THE BARRIERS

The first step in raising awareness of the pain epidemic is to identify the barriers to good pain care. The next step involves reframing these barriers — viewing each as an opportunity and a specific target for change. Some of these barriers/targets of change are the result of the following:

- Pain care gets scant attention in most major healthcare organizations and research institutions.
- There are no federal laws mandating research, professional education, or public awareness or guaranteeing the rights of patients in pain to effective pain management.
- Most healthcare providers have not been trained to assess or treat pain, so most people with chronic pain have a difficult time finding the treatment they need.
- The most effective treatments for patients are often not reimbursed by insurance companies.
- Pain carries a stigma and many people with pain suffer silently. They do not seek treatment and do not let their families, friends, or healthcare providers know that they are in pain.
- There are widespread misconceptions about pain and pain medications among healthcare professionals, patients, and law enforcers; and these are being perpetuated by sensationalized and inaccurate media stories.
- The most effective treatments for patients often are not reimbursed by insurance companies or may be too costly.

WHAT WILL IT TAKE?

Removing the barriers and changing the pain management landscape for the better will require the work of many individuals and organizations who:

- Share a common vision and message
- Are passionate about the issue
- Are willing to collaborate with others to achieve common goals
- Are committed to taking action

Improving pain management will require different strategies ranging from personal advocacy (directly helping and supporting people with pain along with their families and caregivers) and grassroots actions that motivate the public to demand effective pain management (bottom-up strategies) to directly influencing legislators and regulators to create pain care laws and policies (top-down strategies).

Those of us working to improve pain management can take valuable lessons from the successes of other patient and professional advocacy groups. Consider the following:

> One reason cancer patients finally have greater access to medications in late stages of research is that cancer groups have learned how to deliver their messages repeatedly and effectively. Partners in that success story are the men and women with AIDS who formed the organization "Act-Up." Those AIDS treatment activists

tutored the cancer advocates on how to be heard and gain access to medications at earlier stages…. Later patients and professionals used advocacy tools to de-stigmatize depression — forever establishing the fact that depression is not a weakness, but instead, an easily treatable medical condition. (Hospice and Palliative Nurses Association Advocacy Toolkit online at http://www.hpna.org)

ADVOCACY: FROM THE ONE TO THE MANY

So, what does a *pain management advocate* do and how do you become one? By becoming an advocate, you can raise awareness of pain management issues, help break down the barriers to effective pain care, and give voice and support to people with pain. As an *advocate*, you are a *believer*, a *supporter*, a *defender*, a *champion*, and an *activist*. To be an advocate, you need to be informed and educated about pain management issues, empowered, committed to taking action, and willing and prepared to stand fast in the face of challenge or adversity. How you do this, and the level to which you do it, is up to you.

> *Why become a pain management advocate? Because it's the right thing to do!*

TYPES OF ADVOCACY

Although there are many ways to be a pain management advocate, the Academy separates *advocacy* into three, often interrelated, categories:

1. **Personal Advocacy** — Providing support and information to people with pain (your patients and others) so they can learn to advocate for themselves, and when necessary, standing up for them and helping them get the care they need.
2. **Grassroots Community/Public Awareness Advocacy** — Reaching out to consumers, healthcare providers, policy makers, and the media with information about pain and pain management issues, and calling on them to take positive action.
3. **Legislative/Policy Advocacy** — Taking actions to influence legislators and other policy makers for the purpose of introducing or changing pain management laws and policies from the state to the national level.

Described below are a variety of ways that you, as a healthcare professional, can take action as a personal, public/community awareness, or legislative/policy advocate. Also included are examples of others who have taken action and a listing of useful resources.

The Healthcare Professional as a Personal Advocate

In addition to providing the very best pain treatment for your patients, you can serve also as their personal advocate. Patients who are educated and informed, who feel supported, partner with their healthcare professionals in reaching the goals of their treatment plan, and know how to self-advocate to obtain the very best results and relief possible. It is a "win/win" situation for both the healthcare provider and the patient.

Another and more challenging way to be a personal advocate for your patients is to help them overcome the medical, personal, and legal barriers they may be facing. This can include assisting them to navigate through the healthcare system, providing resources, intervening when there are insurance problems, and serving as a mediator between them and their employers or family members.

Action Steps

- **Believe and accept your patients' reports of pain.** This is the first, second, and third rule of good pain management! Consumer advocacy organizations hear regularly from people in severe pain who say their healthcare professionals have not believed, or even accepted, their reports of pain. This is true particularly for those with persistent pain who look well and whose tests show nothing wrong. From a clinical perspective, disbelief often leads to pain that goes untreated or undertreated and to pain that progresses. From a behavioral perspective, it often leads to stress, depression, a sense of being crazy, and extreme frustration and anger — all of which can exacerbate pain conditions.
- **Tell your patients that you are willing to serve as their advocate — their supporter** — and demonstrate this through your actions. Let them know that, in addition to providing them with the best treatment possible, you are there to listen to them and support their efforts to achieve relief from pain. Tell them that you are there to help them if they are having problems getting the care they need.
- **Let your patients know they have the right to effective pain care.** Post a Pain Care Bill of Rights poster in a visible place in your office, and give each patient a Pain Care Bill of Rights card (available through APF in English and Spanish).
- **Encourage your patients to participate actively in their pain care and provide them with the information about their pain problem.** This may include information about their

particular conditions or diseases, communications tips on how to describe their pain (which will also help with your assessment), treatment options, and where to find pain support groups in the area. (See resource section for organizations that provide support and materials for patients.)
- **Refer patients to other healthcare professionals** if you are unable to give them the treatments they need or if they can benefit from additional/complementary types of therapy.
- **Teach your patients and their caregivers how to become pain management advocates for themselves and others.** People with pain who advocate for themselves most often get optimal care and make the best recoveries. By taking action, they also gain purpose, renewed energy, and a sense of empowerment. In addition, patients and caregivers can be the most effective messengers of the pain problem. They can be asked to tell their stories, give support to others with pain, speak at local events, give media interviews, and write letters to their state or federal legislators.

Case Study — Speaking Truth to Power: The Pain Management Nurse Who Fought for a Patient's Rights

Shannon L. is 33 and has lived with a debilitating pain condition called reflex sympathetic dystrophy or complex regional pain syndrome for the last 14 years. Although doctors told her that she would spend her life in a wheelchair, she was determined and worked hard to get the treatment she needed to continue working and being active. There were, however, many barriers to overcome. Navigating the healthcare system, finding people willing and able to treat her, going to work, and maintaining personal relationships still presented enormous challenges. Then, 8 years ago, Shannon met Micke Brown, a pain management nurse in a local pain clinic, who has been at her side ever since working to break down these barriers one by one.

On Shannon's first visit to the pain clinic, Micke told her about the pain service and the doctors. She also told Shannon to call her if she had any questions — no matter what time or how often. During this visit, Micke stayed with her explaining difficult terminology and answering questions. Most of all, Micke let Shannon know that she was there to intervene on her behalf if there were ever any problems.

Through the years, Micke stayed true to her word and became Shannon's supporter, teacher, and on several occasions, her defender — and that continued even after Shannon left the practice Micke was in. For example, in February 2003, Shannon faced a very serious problem. She was

wrongfully discharged from the subsequent pain practice and asked Micke to "go to bat" for her. Shannon reports:

> After taking a hard fall that caused my pain to shoot to an unbearable level, I took an extra pill [an opioid] and called the doctor's office immediately because I feared I had broken my narcotics contract," Shannon explained. "When the office failed to return my first call, I called the doctor on call for the practice, whom I trusted, and asked for help — pain medications, sleeping pills — anything that would give me relief. The pain was going wild and I couldn't sleep. Unfortunately, he wasn't able to call in a prescription for opioids over the phone and instead prescribed a medication I was allergic to. On Monday, when my mother went into the office to get new medications, my treating doctor saw that I had taken one extra pill and discharged me from the practice. No one spoke with me directly and I was not referred to another doctor. I was left high and dry. I think part of the reason was that my treating doctor was angry that I had called the doctor on call and not him.

Shannon called Micke in desperation. Micke, having known Shannon for several years, was confident that she was not abusing her medications. Micke called the doctor whom Shannon trusted (and who was in charge of the practice) and told him that she was deeply concerned that Shannon had been treated unfairly, and asked him to intervene. She suggested that he personally reassess Shannon's pain problem and consider readmitting her to the pain clinic. As a nurse, who worked closely with this doctor in the hospital, Micke took a risk by speaking out against his partner's actions.

Micke's efforts paid off. The doctor called Shannon and listened carefully to her side of the story and took her back under his care. Her pain is better controlled and she feels reassured that she is being treated in an environment where there is mutual trust.

Today Micke works for American Pain Foundation (APF) as the Manager of Public Outreach. Shannon serves on the board of directors of the Maryland Pain Initiative. Together with Micke, she is organizing meetings for people with pain in which they can talk about their experiences and barriers to care. She also serves as an advocate for other people with pain in her community.

THE HEALTHCARE PROFESSIONAL AS A GRASSROOTS COMMUNITY ADVOCATE

As a healthcare professional, you are in an ideal position to bring awareness of pain issues to your community and give voice to your patients with pain by working on their behalf. Some ways you can be a grassroots community advocate include educating others (the public, people affected by pain, other healthcare professionals, and policy

makers) about the importance of pain management, hosting meetings or events targeting various audiences, and reaching out to the media.

You can do this type of advocacy on your own, but we suggest that when possible, you join with others. Investigate public awareness campaigns, such as

- *Power Over Pain* — APF and the American Alliance of Cancer Pain Initiatives (AACPI)
- *Partners for Understanding Pain* — the American Chronic Pain Association (ACPA)
- *Pain Ambassadors Program* — National Pain Foundation (NPF) and the American Academy of Pain Medicine (AAPM)

(See Resources section for more information about these campaigns.)

Action Steps

- First, identify yourself as a pain management advocate. Then, start spreading the word. Let others know about the work you are doing. Whenever appropriate, talk with others in your community, your family and friends, people on trains and planes — talk with anyone who will listen. Most often, you will find that they have a pain story and will want to share that with you. **Don't be afraid to be passionate. Pain is a serious problem. You know that. If you have strong feelings, express them. Passion can be contagious.**
- Check to see if there is a group in your area working to improve pain management and find out about public awareness initiatives (see Resources section).
- If there is not an existing group — start one! Build a team of pain advocates who will reach out, speak out, and spread the message from a variety of perspectives. Think broadly. Whom do you know? Consider healthcare professionals who treat people with pain, pharmacists, patients, caregivers, and others. Reach out to people representing diverse communities (e.g., minorities, seniors) and include them in your outreach.
- Develop a targeted public awareness plan including specific activities and media outreach. Determine how to reach out to various audiences such as people affected by pain, other healthcare professionals (representing different disciplines), the general public, the media, and government officials.

Activity Ideas

Groups conducting pain management public awareness activities are using a number of tactics to reach various key audiences in their states/communities. Below are some examples of actions you may take.

- **Get your state or local government to proclaim September as Pain Awareness Month** — Groups in states around the country have gotten Pain Awareness Month Proclamations from their state, county, and city governments and are using them to call attention to pain as a national healthcare problem and to gain media attention. The idea was developed by Partners for Understanding Pain, a national public awareness initiative led by the American Chronic Pain Association. For more information go to www.theacpa.org.
- **Give presentations/workshops for:**

  People with Pain — Let people with pain know that they have the right to have their pain addressed and treated, and that their pain can be relieved or greatly eased with proper pain management. Think about giving short, easy-to-understand presentations that include useful information about pain — what it is, what causes it, ways it can be managed, commonly held myths and misconceptions about pain and pain treatments, how to speak to healthcare professionals about pain, and resources. These can be held in locations such as community organizations, health centers, libraries, or public schools. (Powerpoint® presentations are available through APF.)

  Local Organizations (reaching the general public) — Organizations such as Rotary, Kiwanis, local chambers of commerce, faith-based groups, Y's, senior organizations, and large businesses offer excellent opportunities to inform people about the pain problem, to educate them about the importance of treating pain, and to involve them in your advocacy efforts. Some tips: Prepare your talking points carefully and include a number of compelling pain facts (if you have pain facts relevant to your local area, all the better); present real pain stories (especially stories about people who have struggled to find relief and then succeeded); consider having a patient or caregiver speak to the audience as well; and call on the group to help you spread the word. Be sure to invite the press. (Powerpoint presentations are available through APF.)

  Healthcare Professionals — Until recently, pain was overlooked as a healthcare problem by most healthcare professionals, and pain screening has not been part of routine examination. The purpose of giving this type of presentation/workshop is to provide healthcare providers with pain management basics. And do not forget about students, particularly those preparing to be healthcare professionals. (Powerpoint presentations are available through APF.)

Other Suggestions

- Distribute the APF Pain Care Bill of Rights cards and posters, and other patient materials to hospitals, nursing homes, pharmacies, and the offices of healthcare professionals.
- Ask librarians and bookstore owners to set up a special display of books about pain management.
- Set up a booth at a local health fair where you can distribute patient information brochures and talk to people about their pain rights and where to find help.
- Ask local clergy to present pain information as part of their services.

Case Study — Reaching Out to the Community with a Public Awareness Campaign: A Nurse's Vision

Five years ago, as part of the planning for a nationwide campaign that was to be called Stop Pain Now, APF developed a Community Action Kit, which included organizing information, activity suggestions, a media guide, and resources. Although the campaign was stalled, APF distributed a number of the kits to groups and individuals asking for public awareness ideas. One of those people was Ellyn Radson, a pain management nurse and president of the North Florida Chapter of the American Society of Pain Management Nurses (recently renamed the American Society for Pain Management Nursing).

Intent on getting a public awareness/educational campaign started in Gainesville, Ellyn used the APF kit as a starting point, and then organized her ASPMN chapter and others in the community (including doctors, pharmacists, and journalists). She also brought APF on as the national partner and convinced all of the area hospitals to come on board.

In January 2002, the group launched a local campaign called Power Over Pain (POP). It was kicked-off with proclamations by both the City of Gainesville and Alachua County. This was followed by week-long activities including presentations to a variety of audiences, participation in health fairs, and displays placed in all of the area hospitals. The group also produced a large calendar (with

information about where to go for help in the community and a list of national resources) and distributed patient materials and POP pins.

The following year, inspired by the success of Ellyn's local campaign, APF in collaboration with AACPI, with participation by divisions of the American Cancer Society and ASPMN, piloted POP statewide in Florida, Louisiana, and Massachusetts. Each of the 2003 POP campaigns was launched with a statewide survey conducted in September during Pain Awareness Month.

Ellyn's group expanded their activities in Gainesville (and continue to serve as a model) and joined with the Florida Pain Initiative and the Florida Division of the American Cancer Society.

The POP campaign is expanding into other states. Check to see if there is a campaign in your state that you can join (www.aacpi.org), or begin organizing POP activities in your community. You can order a POP Community Action Kit from APF. The kit contains information on building coalitions, specific action ideas, Powerpoint presentations for healthcare professionals and consumers, a comprehensive media kit, facts about pain, and resources.

LEGISLATIVE/POLICY ADVOCACY

As a healthcare professional and a pain management specialist, you can use your position and expertise to take political/legislative action that will promote policies and laws to improve pain management.

Action Steps

- **Get informed.** Learn about the government and how the legislative process works. Information can be found on the Internet at Project Vote Smart (www.vote-smart.org), Thomas Legislative Information (www.thomas.loc.gov), and the League of Women Voters (www.wv.org). Learn how to use Thomas as a research tool. Created by the Library of Congress, the site provides comprehensive information on all bills introduced in Congress, text of the Constitution and other historical congressional documents, information on congressional representatives and committees, and much more.
- **Learn about specific legislative issues** that affect patients with pain, their families, friends, and caregivers, as well as healthcare professionals.
- **Educate yourself about pain management issues from the local to national level.** Get a sense of how people in your community are affected by pain management issues so you can communicate that information to your public officials.

- **Follow local and national news stories about pain and pain management issues.** Get a sense of how pain issues are covered and what is of interest to the media.
- **Make sure that you are registered to vote — and exercise that right!**
- **Join with professional organizations that are working on this issue.** Your own professional organization is a good place to start. Find out if pain management is on their "radar screen," and if not, ask that it be placed on their list of legislative priorities.
- **Sign up** with the American Pain Foundation for legislative updates and alerts at www.painfoundation.org.
- **Write a letter.** Members of Congress are genuinely interested in the opinions of the people they represent. Letters to Congress are a primary means of access to decision makers by their constituents. All written correspondence from constituents are not only noted and counted, but count for thousands more. Also, think about taking the next step and organizing a writing campaign. Even 10 to 20 letters can be perceived as a "groundswell" of support. Provide others with sample letters and talking points. Some tips:

  Write only to your representatives or senators, unless circumstances require you to write to others such as the chairpersons of committees. Send original letters, not copies, to each individual.

  Address the letter correctly. Be sure to spell the legislator's name correctly and use the right forms of address. Terms of address should be Senator, Representative, or Member, not Congressman or Congresswoman.

  Be polite (never confrontational), brief, and to the point. Discuss only one issue or bill. Try to keep your letter to one powerful page. *Do not use form letters.* The letter should be in your words. Do not send postcards. Handwritten letters are still highly valued.

  Get right to the point. Describe the issue or bill in the first paragraph. Identify the bill you are writing about (provide the bill number) and clearly state what action you are seeking.

  Describe how the issue or bill affects you as a healthcare provider and how pain affects the lives of your patients.

  If you know how your legislator has voted on related issues, mention it. It will show that you are checking voting records.

Send a follow-up letter after you receive a response from your legislator. Send a thank you letter if positive action has been taken on your request. Repeat your request if action was not taken.

- **Meet with your legislators or their staff.** Some tips:

  Make an appointment first.

  Be prepared with talking points and have an information sheet prepared that you can leave behind.

  Be clear, concise, and courteous. Do not stay more than 15 minutes, unless encouraged.

  Describe not only the number of people suffering with pain (nationwide and in their districts), but the impact of pain on their lives.

  Offer solutions. Let you legislators know what specific actions they can take to improve pain management in your district or state, and how those actions will benefit their constituents.

  Follow-up with a thank you letter to your legislators and their staff. Repeat your messages in the letter. Public officials get lots of requests. Remember the squeaky wheel .…

- **Send an e-mail.** As with letter writing, keep your e-mail message brief and to the point. State that you are a constituent. Include the name and number of the bill. In addition, be sure to include your full home address, time your e-mail so that it arrives on a Monday or Tuesday, or Friday, and follow up.

- **Make a telephone call** — When you call a legislator, remember that you need to be brief and communicate key information. Most often, you will reach a staff person. Ask to speak with someone who handles healthcare legislation. State your name and address, let her know that you are a constituent, tell her you are a healthcare provider calling to express concerns about pain management (state your position as specifically as possible). Be sure to stick with talking points prepared before calling and stay on point. Limit your call to under 5 minutes and ask for a written response.

- **Write a letter to the editor** — This has even more weight than a letter sent directly to your legislator. A letter to your legislator is an important expression of your opinion, but a letter to the editor lets the legislator know that your views will be read and thought about by other voters. Letters to the editor are usually written by readers for the opinion section of newspapers and magazines, either in response to something that has been published in the paper or to something significant that is happening in your area. Letters should be kept short, no longer than 500 words, and should focus on one major point.

- **Encourage others to take action** — Ask your colleagues, family, friends, etc., to write, call, or visit legislators as well. Provide them with sample letters and suggestions.

Case Study — A Hospice Organization Fights to Preserve Patient Benefits — and Wins

In January 2003, hospice programs in Ohio faced cutbacks in services funded through Ohio Medicaid. In order to fight the elimination of funding for hospice services, the Ohio Hospice & Palliative Care Organization (OHPCO) recognized the importance of educating Ohio legislators and regulators about the importance of preserving these services for the Ohio citizens, who were facing end-of-life decisions.

OHPCO made it a priority to organize and advocate for its constituents both locally and statewide. Each of the member hospices was asked to designate an advocacy coordinator. An all-day training program was provided for the coordinators. Each coordinator was asked to identify at least 10 advocates.

A grassroots advocacy campaign was planned and launched. This included a letter-writing campaign and visits to legislators and regulators by staff, volunteers, patients, families, board members, vendors, and physicians. In their letters and visits, advocates wove statistics and personal stories together to show both the financial and holistic benefits of hospice. On June 26, 2003, Ohio Governor Robert Taft signed off on the budget retaining vital eligibility and funding provisions for Ohio's Medicaid Hospice Benefit.

OHPCO was able to use a state-wide directed effort, supported by passion, knowledge, and persistence to net the desired results — continued coverage of hospice for Ohio's citizens.

USING THE MEDIA: MAKING PAIN NEWS

One of the most effective ways to communicate pain information is through the news media. In fact, that is where most people go to get information. The more often a story is reported, the more concerned people get about it.

Pain is now making front-page health/medical news. But, in both senses of the word *news*, there has been both the good news and the bad news about pain. The good news is that the undertreatment of pain, as a healthcare problem, has been getting wide media coverage since the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards went into effect in January 2001. The bad news is that there has been a rash of harmful news stories related to pain and pain medications. The abuse and

diversion of opioids, for example, have become a focus of local and national media. And, while most of these sensationalized stories have focused on the dangers of these medications, few have addressed the real news — that millions of Americans are suffering needlessly with pain.

Because people tend to believe that what appears in the news is true, both the good and bad stories influence the way that the public, healthcare professionals, policy makers, law enforcers, and others understand and respond to pain management issues. So an essential part of grassroots and legislative advocacy work is creating accurate, current, and compelling stories that carry our messages and motivate people to take positive action.

DEVELOPING KEY MESSAGES

Everyone is concerned about messages these days — from the President of the United States to grassroots advocates. So, what are messages and why are they so important? Messages are the key understandings about your work — they are your theme. To be successful in your advocacy work, your messages should be powerful, organized, logical, and persuasive. Ethel Klein, a well-known public health media strategist, said that messages should be morally authoritative and capable of evoking passion.

Messages should be tailored to your audiences, so think about what it is your audience needs to know, the best way to say it, and what you want the audience to do with the information. Note: Messages are not sound bites, slogans, persuasive arguments, or statistics, although all of these can be used to support your messages.

DELIVERING MESSAGES TO THE MEDIA

If you are working with a group, think about who will be the spokespeople — the people who will speak publicly about the work you are doing and give interviews to the media. Choose people who are "authorities" on the subject — who have experience from a variety of perspectives. You may want to identify consumers (patients suffering pain, family members, caregivers) and healthcare professionals (pain specialists — doctors, nurses, social workers). Spokespeople should be articulate, able to convey key messages clearly and succinctly, and readily available to speak with the media. If you are contacted by a reporter, respond immediately. Reporters are often impatient or on a deadline and will move on to other sources. So it is also important to have back-up speakers.

SAMPLE MESSAGE TRACK

Pain is a national public health crisis. *It Is Our Nation's Hidden Epidemic.*

- More than 75 million Americans suffer with chronic pain.

- Pain is the Number One reason people seek medical care.
- Uncontrolled pain diminishes quality of life and decreases work productivity.
- Pain has serious economic consequences—pain costs our economy $100 billion in medical costs and lost workdays.

Undertreatment of pain has serious physiological, psychological, and social consequences.

- Pain weakens the immune system and slows recovery from disease or injury.
- Uncontrolled pain adversely affects almost every aspect of a person's life including sleep, work, and social and sexual relations.
- Pain causes anxiety and depression, and may lead to thoughts of suicide.

Most pain can be controlled with proper pain management.

- When pain is controlled, people can experience a better quality of life.

Unfortunately, there are barriers that prevent effective pain treatment.

- Most healthcare professionals have little or no training in pain management (and are unable to effectively respond to patients' reports of pain).
- **Exaggerated concerns about addiction lead to undertreatment of pain**. Addiction to opioid analgesics is unlikely for people with no history of substance abuse and when opioids are properly prescribed and taken under medical supervision.
- **Pain carries a stigma**. Many people with pain are fearful or embarrassed about letting their families, friends, and even their healthcare professionals know they are in pain, because they don't want to appear weak, or be considered a bad patient.
- **Some government policies** impede pain relief by restricting access to pain treatment.

People with pain, their families, and caregivers need to advocate for good pain management and insist on the treatment they need.

MEDIA ACTION STEPS

- **Familiarize yourself with the local media.** Read the newspapers, listen to radio stations, and watch TV programs in which you want your stories covered. Find out what kinds of stories

they cover and from what angles. Tailor your messages to their audiences.

- **Develop relationships with the people who make the news.** It is far easier to get your story in print or on the air if you have working relationships with reporters, editors, and producers. One way to do this is to let them know that you can serve as a credible source of information and a leader on the issue.
- **Have a clear objective when approaching the media.** It may be to call attention to a pain management issue or problem in your area, to call for action on the part of an elected official, or to let the public know about an upcoming event.
- **Write strong news releases that have a standardized look.** All release should include the five Ws — who, what, where, when, and why. Make sure your release is focused and contains enough information for a story. Include the local angle (why the story is of particular interest to their readers or viewers). Structure your story as a pyramid. Capture the essence of the story in the lead paragraph — tell something important and tell it fast. Give all the facts. Have a concluding paragraph.
- **Follow-up with a phone call to reporters.** You want to make sure your release lands on the right desk, but more importantly, a phone call gives you a chance to pitch your story.
- **If you are interviewed by the media, stay on message.** Remember, you are the expert on the subject. Also, do not let the reporter get you off topic. Learn how to redirect questions by saying, "That's a good point, but I want to emphasize that …." If you are asked a question you can't answer, say that you are not sure and that you will get the information for them. You can also offer to put them in touch with others.
- **Opinion pages and editorials offer great opportunities for advocates to get their messages out.** The editorial section of the newspaper is one of the most widely read. This is often the place where policy makers go to find out what issues are hot topics among their constituents. You can request a meeting with the editorial board or write an op-ed piece or a letter (don't forget, you are an expert).
- **Submit items to community print and online newsletters, calendars, and bulletins.** Think about various ways to get your story out.

CONCLUSION: REALIZING THE VISION

We will know that we have succeeded in our work as pain management advocates when:

- Pain will be recognized as a serious public health problem.
- Federal and state governments will invest adequate funding for pain research, healthcare professional education, and public awareness.
- Patients with pain will have access to the treatment they need.
- It is understood that pain is harmful to the body and should be treated as the fifth vital sign.
- Pain does not carry a stigma.
- All healthcare professionals are knowledgeable about pain management, and there are more pain management specialists.

So, what are you waiting for? Take action now!

RESOURCES

Personal Advocacy (Printed Materials, Web sites, and Support Groups)

American Alliance of Cancer Pain Initiatives (AACPI) is a national organization that promotes pain relief nationwide by supporting the efforts of state and regional pain initiatives. The organization offers printed materials for patients and a Web site that contains a media toolkit, sample letters, press releases, and op-ed pieces. For state and local contacts, check its Web site for state initiative information. Several state initiatives are now addressing pain in general.
Address: 1300 University Avenue, Room 4720, Madison, Wisconsin 53706
Web site: www.aacpi.org
Telephone: 608-265-8655

American Chronic Pain Association (ACPA) — A nonprofit organization offering support groups throughout the world and a variety of useful materials for people with pain. The ACPA is also leading a nationwide public awareness campaign called Partners for Understanding Pain.
Address: P.O. Box 850, Rocklin, California 95677
Web site: www.theacpa.org
Telephone: 916-632-0922

American Pain Foundation (APF) — A nonprofit organization serving consumers affected by pain, through information, education, and advocacy. The organization offers a comprehensive Web site (including links to disease-specific pain), PainAid (online community support),

consumer publications, a monthly e-newsletter, a toll-free information line, and public awareness and legislative activities.

Address: 201 N. Charles Street, Suite 710, Baltimore, MD 21201

Web site: www.painfoundation.org

National Chronic Pain Society (NCPS) — Provides peer support groups for people with chronic pain and their families. It also provides current, accurate information from qualified professionals through the *Chronic Pain Report* (*CPR*), a quarterly newsletter, and through multidisciplinary conferences.

Address: P.O. Box 903 Tomball, Texas 77377-0903

Web site: www.ncps-cpr.org

Telephone: 281-357-HOPE (4673)

National Pain Foundation — Offers online education for patients experiencing pain and their families including information about pain, treatment options, links to support groups, and physician-led public awareness activities.

Web site: www.painconnection.org

Telephone: 303-756-0889

Public Awareness Advocacy (Public Awareness/ Grassroots Campaigns and Resources)

Power Over Pain (POP) — a grassroots action/ media campaign, conducted collaboratively by APF and AACPI. To see if there is a POP group in your state, go to www.poweroverpaincampaign.org or send an email to info@painfoundation.org.

Pain Ambassador's Program — a public awareness initiative of the National Pain Foundation and the American Academy of Pain Medicine. Designed for pain-trained physicians, the purpose of the program is to spread the word about the importance of pain management, provide useful information to consumers, and teach pain management basics to other healthcare professionals. Pain Ambassadors are provided with toolkits, a newsletter, and regularly updated information. To learn more, go to www.painconnection.org.

Partners for Understanding Pain — organized by the American Chronic Pain Society, it is a network of organizations working to create greater understanding and awareness of the impact of pain on the economy, social structure, and lives of individuals. To find out more, go to www.theacpa.org/publicawarness.htm.

Legislative/Policy Advocacy

Pain & Policies Studies Group — An organization dedicated to "balancing" international, national, and state policies to ensure adequate availability of pain medications for patient care while minimizing diversion and abuse. This organization also supports a global communications program to improve access to information about pain relief, palliative care, and policy.

Address: 406 Science Drive, Suite 202, Madison, Wisconsin 53711-1068

Web site: www.medsch.wisc.edu/painpolicy

Telephone: 608-263-7662

Media Outreach (Media Toolkits and Information Specific to Pain)

Power Over Pain Community Action Kit contains two media guides: "Making Pain News!" (a comprehensive guide) and "Striking a Balance: The Abuse of Opioid Analgesics and the Media, A Rapid Response Action Kit." Both are available online at www.poweroverpaincampaign.org. "Striking a Balance" can also be found at www.aacpi.org.

September Pain Awareness Month media materials can be found at www.theacpa.org in the Partners for Understanding Pain section.

Pain Control Advocacy Toolkit, a resource of the Hospice and Palliative Nurses Association that offers media tips and ways to reach legislators can be found online at www.hpna.org.

National Professional Pain Organizations

American Academy of Pain Management — A national multidisciplinary pain society that provides credentialing to practitioners in the area of pain management. A good source for complementary and alternative practitioners. Offers information on finding healthcare professionals and programs.

Address: 13947 Mono Way, Sonora, California 95370

Web site: www.aapainmanage.org

Telephone: 209-533-9744

American Academy of Pain Medicine — A national organization of pain physicians promoting quality care of patients with pain as a symptom of disease (eudynia) and primary pain disease (maldynia) through research, education, and advocacy, and through the advancement of the specialty of Pain Medicine.

Address: 4700 W. Lake Avenue, Glenview, Illinois 60025
Web site: www.painmed.org
Telephone: 847-375-4731

American Pain Society — A multidisciplinary pain organization serving people in pain by advancing research, education, treatment, and professional practice.
Address: 4700 W. Lake Avenue, Glenview, Illinois 60025
Web site: www.ampainsoc.org
Telephone: 847-375-4715

American Society for Pain Management Nursing — An organization of professional nurses dedicated to promoting and providing optimal care to patients with pain through education, standards, advocacy, and research. Check Web site for local chapters.
Address: 7794 Grow Drive, Pensacola, Florida 32514
Web site: http://www.aspmn.org/
Telephone: 209-533-9744

International Association for the Study of Pain — A professional organization dedicated to furthering research on pain and improving the care of patients with pain. Membership in IASP is open to scientists, physicians, dentists, psychologists, nurses, physical therapists, and other health professionals actively engaged in pain research and to those who have a special interest in the diagnosis and treatment of pain.
Address: 909 43rd Street, Suite 306, Seattle, Washington 98105
Web site: www.iasp-pain.org
Telephone: 206-547-6409

ONLINE PAIN RESOURCES

City of Hope Pain Resource Center — Serves as a clearinghouse for information and resources that enable individuals and institutions to improve the quality of pain management.
Web site: prc.coh.org

Mayday PainLink — A virtual community of health professionals committed to alleviating pain.
Web site: www.edc.org/PainLink

The Problem of Pain for the Healer and the Art of Healing

Richard H. Cox, MD, PhD, DMin, and Betty Lou Ervin-Cox, PhD, PsyD

Most, if not all, that is contained in this chapter is familiar to most healers. However, because we learn best by repetition, and we learn new material in terms of what we already know, a revisiting of our basic premise of being holistic practitioners may be welcome. Further, as much as we might like to think that all of the healing world thinks as we do, let us not be deceived. Many have heard, some have listened, and fewer have followed the actual practice that we verbalize so well.

Healing is seen by many, professionals and laypersons alike, as a science, which to be certain it is. However, long before the human race understood much, if any, of the actual science involved, it was an art and only specifically gifted and trained persons were capable of practicing it. The more a specialty becomes a science, the more it is teachable and sometimes becomes devoid of the unseen, intuitive, "giftedness" aspects that make it also an art. With the advent of so much wonderful technology entering the healing field, we have seen a diminution in the interest and manifestation of the need for the art and the greater emphasis on the science, which often is relegated to numbers, laboratory, and other diagnostic procedures of a more mechanical and lesser human involved nature.

Ancient medicine, and for that matter, all of medicine until recent times relied on the human ability to diagnose by virtue of not having the "scientific" data available. As a result, as much, if not more, emphasis was placed on the healer than on the healing. The medicine man, the guru, the shaman, and our Western predecessors shared the necessity of gaining self-knowledge and relying on their intuitive, instinctual, and "gut-feelings" as well as

the "I've seen it before" diagnosis. Until modern times healing was seen as something that happened as a result of powers far beyond human control. The "spirits," the "gods," or even long-dead relatives were responsible for the results of treatment, not the antibiotics, anxiolytic, or oncolytic agents. Credit for getting well was rarely given to the healer. The displacement and projection of the cure from an unknown entity to the "known" doctor/treatment shifts our thinking from "healing" to "cure." There is a difference. Becoming "cured" is most often seen as having been relieved of specific symptoms, therefore, the relief from the condition or pain that was defined as the illness. Becoming "healed" is a much deeper, more comprehensive becoming "whole" rather than simply ridding one of symptoms, which in return aids the body/mind in returning to a total state of health. Curing may relieve symptoms; healing moves toward producing a whole person.

Pain can be a friend. It warns us that the body is in danger and, without pain, someone has said, we could die without knowing that we were even sick. Hence, we pay proper tribute to pain and recognize its value; yet, pain is always in some way related to death. The child with an abrasion on the knee runs into the house crying, "Mommy, I'm dying, I'm dying!" Someplace in our primitive and unconscious minds pain has become associated with the process of death. Pain becomes the constant reminder of our mortality and that thought often cascades into a torrent of terror, which in turn energizes the process of actually dying. The healer therefore not only relieves symptoms but saves from death. In spite of this finding, there are patients who for strange reasons *need* their pain and when

relieved of it will find the most ingenious methods all the way to Munchausen's syndrome to reinstitute it. Whether this extreme attempt to regain pain is a suicidal act is open to debate, but it certainly succeeds in keeping the patient in contact with the Freudian concept of a death wish.

As medicine advanced through the ages we attempted to understand it all by simple unifications of symptoms into disease or syndrome entities, thus the "unified" disease approach whereby we attempted to meld all symptoms, regardless of how diverse they might be, into one syndrome or disease entity. The more information we gained, the more this approach, although still practiced, had of necessity given way to the "dual diagnosis" and even "multiple diagnosis model." The importance of this observation is that in the "healer emphasis" model, the focus was on the healer bringing healing to the *person who had an illness*, as against the more prevalent model today of the focus on the *illness that is in a person.* When one views symptoms that happen to inhabit a body, it is quite different from viewing an individual who wishes to be made whole. Making one whole is considerably more than relieving the symptoms. Many patients are relieved of their symptoms and yet are quite ill as persons. The true healer dealt (and deals) with putting a person back together again, knowing that being well is much more than simply not being sick. We are constantly reminded that the word "health" is derived from the same Greek word *holos* as "whole," "holy," "wholesome," and many more words defining a totality of health in the being not sufficiently described by the word "health" alone.

The "healer," by the same token, is the agent of this wholeness, which is much more than one who diagnoses and renders treatments. Diagnoses and treatments are simply tools of the trade that promote a condition that may provide the basis for wholeness to return to (or begin in) a person. Often, as we know, the "treatment" is not in any way corrective or capable of dealing with the pathogen or condition at hand, but works anyway. Such is the case with our commonly called "placebo" treatments. In truth, there is no such thing as a "placebo" because all administrations by healers are intended to bring about symptom relief; therefore, in the patient's mind the tool has been applied to commence the process of healing.

The effect of the patient's response and belief in the healer cannot be ignored. When a patient believes that a treatment will work, sometimes the doctor is also convinced! Dr. Herbert Benson relates an incident in which a fearful patient asked him to accompany her as she received anesthesia in her hospital room presurgery. He states:

> As the anesthesiologist began the anesthesia drip, I repeated out loud along with her quiet recitation, The Lord is my shepherd … The Lord is my shepherd … The Lord is my shepherd … on each of her outbreaths until eventually anesthesia took effect and she lost con-

sciousness. When I looked up, the anesthesiologist — whom I'd likened to Dick Butkus just moments before — was softly shaking, his mask soaked with tears. For the woman herself, the recitation of a familiar psalm with a doctor she trusted was a deep source of calm. But the ritual also carried with it power that I could not have predicted, eliciting in this straightforward, dutiful anesthesiologist a profound emotional response. (1996, p. 1780)

When we introduce the factor of pain into the picture, healing becomes even more complex. Traditionally, pain was considered simply to be a concomitant or result of illness. Pain as an *entity* or even as an independent *illness* was incomprehensible. We now know that pain not only accompanies and results from illness, but also may *produce* illness. This places the role of the healer in a very different position. The healer must attend to how the patient *feels* as well as what is happening in the laboratory reports. As we all know, the doctor can assure the patient that "you are getting better," but until the patient accepts that as a personal *feeling of truth,* it often does not make any difference what the doctor says. Once the patient *owns the feeling* of getting better, often the healing is well on its way.

The cultural implications and meaning of pain are far beyond the intents of this chapter. However, we must pay attention to the depth of cultural meaning in pain. From time immemorial pain has been attributed to some kind of god-sent retribution for personal evil done. From the birth pangs initiated with Eve and the sweat of the brow curse given to Adam, we have associated pain with evil. The healer must then of necessity become the holy one. No wonder so much trust and awe has been given to doctors! As the Western world becomes more "scientific" about pain, the doctors are less seen as miracle workers, but are replaced by wonder technology and chemicals. The modern healer must work to regain a power that is beyond drugs and surgery. Faith in doctors alone was doubtless in vain; however, faith in the medicines alone may leave us devoid of the powerful relationship between healer and patient that allows the therapeutics to bring about healing.

In spite of our efforts, many persons are unable to relinquish the idea that pain and evil are twins. The lack of illness is not necessarily the presence of health, and the presence of illness is not necessarily the presence of evil. "There are many persons who suffer indescribable pain who are indeed holy" (Cox, 1997, p. 46). By the same token, there are many who suffer no pain who certainly do not seem to be holy. We must be careful not to rush to judgment regarding another's spiritual status. Furthermore, at times there is no evidence that the patient's spiritual status has much to do with whether healing occurs. In the New Testament healings of Jesus it seems that the willingness to want to be made whole and the intent to

change one's lifestyle were the important elements. Jesus simply asked, "Wilt thou be made whole?" This is a curious question; i.e., Jesus does not ask if the person wants symptom relief, but if he wishes to be made *whole.* And, therein may lie the mystery of healing, i.e., the wish for the total renewing of the person as against the simple elimination of troubling symptoms. Even blindness, lameness, or paralysis to Jesus seemed to evoke the same method for healing; namely, a teamwork of faith, willingness to accept the healing, and the energy of the moment.

Not only in the healings of Jesus, but of many others recounted in literature from shrines to evangelistic happenings, it seems that the common denominator is not the symptom but the process and the energy created by the combination of human and divine sources. It may be that the modern-day healer is too concerned with the specificity of symptoms and insufficiently connected to the energizing, life-giving resources of the spiritual/energy world (see below; Shealy, 1999, p. 55).

Harold R. Nelson, in his book *Senior Spirituality,* states, "When I had open-heart surgery in 1993, I had the good fortune to have a cardiac-thoracic surgeon who is highly skilled and yet very caring. When he entered my hospital room to check me over, I felt a healing presence that bolstered my own healing process" (Nelson, 2004, p. 63). Literature is replete with the healer's own attitude as being an integral (and maybe central) part of the healing process. Norman Cousins has written extensively in support of such. The narratives of the healings of Jesus and the many "spontaneous" recoveries over the centuries leave us no room to doubt the role of "faith" on both the part of the patient and the healer. Benson writes, "The sound of a doctor's voice, the words he or she chooses, the hope he or she can instill, and the time required to develop a good doctor-patient conversation promote health in ways many doctors and most insurers underestimate today" (Benson, 1996, p. 252).

The Rev. Nelson, a person with a lifetime as a hospital chaplain, also recounts, "I was anxious, angry, and threatened by a diagnosis of diabetes, and I needed to find a place of calmness, serenity, and peace with myself" (Nelson, 2004, p. 71), which he found through modalities that are considered "secular" but became sacred, such as hypnosis. In the end, all modalities become routes to the spiritual. Here is a person one would think might start at the spiritual to find healing. And indeed he did, but only to find that he was "in a no-man's land for a considerable period of time, struggling with identity and being caught up in despair. The journey taught me valuable lessons about the meaning and purpose of my life" (Nelson, 2004, p. 36). He states that he then "instinctively turn[ed] to spirituality at a time of loss. It is a built-in, automatic response that has resulted from all my previous spiritual experiences" (p. 95). He is correct in stating, "The utilization of faith at a time of loss is highly individualistic

and unique" (p. 95); however, suffice it to say that whether the person has ever been "spiritual" or not, most persons inevitably seem to become more than casually interested in the world of belief, faith, hope, and spirituality when confronted with pain and the possibility of death.

There are many articles and books written to assist patients with their part in the healing process. There are considerably fewer helping the healer to find his or her own inner resources for such. The complexity of helping us as healers begins with being able *to get outside of ourselves while getting very deeply inside ourselves!* This process is being able to deal with *imminence* and *transcendence.* In the final analysis, all healing is essentially spiritual. Although the healer, the patient, the diagnosis, and the therapeutics are very tangible, the energy beneath it all is doubtless of a nature that is not describable, nor is it quantifiable. We only need to read about "Therapeutic Touch" (Goldberg Group, 1995) to realize that all sorts of energies, ideas, approaches, techniques, and methods combine into something about which we know virtually nothing, namely, spiritual energy. The Therapeutic Touch approach, in which there is often no physical touch at all, has actually "altered enzyme activity, increased hemoglobin levels, and accelerated the healing of wounds" (Goldberg Group, 1995, p. 111).

Imminence is the language of the here and now, i.e., that which is apt to happen very soon. Modern healing, whether in acute or chronic illnesses, tends to wrest itself of the existential nature of health and illness by addressing that which needs to be done immediately. As important as that certainly is, that which is imminent may be less so when placed into the context of the existential. Further, the term "imminent" tends to indicate the negative, such as "a storm is imminent." Patients are often so focused on the imminent, thus possibly the negative, that they are literally unable to surmount their discomfort and pain without the healer's ability to transcend the patient's immediate symptoms and apprehensions.

Transcendence speaks of *hope.* Tillich and other prominent psychologically astute theologians remind us that humans not only have all the concerns of every other living creature, but also have spiritual concerns. They speak of our capability and necessity for reaching beyond the here and now and finding that indefinable and yet absolutely defined element we call *hope*. Hope is found in transcendence: transcending the situation, the discomfort, the pain, and perhaps most importantly, the ambiguity of most illnesses, thus allowing both the patient and the healer to admit to human frailty, incomplete, and even incorrect knowledge.

Transcendence is to rise above, go beyond, and experience more than the here-and-now could predict or anticipate. The languages of this process are many. They range from that which is called faith to that which is called psychic. The language is not important. The experience

with the inner force it generates is essential. It could be argued that many healers have left the healing business for the treatment business; i.e., the emphasis is on the business of treatment that hopefully could result in healing, rather than being in the healing business that intends to make persons whole. Although this may be seen as a triviality of words, it is not. Transcendence disallows primary focus on the immediate, the imminent while still considering the immediate to be essential. But it recognizes that the best way to get to the immediate is through the transcendent instead of the other way around.

Both imminence and transcendence are based in belief. Both are processes of directing oneself outside oneself to something one does not know. Both go beyond that which can be measured; therefore, there is no norm. This fact and acceptance of such is essential to the healer. Both the patient and the healer *know* that there are in truth no norms for any individual patient, but only numerical and statistical *norms* for patients with similar symptoms when all are grouped together. It is essential when dealing with pain in particular that we accept this fact. No two persons' experiences of pain are the same. We still have no reliable measure of pain. The experience is entirely subjective; hence, the healer must be willing to allow and encourage the individual process of transcendence, which allows belief to start a process that is not rooted in the imminent, i.e., laboratory results, x-rays, and other *norms.*

We may be helped by viewing the healer as a *change agent* instead of a physician, psychologist, nurse, or other practitioner. By definition, a change agent is one who is authorized by another to act on his or her behalf. There are many inherent assumptions, *possibilities*, and dangers in being an agent. The responsibility is huge. The task is enormous, and the ethics of such are beyond description when caring for another soul.

The literature of many cultures shows how pain is "given over" to a change agent. Hebrew literature transferred it to a "scapegoat," and some primitive cultures "throw it in a fire on a bedeviled twig." The book *Treating Spiritual Disorders* states, "When we purposely expand our sense of self to include the natural world in which we unceasingly participate, we seem to draw toxicity from our bodies and distribute it among willing partners of our day-to-day lives" (Simms, 2001, p. 147). Change agents have been utilized in various, and to us possibly strange ways, from time immemorial. It is a respected, even perhaps an enviable spiritual gift to be in the position of a change agent.

Rarely, if ever, do patients know what they are doing when allowing a therapist, physician, or other healer to become their agent. In truth, the giving of this authorization is probably rarely conscious and deliberate but implied, which makes the task all the more daunting for the healer. Healers are not trained to fully understand what it means to care for another soul and to assume the respon-

sibility of another's most sacred self. Most healers see their role as being able to bring certain treatments, medicines, and procedures for the effecting of very specific symptoms or conditions. As humans, we cannot be separated in this way. We are not symptoms, pains, feelings, and conditions, but whole persons who cannot be dissected by various nomenclatures, systems, and nosologies.

The human, as we all know and to which we give verbal assent, is a totality, a whole. To treat one part is to treat all parts. To ignore one part is to ignore all parts. This wholistic approach is sometimes hard to see even in the most dedicated healer's practice with the seemingly endless parade of *specialties* we now have. While it is doubtless good to know as much about any one illness as possible, it is also possible to be so myopic as to lose sight of the whole person who cannot be separated from the *specialty illness.*

Patients need to know the value base of their healer. The healer seriously involved in the healing process rather than the dispenser of therapies will thus form a bond with the patient. Why attempt to hide that which will establish a healing relationship? It has been promulgated that healers should keep their private view to themselves. This is not possible. Patients are perceptive. Patients often invest far more in the person and the abilities of their healers than the healers do in their patients; thus, the psychological intensity of identification with the healer is beyond description. The patient sees the frown that that the healer is unaware of having, the side glance to the nurse that the healer thinks is private, the worried look on the healer's face, or sometimes the "air" of confidence or consternation in the very atmosphere of the room. The evidence of a faith in themselves, their patient, and the treatment method produce a spiritual basis that allows both healers and patients to transcend themselves and the imminence of the illness.

Dr. Benson states, "Clearly when patients *believed* in therapies that were recommended by their doctors, this fervor worked to alleviate a variety of medical conditions including angina, asthma, herpes simplex cold sores, and duodenal ulcers. But as soon as patient confidence was undermined, so was the effect. This pattern was noted by the nineteenth-century French physician Armand Trousseau" (1996, p. 35).

The healer must not be afraid to reach beyond the limits of his or her specific professional discipline to borrow and learn from others. Sometimes the physician, for example, seems to function as if everything the clergyperson (or other professional) would do is off limits for the medical or specialty person. And, by the same token, the clergypersons (or other disciplines) do not want to practice medicine without a license. However, there is a ground between all disciplines and professions where we can borrow techniques, use methods, refer more properly, and allow all disciplines to become one team, i.e., one healing

agent, when we practice with mutual respect, equality although difference of knowledge, and see healing as the art and many artists joining hands to become one master-artist/healer.

Dr. C. Norman Shealy, founder of the American Holistic Medical Association, in his book, *Sacred Healing,* states, "Why can a healer transmit energy while a regular person cannot? A master healer's mental attitude and life of prayer and devotion produce a more direct connection with divine energy. For this reason a healer can tap into divine energy more effectively than individuals who do not have spiritual practices. A master healer pays continuous attention to and is totally devoted to God. To heal, the healer must continuously be in touch with God, maintaining a constant mental and spiritual connectedness" (1999, p. 73).

As agents for change, we must not attempt to determine the changes, but only allow for all possibilities. By being open to all possibilities we are more apt to experience the transcendent. When allowing for all possibilities we sometimes find that we are actually treating something quite different from what had been initially diagnosed. For example, a patient with a phobia (or a fever for that matter) may actually simply be too engrossed in the pathology of the symptom to actually reveal the underlying problem. Sometimes the problem is entirely too painful to bring forth; hence, a disguised form appears in the hope of finding a healer who can become transcendent.

Without the transcendent, all diagnoses and treatment strategies are sterile and without vitality. Obscuring the whole patient in favor of the immediate symptoms often diminishes the patient and encourages (and maybe even forces) the acceptance of a wrong diagnosis in favor of no diagnosis at all. There is an axiom in medicine that "the correct diagnosis leads to the correct treatment." As certainly true as that is, it is equally true that the wrong diagnosis leads to the wrong treatment, and further in that case, no diagnosis is better than the wrong one. In the transcendent mode the healer is permitted to accept "intuitions," "hunches," "it just seems like," and other less describable definitions of what is going on while carrying out the due diligence of required and reasonable imminent therapeutic activity.

Healers who are able to move into the transcendent are able to emphasize the overall wellness of a person while attending to the immediate illness. Recognizing that an elbow hurts is essential, but it is also essential to recognize that there are many other joints in the body that do not hurt and are functioning well. The psychology of attention has been well taught to us. We need not be reminded that to ask one *not* to remember that a pen is black is to be assured that it will never be forgotten. The negative aspect of memory, i.e., retroactive inhibition, can undo many positive aspects of what we really wanted the patient to remember. Proactive inhibition, i.e., interfering with new learning created by memories from prior learning, may actually disallow a patient to learn new material. The healer knows that none of us starts with a *tabla rasa* when it comes to pain. We have all been there. We have all formed our opinions as to what constitutes a "slight hurt" and a "really bad pain." New definitions coming from a healer are meaningless. What counts is the healer's ability to put the current discomfort into the context of process, the process of wellness. "Pain" is described in various ways by both patients and healers, and often the descriptions are very different in personal meaning. The terms "ache" or "burning sensation" or "stabbing pain" are valuable though nonetheless inadequate attempts to bring the healer into identification with the imminent experience of the patient. Some writers have suggested that the deepest of all pain is "soul pain," which may be separate from or accompany actual physical and mental pain. The concept, however correct it may be, is valuable to the healer in understanding the depth of another's experience. The patient is usually attempting to gain new understanding of the concept of pain but at the same time is dealing with all the past memories of pains of the past.

Pain in wellness is different from pain in illness. Pain in wellness is microscopic. Pain in illness is macroscopic. The pain is not trivialized; it is contextualized. The healer then has the option of utilizing all the energies of the patient as part of the treatment regimen rather than assuming the patient's illness as a personal responsibility and searching for acceptable modalities. There is frequently a degree of paranoia in the pain process with which the healer must contend. Pain is seen as negative. Something uninvited has invaded us and we are being visited by an enemy. It is difficult to be *narapoid* (a new word listed in the *Dictionary of Psychology*, Corsini, 1999, p. 626) in the face of such odds. The healer, however, can instill *narapoia*, i.e., "the belief that all people are beyond suspicion and represent no harm or threat," the opposite of paranoia. Casting out doubt is an essential antecedent to belief or faith. The healer needs to do everything possible to create an atmosphere of hope, faith, belief, and therefore healing. The mind and body cannot be separated as we know, but do not always practice.

Larry Dossey describes an illustration of using the higher art of healing in clinical practice by cardiologist Randolph Byrd who found unexpected success when patients were the subjects of prayer. His results are reported as even staggering to others, and he quotes, "Dr. William Nolan, who has written a book debunking faith healing, acknowledged, 'It sounds like this study will stand up to scrutiny…Maybe we doctors ought to be writing on our order sheets, Pray three times a day,' If it works, it works" (Dossey, 1995, p. 250).

Transcendence and imminence are not simply linguistic terms. They are ways of thinking, styles of living, the presence or absence of confidence, types of maturity, and

the bases for developing a healer whose countenance is obviously one of health rather than illness and the very wholeness in which the healer displays the hope and optimism of that which is beyond symptoms and treatment.

The healer is not simply a person who diagnoses and renders therapeutic regimens. Healing comes from deep within both the healer and the patient. Healing is a team effort, a duet, trio, or more, but never a solo performance. Granted, thankfully from time to time we see persons being made whole with only our partial and dimly understood attempts to help. However, with deliberate intentionality of purpose with the Divine, we may gradually learn to transcend ourselves and enter into a more perfect teamwork for total healing.

Assessing Patient Spirituality: A Compelling Avenue for New Discovery

C. Stephen Byrum, PhD, and Richard S. Materson, MD

BACKGROUND AND INTRODUCTION

There is a fairly recent maxim that by now has probably already reached "old adage" status that conveys the conviction that something is "real" and has "value" only to the extent that it can be *measured*. On the fringe of what some people still judge to be the "modern world" and others are claiming a world that has now become "postmodern," the efficacy of the conviction about *measurement* is, at least, debatable.

Numerous voices in modern health care, and especially those voices that advance conversations relating to nontraditional modes of patient treatment, are likely to be pleased when conversations turn to measurability *not* being an absolute and rigid necessity.

This discussion, however, is not interested in taking advantage and claiming that so-called "soft side" issues get a pass on measurement. In fact, the strong position of this discussion is that certain *realities* that have not been easily measured in the past may be demonstrably quantifiable if valid and verifiable tools are present that can serve as measuring instruments. At the very minimum, if such *realities* are even somewhat conducive to measurement, there should be at least a somewhat heightened interest and curiosity about areas of concern that may previously have been fairly well dismissed.

What *realities* are being referenced here? Primarily, there is interest in being more discerning, discriminating, and definitive about issues relating to *spirituality*. A great deal of the history of health care, of course, has been wrapped up in "faith-based" approaches to medical care.

There has been a vast array of health care institutions that have come to exist and sustained their existence under the banners of various religious organizations. In these environments, many religious rites, rituals, and persons (chaplains, ministers, priests, and nuns) have been actively present. To a major extent, these religious expressions have diminished in quantity, if not in intensity, and it may be difficult to distinguish a "sacred"-oriented institution from a "secular" one. Clearly, "profit" and "not-for-profit" labels are of little help in discerning whether an organization is religious or not. However, this particular view of spirituality is not what we are getting at.

On the other hand, a fairly standard conversation surrounds both "sacred" and "secular," "for-profit" and "not-for-profit" organizations concerning the *spiritual* (for want of a better word) dimension of a person's overall existence as a human being. Especially when discussions of the "whole person" take place, it is not unusual to speak — with some parity of emphasis — about the physical, mental, emotion, social, and *spiritual* person. What is lacking is some way to *measure* this *spiritual* dimension. This discussion is not directed toward those kinds of outcome measures and studies that have done research, for example, in such areas as the improvement of patient outcomes when prayers have been offered on the patient's behalf.

We have previously ventured into this entire arena of *spiritual* measurement in two recent articles (Byrum & Materson, 2001, 2002). These articles introduced a measurement instrument known as "The Spiritual Tendencies Inventory." The STI was specifically designed to give quick access into this spiritual dimension, to stand beyond

traditional religious biases associated with most profiling inventories developed in this area of emphasis to date, and to suggest not only a "diagnosis" of a person's spiritual strengths and obstacles, but also remedial activities that should increase strengths and diminish obstacles. Patients can use the tool independently of physicians, and physicians can use the tool to better understand the patient strengths and obstacles that will have direct implication for the work they are doing with patients.

The response to these articles and to the STI in general has been encouraging and positive. Significant research is now taking place with the instrument at SUNY Buffalo and the Hermann Hospital (a part of the Memorial Hermann Healthcare System) in Houston. Final negotiations are at present under way that will lead to the publication and general distribution of STI on both individual and institutional levels.

THE HARTMAN VALUE PROFILE

The primary purpose of the present discussion is to show how the work of measuring spirituality has moved beyond the STI to include a second instrument, the Hartman Value Profile (HVP). Historically, the HVP is a much older instrument than the STI — first used in the mid-1960s — and has been exposed to an exhaustive array of both applications and validations. The HVP is a much more complex instrument than the STI. It has not, however, been previously used in the area of application explained here. If the STI can be seen as a first instrument of inquiry and catalyst for discussion, the HVP will take that inquiry and discussion to extended levels of insight. What has been learned in using the STI can guide the way for the use of the HVP. The two instruments can be used in conjunction with each other, and their use will have the greatest ease of application in circumstances of chronic illness, pain management, or other forms of extended treatment where there is time to better understand the fuller dynamics of a patient's existence as a human being. Usefulness and benefit will be even greater in situations where patients are contributing partners in their overall care plan and treatment agendas.

The HVP was developed and first used by Robert S. Hartman. There is a vast array of information on Hartman and the research institute named in his honor. At the time he created the HVP, he was understood to be the world's leading *axiologist*. Axiology is a division of philosophy — as opposed to psychology — and operates from the leading premise that human beings are primarily driven by their *value systems*. The word *axiology* is derived from the Greek *axia,* which generally means "worth" or "value."

My "value system" is not something I have. Instead, it is who I am. I am a system, a "package" of values. This "value package" defines me much more clearly than my intellectual rationality, my emotional balance, or my personality. In fact, this "value package" — this unique "lens"

that has developed across my life and directly affects everything that I do — will be the primary driver that determines how rationality, emotion, or personality comes into play in the roles, decisions, and engagements that make up my daily life.

My "value system" clearly is manifested in the set of personal beliefs that I hold — for whom I vote, if and how I choose to worship, what I feel about some social issue. However, more significantly, my "value system" is manifested in the *judgments* I make — the way I evaluate situations, weigh out priorities, and "size things up." *Judgment*, while it does involve rational intelligence and emotional feelings, is a higher-order property of human beings. *Judgment*, regardless of the conclusions of Descartes and their impact on Western civilization in the modern age, is much more than thinking. *Judgment* — the most available manifestation of human "value systems" — ultimately will drive how thinking and emotion are used. It is critical, therefore, to be able to measure *judgment,* to see evaluative judgment as such a unique capacity of human beings. It may very well be appropriate to call it *spiritual.*

In other words, the word *spiritual* is being described here without patently religious connotations. Those connotations, and the practices that have been derived from them and applied to health care, are not being demeaned in any way. There is simply an attempt here to move the conversation concerning the *spiritual* dimension of human existence to a new, next level of consideration. Now, *spiritual* is being defined as that dimension of human existence — beyond purely intellectual rationality, emotion, and thinking — where contemplation, reflection, evaluation, and judgment take place as preludes to decision making, choice, and action. The HVP is particularly adept at measuring this dimension.

PATIENT IMPLICATIONS

Without question, the role of patient *judgment* in the overall spectrum of the enhancement of health and recovery from illness, injury, or malady is critical. If patient *judgment* is not effective and efficient, all of the care strategies, technologies, therapies, and medications available to the modern practitioner may be rendered useless or, at the very minimum, all but negated in their positive potential. Most care plans and treatment protocols are a "two-way street." The medical profession in all of its manifestations has a part to play; the patient has a part to play. If the patient's part is not played well — if good patient *judgment* is not used — the entire care plan is put in jeopardy.

But, what do practitioners know about patient *judgment*? More specifically, what do they know about patient *judgment* before the fact of dismissal or patients taking responsibility for the "hand off" of their own care beyond the physician and the hospital, for example, where the plan of care has been more practitioner driven than patient

driven? More often than not, the patient's capacity for good judgment is known only after the fact when the patient is back in the hospital or back under more direct physician care because some element of the care plan has not been supported by good patient *judgment*. The escalation of complication and cost in such instances can be dramatic.

Therefore, there is a great need to look at the patient's judgment capacity, the *spiritual* dimension of a patient's existence as a human being. The only change in traditional thinking that must take place here is, again, to see the *spiritual,* not, for example, as how often a patient attends church, synagogue, or mosque, or what kind of "prayer life" a patient has; *spiritual* is now being assessed as that "highest-order activity" of human beings where *judgment* takes place.

At the conclusion of this introductory discussion and initial explanation, the actual report that would be prepared by the practitioner is seen. The value of this document can be established quite easily by a practitioner's simply asking whether the kind of information presented in the document would be of benefit in helping the practitioner better understand the patient. In fact, the conviction of this discussion is that the document will provide insight for the practitioner that has never been available previously. The document can also become a vehicle for better understanding the patient, and a catalyst for important dialogue with and monitoring of the patient that has not been available.

The HVP document, "Implications for Physician/Patient Interactions," is divided into three major report areas:

1. A review of 14 individual indices out of approximately 50 indices on the overall HVP that have particular bearing on patient judgment that relates to how patients will be responsible for their own care plan. The review of these critical indices, all of which have significant individual importance, is followed by two comprehensive grids that convey the information from the 14 indices in a highly visual manner.
2. Reviews of the problem-solving capacities of the patient especially as these capacities tend to be more reactionary or more deliberative. Tendencies toward reactionary responses are also judged by the data to be more intelligent or less intelligent.
3. A review of "balance" issues that relate to how the patient sees himself or herself in terms of "self-esteem," "self-concept," and "self-image." Balance in these three decisive areas will provide a wonderful foundation for positive decision making and good judgment. Problems in these areas will clearly handicap good judgment potential.

CONCLUSION

A great deal of the entire treatment program and care plan that surrounds a patient is driven by gaining as much information about the bodily functions, mental functions, and perhaps, even social functions of a patient's overall existence. Now, there is the added advantage of being able to assess a patient's *judgment* capacity, and to understand the degree to which successful recovery will be enhanced or diminished by these *judgment* capacities. The HVP, and this application of the profile in particular, make it possible for this dimension of critical information to be available. Now, there is truly a concrete and decisive manner in which a patient's *spirituality* can be part of a pragmatic and practical discussion and a pragmatic and practical application.

Now, simply look through the following report. Look at the kind of varied insights into patient judgment that are being assessed. Consider whether having this kind of information would be valuable in your care and treatment of a patient. Would this profile report give you valuable information about your patients that you do not at present have? What implications for successful treatment might this kind of information hold?

THE HARTMAN VALUE PROFILE — IMPLICATIONS FOR PHYSICIAN/PATIENT INTERACTIONS

RATIONALE

In modern health care settings, there is a continual need that is expressed, on the part of both physicians and their patients, for greater understanding. Patients want to be seen as *whole*, unique human beings, and the best physicians want to gain any additional insight into patients that will be beneficial to their treatment. The ideal of greater patient insight is particularly beneficial when the physician can gain greater insight into how the patient will respond to treatment and care, both in the hospital setting and after discharge.

Without question, the healing process has many complexities, not the least of which is the *judgment capacity* that the patient brings to his or her part of the treatment and care program outlined by the physician. How a patient will respond in terms of his or her own choices and decisions — that is, *judgments* — will be a critical, and sometimes even decisive, element in successful treatment outcomes. For example, on the most basic level, whether a patient responds wisely to the *directions* that accompany discharge will have a large impact on recovery, whether the patient will be satisfied with the physician, whether the patient will return to the hospital with extenuating problems, and — of course — the overall cost of health

care in general. "Responding wisely," in this instance, is a matter of *judgment*.

The Hartman Value Profile is designed to be particularly adept at understanding human *judgment capacity*. In this specific application, attention is given to individual indices of the profile's interpretative mechanism that lend themselves to special areas of patient response to treatment and care. By paying attention to the various indices of assessment found in the profile, health care professionals can gain a deeper and more articulate insight into the *judgment capacities* of their patients in areas of concern that have profound implication for the treatment, healing, and recovery processes.

At the very minimum, this application of the profile shows strength or weakness of judgment in the areas assessed. The profile can also be used to establish helpful conversation and dialogue between the physician and patient about the patient's own responsibility and accountability in the care process. Both professional homecare and family caregivers will gain insight into how to assist, enhance, or monitor patient responsibility and accountability based on the profile's results.

David Johns, a highly-respected physician who has made a life study of "additional" — not "alternative" — pathways to healing, well-being, and recovery of human wholeness, is convinced that relationship-medicine, as opposed to transaction-medicine, is a critically important element in the healing process. For Johns, it always takes a special physician — or health care provider in general — who sees and pursues the value in developing some degree of relationship with his or her patient. Much of modern health care focuses obsessive attention on the economic transaction of moving a patient in and out of the treatment setting as quickly as possible. The application of the Hartman Value Profile seeks to give Johns's "special physician" a tool that will lend itself to establishing meaningful relationships effectively, efficiently, and in ways that have a measurable quality to them that can be appreciated in the most economic and science-based health care practice.

TECHNICAL OVERVIEW

This application of the profile is divided into two parts. First, there is a review of findings based on 14 different indices. Each index is identified and then explained in terms of the likelihood of patient response based on scores that have been processed. Each index is broken down into seven categories: "highly likely," "likely," "somewhat likely," "neutral likelihood," "somewhat unlikely," "unlikely," and "highly unlikely." The "highly likely" scores are most desirable, and the greater distance of scoring from this highest echelon, the greater the potential

problem in positive responsibility and cooperative accountability. Any scores in the three "unlikely" categories should be given detailed attention.

Following a description of the individual indices and the scores established by a patient, there are two visual presentations of the information: (1) a grid will show a review of all of the scores and (2) a composite score line will show the relative judgment strengths exhibited by the combined scores.

On a more sensitive level of consideration, but a level that is highly insightful, three specialized scoring areas will make an assessment of the patient's overall sense of self-regard. Here, valuable information will be gained about how the patient feels about himself or herself in terms of "Self-Esteem," "Self-Concept," and "Self-Image." Without question, how a patient feels about himself or herself — that is, the character and quality of a patient's self-*judgment* — will be critical to any and all positive treatment and care outcomes. This second part of the profile report for this application is more subtle, but can be the catalyst to tremendously beneficial insight.

In terms of actual use, the profile can be administered prior to hospitalization, during the in-patient period of care, or prior to discharge. In most respects, the sooner the information is gained, the sooner its insights can become helpful.

INDEX OF CRITICAL SCORES*

1. **Differentiation/DIF (Part 1)** — Measures the likelihood of the patient to notice subtle changes in his or her own body, the kinds of subtle changes that may indicate that treatment is or is not working in some critical manner.

Highly Likely	Likely	Somewhat Likely	Neutral Likelihood	Somewhat Unlikely	Unlikely	Highly Unlikely

2. **Dissimilarity/DIS (Part 1)** — Measures the likelihood of the patient to be careful in following directions given regarding elements of treatment and care for which the patient will need to be responsible.

Highly Likely	Likely	Somewhat Likely	Neutral Likelihood	Somewhat Unlikely	Unlikely	Highly Unlikely

3. **Sub-Dimension Systemic/DIM-S (Part 1)** — Measures the likelihood of the patient to under-

---

* Please note: In both this section on the Index of Critical Scores and in the Overview of Critical Scores found below, not all of the more than 70 indicators on the Hartman Value Profile are used. Only scores found to be of utmost significance to patient insight are examined.

stand the care plan *conceptually*; the ability to create a "mental map" of the care plan.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

4. **Sub-Dimension Systemic/DIM-S (Part 2) —** Measures the likelihood of the patient to *integrate* into real choices, decisions, and actions that which has been *conceptualized* about the care plan; the ability to have strong, personal initiative to act on the care plan.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

5. **Integration/INT (Part 1) —** Measures the likelihood of a patient to be a clear and decisive problem solver, solution finder, and strong decision maker. Strong scores on these scales are critical to assessing the degree to which a patient will be an aggressive and active participant in a treatment and care plan. Poor scores may indicate a tendency to give up, take on a victim role, or be passive in approaching negative circumstances.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

6. **Integration%/INT% (Part 1) —** Measures the likelihood of the patient to recognize, organize, and mobilize resources at his or her disposal that can have a positive impact on the healing and recovery process. Strong scores indicate that a substantial amount of personal "energy" is present to deal with negative situations. Weak scores indicate that this personal "energy" is diminished and the patient is likely to be struggling with exhaustion in regard to negative health circumstances; resolve and the ability to "keep coming back" may be diminished.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

7. **Attitude Index/AI% (Part 1) —** Measures the likelihood of the patient to be resilient in the face of negative circumstances. Strong scores indicate that a patient has excellent coping skills and will approach negative circumstances with optimism and a positive attitude.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

8. **Differentiation/DIF (Part 2) —** Measures the likelihood of the patient to have a strong sense of self-regard that is manifested in actual activities and actions of self-care.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

9. **Dimension%/DIM% (Part 2) —** Measures the likelihood of the patient to deal well with changes that health care problems may cause that have an impact on role identity, work, or general activities and a degree of self-determination that has become a part of a person's "identity."

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

10. **Integration/INT (Part 2) —** Measures the likelihood of the patient to have a strong sense of what is *important* in regard to self-care as opposed to what is peripheral.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

11. **Integration%/INT% (Part 2) —** Measures the likelihood of the patient to resist getting caught up in actions and attitudes of self-criticism and self-blame. Taken to an extreme ("Somewhat Unlikely" > "Highly Unlikely"), such tendencies to the negative end of the spectrum can become self-limiting and even self-destructive of the care plan being successfully sustained.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

12. **Sub-Integration Intrinsic/INT-I (Part 1) —** Measures the likelihood of the patient to feel that he or she can solve problems *without* outside help. Strong scores ("Highly Likely" > "Likely) can be a deficit in terms of delaying the time when help should be sought.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

13. **Dimensional Integration/DI (Part 2) —** Measures the likelihood of the patient to be outspoken, open, honest, and even assertive in regard to expressing feelings, asking questions, and conveying information about health issues. Weak scores may indicate conflict avoidance and even denial.

———— ———— ———— ———— ———— ———— ————
Highly   Likely   Somewhat   Neutral   Somewhat   Unlikely   Highly
Likely   Likely   Likelihood   Unlikely   Unlikely

14. **Attitude Index%/AI% (Part 2)** — Measures the likelihood of the patient to have personal resources (mate relationships, family, friendship and support structures, faith, all of the above) that can act as a "foundation" during times of challenge to health and well-being.

OVERVIEW OF CRITICAL SCORES

Please note: In the score column on this overview, there will be both a phrase and a number used to suggest the strength, or absence thereof, being measured by each index. These phrases and numbers reflect the language and mathematics implicit in the Hartman Value Profile. Each index has been assigned three echelons "Strong," "Moderate," "Weak," and three numbers "3," "2," and "1."

Index	Measuring	Score		
		Strong	Moderate	Weak
1. DIF 1	Noticing Subtle Changes	____	____	____
2. DIS 1	Following Directions	____	____	____
3. DIM-S 1	Conceptualizing Care Plan	____	____	____
4. DIM-S 2	Acting on Care Plan	____	____	____
5. INT 1	Active in Problem Solving	____	____	____
6. INT% 1	Using Resources to Face Problems	____	____	____
7. AI% 1	Coping Skills/ Tenacity	____	____	____
8. DIF 2	Adequacy of Self-Regard	____	____	____
9. DIM% 2	Ability to Deal with Change	____	____	____
10. INT 2	Sense of What Is Important	____	____	____
11. INT% 2	Resisting Self-Criticism/Blame	____	____	____
12. INT-I 2	Tendency to Seek Help of Others	____	____	____
13. DI 2	Assertiveness/ Openness	____	____	____
14. AI%	Underlying, Personal "Foundation"	____	____	____

COMPOSITE STRENGTH GRID

Using a combination of all of the numbers on the 14 points on the "Overview of Critical Scores" template, the following general assessment of patient strength of judgment in taking accountability for patient aspects of the treatment

Highly Likely	Likely	Somewhat Likely	Neutral Likelihood	Somewhat Unlikely	Unlikely	Highly Unlikely
_____	_____	_____	_____	_____	_____	_____

PROBLEM-SOLVING STYLES

Across their lives, human beings develop different problem-solving styles. According to the excellent work of Robert K. Smith (www.cleardirections.com), these problem-solving styles fall into two major areas. Some people relate to problems *automatically.* Others relate to problems *deliberatively.* On the "automatic" side of the ledger, there are two primary manifestations: *direct, immediate response* — the "don't just stand there, do something" response — and a more intense response of *reaction.* On the "deliberative" side, there are two primary manifestations: relating to problems through *relationships* and relating to problems through *reflection.*

In Smith's work, the "automatic" response occurs 85 to 95% of the time, and the "deliberative" response occurs 5 to 15% of the time. The worst decisions are usually reactive. The next worse — but most typical — are direct, more immediate responses. The best decisions are made deliberatively with others in relationships and in moments of reflection. The problem with decision making, of course, is that most people do not take time to get help from others or take time to reflect. Smith even says, instructively, that of the six brain centers that are used in problem solving, only one is used when people are in the reactive mode. Two or three are used when there is immediate, direct response. Four or five are used when problems are solved through reflection. All six are used when we take time to use relationships to help us deal with problems. The irony in all of this discussion, of course, is that we solve most of our problems using the least of our thinking and contemplative energy.

It is critical to better appreciate how a patient will likely respond to problems. In most instances, it will help patients determine when automatic response and reaction are more appropriate and when deliberative relationships and reflection are better. For many patients, any conversation that encourages relationships and reflection will be an advantage.

The **Dimension/DIM (Part 1)** scores of the Hartman Value Profile give a clear indication of what problem-solving style is most likely to be a patient's primary way of dealing with negative situations.

Dimension/DIM (Part 1) Scale

More Reactive	Responsive	More Deliberative	Responsive	More Reactive
_____	_____	_____	_____	_____

More Intelligently Expressed   Less Intelligently Expressed

SELF-BALANCE INDICATORS

While it is critically important to have judgment *strength*, it is also important to have judgment *balance.* Robert Hartman (1967) taught that human beings have a tendency to both *overvalue* (which he called a "composition") and *undervalue* (which he called a "transposition"). For example, indulge a child, and a "composition" or *overvalue* is created; neglect a child, and a "transposition" or *undervalue* is created. Neither is good for the child, so *balance* would be desired. *Overvalue* money, and a person can become greedy or a thief, or only see people in terms of socioeconomics. *Undervalue* money, and he may fail to pay his credit card and may be unable to buy gasoline. Again, *balance* would be desired.

In the following, final schematic, the *balance* that human beings have in three critical areas of personal existence is measured.

Self-Esteem — How a person feels affirmative (or not) about himself or herself, the base of self-confidence. Extreme overvaluing can lead to aggressive arrogance, and extreme undervaluing shows a lack of important ego strength. This scale may also reflect the degree/impact of either criticism (–) or affirmation (+) by which a person has been influenced.

Extreme Overvalued	Moderate Overvalued	Balanced	Moderate Undervalued	Extreme Undervalued
_____	_____	_____	_____	_____
Self-Concept — How a person feels affirmative (or not) about the roles that the person is playing in his or her life. Extreme overvaluing reveals too much emphasis being placed on roles. Extreme undervaluing indicates participation in roles that are not adequately fulfilling.

Extreme Overvalued	Moderate Overvalued	Balanced	Moderate Undervalued	Extreme Undervalued
_____	_____	_____	_____	_____
Self-Image — How a person projects an image of himself or herself (or fails to do this) and, thus, gives a system of goals, objectives, ambitions, dreams, and aspirations to live up to. Extreme undervaluing leads to lack of self-motivation. Extreme overvaluing leads to the creation of ideals that cannot be achieved and will likely be self-defeating.

Extreme Overvalued	Moderate Overvalued	Balanced	Moderate Undervalued	Extreme Undervalued

Religion and Spirituality in Pain Management

Bruce Y. Lee, MD, and Andrew B. Newberg, MD

INTRODUCTION

Throughout history, religious and spiritual activities have been used in the management of pain. The attitudes of health care practitioners toward these activities have varied considerably. Some have acknowledged, embraced, or even used such activities. Others have ignored or opposed them. But regardless of one's personal beliefs, understanding how religion and spirituality affect pain may influence one's practice of pain management.

After all, studies have clearly shown that many patients consider religion to be very important and would like their physicians to discuss religious issues with them. Popular news magazines such as *Time* and *Newsweek* and television shows have devoted ample coverage to the interplay of religion and health (Begley, 2001). Over the past decade, many spiritual activities such as yoga have become very popular (Corliss, 2001; "Yoga," 2002). There is an ever-increasing number of researchers, books, and groups covering these subjects. Therefore, there is a good chance of encountering a patient or physician who has used or is interested in using religious and spiritual activities in pain management.

This chapter briefly chronicles the history of religion and health care, defines key terms such as *spirituality* and *religion*, and compares several prominent religious and spiritual activities. We also review what is currently known about the physiological and clinical effects of religious and spiritual practices, particularly with regard to pain management, and the challenges that researchers and health care practitioners may face in designing appropriate studies and translating results to clinical practice. Finally, we discuss future directions in the roles of religion and spirituality in pain management.

THE IMPORTANCE OF RELIGION AND SPIRITUALITY TO PATIENTS AND PHYSICIANS

There is abundant evidence that religion and spirituality play large roles in people's lives. Studies have shown that more than 90% of Americans believe in God or a higher power, 90% pray, 67 to 75% pray on a daily basis, 69% are members of a church or synagogue, and 40% attend a church or synagogue regularly (Bezilla, 1993; Gallup, 1994; Poloma & Pendleton, 1991; Shuler, Gelberg, & Brown, 1994). According to 1998 Gallup polls, 60% of Americans consider religion to be very important in their lives, and 82% acknowledge a personal need for spiritual growth. Both these numbers have increased significantly from 1994 Gallup polls, suggesting that overall interest in spirituality is on the rise (Miller & Thoresen, 2003).

With the widespread prevalence of religious and spiritual beliefs and practices, it is not surprising that more than 75% of surveyed patients want physicians to include spiritual issues in their medical care, approximately 40% want physicians to discuss their religious faith with them, and nearly 50% would like physicians to pray with them (Daaleman & Nease, 1994; King & Bushwick, 1994; King, Hueston, & Rudy, 1994; Matthews et al., 1998). Studies of family physicians, pediatricians, internists, neurologists, and surgeons all had similar findings: while a majority considered spiritual well-being an important component of health and agreed that it should be addressed with patients, only a minority (fewer than 20%) did so with any regularity (MacLean, Susi, & Phifer, 2003; Monroe, Bynum, & Susi, 2003). The most common reasons given for this discrepancy included lack of time, inadequate training, discomfort in addressing the topics, and difficulty in identifying patients who want to discuss spiritual issues (Armbruster,

Chibnall, & Legett, 2003; Chibnall & Brooks, 2001; Ellis, Vinson, & Ewigman, 1999).

Therefore, some investigators and educators have called for increased education regarding religious and spiritual issues in medical schools, postgraduate training, and continuing medical education. From 1994 to 1997, the number of U.S. medical schools offering courses on spiritual issues grew from 3 to nearly 30. In April 1997, the deans and faculty of more than 45 medical schools attended the *Spirituality in Medicine: Curricular Development* conference, where the prevailing opinion was that religion and spirituality are not optional but essential parts of patient care. Some residency training programs have already implemented spirituality and medicine curricula (Pettus, 2002).

However, not everyone agrees that religious and spiritual issues should be included in formal medical education. Some feel that discussing religion and spirituality in the medical classroom and with patients is inappropriate and argue that these issues are irrelevant (or at least not relevant enough) to patient care. There are concerns that some health care workers may have hidden agendas in addressing religious issues, such as imposing a personal religious belief on a patient. Even well-meaning health care practitioners can inadvertently be biased or overbearing in their approach. Editorials and commentaries have questioned the ethics of physicians who want to discuss patients' spiritual needs and have suggested reserving such discussions to professionals trained in pastoral care. Sloan and colleagues have suggested that the evidence linking religion and health is not strong and stated that there is the potential concern that patients may believe their illness was due to poor faith (Sloan & Bagiella, 2002; Sloan, Bagiella, & Powell, 1999). However, this has been a concern for advocates of the relationship between religion and health as well. In fact, many religious individuals have become concerned that religion is being treated as an intervention in the medical setting rather than maintaining its spiritual meaning. Another concern is that including religion in medical care may be difficult for agnostic or atheist health care providers. Others believe that these issues have some place in medical education and care, but disagree over the manner in which they should be integrated (Levin, Larson, & Puchalski, 1997).

Although considerable controversy remains, these issues have grown in prominence to the point where they are difficult to ignore. The *Diagnostic and Statistical Manual of Mental Disorders* (4th ed., 1994) recognizes religion and spirituality as relevant sources of either emotional distress or support (Kutz, 2002; Lukoff, Lu, & Turner, 1992; Turner et al., 1995). The guidelines of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) require hospitals to meet the spiritual needs of patients (La Pierre, 2003; "Spiritual," 2003). Many published medical journal articles contain religious terminology, and the frequency of studies on religion and spiritu-

ality and health has increased over the past decade (Levin et al., 1997). Thus, it seems reasonable to engage in further analysis and discussion regarding religious and spiritual issues in the health care setting to assess fully the relationship, inform health care providers the best ways of dealing with these issues, and help to avoid the pitfalls that both critics and advocates have raised.

DEFINING RELIGION AND SPIRITUALITY

The terms *religion* and *spirituality* are difficult to define and have often been mistakenly used synonymously. The two overlap, but are distinct (Powell, Shahabi, & Thoresen, 2003; Tanyi, 2002). Countless subtly different definitions of each have emerged, and investigators have struggled to reach consensus on formal definitions. In the *Handbook of Religion and Health,* a widely cited book considered by many to be an authoritative source on religion and health, Koenig, McCullough, and Larson (2001) defined the two as follows:

> **Religion***:* An organized system of beliefs, practices, rituals, and symbols designed to (a) facilitate closeness to the sacred or transcendent (God, higher power, or ultimate truth/reality) and (b) to foster an understanding of one's relationship and responsibility to others in living together in a community.

> **Spirituality:** The personal quest for understanding answers to ultimate questions about life, about meaning, and about relationship to the sacred or transcendent, which may (or may not) lead to or arise from the development of religious rituals and the formation of community.

A panel of experts convened by the National Institute of Healthcare Research (Larson, Swyers, & McCullough, 1998) define *spirituality* as "the feelings, thoughts, experiences, and behaviors that arise from a search for the sacred." After reviewing 76 articles and 19 books, Tanyi (2002) concludes that spirituality is "a personal search for meaning and purpose in life, which may or may not be related to religion."

Regardless of the exact definitions, an often-noted key distinction between religion and spirituality is that the former tends to involve a group or community and the latter primarily an individual. However, even if universal definitions were established, considerable debate would remain over whether to classify specific practices as either or neither.

For example, where does one draw the line between religions and cults? In fact, one of the definitions of cult in the *Merriam Webster Dictionary* (http://www.m-w.com) is "a religion regarded as unorthodox or spurious." This, in turn, begs the question: what is the criterion for being unorthodox and spurious? In fact, as history has often dem-

onstrated, what formerly was considered a cult and spurious can eventually become a major religion, and vice versa.

BRIEF HISTORY OF RELIGION AND HEALTH CARE

The relationship between religion and health care has cycled between cooperation and antagonism throughout history. Artifacts and writings from as early as 5000 B.C. demonstrate that some of the most advanced civilizations of ancient times (such as the Assyrians, Chinese, Egyptians, Mesopotamians, and Persians) equated physical illnesses with evil spirits and demonic possessions. Treatment was aimed at banishing these spirits. Priests or the equivalent were often called to treat the ill using some combination of incantations, rituals, and medications.

Ancient originators of today's health care theories and practices emphasized the importance of the metaphysical. Scholars in early Chinese society believed that good physical health occurred when spirits were balanced in the body and developed acupuncture to alleviate imbalances. Hippocrates postulated that illness was caused by imbalance of four bodily fluids (blood, phlegm, yellow bile, and black bile), and Plato emphasized the need to treat the soul along with the body.

Health care and healing were involved prominently during the origins of most of today's major religions. The Old Testament contains passages that attribute illness to sins and healing to God (Deuteronomy 28:28, New International Version [NIV], Deuteronomy 32:39, NIV, Exodus 15:26, NIV, and Jeremiah 33:6, NIV). Hindus practice meditation to free themselves from the cycle of death and disease. Early Buddhism approved of using religious beliefs and rituals for healing.

In the eyes of religious groups, physicians and other health care providers have been viewed as everything from evil sorcerers to conduits of God's healing powers. Similarly, physicians, scientists, and health care provider's views of religion have ranged from interest to disinterest to disdain. A number of prominent scholars from Sigmund Freud to Albert Ellis warned of the dangers of religion, describing religion as a "universal obsessional neurosis" and emphasizing that it might result in negative consequences such as decreased self-acceptance and increased intolerance, inflexibility, and irrational behaviors. Indeed, a number of studies have linked disorders such as mania, schizophrenia, and temporal lobe epilepsy with unusual religious experiences or feelings (Lewis, 1994). However, while a certain subset of religious and spiritual feelings may be attributable to mental illness, the high prevalence of religious devotees and practitioners compared with relatively lower prevalence of mental illness makes it less likely that most religious experiences are due to established psychopathology.

In recent years, members of the medical and scientific community have strived to understand the effects of religion on health. In 1910, Sir William Osler, a pioneer of modern scientific medicine, wrote in the *British Medical Journal* about "the faith that heals," and that "nothing in life is more wonderful than faith" (Osler, 1910). A new discipline dubbed the "epidemiology of religion," which examines the association of religious belief and mortality and morbidity, has emerged and is growing (Levin, 1996). Institutions and organizations such as the National Institutes of Health (NIH), the John Templeton Foundation, and the American Association for the Advancement of Science have either funded research or convened meetings and symposia focusing on the effects of religion on physical and mental health.

METHODOLOGICAL ISSUES WITH CLINICAL STUDIES

To better understand the relationship between spirituality and health in general, or spirituality and pain management in particular, it is necessary to consider methodological issues that pertain to studies exploring these issues. This field of study has many traditional issues with regard to study design such as statistical and power analysis, retrospective versus prospective analysis, and cross-sectional vs. longitudinal analysis. However, there are also unique issues related to the measurement of spiritual experiences and practices, measurements of religiosity, and finding ways of preserving the rigors of science while not interfering with the religious or spiritual interventions being evaluated. For these reasons, a review of the literature on religion and health reveals that on one hand, there are a growing number of studies, and on the other hand, many studies have design issues that may complicate interpretation of their findings. Some problems with methodological issues arise from the lack of adequate interest and funding among the medical and scientific community, leaving investigators who do not have sufficient resources or training in proper experimental design to conduct studies. Such a statement can be made of many fields of study in their early phases of development. And this does appear to be improving with more expert researchers beginning to address religious and spiritual issues either directly or as subcomponents of larger trials. There are other methodological issues with these studies that are described below. These issues should be considered whenever evaluating a report in the literature to help better assess its relevance to clinical practice.

ANECDOTES AND EDITORIALS

A large percentage of the literature consists of anecdotes and editorials. While these are helpful in generating discussions, formulating ideas, and fueling future studies,

they do not establish causality or scientific support of specific interventions.

Co-Relational Studies

The majority of the studies have been co-relational. Many of these co-relational studies have not adjusted for confounding variables such as socioeconomic status, ethnicity, and different lifestyles or diets. Members of a church or religious group can have a larger social support network or better access to health care. Co-relational studies also do not establish cause-and-effect relationships as clearly as other types of studies. Poor health can prevent a patient from going to church or leave a patient so discouraged that he or she does not want to participate in religious and spiritual activities. Conversely, patients may become more religious when they encounter serious health problems especially when such health problems result in pain and disability.

Problematic Numbers and Controls

Designing studies with sufficient numbers of subjects and adequate controls can be problematic. There are a limited number of adequately performed randomized controlled trials (RCT) on spirituality and health. Of course, in some cases, RCTs are difficult to perform because patients may be reluctant or unable to change their religious beliefs and practices. The inherent issues pertaining to the study of religious phenomena often make such studies difficult to randomize or control. For example, it is not possible to have nonreligious individuals pray and, conversely, religious individuals may not want to take part in a study in which they are not allowed to pray. It is also not easy to isolate subjects in an effort to prevent external forces from interfering with a study. In other words, it may be possible to prevent the pastoral care team at the hospital from interacting with a patient, but the patient may have friends and family who can perform many similar functions.

Problems with Measurement

Religiousness can be measured in many different ways. The degree to which one participates in formal church, synagogue, or temple activities (defined as *organizational religiosity*) can differ from the degree to which one performs private religious activities such as praying, reading religious scriptures, and watching religious television (*non-organizational religiosity*). Participation in religious activities alone does not determine how closely an individual's beliefs conform to the established doctrines of a religious body (*religious belief*). Moreover, individuals can feel that they are very religious (high *subjective religiosity*), but score low on objective measures (low *religious commitment/motivation*) of how committed they are to their religion. Additionally, religiousness can be mea-

sured by how knowledgeable or informed individuals are about their religion's doctrines (*religious knowledge*) or how well their actions, such as working for the church and acts of altruism, support their religion (*religious consequences*). Therefore, studies should clearly state the exact measures of religiousness used, and conclusions should not make any claims about measures not used.

Often questionnaires or interviews with the patients are used to measure religious commitment or spirituality. Even though patients report that they are religious, more objective measures (e.g., how closely their lifestyle fits religious doctrines and how often they pray) may not support that claim. In fact, patients may forget or be unwilling to admit lapses. In the absence of objective measures, questionnaires should be at least well validated. Unfortunately, many studies do not indicate whether and how their questionnaires were validated. Similarly, some studies did not use objective measures or well-validated instruments to measure health outcomes.

To establish a true cause-and-effect relationship, it is helpful to elicit a dose–response curve, i.e., determine if increased religiosity corresponds to better health. Someone who does not belong to a church but regularly prays and follows religious doctrine may, in fact, have greater religious commitment than a person who belongs to a church but does not believe in or care to comprehend religious doctrine. Many studies simply divide patients into dichotomous groups (e.g., do they belong to a church?), which does not account for significant variation within each of the two groups.

Components of Religion and Spirituality

It will be important for investigators to be clear regarding the components of religion and spirituality studied. There are many aspects of religion and spirituality that may affect health. The social interactions, friendships, and activities that accompany membership in a religious group and specific activities such as prayer, meditation, or studying religious scriptures could all have beneficial health effects. Church activities can provide exercise, reprieves from unhealthy environments, and contact with people who may be able to assist. Many studies have not looked at such specific components and therefore have yet to determine which components represent the "active ingredients."

Variations in Practices and Doctrines

There are significant variations in practices and doctrines among and within different religious affiliations and denominations. It will be important for studies to account for the variations in practices and doctrines both within traditions and across traditions. For example, prayers may be silent or vocal. Behavior that shows an adequate level of religious commitment in one religion may not be suf-

ficient in another religion. For example, more orthodox denominations may have dress codes or prevent use of certain devices. The degree of hierarchy in a religion and an individual's place in that hierarchy can vary significantly and, in turn, affect a person's sense of well-being. Moreover, a person's socioeconomic status, gender, and ethnicity can affect how well he or she is accepted in a given religious group.

THE POSITIVE EFFECTS OF RELIGION ON PAIN AND HEALTH

In spite of many methodological issues, a large body of research has suggested that religion and spirituality may have a positive impact on health. Systematic reviews and meta-analyses show religious involvement to be an epidemiologically protective factor (Ball, Armistead, & Austin, 2003; Braam et al., 1999; Brown, 2000; Kark et al., 1996; Kune, Kune, & Watson, 1993; McCullough & Larson, 1999; Oman et al., 2002), and high levels of religious involvement may be associated with up to 7 years of longer life expectancy (Helm et al., 2000; Hummer et al., 1999; Koenig et al., 1999; Oman & Reed, 1998; Strawbridge et al., 1997). Comstock and Partridge (1972) found that among 91,000 people in a Maryland county, those who regularly attended church had a lower prevalence of cirrhosis, emphysema, suicide, and death from ischemic heart disease. Oleckno and Blacconiere's (1991) study on college students revealed an inverse correlation between religiosity and behaviors that adversely affect health.

Studies also have suggested that religiousness may correlate with better outcomes after major medical procedures. In Oxman, Freeman, and Manheimer's (1995) analysis of 232 patients following elective open heart surgery, lack of participation in social or community groups and absence of strength and comfort from religion were consistent predictors of mortality. In Pressman and colleagues' (1990) look at 30 elderly women after hip repair, religious belief was associated with lower levels of depressive symptoms and better ambulation status.

RESOURCES AND LIFESTYLES OF RELIGIOUS GROUPS

Many reasons for these associations have been postulated. Religious groups may promote or provide access to better health care, by encouraging healthy lifestyles (e.g., avoiding substance abuse and risky sexual practices) and sponsoring health improvement programs (e.g., blood pressure screening, blood drives, soup kitchens, and food drives) (Heath et al., 1999; Koenig et al., 1998; Stewart, 2001; Zaleski & Schiaffino, 2000). Groups, such as the Catholic Church, have substantial resources and positions that allow them to positively influence people in ways that many secular organizations cannot. Additionally, many

hospitals and health care clinics are supported by, affiliated with, or even owned by religious groups.

PSYCHOLOGICAL EFFECTS OF RELIGION

Some have suggested that religion simply serves as a distraction from pain. But several studies have actually found a positive correlation between the "diverting attention" and "praying" factors on the Coping Strategies Questionnaire (CSQ) and pain levels (Geisser, Robinson, & Henson, 1994; Swartzman et al., 1994; Swimmer, Robinson, & Geisser, 1992). There is some evidence that the social network and support provided by religions is associated with lower pain levels, and religious belief may improve self-esteem and sense of purpose (Hays et al., 1998; Musick et al., 1998; Swimmer et al., 1992). Based on his longitudinal study of 720 adults, Williams concluded that religious attendance buffered the effects of stress on mental health (Williams et al., 1991). Coward's study (1991) of 107 women with advanced breast cancer suggested that spirituality may improve emotional well-being.

RELIGIONS AND THE MEANING OF PAIN

Religious belief may help patients give meaning to and, in turn, better cope with their pain (Autiero, 1987; Foley, 1988). While many major religions deem pain and suffering the result of sin, they also believe that pain can be strengthening, enlightening, and purifying. Different religious teachings have suggested that pain is the inevitable fate of humankind and can be cleansing, test virtue, educate, readjust priorities, stimulate personal growth, and define human life (Amundsen, 1982). Despite these positive views of pain, members of different religions may differ in how to face pain. Many Buddhists believe in enduring pain matter-of-factly (Tu, 1980). Hindus may stress understanding and detachment from pain (Shaffer, 1978). Muslims and Jews often favor resisting or fighting pain (Bowker, 1978). Many Christians stress seeking atonement and redemption (Amundsen, 1982). Of course, these are generalizations, and differing opinions exist within members of each religion.

PHYSIOLOGICAL EFFECTS OF RELIGIOUS PRACTICES

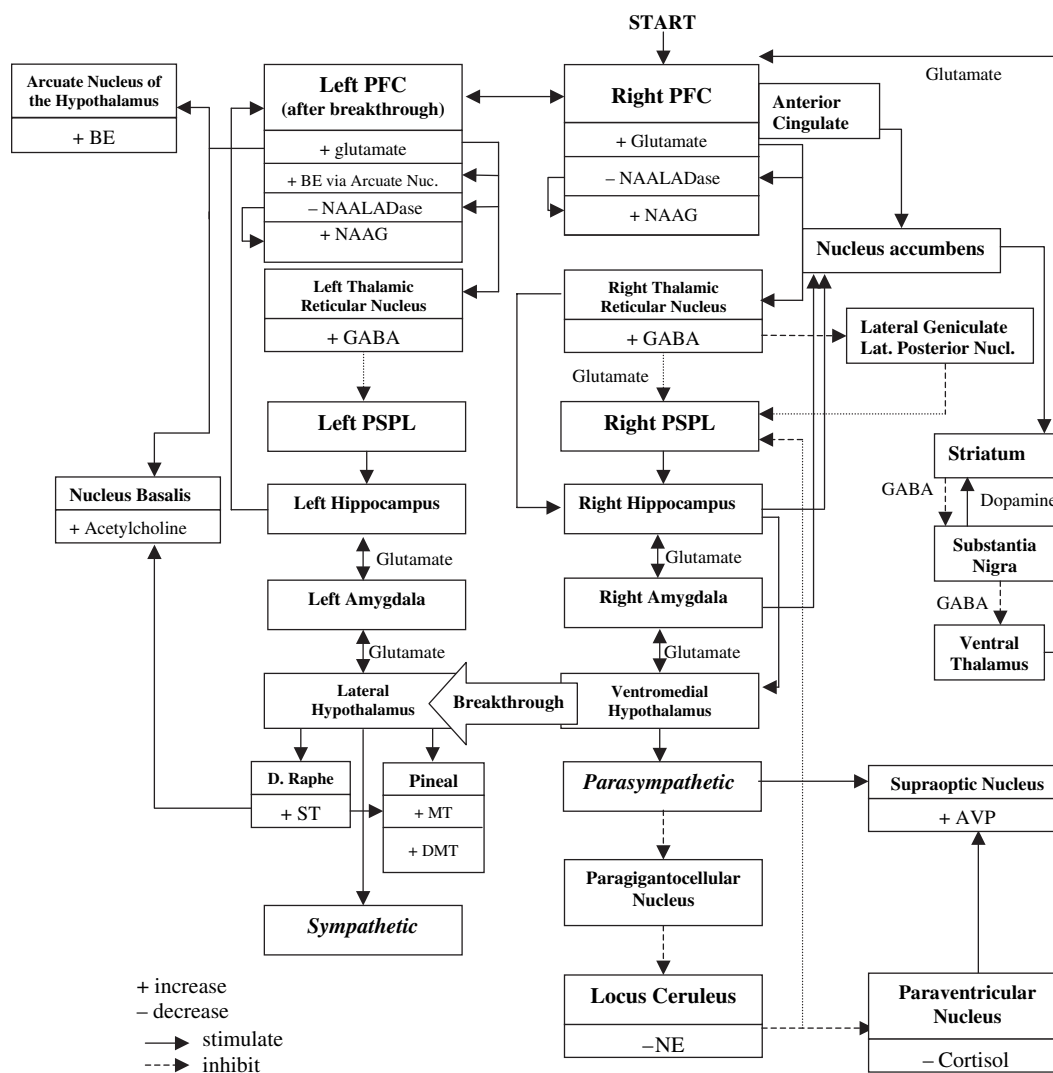
Research on the physiologic effects of various religious and spiritual practices and experiences is growing rapidly, especially with the development of real-time brain imaging technologies such as positron emission tomography (PET), single photon emission computed tomography (SPECT), and functional magnetic resonance imaging (fMRI). Choosing the appropriate imaging technique for a research study can be challenging. Each provides different advantages and disadvantages. fMRI provides better resolution and anatomic information than SPECT or PET. However, the MRI machine generates significant noise


FIGURE 98.1 Schematic overview of the neurophysiological network possibly associated with meditative states. The circuits generally apply to both hemispheres; however, much of the initial activity is on the right. AVP = arginine vasopressin; D = dopamine; DMT = 5-methoxy-dimethyltryptamine; NAAG = N-acetylaspartylglutamate; NAALADase = N-acetylated-alpha-linked-acidic dipeptidase; ST = serotonin. From Newberg, A.B. & Iversen, J., 2003, *Medical Hypothesis, 61*, 284. Reproduced with permission.

and requires a subject to lie down, both of which may disturb meditation or prayer. PET and SPECT make it possible to radiolabel neurotransmitters and determine how they are affected by spiritual practices. But, radio-pharmaceuticals may not be as readily available during hours when research centers and hospitals are most quiet and therefore conducive to spiritual practices.

Taken together, the studies on religious and spiritual practices such as meditation have begun to elucidate a comprehensive model regarding the underlying physiological effects occurring in both the brain and the body. Such a model has many implications for the study of pain and pain management. A summary of this model is described below and is also outlined in Figure 98.1.

Brain imaging studies suggest that willful acts and tasks that require sustained attention are initiated via activity in the prefrontal cortex (PFC), particularly in the right hemisphere (Frith et al., 1991; Ingvar, 1994; Pardo, Fox, & Raichle, 1991; Posner & Petersen, 1990). The cingulate gyrus has also been shown to be involved in focusing attention, probably in conjunction with the PFC (Vogt, Finch, & Olson, 1992). As practices such as meditation require intense focus of attention, it seems appropriate that a model for meditation begin with activation of the PFC (particularly the right) as well as the cingulate gyrus. This notion is supported by the increased activity observed in these regions on several of the brain imaging studies of volitional types of meditation including that from our laboratory (Cheramy, Romo, & Glowinski, 1987; Portas et al., 1998; Vogt et al., 1992). Several animal studies have shown that the PFC, when activated, innervates the reticular nucleus of the thalamus (Cornwall & Phillipson, 1988), particularly

as part of a more global attentional network (Portas et al., 1998). Such activation may be accomplished by the production and distribution by the PFC of the excitatory neurotransmitter glutamate, which the PFC neurons use to communicate among themselves and to innervate other brain structures (Cheramy et al., 1987). The thalamus itself governs the flow of sensory information to cortical processing areas via its interactions with the lateral geniculate and lateral posterior nuclei and also likely uses the glutamate system to activate neurons in other structures (Armony & LeDoux, 2000). When excited, the reticular nucleus of the thalamus secretes the inhibitory neurotransmitter gamma-aminobutyric acid (GABA) onto the lateral posterior and geniculate nuclei, cutting off input to the posterior superior parietal lobe (PSPL) and visual centers in proportion to the reticular activation (Destexhe, Contreras, & Steriade, 1998). During meditation, because of the increased activity in the PFC, particularly on the right, there should be a concomitant increase in the activity in the reticular nucleus of the thalamus.

The PSPL is heavily involved in the analysis and integration of higher-order visual, auditory, and somaesthetic information (Adair et al., 1997). It is also involved in a complex attentional network that includes the PFC and thalamus (Fernandez-Duque & Posner, 2001). Through the reception of auditory and visual input from the thalamus, the PSPL is able to help generate a three-dimensional image of the body in space, provide a sense of spatial coordinates in which the body is oriented, help distinguish between objects, and exert influences in regard to objects that may be directly grasped and manipulated (Lynch, 1980; Mountcastle, Andersen, & Motter, 1981). These functions of the PSPL might be critical for distinguishing between the self and the external world. Deafferentation of PSPL has been suggested to be an important concept in the physiology of meditation which has been supported by several imaging studies.

In addition to the complex cortical-thalamic activity, meditation might also be expected to alter activity in the limbic system especially since stimulation of limbic structures, such as the amygdala and hippocampus, is associated with experiences similar to those described during meditation (Fish, Gloor, Quesney, & Olivier, 1993; Saver & Rabin, 1997). The results of the fMRI study by Lazar, et al. support the notion of increased activity in the regions of the amygdala and hippocampus during meditation (Lazar et al., 2000; Pardo et al., 1991).

The hypothalamus is extensively interconnected with the limbic system. Stimulation of the right lateral amygdala has been shown to result in stimulation of the ventromedial portion of the hypothalamus with a subsequent stimulation of the peripheral parasympathetic system (Davis, 1992). Increased parasympathetic activity should be associated with the subjective sensation first of relaxation and, eventually, of a more profound quiescence.

Activation of the parasympathetic system would also cause a reduction in heart rate and respiratory rate. All of these physiological responses have been observed during meditation (Jevning, Wallace, & Beidebach, 1992).

Typically, when breathing and heart rate slow, the paragigantocellular nucleus of the medulla ceases to innervate the locus ceruleus (LC) of the pons. The LC produces and distributes norepinephrine (NE) (Foote & Morrison, 1987), a neuromodulator that increases the susceptibility of brain regions to sensory input by amplifying strong stimuli, while simultaneously gating out weaker activations and cellular "noise" that fall below the activation threshold (Waterhouse, Moises, & Woodward, 1998). Decreased stimulation of the LC results in a decrease in the level of NE (Van Bockstaele & Aston-Jones, 1995). A reduction in NE would decrease the impact of sensory input on the PSPL, contributing to its deafferentation.

The locus ceruleus would also deliver less NE to the hypothalamic paraventricular nucleus. The paraventricular nucleus of the hypothalamus typically secretes corticotropin-releasing hormone (CRH) in response to innervation by NE from the locus ceruleus (Ziegler, Cass, & Herman, 1999). This CRH stimulates the anterior pituitary to release adrenocorticotropic hormone (ACTH) (Livesey et al., 2000). ACTH, in turn, stimulates the adrenal cortex to produce cortisol, one of the body's stress hormones (Davies, Keyon, & Fraser, 1985). Decreasing NE from the locus ceruleus during meditation would likely decrease the production of CRH by the paraventricular nucleus and ultimately decrease cortisol levels. Most studies have found that urine and plasma cortisol levels are decreased during meditation (Dollins et al., 1993; Jevning, Wilson, & Davidson, 1978; Sudsuang, Chentanez, & Veluvan, 1991; Tooley et al., 2000).

As a meditation practice continues, there should be continued activity in the PFC associated with the persistent will to focus attention. In general, as PFC activity increases, it produces ever-increasing levels of free synaptic glutamate in the brain. Increased glutamate can stimulate the hypothalamic arcuate nucleus to release beta-endorphin (Kiss et al., 1997). Beta-endorphin (BE) is an opioid produced primarily by the arcuate nucleus of the medial hypothalamus and distributed to the brain's subcortical areas (Yadid, 2000). BE is known to depress respiration, reduce fear, reduce pain, and produce sensations of joy and euphoria (Janal et al., 1984). That such effects have been described during meditation may implicate some degree of BE release related to the increased PFC activity. Meditation has been found to disrupt diurnal rhythms of BE and ACTH, while not affecting diurnal cortisol rhythms (Infante et al., 1998). However, it is likely that BE is not the sole mediator in such experiences during meditation because simply taking morphine-related substances does not produce equivalent experiences as in meditation. Furthermore, one very limited study demon-

strated that blocking the opiate receptors with naloxone did not affect the experience or EEG associated with meditation (Sim & Tsoi, 1992).

In the early 1970s, Gellhorn and Kiely developed a model of the physiological processes involved in meditation based almost exclusively on autonomic nervous system (ANS) activity, which, although somewhat limited, indicated the importance of the ANS during such experiences (Gellhorn & Kiely, 1972). These authors suggested that intense stimulation of either the sympathetic or parasympathetic system, if continued, could ultimately result in simultaneous discharge of both systems (what might be considered a "breakthrough" of the other system). Several studies have demonstrated predominant parasympathetic activity during meditation associated with decreased heart rate and blood pressure, decreased respiratory rate, and decreased oxygen metabolism (Hugdahl, 1996; Peng et al., 1999; Travis, 2001). However, a recent study of two separate meditative techniques suggested a mutual activation of parasympathetic and sympathetic systems by demonstrating an increase in the variability of heart rate during meditation (Infante et al., 1998). The increased variation in heart rate was hypothesized to reflect activation of both arms of the autonomic nervous system. This notion also fits the characteristic description of meditative states in which there is a sense of overwhelming calmness as well as significant alertness. Also, the notion of mutual activation of both arms of the ANS is consistent with recent developments in the study of autonomic interactions (Hugdahl, 1996).

Other neurotransmitters may also be associated including serotonin and melatonin. Serotonin, which appears to be increased in practices such as meditation, has a central role in depressive symptoms as well as the potential to be hallucinogenic. Increased serotonin combined with lateral hypothalamic innervation of the pineal gland may result in increased production of melatonin (MT). Melatonin has been shown to depress the central nervous system and reduce pain sensitivity (Shaji & Kulkarni, 1998). During meditation, blood plasma MT has been found to increase sharply (Tooley et al., 2000), which may contribute to the feelings of calmness and decreased awareness of pain (Dollins et al., 1993).

Overall, there appear to be a number of physiological effects of spiritual practices and their associated experiences. The results from existing studies have helped to demonstrate that many of these effects have a positive impact on human health and well being.

THE NEGATIVE EFFECTS OF RELIGION ON PAIN AND HEALTH

There may also be a number of negative consequences that religion and spirituality may have on health. For example, religious groups may hinder the delivery of health care by directly opposing certain health care interventions, such as transfusions or contraception, and convincing patients that their ailments are due to noncompliance with religious doctrines rather than organic disease (Donahue, 1985). Moreover, some fear that church-sponsored health initiatives may ignore populations that do not belong to the church. There may be social problems stemming from religions such as the recently publicized clergy-perpetrated child sexual abuse in the Catholic Church, violent behaviors associated with religious fundamentalism, and military action arising from religious conflicts, that ultimately affect health (Rossetti, 1995; Tieman, 2002).

Pain management practitioners must be aware that religion may also be a source of a patient's pain. Emotional and psychological anguish brought on by guilt or shame from a moral or religious transgression can manifest as physical discomfort. This has been described as religious and spiritual pain and can be difficult to distinguish from pure physical pain (Satterly, 2001). Spiritual pain can come from spiritual abuse (convincing people that they are going to suffer eternal purgatory) and spiritual terrorism, an extreme form of spiritual abuse. Spiritual abuse can be overt or insidious; i.e., it can be implied that a patient will be doomed, although not actually stated (Purcell, 1998a, 1998b). At times when sources of pain are mixed among religious, spiritual, and organic, treatment can become complicated. Neglecting to account for religious or spiritual pain may result in overtreatment (e.g., too much pharmacological therapy). Conversely, overascribing pain to religious or spiritual causes may lead to undertreatment.

Finally, it is important that religion and spirituality do not become an intervention such that a patient with pain is told to go home and pray for relief. On the one hand, this prevents standard of care for such problems, but also takes the meaning out of religion. Religious and spiritual practices and beliefs should not be for health-related purposes. However, if a patient has a strong religious or spiritual belief, then the patient could be encouraged to utilize the resources that have been an important part of his or her life.

THE EFFECTS OF SPECIFIC RELIGIOUS AND SPIRITUAL ACTIVITIES

People practice different specific religious and spiritual activities. While many of these activities either emerged from or at some point may have been associated (correctly or incorrectly) with specific religions, today many people can practice these activities in either a religious or secular manner. Moreover, the line between different activities continues to grow more indistinct. Individuals often combine the different activities or develop hybrid techniques. Thus, whenever considering a particular practice, it is important

to be as specific as possible. This is also true when reviewing the literature because some studies are not specific as to the particular approach used by the subjects.

PRAYER

Prayer may be the most commonly used religious and spiritual activity. Eisenberg and colleagues' (1998) survey of alternative medicine usage among Americans found that one fourth of respondents used prayer to cope with physical illness. Previous studies have suggested that prayer may be associated with less muscle tension, improved cardiovascular and neuroimmunologic parameters, psychologic and spiritual peace, a greater sense of purpose, and enhanced coping skills. Rapp, Rejeski, and Miller (2000) followed 394 elderly patients with knee pain for 30 months and found that prayer was associated with less disability and better physical function.

There are numerous types of prayer. *Petitionary prayers* ask for something specific (e.g., asking for God to heal knee pain). *Intercessory prayers* pray for someone else (e.g., a friend) and may be performed remotely (e.g., some Internet Web sites allow people to submit prayers for others). *Prayers of adoration* praise or honor God or some other divine being. *Prayers of confession* admit a wrongdoing and ask for forgiveness. *Ritual prayers* involve reciting specific passages or repeating specific behaviors. *Colloquial prayers* ask a higher power for guidance. *Contemplative prayers* and *meditative prayers* do not ask for anything specific and are very similar. In *contemplative prayers*, individuals may listen to or think about God. In *meditative prayers*, individuals try to clear their minds and focus on specific words or ideas.

Investigators have looked at different types of prayers. Poloma and Pendleton (1991) found that *petitionary* and *ritualistic prayers* were associated with lower levels of well-being and life satisfaction, while *colloquial prayers* were associated with higher levels. Byrd and colleagues (Byrd, 1988) performed a double-blind study of the effects of *intercessory prayer* on outcome after admission to a coronary care unit (CCU). They found significantly more patients that were prayed for had a "good" outcome (163 vs. 147) and significantly fewer had a "bad" outcome (27 vs. 44). Harris and colleagues (Harris et al., 1999) also found improved CCU outcomes with remote *intercessory prayer*. However, these findings have not been replicated by similar subsequent studies (Aviles, et al., 2001; Matthews, Conti, & Sireci, 2001; Matthews, Marlow, & Mac-Nutt, 2000; Townsend et al., 2002).

MEDITATION

Meditation-related practices are the most widely used alternative therapy techniques. More than 16% of respondents in Eisenberg's national survey (1998) on comple-

mentary and alternative medicine used "relaxation" techniques. Numerous physicians regularly recommend Transcendental Meditation (TM) techniques to their patients, and meditation is often part of integrated health programs such as Dean Ornish's popular heart disease programs. Preliminary studies suggest that meditative practices may benefit patients with hypertension, psoriasis, irritable bowel disease, anxiety, and depression (Barrows & Jacobs, 2002; Carlson et al., 2001; Castillo-Richmond et al., 2000; Kabat-Zinn et al., 1992, 1998; Kaplan, Goldenberg, & Galvin-Nadeau, 1993; Keefer & Blanchard, 2002; King, Carr, & D'Cruz, 2002; Manocha et al., 2002; Reibel et al., 2001; Williams et al., 2001). Furthermore, these practices have the potential to provide support to patients suffering from both acute and chronic conditions. Psychological studies have suggested that meditation may decrease anxiety, depression, irritability, and moodiness as well as improve learning ability, memory, self-actualization, feelings of vitality and rejuvenation, and emotional stability (Astin, 1997; Astin et al., 2003; Bitner et al., 2003; Solberg et al., 1996; Walton et al., 1995). Research has found that meditators can achieve a state of restful alertness with improved reaction time, creativity, and comprehension (Domino, 1977; Solberg et al., 1996).

Meditation has been used for pain management as well. Pregnant women often use meditative and relaxation techniques learned from childbirth preparation classes to cope with labor pains and anxiety. At Stanford, meditative techniques have been incorporated in a 12-hour comprehensive arthritis self-care course that has been taken by more than 100,000 patients. Graduates of the course have reported a 15 to 20% reduction in pain. Kabat-Zinn and colleagues (Kabat-Zinn, 1982; Kabat-Zinn, Lipworth, & Burney, 1985) reported significant chronic pain improvement after patients completed training in mindful meditation. Kaplan and colleagues (Kaplan et al., 1993) saw symptom improvement in all 77 men and women with fibromyalgia who completed a 10-week stress-reduction program that used meditation.

Unfortunately, studies have not always defined the type of meditation being investigated. Results from one type of meditation do not necessarily hold true for others. Different types of meditation can vary significantly in the amount of physical and mental control required. In some methods (e.g., Zazen, Vipassana), the body is immobile; in others (e.g., Siddha Yoga, the Latihan, the chaotic meditation of Rajneesh), the body is let free; and in still others (e.g., Mahamudra, Shikan Taza, Gurdjieff's "self-remembering"), the person participates in daily activities while meditating. The common denominator is that all attempt to calm the mind, filling it with certain sounds, words, or images and keeping the mind on the present, not the past or future.

Studies have shown that during mediation (especially TM) patients may experience decreases in heart rate (aver-

age of several beats less per minute), respiration rate (an average of two fewer breaths per minute), plasma cortisol, and oxygen consumption (in some cases, down to 80% of normal) (Barnes et al., 1999; Castillo-Richmond et al., 2000; Cunningham, Brown, & Kaski, 2000; MacLean et al., 1994; Michaels et al., 1979; Walton et al., 1995; Wenneberg et al., 1997; Werner et al., 1986). Hypertensive patients also may experience a drop in blood pressure (Schneider et al., 2001). Meditation can be accompanied by increases in electroencephalogram alpha (a brain wave associated with relaxation), skin electrical resistance (high during relaxation and low during anxious states), and relative parasympathetic activity (Infante et al., 2001; Kumar & Kurup, 2003; Travis, 2001; Travis et al., 2001, 2002). Benson and Wallace (Benson, Malvea, & Graham, 1973; Benson et al., 1974; Wallace, 1997; Wallace, Benson, & Wilson, 1971) conducted some of the earliest physiologic studies on TM in the 1960s and described the meditation state as wakeful and hypometabolic.

There are indications that long-term physiologic changes may result from regular meditation (Calderon et al., 1999; MacLean et al., 1997). Meditators have been found to have better respiratory function (vital capacity, tidal volume, expiratory pressure, and breath holding), cardiovascular parameters (diastolic blood pressure and heart rate), and lipid profiles than nonmeditators (Wallace et al., 1983; Wenneberg et al., 1997). Cooper and Aygen (1979) found that over an 11-month period, patients with hypercholesteremia who used TM had significant reductions in fasting serum cholesterol levels compared with controls.

There is evidence that many of these physiologic changes are not simply due to patients changing body position. Experiments have shown that blood lactate levels drop four times faster when subjects meditate than when subjects simply lie on their backs (Delmonte, 1985; Ghista et al., 1976; Swinyard, Chaube, & Sutton, 1974). Increased blood flow and oxygen delivery to the muscles may account for this decrease in lactate levels. It remains uncertain whether these physiological changes are significantly different from those achieved during sleep or hypnosis (Michaels, Huber, & McCann, 1976; Swinyard et al., 1974; Wallace, 1997). Meditation has also been found to enhance the effectiveness of biofeedback.

Although physically non-invasive, meditation does have its dangers. Meditative practices can aggravate and precipitate psychotic episodes in patients who are delusional or strongly paranoid. They can also heighten anxiety in people with overwhelming anxiety. Therefore, discretion should be used in patients with psychiatric illness. Because psychiatric illness is not always evident to health care providers not trained in mental health and meditation can trigger the release of repressed memories, all patients using meditative techniques should be monitored, especially when a patient first starts using meditation.

Yoga

Originated in India and practiced for more than 5,000 years, yoga emphasizes the interrelationship between the mind and body. A common misconception is that yoga is derived from Hinduism, when in fact it predated Hinduism by several centuries. In fact, yoga techniques have been adopted by many religions, including Christianity. The American Yoga Association emphasizes that because yoga practice does not specify particular higher powers or religious doctrines, it can be compatible with all major religions.

One of the central tenets of yoga is that all people are searching for true happiness. Early in a person's spiritual development, he or she settles for temporary pleasures that cannot provide eternal satisfaction. Nature or God uses pain to prompt people to continue the search. Later in a person's spiritual development, the reward of peace and happiness replaces the punishment of pain as the primary motivator. Yoga practitioners believe that most diseases are due to a shortage of life force to either the entire or parts of the body, resulting in decreased immunity or resistance to disease. Good nutrition, sleep, a positive mental attitude, and yoga can augment the amount of life-force in the body. Misalignment of body parts can block the proper flow of life force to an organ and ultimately cause disease in that organ.

In yoga, a person follows a series of stretching, breathing, and relaxation techniques that prepare the mind and body for meditation. The stretching movements or postures (*asanas*) aim to stimulate and increase blood supply and *prana* (vital force) to various parts of the body as well as increase the flexibility of the spine. Increasing the spinal flexibility is believed to improve the nerve supply. Many *asanas* involve the spine, which is thought to be central to good health. The breathing techniques (*pranayamas*) are thought to improve brain function, eliminate toxins, and store reserve energy in the solar plexus region.

A few limited studies on yoga have been encouraging. They have shown altered EEG patterns; increased endorphine and dopamine release; reduced serum total cholesterol, LDL cholesterol, and triglyceride levels; and improved pulmonary function tests associated with yoga (Arambula et al., 2001; Birkel & Edgren, 2000; Schell, Allolio, & Schonecke, 1994; Selvamurthy et al., 1998; Stancak, 1991; Stanescu et al., 1981; Udupa, Singh, & Yadav, 1973). Yoga has shown benefit in patients with asthma, hypertension, heart failure, mood disorders, and diabetes (Jain et al., 1993; Malhotra et al., 2002a, 2002b; Manocha et al., 2002; van Montfrans et al., 1990). Two small controlled but nondouble-blinded studies showed Hatha yoga to significantly improve pain in osteoarthritis of the fingers and carpal tunnel syndrome (Garfinkel et al, 1994, 1998). Some of these benefits may arise from the muscle strengthening and stretching from some *asanas*.

There are some dangers to yoga. Certain asanas may be strenuous and cause injury. Moreover, some asanas are believed to cause disease. Although there is some credentialing process in yoga, it is neither rigorous nor universally accepted. So caution should be taken in selecting a yoga instructor and beginning a yoga program.

FAITH HEALING

Evidence suggests that many patients have seen faith healers, religious leaders who use prayer or other practices to treat and cure disease. Surveys have found that a fair number of patients in rural (21%) and inner city (10%) populations have used faith healers, and many physicians (23%) believe that faith healers can heal patients (McKee & Chappel, 1992). Numerous anecdotes of healing miracles exist, but to date there has been no consistent and convincing scientific proof that faith healers are effective (King & Bushwick, 1994). Additionally, it has not been determined whether faith healers affect patients psychologically or physiologically, and what factors may make them effective. Further research is needed before any conclusions can be drawn.

THE ROLE OF THE PAIN MANAGEMENT PROFESSIONAL

It is apparent that religious and spiritual practices are widely used and that their mechanisms and effectiveness, while currently under growing exploration, have not been clearly established. How then should they affect the practice of pain management professionals? This depends to some extent on personal philosophy, whether the practitioner uses and promotes religious and spiritual practices or simply has patients interested in using these practices. Regardless of where a practitioner falls along this spectrum, there are certain steps to consider regarding religious and spiritual issues when engaging with patients. Based on existing studies and clinical information, several approaches that pain management professionals might consider regarding religious and spiritual issues include the following areas.

TAKING A RELIGIOUS/SPIRITUAL HISTORY

Even though many health care practitioners have advocated taking a religious history as part of the initial history and physical, surveys indicate that many do not. One survey revealed that 59% of family physicians feel "uncertainty about how to take a spiritual history" and a "lack of experience or training." In a chart review of 92 elderly hospitalized patients facing end-of-life issues, only 6.5% of the patients had spiritual histories documented in their charts and only 29% had either a spiritual history or some mention of chaplain or psychiatrist involvement.

The purpose of the religious/spiritual history is to better understand the patient's religious background, determine how he or she may use religion to cope with illness, and open the door for future discussions about any spiritual or religious issues. Moreover, learning about a patient's spiritual practices may alert the pain management professional to watch for potential affects on patient compliance, acceptance of treatment, and how patients will make decisions about their health care choices. Questions should be nonjudgmental, open-ended, and general. Recommended questions include (Kuhn, 1988; Matthews & Clark, 1998):

- Are religious or spiritual beliefs an important part of your life?
- How do your religious or spiritual beliefs influence the way you take care of yourself?
- Do you rely on your religious or spiritual beliefs to help you cope with health problems?
- Are you part of a religious or spiritual community?
- Are there any religious or spiritual issues that need addressing?
- Who would you like to address religious or spiritual issues should they rise?
- How would you like me to address your spiritual needs?

For patients with severe illness, an American College of Physicians consensus panel led by Bernard Lo, Timothy Quill, and James Tulsky (1999) recommended the following questions:

- Is faith (religion and spirituality) important to you in this illness?
- Has faith (religion and spirituality) been important to you at other times in your life?
- Do you have someone to talk to about religious matters?
- Would you like to explore religious matters with someone?

ASSESSMENT OF SPIRITUAL DISTRESS

Because significant physical pain can result in spiritual distress, which in turn can exacerbate pain, it is important to recognize indicators of spiritual distress. Patients may question the meaning of life, pain, treatments, or illness; express anger at God, hopelessness, or despair; feel anxious about the afterlife, persecuted, guilty, or abandoned; or withdraw from friends and family. Abrahm (2001) suggests asking several questions to detect spiritual distress:

- Do you feel at peace with the changes in your life that have come about because of your illness?
- Are there any religious activities or practices that have been interrupted because of your illness?
- Pain is a hard thing physically. Has it been a hard thing for you spiritually?
- Would you like to speak with someone about your spiritual concerns?

FACILITATING ACCESS TO RELIGIOUS RESOURCES

If a health care practitioner is uncomfortable with either asking the above questions or dealing with the answers, he or she can seek help from religious professionals who can better address these issues. Religious resources are especially important during end-of-life care (Lo et al., 2002).

Evidence suggests that many health care providers are not familiar with the roles and training of various religious professionals in health care settings and, thus, do not consult them appropriately. Koenig, McCullough, and Larson (2001) have argued that chaplains should be included on pain management teams more frequently. Typically, chaplains have completed 8 to 12 years of education and training, passed written and oral examinations administered by the Association of Professional Chaplains, and been trained to work closely with physicians and nurses. Unlike parish ministers who have many responsibilities including administration and leading worship and often champion a particular faith, chaplains are trained to counsel patients and deal with all belief systems. Chaplains are available to counsel patient families, hospital staff, and physicians as well. Chaplains often sit on hospital ethics committees. However, not all hospitals have chaplains on staff. Pastoral counselors include any clergyperson who provides formal or informal individual, family, or group counseling.

PERFORMING CLERGY-LIKE DUTIES

Most health care providers have probably been asked to pray with a patient at some point in their training. Whether a health care provider is comfortable with this and how such an issue is handled are important to the patient and the relationship between the patient and provider. For example, ignoring such a request may anger, hurt, or embarrass the patient. Health care providers who have religious views that conflict with the patient or are agnostics or atheists can provide silent, nondenominational, or secular support. For example, the word *amen* means "so be it" and does not imply a belief in a higher power. Silent gestures such as holding a patient's hand or lowering the head while a patient prays can provide support as well. It is probably helpful for most health care providers to con-

sider what their approach to such issues will be, what their level of comfort is with regard to participating in religious practices with patients, and how they will ultimately deal with such issues prior to engaging in these aspects of religious or spiritual practices.

USE OF SPIRITUAL PRACTICES

Several spiritual practices are described in the literature. One of these tools is *listening authentically* to the patient. Studies have shown that many patients suffering from pain lament that health care providers do not adequately listen, which exacerbates their pain. Listening includes noticing a patient's body language, expression, demeanor, and tone of voice. The simple acts of being physically and emotionally with the patient without necessarily doing or saying anything (*presence*), allowing patients to express their feelings without judging or recoiling (*acceptance*), and offering one's own spiritual thoughts or experiences (*sharing of self* or *judicious self-disclosure*) may have therapeutic benefits. Pain management professionals can use *intuition* to recognize and understand the spiritual needs of a patient. Separate studies by Morse and Proctor (1998) and Proctor and colleagues (Proctor, Morse, & Khonsari, 1996) suggested that *comfort talk* can reduce pain. For more advanced spiritual practices such as meditation, health care providers should either obtain appropriate training to utilize such practices or explore the local community resources and practitioners who might be able to assist patients in such practices. In fact, it may be beneficial to meet with practitioners of spiritual practices to assess their qualifications and approaches to ensure that a patient will receive excellent instruction and will not encounter an obstruction to appropriate health care.

CONCLUSIONS AND FUTURE DIRECTIONS

Current evidence suggests that religious and spiritual activities can significantly aid in the management of pain. Many studies exist in the literature with varying degrees of methodological rigor. However, available evidence suggests that these activities do have physiological, social, and psychological effects, but the mechanisms require further elucidation. A number of pain management professionals and programs already have incorporated these activities in their practices. Anyone doing so should understand the complexity of and the subtle differences among these activities, as well as the potential problems. Even if one does not plan to incorporate these activities into practice, the prevalence of religious and spiritual activities makes it important for all pain management professionals to understand and be prepared to discuss these issues. Many patients and health care practitioners feel that religious and spiritual issues should be better integrated into patient care, a sentiment that is likely to grow in the future.

The Role of Prayer in Pain Management

Myrna C. Tashner, EdD

Dedication: This chapter is dedicated to the memory and spirit of Richard S. Weiner, Ph.D., who welcomed us into AAPM with open arms and encouraging words. Dr. Weiner shared my passion in believing in the patient's power to heal with the assistance of Spirit.

THE MYSTERY, THE MIRACLE, THE SCIENCE, AND THE ENERGY OF PRAYER

What is this thing called prayer and what is its role in healing? In this chapter we review some literature on prayer, examine the science of prayer, and look at some results of prayer and the ways prayer can be a part of the pain management practice.

This is a timely discussion, as there is increasing interest in the subject. *Newsweek* devoted its November 10, 2003, cover story to "God and Health." Articles addressed physicians' experiences with patients requesting prayer, and/or finding a patient's need for prayer, and the awareness and comfort with prayer becoming more important to their practice of medicine. On Christmas Day 2003, *Paula Zahn NOW* focused on "Faith in America." She talked with Dr. Herbert Benson of Harvard Medical School's Mind/Body Medical Institute, among others. With 35 years of study and research behind him, Dr. Benson told her, "Belief is very, very important in healing. When you focus on a sound, a prayer, or a phrase, and repeat it, disregard other thoughts, distinct physiological changes occur in the body which are exactly opposite those of the stress" (Zahn, 2003). Dr. Benson went on to say that "60–90% of visits to health care professionals are in the area of mind-body stress-related realm. So, it affects not only blood pressure, but heart rate, affects many forms of pain, anxiety, depres-

sion, insomnia. In other words, there's discrete medical proof that evoking what we call the relaxation response, often through prayer, can treat many, many different diseases. And the extent that any disease is caused or made worse by stress to that extent, this intervention will work" (Zahn, 2003). Dr. Benson went on to say that when people pray for themselves, and pray in a repetitive fashion, nitric oxide (NO) is released in the body system. This particular gas has tremendous manifestations in various biochemical systems. Dr. Benson has been able to quantify these body–mind effects, including spirituality, and bring together a doubtful society with science.

In addition to Dr. Benson, another physician who has followed and researched prayer during his medical career is Dr. Larry Dossey. In *Prayer is Good Medicine,* he writes, "Prayer is back." He says doctors are taking it into their offices, clinics, hospitals, as well as experimental laboratories. He notes that medical journals are publishing studies on the healing effects of prayer and faith. He points out that "75% of patients believed their physician should address spiritual issues as a part of their medical care and 50% wanted their doctor to pray not just for them but with them" (1996, pp. 1-2).

In *Spontaneous Healing,* Dr. Andrew Weil (1995) says Dr. Dossey is one of the few doctors who has looked at the relationship between prayer and healing. Dr. Dossey writes of the power of prayerfulness in *Healing Words, the Power of Prayer and the Practice of Medicine,* that "prayerfulness allows us to reach a plane of experience where illness can be experienced as a natural part of life, and where its acceptance transcends passivity. If the disease disappears, we are grateful; if it remains, that too is reason for gratitude" (1993, p. 23).

Dr. Dale Matthews wrote in *The Faith Factor,* that he was horrified at the lack of humanity in his medical training when he went to school "hoping to learn and practice compassionate, person-centered doctoring" (1998, p. 7) and caring for the whole person, not just organs and tissues. He wrote that what he sees emerging is the "biopsychosocial model" and solid scientific evidence for the role of beliefs and meditative practice in human health and that beliefs, religious or otherwise, have a profound effect on physical and mental health. Matthews said that what he sees is that faith is good medicine and that the medical effect of religious commitment is not a matter of faith but of science. He said patients were the pioneers in this area. He cited a study by Dr. D. King of East Carolina University, which showed that 48% of hospitalized patients wanted their doctors not just to talk about spiritual issues with them, but actually to pray with them. *The Faith Factor* is Matthew's summary of science, research, and narratives about the healing results of faith in medical practice.

OTHER STUDIES

There have been many studies about prayer in recent years. It is not the purpose of this chapter to do a review of the literature; others have done that (Matthews & Saunder, 1995–1997), but suffice it to give a few examples. There were studies of geriatric patients and their reliance on prayer and religion as coping mechanisms when faced with the stress of life and events including health problems (Bearon & Koenig, 1990), D. A. Matthews et al. (1998) assessed effects in conjunction with standard medical treatment of experimental intercessory prayer for healing in patients with rheumatoid arthritis. Results suggested that patients derived significant short- and long-term benefits from in-person intercessory prayer ministry (Matthews et al., 1998).

There have been studies of the effects of intercessory prayer, probably the most widely provoking one done by Byrd (1988). He studied intercessory prayer and cardiac patients in a San Francisco coronary unit. It was a randomized study of 393 patients, after signed consent, conducted in a double-blind protocol. Results were significant for patients in the control group who required ventilator assistance, antibiotics, and diuretics more frequently than patients in the intercessory prayer group. In 1999, a similar study was conducted in Kansas City at the University of Missouri Medical Center, Division of Cardiology, Department of Medicine by Harris et al. (1999). The sole purpose of the study was to attempt to replicate Byrd's findings by testing the hypothesis. However, in their study patients were unknowingly and remotely prayed for by blinded intercessors. The hypothesis stated that these patients would experience fewer complications and have a shorter hospital stay than patients not receiving such prayer. The

result suggested that prayer may be an effective adjunct to standard medical care. Except for two patients, the length of stay for the prayer group dropped by about a day. The intercessory prayer group of patients lowered the hospital course score but did not significantly affect length of stay. The researchers gave a number of reasons for lack of exact replication including, and significantly, that it was conducted under completely blinded conditions. In this study informed consent was not sought from the patients and the patients were not prescreened for their willingness to be prayed for. Among research committees it is not the policy to permit studies of patients without the written consent, but this research group convinced the committee otherwise. Permission was granted for this type of study, rationalizing that it eliminated any possible bias (Harris et al., 1999). Therefore, it cannot truly be said that this was a replication of the Byrd study.

The conclusions of these studies are interesting for our purposes. If you think about it for a minute, knowing they are possibly being prayed for does have some effect on the body, mind, and spirit of the patients, if the results of the study are to be believed, versus not knowing someone is possibly praying for their healing. Maybe two comparison points of these studies are the effect and impact of knowing someone is praying for you, which may be in what and of itself encourages the body to heal, for we are wired for healing according to Dr. Benson (*Harvard Health Letter,* 1998). Lack of awareness of being prayed for just does not have the same effect, and is unethical to some extent. Why? Because prayer is an exchange of energy and each of us is an energy being. In praying for you, I am asking that your energy field be in some way positively affected with the assistance of God. (Throughout this chapter, please see the word "God" to mean God as you know it.) You do have a right to know if you are being prayed for, as it is your energy field that is being affected. You have the right to know so you can choose to accept the energy or refuse to cooperate with the energy.

There are studies that suggest that prayer did not work. In one study, effects of prayer were compared to positive visualization in patients on kidney dialysis. The authors of this study were not able to distinguish the *effects* of prayer and positive visualization for expectancy (Matthews et al., 2001).

WHAT IS PRAYER?

Prayer is talking with God (the Divine, Higher Power, Allah, Yahweh, or simply God as you understand it). It is really that simple. It was the way Abraham, Moses, Jesus, and Mohammed prayed; they talked with God. There are formal prayers, formats for prayer, etc., but it really comes down to talking with God. As such, prayer is made up of thoughts and words; and just as our words have power to create or destroy, so does prayer. Praying is more. It could

be defined as the transfer of energy. Prayer generates energy, and praying for someone is at the least an energy exchange, probably of the highest form we have in this earth plane.

Our proof for that is demonstrated in the Bible. Have you ever noticed that the healer Jesus never healed anyone unless they asked to be healed? And he would end the encounter with something to the effect, "… your faith has made you well; go in peace" (Luke 8:48 RSV), or "Do not fear; only believe" (Luke 8:42 RSV). The woman with the issue of blood is a good example. She believed that if she could just touch the hem of his garment she could be healed. In that instance, when touched by someone who wanted to be healed, He knew someone had touched Him. He demanded to know who it was who touched Him. When His disciples questioned Him as to how He could know someone had touched Him as they were in a crowd, He responded that He felt the energy leave Him (Luke 8:43–48).

We may look to sacred writings to teach us right prayers to say. In the Bible, when His disciples asked Jesus how to pray, He offered them a series of affirmations about God and their relationship to God, which we call the Lord's Prayer. David's prayers as reported in the Bible were with songs of praise called Psalms. Mohammed's prayers were verses, which revealed God's wisdom and goodness, and are recited as prayers today (*The Holy Qur'an,* 1989).

Christian Science believes, "Prayer cannot change the science of being, but it tends to bring us into harmony with it" (Eddy, 1875, p. 2).

Myss in *Anatomy of the Spirit* (1996) described authentic prayer as one's conscious connection with God. "Authentic prayer does not mean to turn to God in order to get something; it means to turn to God in order to be with someone. Prayer is not so much our words to God as our life with God. When this is understood, then prayer becomes 'energy medicine'" (1996, p. 282).

A retired Catholic priest, now healer, Roth suggests a very simple prayer. With the inhale of breath he suggests saying, "Come Spirit" (spirit being another word for breath), and with the exhalation, "God Is Light." This creates relaxation in the mind and body. It is in the relaxed state that the body, mind, and spirit can return to their natural state of wholeness and health (Roth & Occhiogrosso, 1997).

Harold Koenig of Duke University said of science, religion, health, spirituality, and prayer, that the evidence is there. Prayer brings us closer to God. It changes us, causing us to set better priorities. This enables the body to heal itself. Prayer releases God to perform miracles (Koenig, 2004).

This is quite consistent with the now famous Harvard cardiologist Herbert Benson's relaxation response, now prayer process. His research has proven that when one engages in a repetitive prayer, and when intrusive thoughts are passively disregarded, a specific set of physiological changes ensues. He teaches that a repeated word, as the word "one" (or some other word that is meaningful to the person), sets off these physiological changes. His latest research has shown that this effective letting go of a problem triggers the internal release of nitric oxide, which has been linked to the production of neurotransmitters rich in endorphins and dopamine, which are natural tranquilizers. Nitric oxide alters the body's chemistry so significantly that personal changes become possible (Benson & Proctor, 2003).

In a sense, Dr. Benson has provided us with a plausible scientific explanation for what happened to Jesus as written. "He took with him Peter, James and John, and went up on the mountain to pray. And as he was praying, the appearance of his countenance was altered, and his raiment became dazzling white" (Luke 9:28–29, RSV).

Dr. Dossey wrote, "In its simplest form, prayer is an attitude of the heart — a matter of being, not doing. Prayer is the desire to contact the Absolute, however it may be conceived. When we experience the need to enact this connection, we are praying, whether or not we use words" (1996, p. 83). He wrote in *Reinventing Medicine* that he discovered early in his investigation of prayer research that members of the clergy almost never perform scientific studies to evaluate the effects of prayer. He said that they believe that empirical scientific proof is unnecessary, and some see science as the enemy of faith or testing God (Dossey, 1999, p. 49).

By and large that is true. However, there was a husband and wife who both experienced healing through prayer; and he, Charles Fillmore, spent the rest of his life studying, researching, and writing about how prayer was part of his healing. In his passion for his discovered truth, he and his wife had a vision for a place where people could come and learn about the truths of belief and the science of prayer. He was a prolific writer in the late 1800s, early 1900s, although he did not have significant formal education. He defined prayer as the "communion between God and man. This communion takes place in the innermost part of man's being. It is the only way to cleanse and perfect the consciousness and thus permanently heal the body" (Fillmore, 1959, p. 152). Fillmore wrote that prayer was more than supplication; it was affirmation of Truth (Truth meaning eternal absolute) that eternally exists, but which had not yet come into consciousness, which is done through affirmation, faith, praise, and acknowledgment.

THE SCIENCE OF PRAYER

When Dr. Benson stumbled on the scientific effects of the relaxation response, life and healing became less a mystery. For a long time we knew that animals in the wild

survived because of their ability to feel a dangerous situation. Psychology calls that the "fight or flight" response.

In our little human living circumstances, we also come upon things that threaten our existence and/or survival. We, too, would like to run to escape eminent danger. And sometimes we can do that, and do that. But there are other times, such as in the time of pain, illness, or stress when we can't run or escape. What happens to the fight-or-flight energy when this occurs? We can't run or escape to get rid of it. It is in our bodies, energizing the system, so to speak. We can sustain that state of energy alertness or hyperstate for a time, but unattended it can have ill consequences and causes illness or pain.

According to Dr. Benson's research, the practice of relaxation releases that energy. In the state of relaxation, we let go, release our tension, so the body's natural sense of balance can come in and heal that environment that has been disturbed. This simple act brings homeostasis to the body system. By paying attention to the breath and focusing attention on a word, mantra, or prayer, the mind is kept busy, so the body has a better chance of relaxing.

In his latest book *The Breakout Principle,* Benson reviews how to elicit the relaxation response. He calls it Meditation 101 and gives a four-step method, which his research suggests releases nitric oxide.

Step 1: Choose a meaningful word or short phrase that can be silently repeated on the out breath or exhalation.

Step 2: Assume a comfortable position, close your eyes and breathe easily and on the out breath say your word.

Step 3: Don't get upset with distracting thoughts or interruptions, just turn them away and return to the silent repletion of your word.

Step 4: After 10 to 20 minutes have passed, open your eyes and sit quietly for a few minutes to allow thoughts of the day to enter (Benson & Proctor, 2003, pp. 89–91).

He states that the release of the nitric oxide gives "puffs of insight," as well as reverses the effects of the released stress hormones, which in the case of pain make it worse by lowering the threshold of pain. The release of nitric oxide counteracts the stress hormones, enhances the release of pleasurable neurotransmitters (endorphins and enkephalins), and effects a host of biochemical changes. With the relaxation response the brain itself is quieted, as are the specific areas of the brain that control heart rate and blood pressure (Benson & Proctor, 2003).

Prayer works in the same way. Unity Institute (formerly Unity School of Christianity founded by C. and M. Fillmore) teaches five steps of prayer. I feel these five steps are best summarized in the following way.

STEP 1 RELAXATION

Relaxation is the first step of prayer. We signal our mind and body and spirit with three deep breaths, which signal our mind, body, and spirit, that we are changing our focus. This allows us to then turn our thoughts to noting where the tension resides in our body and invites the body and mind to release the tension. In that process we draw attention away from our cares and concerns, so we can focus our attention on Truth.

STEP 2 DENIAL

The second step naturally follows relaxation and is sometimes forgotten. In this step we deny, or take our energy off, of the negative thought or thing which concerns us. We know the power of denial, that when we take our energy off something, even for a short time, it ceases to exist.

STEP 3 AFFIRMATION

In the third step we affirm the Truth. For example, if pain relief is our prayer goal, then we may chose the scripture that declares that we are children of God, and if we are children of God, then we have a right to the gifts of God, one of which is healing. Our affirmation might go something like this, "I am a child of God and I have the right to be whole and healthy," or some other description that would be appropriate for our life and our beliefs.

STEP 4 MEDITATION/CONTEMPLATION

We hold the thought of Truth in our mind so it can take root in our mind, body, and spirit. We meditate on the thought, engage our sense in the feeling and experience of what feeling healthy and well would be like. And again we would be engaging our powerful sense of relaxation, which would release nitric oxide in the body system for activating changes. And while we meditate, we relax and become open to the insights that come from the God, as we understand God.

STEP 5 GRATITUDE

We give thanks for the healing that is taking place in our body. Jesus talked about giving thanks in advance, and he did so before he healed people and also before he had manifestations, as with the loaves and fishes (John 6:11 RSV). In the act of giving thanks, we are expressing belief and faith in the power of prayer and the spirit of healing.

EXPERIENCES OF PRAYER IN HEALING

Relaxation is a bridge that connects us with the natural healing powers of our body–mind–spirit. We are wired for healing. It is our natural state, a state of wholeness. That

is part of our creation. We are created in wholeness and that is part of the mystery of life. But we have lost that contact when we are in pain (physical, mental, emotional, and/or spiritual). This awareness was made real for me when my chiropractor would distract my attention from the stressed position with the word "relax," and then proceed with the adjustment. At another level, I felt that he was addressing the body–mind–spirit to relax into the correct position for healing.

Have you ever noticed how much you enjoy hearing personal stories of healing? In fact, when patients ask if the treatment we are prescribing really works, what they are asking us is if we know from our experience that someone has gotten better by what we are asking them to do. This serves to encourage their body, mind, and spirit in the healing process. As a medical professional, the doctor, nurse, therapist, etc., doesn't take the pain on, or away. Rather it is something they do to make the healing happen, and our view needs to be that of facilitating a link, or hook-up, between with the natural health/wholeness and the patient. It is the link, and the hook-up with the natural healer within the patient.

The same is true for our use of prayer. Patients are asking that in addition to what has happened to others, do we as health care providers who experience with prayer working. Health care providers who practice and know the power of relaxation and prayer are not better or different, but already have the knowing of Truth and this bubbles from their hearts. The following stories are offered as testimonies of the power of prayer as this writer has had experience of it, or heard about it.

Myrtle's story — A young mother in 1886 was suffering from tuberculosis, and given a mortal prognosis. She was a told that she had inherited illness and would die of it as her parents had. A metaphysician, Dr. E. B. Weeks, was visiting and lecturing in town one night, and she decided to go and hear him. During the lecture she heard the words, "I am a child of God and therefore I do not inherit sickness." She went home filled with the feeling of these words. She told her husband, Charles. Together, they decided that she would take these words into her heart daily in prayer and meditation. She did this for 2 years, and she was healed. She lived for 45 more years (Whitherspoon, 1977).

Marty's story — A 5-year-old boy slipped into a farm machine's auger left foot first up to his ankle. He was alone, and he tried to free himself, but each time he moved his foot the auger blade made a revolution cutting into his flesh first, then a little further, then into his ankle bone with each complete turn, and finally through his bone to the outside flesh, and to the skin. The father showed up, upon hearing his son's screams for help, turning the machine off. Only an inch of skin was holding the little foot to the leg. As this happened on a very rural farm, the child with his dangling foot was wrapped in a blanket and

rushed to the nearest hospital some 20 miles away, where the surgeon suggested to the father that the foot could not be saved. The father said that they should try to reattach the foot first. If that didn't work, they could always remove it. So the gentle family practice physician (there was no orthopedic surgeon to do the job) painstakingly for hours removed the multiple particles of debris, brought muscle from the back of the leg around to the front, and reattached the foot to the leg. After 12 hours of surgery, the little boy was brought to a private room, to be met by his parents, who were praying. They had called the local monastery to pray with them. The mother sat on a chair at the foot of her son's bed and held the injured/healing foot in her hand and prayed. She would later tell the story of how the foot was cold and blue when she started, but she prayed anyway. In time, some 12 hours later, the foot was warm and turning pink. In the days and weeks that followed, the boy's foot did reattach itself to the leg and without infection. Today the boy is a man, walks with only a drop in that foot at the ankle, and operates the farm where the accident occurred.

My story — It was a sunny early summer day in Kansas and I was in my first year of ministerial education at Unity School of Religious Studies. I had agreed to accompany a second-year student to a rural church about 2 hours out of Kansas City and present the service's meditation that day. As I got out of her car, I turned to shut the door with one hand, and somehow managed to slam the door on my middle finger of the other hand. Having done that many times as a child, I had instant recall of what my finger was going to look like when I opened the door. But I was also a student of metaphysics. I was learning how energy and the mind work to heal the body. So in that second, I began to affirm and know the Truth about my finger, that it was whole and healed as God made it. Rather than thinking about the torn flesh, I focused my attention on a healed finger. There was throbbing and pain, too. When I opened the door, I deliberately didn't look at the finger, but wrapped it in my clean handkerchief and continued to affirm that my finger was as God had created it to be, healed and whole. It was an hour until I was to present the meditation, so I sat in the sanctuary and continued to repeat the truth of my finger's healed state. There were other thoughts from time to time about what the injury would look like, but I kept returning to my affirmation of the whole and healed finger. Later that morning, when I got up to do the meditation, I glanced at my finger and all that was noticeable was a small indentation in the skin, but no break, or torn flesh. Had my finger been broken? Had the flesh been torn apart? There are the memories from my childhood accidents, in which the finger had taken weeks to heal. But on this day, all that was noticeable was an indentation on the flesh.

Joanne's story — As things happen, my ministerial colleague who had agreed to review this writing, related

an experience of physical pain in her life. In one of our conversations during the initial stages of this writing, she was relating her experience with shoulder pain as she swept her front walk in South Carolina. She said that with each sweep of the broom, she found her body tensing to protect the shoulder from pain. But it didn't seem to help much. In fact, while she swept the sidewalk, she had to stop sweeping and take a breath into the pain. And when she did stop and breathe, the pain subsided. She then had a realization. Maybe if she would relax and breathe while she swept her sidewalk, there would be less pain. That is what she did. She told me there was little, if any, pain.

Charles Fillmore had this to say: "If we make living cells through the power of thought, we should know something of the law underlying the process. On every hand thoughtful men are searching for the scientific causes of things" (Fillmore, 1939, p. 127). He proceeded to tell the story of a woman who was an ardent Truth student, and her husband who thought all Truth was foolishness. But he paid attention when his mother was healed of a mole on her face. His mother said of her healing that she withdrew her "nourishing thought." She had mourned over it and wished it weren't there, but that nourished it and sent vital forces to keep it growing. When she quit nourishing it, it gradually withered and disappeared. We nourish the conditions of our bodies with our thoughts. "Our mind draws upon the vital forces and according to physiological laws we alter our tissues" (Fillmore, 1939, p. 127). (Also refer to Fillmore's step 2: Denial.)

What are we to take from these true stories regarding prayer? To some extent, we don't know all of the "science" about prayer, but we are living and when some awareness of an energy greater than ourselves is invited into our lives, some form of healing can take place. There really isn't anything we have to do, but to have the presence and awareness of mind to invite the energy. Then it helps if we can relax and breathe.

The power of relaxation is the first step. That word, *relax* sends a powerful message of release and let go, so new energy can come in. The word, or thought, like *relax*, or *relaxation*, or *prayer* carries power. It is a thought distraction, but also an invitation. Relaxation bridges that connection with the natural healing process. Health and wholeness are our natural state. That is part of our creation. We are created in wholeness and that is part of the mystery, because we lose contact with that wholeness when we are in pain (be it physical, mental, emotional, or spiritual pain). And the medical profession should not take it on, that is, the belief that they have to do something to make wholeness or health happen, but rather their view needs to be that of making a link or hook-up with the natural healing power, or divine energy, within the patient. Medical professionals need to practice prayer and meditation, so they know the power of prayer and relaxation.

This isn't better or different from what they already know, but just a bubbling to the heart.

PRAYER AND OUR PATIENTS

If Dr. Benson's science is correct, and from my studies of metaphysics and my personal experiences all indications are that he is correct, then we are going to see an increased awareness of prayer playing a role in our dealings with patients experiencing pain. First, prayer acknowledges that they are more than a body and mind in the experience of pain. It reminds both the professional health care provider and the patient that they have a spiritual part to consider in this healing process as well. The various medicines and scientific techniques should have an effect to lessen the pain or illness of the body and maybe the mind, but until we acknowledge and address the spirit of our patients, we won't be taking into account all of the factors of the whole patient. And how can we expect to heal if we aren't present to the whole person?

No words or prayers need to be said out loud necessarily, but maybe something like, "Let's relax into this time together." Medical professionals could pause to relax and prepare themselves before each case, and collect energy and awareness before they meet the next patient. This relaxation pause makes a connection in an almost telepathic mind-to-mind manner. It may prepare medical professionals within their being in an inner connectedness that while they are speaking they are able to adjust their words to meet their patient's needs.

What to ask a patient about praying together. As suggested by the results of the University of Missouri, Kansas City study (Harris et al., 1999), it is necessary to ask patients if they would like you to pray with them. According to earlier-cited sources, a growing percentage of patients want their health care provider to pray with them. This could be a challenge, but their medical chart may already indicate the patient's religious preference. So, you might ask if the patient would like to start the time together with a prayer; or even less threatening, suggest something to the effect that we relax a moment together before we begin. The point isn't to get into a discussion about what to say; rather the point is to get together to create a healing atmosphere between the two of you.

What prayers to say. Some professionals may feel uncomfortable saying words, or may feel ill-prepared to pray with their patients. They may feel relieved that patients didn't ask them to pray with them. And that's okay, too. But given what seems to be a growing movement among patients to want to pray with their professional health care providers, it is best to at least have considered your position on prayer. So, what do you say? Maybe you want to pray and ask for divine assistance with this patient, what would be good to say? If prayer is talking to God, as we said earlier, that would be a safe place to

start. Talk with God, and ask God, as each of you understands God, to be in this meeting time with this patient and you. Or you may choose to use a classic and generally known prayer such as "The Lord's Prayer" or some other simple shared prayer. And remember, this should only be done when the patient requests it.

For my part as a patient, I always try to remember to ask the Divine Healer to be present and guide the hand of the doctor who is working with me. I find I can relax better into the appointment. As the health care provider, I may say a silent prayer before I enter the room, asking for divine guidance for me with this patient. In situations where I'm not sure if the patient would appreciate prayer, I may ask if he or she would like to say a little prayer. I have on other occasions asked that we take a deep breath before we start and bring our focus into the room together. It seemed to break the stress and anxiety of the session.

Praying with patients means different things to different people. I have a Native American friend who is a home health nurse. We have discussed prayer and using prayer in working with patients. She said that she asks the Great Spirit to be present at each visit and guide her in what she needs to do with that patient. Some of her patients have made comments to her about their knowing that she has special healing presence, but others don't get it. She also is a practitioner of healing touch. She will use this technique only with the patient's awareness and permission. On the other hand, I have another friend who wouldn't want her physician to pray with her. She feels her physician's work is to do his job with the medicines. I, myself, have asked my health care providers if they believe in spiritual healing and have gotten very different responses. One understood what I was talking about. The other laughed at me, and I found it difficult to work with that provider.

It would be important to remember that when patients are asking to pray, what they are asking for is a sharing of hope and peace in their healing process. They want to release their fear of what is happening. They want to relax and heal.

The ethics of praying with patients. As we know, prayer is a very powerful energy. I don't believe it is appropriate or ethical to be direct with our prayers without asking the person for whom we are praying if he or she wants to be prayed for. I make it a point not to pray for someone unless I first ask if the person would like me to pray. I think the University of Missouri study is proof of that principle. There will be no, or minimal, result for patients if we don't ask if they want to pray or be prayed for. We haven't touched on the fact that, as energy, unwanted/unsolicited prayer will bounce back to us.

If you to choose to ask your patients about their desire for prayer, what are the boundaries? First, prayer is the exchange of energy. It is vital that the patients ask for or agree to prayers. Second, it is important to know that God is in charge of what is going to happen, and together through and by your prayers, you both are affirming that. Third, together you pray that God's will is done. Note that you aren't directing what is God's will, or what the result should be. You are simply asking that God's will be done. Of course, we are seeking healing, but we need to be aware that healing has a variety of expressions from restoration of the body to its original health, or partial recovery, even to and including death of the body physical. We need to be okay with whatever the outcome may be. It is important to be clear with our patients about this as well.

CONCLUSION

Prayer does have a role in pain management. Prayer is scientific and has some basic steps; just as the relaxation response is scientific and has basis steps, as outlined above. At the minimum, prayer can facilitate the release of stress and introduce relaxation. This has been shown to have an effect on pain. According to Dr. Benson, our bodies are wired for healing, and relaxation and prayer are ways of tapping that energy. The stories related above support this idea. At the maximum, by our entering and engaging patients in their belief system about prayer and healing, and their feelings for relaxation and health, patients are engaging in the healing process. As with any treatment, the outcome with prayer and relaxation is up to the individual, and God.

Concepts of Multidisciplinary Pain Management

Robert J. Gatchel, PhD, ABPP, Leland Lou, MD, and Nancy Kishino, OTR, CBE

INTRODUCTION

Pain is a complex experiential state that comprises a panoply of variables, each of which contributes to the interpretation of nociception as pain. The complexity of pain becomes especially noteworthy when it persists over extended periods of time, during which a range of psychosocioeconomic factors can significantly interact with physical pathology to modulate a patient's self-report of pain and concomitant disability and response to treatment. Chronic pain disability is now appropriately viewed as a complex and interactive psychophysiologic behavior pattern that cannot be broken down into distinct, independent psychological and physical components. This *biopsychosocial perspective* has replaced the outdated biomedical reductionist approach of medicine. The intention of this chapter is to review the critical elements of an interdisciplinary treatment approach (based on this biopsychosocial perspective) that has been demonstrated to be efficacious when patients have progressed to the chronic pain disability stage, at which point their management becomes much more complex because of the interactive psychosocioeconomic factors involved.

BIOPSYCHOSOCIAL PERSPECTIVE OF PAIN

The biopsychosocial model of pain, which is now accepted as the most heuristic approach to the understanding and treatment of pain disorders, views physical disorders such as pain as a result of a complex and dynamic interaction among physiologic, psychologic, and social factors, which perpetuate and may worsen the clinical presentation. Each individual experiences pain uniquely. The range of psychological, social, and economic factors can interact with physical pathology to modulate patients' reports of symptoms and subsequent disability. The development of this biopsychosocial approach has grown rapidly during the past decade, and a great deal of scientific knowledge has been produced in this short period of time concerning the best care of individuals with complex pain problems, as well as pain prevention and coping techniques.

In their comprehensive review of the biopsychosocial perspective on chronic pain, Turk and Monarch (2002) point out that individuals differ significantly in how frequently they report physical symptoms, in their tendency to visit physicians when experiencing identical symptoms, and in their responses to the same treatments. Quite frequently, the nature of patients' responses to treatment has little to do with their objective physical conditions. For example, White and colleagues (1961) earlier noted that less than one third of all persons with clinically significant symptoms consult a physician. On the other hand, from 30 to 50% of patients who seek treatment in primary care do not have specific diagnosable disorders (Dworkin & Massoth, 1994). Turk and Monarch (2002) go on to make the distinction between *disease* and *illness* in better understanding chronic pain. The term *disease* is generally used to define "an objective biological event" that involves the disruption of specific body structures or organ systems caused by anatomical, pathological, or physiological changes. *Illness*, in contrast, is generally defined as a "subjective experience or self-attribution" that a disease

is present. An illness will yield physical discomfort, behavioral limitations, and psychosocial distress. Illness references how sick individuals and members of their families live with, and respond to, symptoms and disability. This distinction between disease and illness is analogous to the distinction made between *pain* and *nociception*. Nociception involves the stimulation of nerves that convey information about tissue damage to the brain. Pain, on the other hand, is a more subjective perception that is the result of the transduction, transmission, and modulation of sensory input. This input may be filtered through individuals' genetic composition, prior learning histories, current physiological status, and sociocultural influences. Pain, therefore, cannot be comprehensively assessed without a full understanding of the person who is exposed to the nociception. The biopsychosocial model focuses on illness, which is the result of the complex interaction of biological, psychological, and social factors. With this perspective, diversity in pain or illness expression (including its severity, duration, and psychosocial consequences) can be expected. The interrelationships among biological changes, psychological status, and the sociocultural context all need to be taken into account in fully understanding pain, patients' perception, and their response to illness. A model or treatment approach that focuses on only one of these core sets of factors will be incomplete. Indeed, the treatment efficacy of a biopsychosocial approach to pain has consistently demonstrated the heuristic value of this model (Turk & Monarch, 2002).

PRIMARY, SECONDARY, AND TERTIARY CARE

At the outset, one should also be aware of differences among primary, secondary, and tertiary care. As Mayer et al. (2003) have clearly delineated, the care of acute pain problems is considered *primary care*, usually consisting of control of the pain symptom. Primary care usually lasts between 0 and 12 weeks following the occurrence of a painful episode and includes (but is not restricted to) "passive treatment modalities" such as electrical stimulation, manipulation, temperature modulation methods, and analgesic medications. Moreover, as these investigators note, on the basis of the natural history of many pain disorders, especially musculoskeletal disorders, most patients recover spontaneously or with relatively limited primary care. *Secondary care* refers to the first stage of reactivation during the transition from primary care to return-to-work or normal activities of daily living. This secondary care phase usually occurs 2 to 6 months after the initial pain occurrence and is designed for patients not responding to initial primary treatment, in order to facilitate a return to productivity before progressive physical deconditioning and psychosocioeconomic barriers become firmly entrenched. Secondary care is meant to avoid the occurrence of chronic disability by preventing physical deconditioning and potential negative psychosocial reactions, as well as social habituation to disability. As Mayer and colleagues (2003) highlight, the rationale for secondary care rehabilitation is to recognize and manage early risk factors or signs for the development of disability, thus preventing chronic or permanent disability. Thus, *reactivation* is often the most common need at this point in time.

Finally, *tertiary care* refers to rehabilitation directed at preventing or ameliorating permanent disability for the patient who already suffers the effects of disability and physical deconditioning. It is this tertiary care or rehabilitation that requires an interdisciplinary team approach to accurately assess the various interrelated factors of chronic disability and pain, which then must be linked to the careful administration of a multifaceted pain management program to effect recovery and reduce permanent disability. This is not to say that the interdisciplinary approach is not of potential value for secondary care. However, this form of tertiary care is quite different from secondary care because of the intensity of services required, duration of disability, treatment program protocol, more specificity of physical and psychosocial assessment, and the greater level of coordination among health care professionals. In this chapter, we discuss this interdisciplinary approach, especially as applied to tertiary care.

It should be noted that we, as well as others, clearly distinguish between *interdisciplinary* and *multidisciplinary* treatment. *Multidisciplinary* connotes the involvement of several health care providers. The integration of these services, as well as communication among providers, may be limited. *Interdisciplinary,* in our use of the concept, involves greater coordination of services in a comprehensive program, and frequent communication among the health care professionals providing care. A key ingredient of interdisciplinary care is a common philosophy of rehabilitation and active patient involvement (Turk & Stieg, 1987). Before discussing the specific elements of an interdisciplinary treatment approach, a brief historical overview of the growth of such pain management approaches is provided.

GROWTH OF PAIN TREATMENT CLINICS

As carefully delineated elsewhere (Turk & Gatchel, 1999), following World War II, a number of anesthesiologists developed pain clinics that used nerve block procedures as a primary model of diagnosis and therapy. This subsequently stimulated the rapid growth of such pain clinics, which resulted in the listing of 327 such clinics in a *Directory of Pain Clinics* that was published in 1977 by the American Society of Anesthesiologists, Committee on Pain Therapy. Of these 327 pain clinics, 73% were within the United States. Subsequently, it was estimated that there were more than 3,300 pain treatment facilities and solo

pain practitioners in the United States, treating 2.9 million Americans each year (Marketdata Enterprises, 1995). More than 176,000 patients were estimated to be treated in specialty pain treatment facilities each year. Melzack and Wall (1982) characterized this proliferation of pain clinics as one of the most important advances in patient care during the past 25 years.

The International Association for the Study of Pain differentiated four levels of pain programs (see Loeser, 1990): multidisciplinary pain centers, multidisciplinary pain clinics, pain clinics, and modality-oriented clinics. The *pain clinic* is typically a health care facility that focuses on the diagnosis and management of patients with chronic pain. Such clinics may specialize in specific diagnoses or pain related to a specific region of the body (e.g., headache or back pain). The *modality-oriented clinic* is a health care facility that provides a specific type of treatment, but does not provide comprehensive assessment or pain management. Examples of such clinics include nerve block clinics and biofeedback clinics. In such clinics, there is no emphasis on an integrated or comprehensive interdisciplinary approach. A *multidisciplinary pain center* (in our terms, interdisciplinary) is composed of a group of health care professionals and basic scientists. Such centers include research, teaching, and patient care related to acute and chronic pain. These facilities include a wide array of health care professionals, including physicians, psychologists, nurses, physical therapists, occupational therapists, and other health care provider specialties. Multiple therapeutic modalities are available, and these centers are usually affiliated with major health science institutions and are able to provide evaluation and treatment. Finally, a *multidisciplinary* (interdisciplinary) *pain clinic* is a health care delivery facility staffed by physicians and other health care provider specialists. It differs from the multidisciplinary pain center in that it does not include research and teaching activities as regular features.

Of course, the prototypic pain clinic with which most psychologists are familiar is the one originally developed at the University of Washington by Fordyce and colleagues (Fordyce, Fowler, Lehmann, & DeLateur, 1968). This clinic utilized "pure" operant or behavioral treatment programs in which reinforcement procedures for "well behavior" were the major components used for pain management. The program originally involved a 4- to 8-week inpatient treatment protocol designed to increase gradually the general activity level and socialization of the patient, and to decrease medication use.

As pain treatment specialists began to understand the complexity of evaluating and treating chronic pain problems, simple pain clinics and modality-oriented clinics soon were replaced by interdisciplinary pain centers or clinics (IPCs) in which it was viewed that patients would be best served by a team of specialists with different health care backgrounds. These IPCs were driven by the concept that a complaint of pain was not just the result of body damage, but had cognitive, affective, and environmental origins as well. Moreover, these IPCs treated not only the experience of pain but also associated patient distress, dysfunction, and disability. The major aim was to improve a patient's physical performance and coping skills, and also to transfer the control of pain and the management of its related problems back to the patient. The treatment plan was conceptualized to be rehabilitative rather than investigative or curative. It was designed to increase function so that the patient could make further changes in life quality, environmental stressors, and psychosocial factors (e.g., self-esteem and affect), all of which would assist in pain control and management. Such IPCs emphasized an integrated treatment plan that included comprehensive care such as drug detoxification, cognitive-behavioral treatment methods, functional restoration, and total rehabilitation. These more comprehensive approaches do not ignore operant factors that influence the maintenance of pain and disability. Rather, they incorporate behavioral factors within a broader rehabilitative model.

INTERDISCIPLINARY CHRONIC PAIN MANAGEMENT

The most prevalent chronic pain conditions include the following:

- Pain related to irritable bowel syndrome (20%)
- Osteoarthritis (15%)
- Low back pain (14%)
- Chronic pelvic pain (12%)
- Migraine headaches (12%)
- Chronic tension headaches (3%)
- Fibromyalgia (2%)

As noted earlier in this chapter, when pain becomes chronic, a more intensive tertiary care or interdisciplinary treatment approach is required because of the significant effects of physical deconditioning and chronic disability. The critical elements of this interdisciplinary approach are reviewed below. There have been a number of reviews that have documented the clinical efficacy of such interdisciplinary treatment of patients with chronic pain (e.g., Deschner & Polatin, 2000; Gatchel, 1999; Okifuji, 2003; Wright & Gatchel, 2002). Such interdisciplinary programs are needed for patients with chronic pain who have complex needs and requirements. Although they represent a small minority of patients with pain, there nevertheless are a significant number of patients who have failed to benefit from the combination of spontaneous healing and short-term, symptom-focused treatment. They have also become financial burdens on their insurance carriers, as well as the health care system in general. They have often

failed to experience significant pain relief after repeated and extended contacts with several different physicians and other health care providers. Psychosocial distress, physical deconditioning, secondary gains and losses, and medication issues often complicate their presentation. Therefore, this stage of treatment is much more complex and demanding of health care professionals. As such, the strengths of multiple disciplines working together to address complex issues confronting patients with chronic pain is greatly needed. The overall therapeutic focus should be toward independence and autonomy, while acknowledging when certain physical limitations cannot be overcome. The Commission on Accreditation of Rehabilitation Facilities requires that a certified pain management team include at least a physician, a specialized nurse, a physical therapist, and a clinical psychologist or psychiatrist. However, often, an occupational therapist is required because return-to-work and vocational retraining issues become important in managing patients with chronic pain.

Table 100.1 summarizes the interdisciplinary treatment team. This team consists of the following:

- The *physician* serves as a medical director of the treatment plan, and he or she must have a firm background in providing medical rehabilitation for these types of pain disorders frequently encountered. Formal training may vary from anesthesiology, orthopedic surgery, psychiatry, or occupational medicine to internal medicine. The physician needs to assume a direct role in the medical management of the patient's pain by providing the medical history to the treatment team, and by taking direct responsibility for medication management for any other medical interventions. Often, other team members and outside consultants may be involved in the medical treatment of the patient, but it is the physicians' responsibility to coordinate these medical contributions to the patient's care.

- Although not all programs use nursing services, any pain management program that provides anesthesiology services involving injections, nerve blocks, and other medical procedures will require a nurse. The *nurse* assists the physician, follows up the procedures, and may interact with patients in the role of case manager, as well as providing patient education. The nurse may be viewed as a physician-extender and educator who has a strong impact on the patient.

- Although the physician and nurse play a major role in managing the physical status of patients, the *psychologist* plays the leading role in the day-to-day maintenance of the psychosocial aspects and status of the patient's care. Signif-

TABLE 100.1
Staff Composition of an Interdisciplinary Pain Management Center

Medical Director/Physician: Serves a leadership role responsible for medical issues involved in the diagnoses and management of anatomic, pathologic, and physiologic process associated with complaint of pain.

Nurse: Serves as a physician "extender," and plays a significant role in obtaining patient histories, monitoring medications, and evaluating lifestyle issues that may affect patients suffering pain and their response to treatment.

Psychologist: Assesses the patient's psychosocial functioning, personality characteristics, social support, motivational status, and coping resources that will help treatment planning; provides treatments addressing these issues, as well as the monitoring of therapeutic progress.

Physical Therapist: Performs comprehensive musculoskeletal evaluation, including the examination of gait and postural abnormalities, range of motion, sensation, reflexes, and neurologic indices; this information is then used to specifically tailor a therapeutic program to address any diagnosed defects.

Occupational Therapist: Conducts pre- and post-treatment evaluations that focus on body mechanics and energy conservation needed for activities of daily living, work, and leisure; during treatment, supervises progressive increases in the performance of such functional activities so that patients can return to as normal a level of functioning as possible; also often serves as the liaison between employers and injured workers, and may aid in developing job modifications for accommodation of the injured worker.

Medical-Disability Case Manager: An occupational therapist or vocational rehabilitation professional often is employed to promote vocational and social reactivation throughout the treatment program and will monitor progress compliance and performance, post-program follow-up, and occupational planning and sequencing, with coordination of socioeconomic issues.

icant psychosocial barriers to positive outcomes of the treatment may develop as a patient progresses from acute through subacute to the chronic stage of a pain syndrome (as reviewed earlier in this chapter). The psychologist is responsible for conducting a full psychosocial evaluation, which includes identification of psychosocial barriers to recovery and the assessment of the patient psychological strengths and weaknesses. A cognitive–behavioral treatment approach can then be utilized to address important psychosocial issues such as pain-related depression, anxiety, and fear, as well as psychopathology. A cognitive–behavioral treatment approach has been found to be the most appropriate modality to use with patients in a program such as this.

- The *physical therapist* interacts daily with the patient regarding any physical progression issues toward recovery. Effective communication with other team members is crucial in order

that the patient's fear of exercise will not interfere with his or her reconditioning effort. The physical therapist also helps to educate the patient by addressing the physiological bases of pain, and teaching ways of reducing the severity of pain episodes through the use of appropriate body mechanics and pacing.

- The *occupational therapist* is involved in both physical and vocational aspects of the patient's treatment. The great majority of patients participating in an interdisciplinary program are likely not to be working because of their pain. Often, they have become pessimistic about the prospect of returning to work. The occupational therapist addresses these vocational issues and the physical determinants on underlying disability. This therapist also plays an important educational role in teaching patients techniques for managing pain on the job in ways that do not jeopardize their employment status. Finally, the occupational therapist can play an important role as case manager in contacting employers to obtain job descriptions and other information, as well as vocational retraining if necessary.

Constant, effective communication among all treatment personnel is required during which patient progress can be discussed and evaluated. This is important so patients hear the same treatment philosophy and message from each of the treatment team members. Indeed, many times patients are in conflict about their own future treatment and may seek out any conflict between team members and use it to compromise treatment goals.

A formal interdisciplinary treatment team meeting should occur at least once a week to review patient progress and to make any modifications in the treatment plan for each patient. Individually tailoring treatment for patients is essential. Evaluating and monitoring treatment outcomes in a systematic fashion is essential for not only treatment outcomes evaluations, but also quality assurance purposes for the treatment team.

FUNCTIONAL RESTORATION: AN EXAMPLE OF AN INTERDISCIPLINARY TREATMENT PROGRAM

In recent years, there has been an even greater emphasis in functional restoration as a driving force of IPCs (Baum, Gatchel, & Krantz, 1997). The term *functional restoration*, originally developed by Mayer and Gatchel (1988), refers not only to a treatment methodology for patients with chronic pain, but also to a broader conceptualization of the entire problem, its diagnosis, and its management. Rather than accepting current limits in history taking

---

TABLE 100.2
Important Factors That Determine the Success of an Interdisciplinary Pain Treatment Program

- Understanding and acceptance of the philosophy of the treatment program by all staff
- Systematic monitoring of treatment outcomes to maximize quality assurance
- Regular staffings to maximize frequent communication among team members and mutual reinforcement of the overall goals for each patient
- Mutual reinforcement among team members for each other's role and efforts, as well as the communication of respect for each other's skills with the patients

---

based solely on patients' self-report of pain and of diagnosis through imaging technology, this method involves more objective information. Objective assessment of physical capacity and effort, with comparison with a normative database, adds a new dimension to diagnosis. In keeping with a "sports medicine" approach, this permits the development of treatment programs of varied intensity and duration aimed primarily at restoring physical functional capacity and social performance. Objectives are more ambitious than merely attempting to alter pain complaints and to decrease medications. It is assumed that improvements in quality of life will be greatly enlarged by focusing on increasing physical capacity and decreasing social problems associated with pain. Attention is given to realistic goals such as returning to work, increasing activities of daily living, and reducing the use of the medical system. This functional restoration approach has already helped to change the focus of the traditional pain treatment programs, as well as the criteria for evaluation of effectiveness. Table 100.2 presents the important factors that can significantly contribute to the success of such programs. The clinical effectiveness of functional restoration has been well documented. Indeed, Gatchel and Turk (1999) and Turk (2002) have reviewed both the therapeutic-effectiveness and cost-effectiveness of interdisciplinary programs, such as functional restoration, for the wide range of chronic pain conditions. Fortunately, we now have in our treatment armamentarium the ability to effectively manage what used to be recalcitrant chronic pain syndromes.

MAJOR GOALS OF AN INTERDISCIPLINARY TREATMENT PROGRAM

Table 100.3 presents the major goals that interdisciplinary treatment programs should strive to achieve. As can been seen, these are all goals that can be objectively monitored and quantified. Indeed, emphasizing such objective functional and socioeconomic outcomes has been discussed

TABLE 100.3
Major Goals of an Interdisciplinary Pain Treatment Program

- Return the patient to productivity
- Maximize function, thus minimizing pain
- Patient assumption of responsibility for self-management and progress
- Reduction or elimination of future medical utilization
- Avoidance of recurrence of injury and maintenance of therapeutic gains
- Avoidance of medication dependence and abuse

by numerous clinical investigators (Feuerstein & Zastowny, 1996; Hazard, 1995; Mayer & Gatchel, 1988).

The success of the interdisciplinary approach to chronic pain management, such as functional restoration, has been unequivocally documented in a number of different investigations (e.g., Bendix & Bendix, 1994; Bendix et al., 1996; Hazard et al., 1989; Hildebrandt, Pfingsten, Saur, & Jansen, 1997; Mayer et al., 1985, 1987). For example, in the study by Mayer et al. (1987), patients who had undergone the functional restoration program were followed up 2 years after completion of the program. Results clearly demonstrated significant changes in a number of important socioeconomic outcome measures that were collected: nearly 90% of the treatment group were actively working, as compared with only about 41% of a nontreatment comparison group; about twice as many comparison group patients required additional spine surgery and had unsettled workers' compensation litigation relative to the treatment group; the comparison group also had approximately five times more patient visits to health care professionals and had higher rates of recurrence of reinjury relative to the functional restoration group. There were also significant improvements in self-report measures and physical function measures such as back strength and range of motion in the functional restoration treatment group. Thus, these findings demonstrate the significant impact that an interdisciplinary program such as functional restoration can have on a range of important self-report, physical functioning, and socioeconomic outcome measures.

Finally, it should be noted that the original functional restoration program was independently replicated by Hazard et al. (1989) in this country, as well as Bendix and Bendix (1994) and Bendix et al. (1996) in Denmark, Hildebrandt et al. (1997) in Germany, and Corey, Koepfler, Etlin, and Day (1996) in Canada. The fact that different clinical treatment teams, functioning in different states (Texas and Vermont) and different countries, with markedly different economic-social conditions and workers' compensation systems, produced comparable outcome results speaks highly for the robustness of the research

findings and utility, as well as the fidelity, of this functional restoration approach. In addition, Burke, Harms-Constas, and Aden (1994) have demonstrated its efficacy in 11 different rehabilitation centers across seven states. Hazard (1995) has also reviewed the overall effectiveness of functional restoration.

It should be pointed out that, besides functional restoration, there are other forms of interdisciplinary treatment programs for chronic pain that have been shown to be efficacious with chronic pain sufferers (Turk & Gatchel, 1999; Turk & Stacey, 1997). These other programs differ from functional restoration mainly in terms of less emphasis on the direct quantification of function used to drive the "sports medicine" philosophy of that approach. Overall, Turk and Gatchel (1999) have pointed out that the cost savings of all IPCs can be quite significant. In addition, it was emphasized that more research is needed to examine what combinations of variables are most important in being able to prescribe the most efficient and effective therapeutic "package" in an interdisciplinary treatment program. Future investigation is needed to address this important issue so as to increase the time, cost, and outcome efficiency of this promising interdisciplinary treatment approach to pain management. In addition, a review of the scientific literature by Turk (2002) compared the relative clinical- and cost-effectiveness of comprehensive interdisciplinary pain management programs, pharmacological treatments, surgery, spinal cord stimulators, implantable drug delivery systems, and conservative standard care for chronic pain. Overall, it was found that the interdisciplinary treatment programs yielded significantly better outcomes than the other treatments on the following outcomes: medication use, health care utilization rates, functional activity levels, return-to-work rates, and closure of disability claims, as well as fewer iatrogenic consequences or adverse events.

SUMMARY AND CONCLUSIONS

In a review of the literature, Flor, Fydrich, and Turk (1992) concluded that the overall therapeutic results emanating from IPCs were quite promising, with significant changes demonstrated not only in self-reported pain and mood, but also in important socioeconomic variables such as the return to work and the use of the health care system. The cost of hospital and medical charges for chronic pain have been estimated to be in excess of $125 billion (Frymoyer & Durett, 1997). Based on the meta-analysis that included 3,089 patients published by Flor et al. (1992), even when the cost of treatment of the IPC was included, Turk and Gatchel (1999) calculated a savings of over $1 billion over a period of 19 years. Recall that this is based on 3,089 patients. The market data survey (Marketdata Enterprises, 1995) estimated that more than 176,000 patients were treated at IPCs each year. Extrapolating

potential savings of IPCs would be in excess of $1.5 billion each year. Turk and Okifuji (1998) have also documented the treatment and cost benefits of multidisciplinary pain treatment centers.

Finally, it should also be emphasized that more research is needed to examine what combinations of variables are most important in being able to prescribe the most efficient and effective therapeutic "package" in an interdisciplinary treatment program. As Turk and Gatchel (1999) have concluded, to date "… there are no data available to determine what set of patients with what characteristics are most likely to benefit from what set of treatment modalities, provided in what type of format." Future investigation is needed to address this important issue so as to increase the time, cost, and outcome efficiency of this promising interdisciplinary treatment approach to pain management.

Implementing a Pain Management Program

Anne Marie Kelly, RN, BC, BSN, CHPN

> *The purpose of human life is to serve, to show compassion, and to help others.*
>
> **— Albert Schweitzer**

INTRODUCTION

Relieving pain and suffering is at the heart of the health care profession. Despite attempts at treating pain over the decades, fear of unrelieved pain remains a major concern of patients in all health care settings. In 1992, the Agency for Healthcare Policy and Research (AHCPR) published guidelines on acute pain, which state that the institutional responsibility for pain management begins with the affirmation that patients should have access to the best level of pain relief that may safely be provided. Regarding ethical responsibility, the guidelines stress that the ethical obligation to manage pain and relieve the patient's suffering is at the core of a health care professional's commitment (AHCPR, 1992). Inadequate pain management was thought to be such a wide problem that the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) published standards for the assessment and management of pain in 1999. Today, health care institutions have the responsibility and ethical obligation to develop the necessary means and resources to effectively treat pain in all patients. As the guidelines and standards focus on the assessment and management of pain, the need for programs that address pain management practices is required. The best means to ensure that all patients receive optimal pain relief is the availability of a pain management program that combines the expertise and commitment of a health care team dedicated to the prevention and treat-

ment of pain. Formalized programs are necessary to bring pain management to its rightful place in the health care system. This chapter focuses on the key components required for the successful implementation of a pain management program focused on evidence-based practice and clinical guidelines (Table 101.1).

IDENTIFY INSTITUTIONAL LEADERS

> *Well begun is half done.*
>
> **— Aristotle**

The first step should be the appointment of a task force to determine a plan of action. Seek out the "champions" in the institution who have a vested interest, are strongly motivated, have a good understanding of pain and its management, and will seek change by building a culture of advocacy. It is important to give those who feel a sense of commitment and ownership the opportunity to contribute to the development of the program. Peters (1987) suggests that those vested "look inward, work with colleagues and customers, work with everyone, to develop and instill a philosophy and vision that is enabling and empowering" (p. 482). Once the task force has been selected, conduct an institutional assessment to examine the organization's culture and its strengths and weaknesses related to current pain management practices. Health care institutions, whether they are hospitals, long-term care facilities, or home health agencies, each have their own distinct culture, which can either support or hinder effective pain management. The leaders should address the following dimensions:

1. Is pain management recognized as an institutional priority?
2. Do the policies and procedures direct pain management practices?
3. Is pain management education mandatory for facility staff?
4. Is accountability for pain management clearly defined?
5. Is pain management addressed in the Patient's Bill of Rights and the organization's mission statement?
6. Is there a pain management quality improvement process in place?

Although pain is a significant problem, it remains largely an invisible one. The task force serves as a catalyst in promoting increased visibility regarding the problem of unrelieved pain. Its focus is to collect and provide data to initiate efforts in addressing the existing inadequacies. The results can provide strong evidence pointing to the need to standardize pain assessment policies, make changes in institutional procedures, and integrate clinical guidelines that will lead to evidence-based practices (Weissman et al., 1997). Making the problem of pain visible in the institution is the initial step in developing a formalized approach to pain management.

DEVELOP A MISSION STATEMENT FOR THE PROGRAM

It is imperative that the mission statement reflect the values and purpose of the organization related to pain management practices. By articulating its purpose and what it stands for, the institution directs the work of the staff. In describing the importance of a clearly articulated purpose, Ulschak (1988) states, "until there is agreement about purpose, an institution has no direction, no tool to measure progress, no real reason to be motivated, and no clear focus for its energy." To achieve success, strong facility buy-in and commitment from the top are required. The administrator, and not just the director of nursing, must provide leadership that can result in institutional change, encourage employee commitment, and ensure improved standards of care. Leaders in the organization need to educate staff about changes in practice and their relation to the mission. Staff members must clearly see

3. Education
4. Continuous quality improvement

---

that the institution's priority and goal is to promote high standards of safe, effective pain relief to all patients within its care. Institutional commitment and administrative support constitute the foundation on which to build a quality program and are recognized as the key elements essential to success.

DEFINE STANDARDS OF CARE

Defining standards is a key step in developing an effective program. Pain management is arguably one of the most complex topics in medicine today. From dealing with acute, chronic, and cancer pain to providing palliative and compassionate end-of-life care, caregivers are faced with multiple issues that extend far beyond the question of what medication to administer. Written standards and guidelines are necessary to define the expectations of the caregivers and illustrate how the care delivery system is organized and managed. The mission of the institution sets the direction for all written standards. Standards make quality a day-to-day goal.

JCAHO set standards for the assessment and management of pain that health care institutions must implement (Dahl, 1999; JCAHO, 1999). These standards call upon hospitals, home care agencies, long-term care facilities, behavioral health care organizations, outpatient clinics, and health care plans to

- Recognize the right of patients to receive appropriate assessment and management of pain
- Assess the existence and, if so, the nature and intensity of pain in all patients
- Record the results of the assessment in a way that facilitates regular reassessment and follow-up
- Determine and assure staff competency in pain assessment and management
- Address pain assessment and management in the orientation of all new staff
- Establish policies and procedures that support the appropriate prescription or ordering of effective pain medications
- Ensure that pain does not interfere with participation in rehabilitation
- Educate patients and their families about effective pain management
- Collect data to monitor the appropriateness and effectiveness of pain management
- Address patient needs for symptom management in the discharge planning process

These standards must be included in the policies and procedures and serve as criteria by which the facility's pain management practices are evaluated. Standards of clinical practice need to be integrated and reflect the knowledge

and skills of the health care professionals (Berry & JCAHO, 1997). Clinical practice guidelines are essential to promoting optimal pain management care throughout the continuum (Spross, 1994). Clearly defined standards establish the foundation for a system-wide initiative in pain management and positively affect the quality of patient care.

DEVELOP AN INTERDISCIPLINARY APPROACH TO PAIN MANAGEMENT

Because pain is a multidimensional experience, it requires an interdisciplinary approach. Pain profoundly affects not only the physical, but the psychological, social, cultural, and spiritual dimensions of life (Ferrell, Dean, Grant, & Coluzzi, 1995; Saunders, 1984). Successful pain control requires attention to all aspects of care and suffering, and no amount of well-prescribed analgesia will relieve the pain unless the elements that are compounding the problem are addressed. Care provided by a team of specialized health care professionals is essential to treat the diverse aspects of pain. For pain treatment to be effective, institutions need to direct their attention to the importance of interdisciplinary teams who work collaboratively to overcome the inevitable barriers to pain management. The interdisciplinary team is a valuable resource that serves the institution by

- Assisting in the development of policies and procedures, offering consultation, and providing a forum for the resolution of difficult pain and risk management issues
- Utilizing standards and guidelines in developing a formulary for analgesic use including special populations
- Assisting patients with the multiple dimensions of pain management, including end-of-life care, and integrating multimodal therapy to ensure quality of life
- Providing support and guidance to families as they confront the common challenges associated with caring for a loved one coping with pain or requiring palliative care
- Promoting educational programs for families and the community that focus on pain assessment and management, barriers and misconceptions, drug addiction, and how to communicate with their physician and other health care professionals about pain

A holistic approach is critical to breaking down the barriers to pain management and is successful because it allows physicians, nurses and other clinicians to learn more about the "person" than just the disease (NIH, 1987).

TABLE 101.2
Role of Interdisciplinary Team

1. Identify patient, family, and staff needs in pain management
2. Assure pain relief goals are met
3. Collaborate with health care providers to facilitate optimum pain control
4. Promote practice changes through outcome quality improvement monitoring

A pain management team includes professionals from various disciplines who meet regularly to discuss and develop an individualized plan of care for each patient. A typical team may include one or more physicians, nurses, pharmacists, physical therapists, occupational therapists, pastoral care counselors, social workers, dieticians, and staff educators. Depending on the setting, the addition of a certified nursing assistant, therapeutic activity therapist, and trained volunteer can be helpful. A team can address the need for accountability in pain management and prevent further fragmentation of care (Table 101.2). This is the best approach for responding to pain and a critical component of an effective pain management program (Gordon, Dahl, & Stevenson, 1996).

DEFINE ACCOUNTABILITY

Accountability must be established early and clearly defined on two levels. The team members have individual accountability for integrating good pain management practices while the institution has accountability for making organizational changes that promote evidence-based practices (Spross, 2001). Team members have accountability for the following:

- Assessing the physical, psychosocial, spiritual, functional, and cultural needs of the patient
- Using standardized tools to assess the patient
- Discussing summary of findings with attending physician and making appropriate recommendations
- Updating the treatment plan with the patient and family and encouraging participation in decision making
- Implementing multimodal therapies
- Attending regularly scheduled interdisciplinary team meetings to review plan of care and problem solve
- Communicating plan of care to appropriate staff members
- Assessing for pain relief routinely throughout the course of treatment
- Educating patient and family about pain management

The institution has accountability for the following:

- Defining and implementing standards for pain assessment and treatment
- Continuously monitoring outcomes to improve pain management practices
- Establishing protocols for the safe administration of analgesics, which includes special populations
- Providing educational opportunities for staff, patients, and families
- Providing resources regarding drug and non-drug treatments

Positive outcomes are measured by the team's ability to provide pain relief in a safe, timely, and effective manner, and meet the needs of the patient and family. The following case example illustrates these points.

CASE EXAMPLE

Joe was a 79-year-old man with terminal rectal cancer who resided in a long-term care facility. He was an alert, oriented, and spiritual man who understood his prognosis and elected to receive comfort measures only. His pain had been fairly well controlled and his medications had been titrated up to 400 mg of OxyContin® every 12 hours, Actiq® 400 mg every 3 hours as necessary for breakthrough pain, Celebrex® 100 mg twice a day, and Nortriptyline® 25 mg at 9:00 P.M. Joe was able to maintain his independence and did not exhibit any major side effects from the medications. During this time, he was referred to the pain clinic for consultation regarding pain control measures. As the rectal tumor enlarged, his pain escalated and became more difficult to manage. He was once again seen by the anesthesiologist at the pain clinic who recommended the placement of a tunneled, epidural catheter for optimum pain control. Joe consented to the procedure and his attending physician agreed this was the best course to follow. However, this created a problem for the long-term care facility for the following reasons:

1. The facility had no written protocol for the administration of epidural analgesia and the nurses felt ill-prepared having little or no knowledge in this area.
2. Joe wanted to return to the long-term care facility where he felt at home and wished to die in a loving environment surrounded by staff he considered his family.
3. The facility's mission statement clearly articulated that the institution's priority was the relief of pain.

Following a discussion with administration and the interdisciplinary team, all members agreed it was the institution's responsibility and ethical obligation to provide the necessary means and resources to care for Joe during his final days. With administrative support, the members of the interdisciplinary team developed the necessary policies and procedures and provided education to the clinical staff in every aspect of care. With adequate education and support from the team, the nurses felt confident and prepared for Joe's return from the hospital. The nurses knew the moment they saw Joe that they had made the right decision. Upon arrival, Joe looked at the nurses with a smile on his face and stated, "It's a miracle. I have no pain." His pain was controlled with 1% bupivacaine and fentanyl 5 μg/cc at 6 to 14 cc/hour, and bolus doses of fentanyl 5 cc every l0 minutes via a patient-controlled analgesia pump. His pain ratings ranged from 0 to 2 and he remained comfortable until his death, 4 weeks later. Although saddened by his death, the staff's knowledge that they had made a difference in his life tempered their grief. Joe died peacefully, with dignity, and in a loving environment surrounded by dedicated staff who understood that life is a gift to be cherished until its final moments. *His wishes had been fulfilled and the facility's mission was carried out.*

During those 4 weeks, the interdisciplinary team invested all its skill and effort into relieving Joe's pain and suffering. The physician monitored his condition and ordered medications for pain control; the pharmacist ensured the medications were prepared and delivered in a timely manner; the nurses monitored him closely for pain relief and potential side effects from medications; the nursing assistants provided physical care with a compassionate touch; the physical and occupational therapists evaluated his ability to maintain optimum independence for as long as possible and made recommendations for comfort measures; the social worker listened attentively to his expressions of fear and offered support; the pastoral care counselor addressed his spiritual needs by praying with him daily and being present; the dietician monitored his nutritional needs and paid attention to his food preferences and ability to swallow; the recreational therapist provided him with musical tapes he enjoyed and taught him relaxation techniques and guided imagery to distract him from any pain; the staff educator provided ongoing education and assessed the competency of the staff; the hospice nurse offered respite care and support to the patient, family, and staff. The interdisciplinary team, composed of dedicated professionals, played a vital role in diminishing his physical, psychosocial, and spiritual pain. When team members listen, and respond to all aspects of pain, the patient experiences a feeling of worth, dignity, peace, and wholeness.

Although this was a challenging case for the long-term care facility, it was also very gratifying. The staff

clearly understood the meaning of institutional commitment and observed how a committed and knowledgeable team is vital to effective pain management.

DEVELOP AN EDUCATION PLAN

There is no knowledge that is not power.

— Ralph Waldo Emerson

Medical and nursing schools devote very little time to the subject of pain management. Health care providers cannot be expected to practice what they do not know. Inadequacies in the education of health care professionals contribute to fears and misconceptions regarding the use of analgesics, addiction, and consequently inadequate pain management (Liebeskind & Melzak, 1998).

Education is a key step in improving pain management practices that result in institutional changes. Identifying learning needs of the staff is vital to educational efforts. This can be accomplished by

- Administering a pretest to assess the knowledge level of the staff
- Involving the interdisciplinary team in conducting a survey in their areas of practice to assess learning needs of each discipline
- Using the collection data to compare institutional practice with current, evidence-based practices; this is essential for planning educational programs focused on improving staff performance
- Establishing focus groups with staff from various disciplines to gather specific data related to learning needs; including "grassroots" input is useful for correcting misconceptions and biases about pain management that exist in the institution

Once learning needs have been identified, it is important to outline an education plan including curriculum content, staff time, and programming costs. For developing an evidence-based, comprehensive pain management program, these core content areas should be included:

- Standards of practice
- Barriers and misconceptions
- Physiology of pain
- Pain assessment
- Types of pain
- Assessment tools
- Analgesics: non-opioids, opioids, adjuvant medications
- Nonpharmacological interventions
- Symptom management
- Psychosocial, spiritual, and cultural issues
- Pain management for special populations (e.g., older adults, pediatrics, chemically dependent)
- Ethical and legal issues
- Documentation

PLAN EDUCATION STRATEGIES THAT INVOLVE ALL CAREGIVERS

Organizations learn only through individuals who learn.

— Peter Senge

There are a variety of formal and informal teaching strategies as well as educational models that can enhance the learner's understanding of pain management. Educators need to employ creative ways to educate staff, patients, families, and the community in a timely, cost-effective, and informative way. Each teaching strategy is advantageous for certain outcomes and has considerations that influence its choice.

FORMAL EDUCATIONAL MODELS

Preceptorships

Preceptorships (also referred to as internships, fellowships) provide participants the opportunity to observe pain management role models in action. Program includes lectures, patient rounds and interaction, group discussions, observation of procedures, contact with interdisciplinary team members, and case studies. Participants spend days to weeks with experts to learn how to institutionalize pain management and provide evidence-based practice (McCaffery, & Pasero, 1999).

Pain Resource Nurse Programs

Many (PRN) programs are modeled after the original program offered by the City of Hope National Medical Center in Duarte, California, in 1992 (Ferrell, Grant, Ritchey et al., 1993). The purpose of a PRN program is to train a group of staff nurses to function as pain management experts. The program is comprehensive, providing didactic education and preceptor experiences to train nurses in providing safe and effective pain care.

INFORMAL TEACHING STRATEGIES

Pain Management Awareness Day

Designate a day that is set aside for pain management education. This time is a great opportunity to teach every-

one that pain management is an institutional priority. Invite each interdisciplinary team member to set up an exhibit displaying learning materials and equipment that can help participants to understand their role in relieving pain. Team members can be available at alternating times for demonstration, for skill practice, and to answer questions. Communicate this event to everyone through fliers and newspaper articles. This is an excellent way for disseminating information to staff, patients, families, other health care providers, and the public. It stimulates interest in a dynamic way and facilitates education about the different pain control measures used in the facility. This strategy serves as a great marketing tool by conveying a strong message about the organization's commitment to quality pain management practices.

Pain Management Poster Presentations

This is a unique and enjoyable way to involve all departments and demonstrate that pain management requires an interdisciplinary approach. Encourage creativity by inviting employees from all departments to design a poster of their choice related to pain management. Employees can work individually, or as a group, and are given a deadline to complete the project. Display the posters throughout the facility, providing valuable information to insiders and outsiders. Select different categories and ask some of your volunteers or family members to choose the winning posters. Offer prizes that can be donated by your consultants and vendors. Invite the winners to give poster presentations and offer participants continuing education credits. Ask the public relations department to take pictures of the activities and send an article to the local newspapers. This teaching method generates enthusiasm, teamwork, and publicity, and clearly articulates to everyone that successful pain management is the result of interdisciplinary involvement.

Portable Educational Cart

A mobile cart displaying fact sheets and equipment is another useful way to educate staff. Keep carts in an area for a specified amount of time allowing staff members to use the materials when time permits. Quizzes or self-learning modules can be given by the staff educator if validation is required. This is an easy way to impart information that does not require an explanation or discussion. Depending on where the cart is located, it can also be a good format for providing physicians, patients, and families with updated information about pain management. This activity clearly identifies that learning about pain control is everyone's responsibility.

Pain Management Bulletin Board

Employ an education bulletin board strategically placed in the facility where it is visible to everyone. The board can be used to post brochures about upcoming workshops, seminars, and programs on pain management. Post the facility's education calendar indicating the times and dates of all pain management programs. Include a spot on the bulletin board to place self-learning packets, updated articles and handouts, information on new policies and procedures, and flyers on special events related to pain management activities. This is a unique way to demonstrate to "customers" that pain management education is considered important.

OTHER EDUCATIONAL STRATEGIES

These strategies facilitate education that is system wide and promote public awareness about the institution's efforts to provide optimum pain management. It speaks loudly about the value of education to those who enter your doors.

Other methods of education can include lectures, case studies, videotapes, audiotapes, teleconferences, CD ROMs, grand rounds, skills labs, closed-circuit TV, panel discussions, seminars, and workshops. To keep educational costs at a minimum, ask members of your medical, nursing, and other professional staff who are knowledgeable about pain management to provide lectures to the staff. Videotaping the lectures is a cost-effective means of providing education to staff members who are unable to attend the presentations. Education of all staff members involved in the care of the patient is crucial for an effective pain management program. Institutions need to promote education for students involved in clinical care, and continuing education for practicing professionals to keep up with current trends and maintain their skills and competency. Knowledge about pain management empowers physicians, nurses, and other clinicians to assume their most important mission, the relief of pain and suffering.

DEVELOP A QUALITY IMPROVEMENT MONITORING PROCESS

JCAHO (1994) defines quality of care as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." Continuous quality improvement (CQI) is the key component that will help to demonstrate the pain program's benefit to the institution's mission. CQI is a process that ensures optimum pain control by building excellence into every aspect of care and creating an environment that encourages all disciplines to contribute to its success (Table 101.3). Monitoring pain management outcomes is an ongoing responsibility shared by members of the interdisciplinary team. Every organization must choose which processes and outcomes are important to monitor based on its mission and the scope of care and services provided

TABLE 101.3
Why Teamwork in Quality Improvement?

1. Instills ownership of the process
2. Involves the people who know best
3. Creates respect, cooperation, and openness
4. Breaks down barriers between departments
5. Spreads quality
6. "None of us is as smart as all of us"
- More ideas
- Better ideas

TABLE 101.4
JCAHO 10-Step Quality Monitoring Process

1. Assign responsibility
2. Delineate scope of service
3. Identify important aspects of service
4. Identify indicators related to the important aspects of service
5. Establish thresholds for evaluation
6. Collect and organize data
7. Evaluate service when indicated by the threshold
8. Take action when opportunities for improvement or problems are identified
9. Assess the effectiveness of actions
10. Communicate relevant information to the organization-wide program for continuous quality improvement

Note: From Joint Commission on Accreditation of Healthcare Organizations, 1991, Oakbrook Terrace, IL: JCAHO.

(JCAHO, 2003). JCAHO (1991) has designed a 10-step quality monitoring and evaluation process for health care agencies (Table 101.4). In that 10-step process, the first 5 steps establish the mechanism to be used for monitoring and evaluation, steps 6 and 7 encompass collection and evaluation of relevant data, and the last 3 steps reflect attempts to improve the provision of services rendered.

Performance monitoring and improvement are data driven. Institutions need to develop a formal process for evaluating the quality of pain management and collect data related to the needs, expectations, and satisfaction of the populations served. Simple ways of acquiring information from these groups include

- Periodic satisfaction surveys of patients and families including questions about pain intensity, pain relief goals, and staff responsiveness. Chart audits to assess documentation of pain assessments, patients' response to treatment, and teaching outcomes.
- Chart audits to monitor analgesic use and treatment side effects.

- Use focus groups to elicit feedback regarding pain management practices.
- Routinely schedule meetings with family members.

The detail and frequency of data collection are determined as appropriate for monitoring ongoing performance by the organization. Whenever possible, data collection should be incorporated into day-to-day activities. High-quality pain management is not a static destination to be reached, but a dynamic entity toward which clinicians must continually strive. Health care professionals must act on the basic belief that the patient is the reason for their practice.

CONCLUSION

The reward of a thing well done is to have done it.

— Ralph Waldo Emerson

Health care professionals must use their time, skills, and energy to transform their practice environments so that they support evidence-based pain management. It is crucial that quality pain management programs be integrated into all areas of the health care delivery system. Physicians, nurses, and other health care providers must convince patients and families that *pain can be relieved* and make pain control part of their clinical practice. Clinicians involved in a healing ministry must proactively promote optimum pain management, by interdisciplinary teams, who can enhance quality of life and diminish pain and suffering. Health care professionals, as patient advocates, must implement effective programs that spread evidence-based pain management throughout the organization and increase the team's capabilities to serve, to show compassion, and to help patients until the end-of-life.

Interdisciplinary Pain Management Programs: The American Academy of Pain Management Model

Alexandra Campbell, PhD, and B. Eliot Cole, MD, MPA

PROMOTING EXCELLENCE IN INTERDISCIPLINARY PAIN MANAGEMENT: THE AAPM APPROACH

The American Academy of Pain Management (AAPM) was founded in 1988 as a nonprofit corporation by Drs. Richard and Kathryn Weiner (now Padgett). The Weiners' vision was that a professional membership organization, designed specifically to meet the educational and professional needs of clinicians in the emerging discipline of inter/multidisciplinary pain management, could best accomplish its goals by offering certification of professionals, continuing education, university-based specialty training, legislative advocacy, pain facility accreditation, and outcomes benchmarking of pain program success. By 2002, when Richard Weiner passed away, the AAPM had become the largest multidisciplinary pain practitioner membership organization in the nation with 6,000 members from many different professional disciplines including medical and osteopathic physicians, chiropractic physicians, podiatrists, dentists, psychologists, social workers, acupuncturists, clergy, nurses, pharmacists, physical and occupational therapists, rehabilitation counselors, massage therapists, and others.

As Richard Weiner (1993) stated:

> The multidisciplinary team approach, as it has evolved within the context of contemporary pain management, has the unique advantage of overlooking paradigmatic blocks, turf barriers, and linear, restricted vision. The multidisciplinary pain management movement is the harbinger of integrated future health care. (p. 201)

The evidence supporting the clinical success and cost-effectiveness of the integrated multidisciplinary approach to pain management continues to mount (Flor, Fydrich, & Turk, 1992; Kee, Middaugh, Pawlick, & Nicholson, 1997), and the AAPM has demonstrated leadership in bringing this approach into the forefront of pain treatment strategies through its approach to pain program accreditation. See Chapter 100 for a detailed discussion of the multi/interdisciplinary approach to pain management.

MULTIDISCIPLINARY PRACTITIONER CREDENTIALING AND EDUCATION

Although not a requirement for pain program accreditation, the obtaining of credentialed status would be an asset to anyone directing or practicing in an interdisciplinary pain treatment program. Establishing a credentialing process was one of the AAPM's earliest goals. In 1991, 151 individuals sat for the first psychometrically validated credentialing exam, which was developed in cooperation with Applied Measurement Professionals. Credentialing by means of passing a specialty examination is a voluntary process that allows practitioners to attest to their commitment to excellence in pain management.

The AAPM credentialing examination covers the following areas: principles of anatomy and physiology; comprehensive patient assessment; developing and implementing an individual treatment plan and specific treatment modalities; education of patients, clinicians, regulators, and payers; professional, ethical, and legal practice; and outcomes measurement. Regardless of the area of professional expertise, multidisciplinary pain practitioners must have a wide range of knowledge about the entire field, including the practices of those from different disciplines. The examination is periodically updated by means of a job analysis to keep it current with the field of pain management, which is constantly evolving (American Academy of Pain Management, 1999). See Appendix C for more information about credentialing, including how to obtain a self-assessment examination to determine readiness to sit for the exam.

Continuing education is available at the AAPM annual clinical meeting and through other mechanisms. University-based postgraduate degrees and certificates in Pain Management are awarded by the AAPM-associated University of Integrated Studies. See Appendix D for more information regarding these services and programs.

PAIN PROGRAM ACCREDITATION

The April 1992 issue of the AAPM member newsletter (Weiner, 1992) announced the creation of a pain facility accreditation program. Numerous drafts of the accreditation application were scrutinized and refined by the contributions of many clinical and academic professionals through a survey of AAPM members conducted by College of Business and Public Administration, at Old Dominion University, the University of the Pacific School of Pharmacy, and the AAPM. At the same time, the creation of a National Pain Data Bank was announced for the collection and processing of pain management outcomes information. Credentialed pain professionals located across the country were recruited to receive training in the onsite facility review process. During the 1-day review process surveyors are dedicated to helping pain programs raise the bar for quality pain management.

The Joint Commission on Accreditation of Healthcare Organizations (JCAHO; 2001) adopted standards addressing pain assessment and treatment in 2001, and the Commission on Accreditation of Rehabilitation Facilities (CARF; 2003) also incorporates principles of the interdisciplinary approach to pain treatment in its pain program accreditation standards. JCAHO has published valuable resources on how to improve pain management activities in institutional settings (JCAHO, 2000, 2003). See Chapter 101 in this volume for more information on JCAHO and standards. While JCAHO accredits hospitals and CARF accredits multidisciplinary pain programs of a certain type, the AAPM provides accreditation both for large,

comprehensive multidisciplinary treatment programs and for pain management programs offered by smaller networks of solo practitioners and even for syndrome- or modality-oriented clinics.

The purpose of accreditation through the AAPM is to establish credibility for a pain program by demonstrating that patients receive appropriate services in a safe and effective fashion. Pain Program Accreditation (PPA) standards focus on an organization's ongoing business and personnel management, the physical plant (with an emphasis on safety), and the clinical services provided to patients. Much of the following material appears in the AAPM *Pain Program Accreditation Manual* (2001) and in three articles by Dr. Cole (1999a, 1999b, 1999c), which appeared in the AAPM member newsletter.

Two major distinctions are made in the PPA standards. There are *nonclinical standards* and *general clinical standards*, which must be met by all programs, and there are *classification-specific standards*, which must be met only by certain types of programs.

NONCLINICAL ACCREDITATION STANDARDS

There are five *nonclinical standards* concerning the organization's purpose and operation. These standards require a mission statement describing the purpose of the organization and the services available; written policies describing the types of patients served and/or the types of conditions addressed; specifically defined (even if broad) inclusion and exclusion criteria for services (not based on gender, race, color, creed, religion, or national origin, of course); patient education, informational, and marketing materials that truthfully describe the personnel, program, and services provided; and practitioners who possess the appropriate training and experience to provide quality treatment.

These standards are drawn from the AAPM Code of Ethics. The intent of the first five standards is to establish a commitment to pain management, to provide services in an ethical manner, and to provide services within a consistent model. When surveying a program, onsite reviewers actually look for the presence of a code of ethics and patient bill of rights (these may be adapted from the AAPM documents, see Appendices A and B); they read written policies about the services provided, patients or conditions treated; check the truthfulness of marketing and educational materials; check to see if there is evidence of appropriate training and experience for the program pain professionals (usually by reviewing curriculum vitae); and verify that the program director has the requisite skills to lead a multidisciplinary team. If appropriate, materials for special populations need to be made available to patients (e.g., non-English speaking, visually/hearing impaired). Since the Health Insurance Portability and Accountability Act of 1996 (HIPAA; Department of Health and Human Services, 2004) was signed into law and portions of this

law became enforceable in April 2003 (Privacy Rule) and October 2003 (Transactions and Code Sets Rule), pain programs are now asked if they are in compliance HIPAA. The surveyor records the answer that is given by the facility and may look for Notice of Privacy Policies, but accreditation by the AAPM does *not* certify HIPAA compliance. All programs are expected to abide by any and all federal and state/local laws that apply to them. The AAPM provides all surveyed facilities with a written notice that it abides by HIPAA rules in its dealings with surveyed pain programs and will sign business associate contracts if necessary.

Five *nonclinical standards* are in place to assess the business practices of the program. These documentation standards require written administrative policies that are reviewed and updated annually, written patient care policies that are reviewed and updated annually, necessary legal documents to engage in practice; and proof of general liability insurance, and proof of professional liability insurance. Reviewers determine that the administrative and patient care policies for the day-to-day operation of the program are adequate, and then check for creation and review dates. Having a system in place to document that staff annually reviews policies and procedures is crucial, in addition to circulating and documenting review of any new policies and procedures that may be instituted between regular annual reviews. Surveyors check for current business licenses, certificates of occupancy, fire marshal inspection certificates, professional licenses, and similar documents. Numerous insurance certificates are screened for general liability, directors and officers insurance, and professional liability. The intent of this section is to determine if the pain program is operating lawfully and that adequate patient and staff safeguards exist. The exact content of the administrative and patient care policies is not mandated, to allow each unique program the opportunity to develop the policies needed to operate. Specific insurance limit recommendations are not made except for professional liability (recommend minimum: $500,000/$1,000,000). The reviewer takes into account local variations in the business climate that may affect the types and amounts of insurance policies maintained by the program and its personnel.

Personnel management standards require job-specific descriptions for employees and independent contractors; annual performance evaluations reflecting the job-specific descriptions; written personnel policy; and properly maintained personnel files demonstrating necessary education, experience, and skills required for work. Surveyors review personnel files to see if job-specific descriptions and annual reviews exist for all employees and independent contractors.

Surveyors determine that these descriptions have been updated within the past year. Job descriptions need to be current to accurately reflect current performance. Survey-

ors review personnel files looking for up-to-date resumes or curriculum vitae, copies of licenses, documentation of training, and diplomas. To understand employee and employer expectations, surveyors read the program's personnel policy manual. Procedures for resolving grievances, dress codes, duty hours, and assignments are examples of what the surveyors looks for. Employee orientation to workplace regulations needs to be documented with the employees' signatures. Annual documentation of review of personnel policies by all employees is ideal.

Surveyors tour the building and all clinical treatment areas to make a determination about patient and staff safety. The physical plant standards require that the facility be safe for patients and staff by meeting applicable OSHA requirements; is compliant with local codes regarding access for challenged patients consistent with the Americans with Disabilities Act (ADA); has adequate ventilation and is maintained at a comfortable temperature; has written annually updated policies describing the proper handling of waste and the proper handling, storage, and disposal of medications, needles, and soiled linen; maintains electrical equipment free of obvious hazards; has emergency exits that are clearly marked and free of obstructions; has adequate regular and handicapped parking available; has an operating fire detection, warning, and suppression system; has written policies about fire drills and expected employee actions in the event of fire or other emergency situations (e.g., natural disaster, terrorist attack); and complies with local fire codes. Evidence that fire drills and other simulated emergency evacuations are carried out at least annually is important to have on file. Onsite reviewers must walk throughout the building to determine the overall level of cleanliness, ability of challenged patients to get around in the office, appropriateness of ventilation, and observance of policies about hazardous waste management. Reviewers are asked to imagine themselves in the office during different types of emergency situations including possible natural disasters or terrorist attacks. Could employees and patients exit the building without assistance? If they had challenges, could they still get out of the building? Because AAPM reviewers are not usually from the same town where the program is located, seeing a current fire marshal certificate or similar document usually resolves the issue about compliance with local fire codes. Reviewers want to see smoke detectors, fire extinguishers, and sprinkler systems if required by local codes. Reviewers do not test these items; they just determine if they are available.

Some may wonder why there are so many standards having little to do with actual patient care. These *nonclinical standards* have everything to do with ethical business practices; efficiency of practice; and the health, safety, and welfare of employees and patients. Standards have evolved over many years and have been tailored to meet the needs of pain practitioners in a wide variety of practice situations. While many are very specific, most require the

judgment of the surveyor to determine compliance. It is the goal of the AAPM to improve the programs being surveyed and to provide consultative advice during the accreditation survey process. Rather than just question the programs and their staff, PPA surveyors strive to gradually raise the overall quality of pain management services in the United States through a collegial process.

GENERAL CLINICAL ACCREDITATION STANDARDS

The National Institutes of Health (NIH) Consensus Conference entitled, "The Integrated Approach to the Management of Pain" (1986), concluded that while there are a multitude of pharmacological and nonpharmacological treatment approaches for pain, "no single treatment modality is appropriate for all or even for most individuals suffering from pain" (p. 12). Hence, the AAPM's program standards do not dictate which specific modalities must be present in a treatment program. Typically, however, multi/interdisciplinary approaches usually incorporate pharmacological, psychological/behavioral, and physical/rehabilitative components with interventional/surgical and complementary non-allopathic methods (such as acupuncture and massage) possibly being present as well (National Pharmaceutical Council, 2001). Many published clinical guidelines exist that outline the standards of care for acute and chronic pain management. These should be consulted and new publications should be monitored so that appropriate clinical practice standards can be maintained over the years that a pain program is in operation. McCaffery and Pasero (1999) have updated their extremely useful nursing education manual that discusses the mechanisms, assessment, and pharmacological and nonpharmacological treatment of all types of acute and chronic pain problems in adults, infants, and the elderly population, and during pregnancy and childbirth. Also see Chapters 101 and 103 in this volume for more information on implementing and running a pain management program.

Marketdata Enterprises (2003), in its survey of the most commonly used techniques for the treatment of chronic pain, noted a somewhat disturbing trend: the use of nerve blocks increased from 79% of pain practices surveyed in 2001 to 82% in 2003, while physical therapy use dropped from 85% in 2001 to 71% of programs in 2003. The multidisciplinary approach also declined in use from 81% of programs in 2001 to 77% in 2003. This occurred despite the evidence that questions the efficacy of interventionalist strategies and that supports the use of the multidisciplinary approach (Clark, 2000; Okifuji & Turk, 1998; Turk & Okifuji, 1997, 1998), especially where long-standing chronic pain of uncertain pathophysiology is present. Reasons for this alarming reversal of the trend

to establish multi/interdisciplinary pain care include reimbursement issues and economic pressures.

General clinical standards address the core elements of patient care necessary for all pain programs. During an onsite inspection for Pain Program Accreditation, after touring the facility and addressing the nonclinical issues, the reviewer focuses on the scope and quality of care being provided. Reviewers will want to know the schedule of team meetings, and usually staff tries to schedule a meeting for the day of the survey so that the reviewer can observe the team in action and interview each treatment provider and administrative person briefly and informally to get a sense of how they view the workings of the program. Meeting and individually speaking with the treatment team members gives the surveyor a chance to assess how the program actually works on a day to day basis. Sometimes staff will provide useful feedback for improving the program that they have not yet had a chance to communicate to management. The surveyor can then give the suggestions for change to upper management during the out-briefing at the end of the survey day.

Chart review is another crucial element in program evaluation. The reviewer needs to examine a sufficient number of clinical records to adequately address the 20 general clinical standards. Usually, at least 10 randomly chosen clinical records, representing both open and closed cases, are reviewed to answer the questions raised in the general clinical standards. If full compliance with the general clinical standards is not immediately evident, the reviewer examines 5 additional records (or more) to resolve the concerns. Reviewers may ask the facility representative to show them where in the chart necessary documentation exists demonstrating how the program is able to meet the general clinical standards. Reviewers note how many of the charts they review are in compliance with the standards and how many are missing required elements.

Necessary elements of the chart include the presence of a well-documented presenting problem with a thorough history and physical. If this has been done by the referring physician, with a more focused assessment done upon admission to the pain program, a copy of the more thorough examination report needs to be obtained by the program.

The needs of the whole patient should be addressed during the initial assessment process through adequate documentation of functional and psychosocial status. Patient interviews, exams, diagnostic laboratory tests, and scores on validated psychosocial assessment instruments should be used to develop a multidimensional conceptualization of the biopsychosocial processes that are contributing to the patient's pain problem. Individualized assessments by providers from different disciplines (when indicated) need to be clearly formulated with working diagnoses and signed notes. Initial therapeutic goals

should be formulated in clearly behavioral and specific terms with a treatment plan that the patient agrees to and signs. (AAPM provides examples of controlled substance agreements, pharmacy agreements, and treatment attestation forms to help protect prescribing physicians on its Web site.) Over time, charting should reflect progress toward these goals and/or adjustment of the goals themselves. At admission, a discharge plan with measurable goals should be formulated so that progress can be assessed more objectively. Expected timeframes for improvement and the method for evaluating treatment progress should be clearly spelled out from the beginning of treatment.

All charts need to contain an area for consultations, reports, and results of laboratory tests in addition to ongoing treatment notes from all treatment providers that discuss the relevant clinical information. Written evidence that the different treatment providers both within and from outside the facility (as when referrals are made) communicate with each other is a critical charting element. Particularly when invasive procedures are used, documentation of pain levels pre- and post-procedure through the use of a verbal or numerical rating scale provides basic outcomes information. A discharge summary documents the patients' strengths and weaknesses at the time when the bulk of treatment has been delivered and describes any specific limitations and recommendations for activity levels, employment, diet, etc. Referrals to appropriate aftercare or follow-up services should be documented. Some programs follow patients indefinitely and do not have clear discharge dates. If patients continue to be seen on a maintenance follow-up basis (for example, to prevent relapse of chronic pain behaviors), this needs to be appropriately documented as well. Sometimes individuals are designated as "program" patients during an initial period of more intensive interdisciplinary treatment, and later, after a significant portion of the expected degree of improvement in pain and functioning has been accomplished, converted to "clinic" patient status for follow-up medication management or cognitive-behavioral "booster" individual or support group sessions.

The presence of a general informed consent for the patient to be treated in the program, in addition to specific consents for individual procedures, may be useful, especially for the legal protection of the program. This general consent covers the patient who is going through the evaluation process and may have to attend several appointments before a complete treatment plan is generated and begun. It is also necessary to have unique consent forms for every type of invasive/surgical procedure patients may receive that name the procedure, note the person performing the procedure, and state that no specific guarantees are being made to the patient about the outcome of the procedure. The patient's name should appear on the consent form and the patient's signature confirms that the

patient has been informed of the common risks and benefits of the procedure and has been informed of any treatment alternatives that may be available, and that all of the patient's questions regarding the procedure have been answered to the patient's satisfaction. AAPM recommends that all of a patient's questions and the answers given be documented in order to provide extra legal protection for treatment providers. The patient needs to be further informed that consent may be revoked at any time.

Medical releases of information should be specific regarding the purpose of the disclosure and time-limited, with separate releases (even if on the same form) for treatment-related information pertaining to mental health services, substance abuse treatment information, and HIV status.

Printed patient materials that explain financial responsibilities and how third-party payers are handled can be helpful in making billing policies clear, especially for those programs where self-payment may constitute a significant proportion of program revenues.

Provision needs to be made for the secure storage of medical records, preferably in a centralized location. Access to the records needs to be restricted to appropriate staff, and there should be a designated person who is responsible for maintaining and securing the medical records on a continuous basis. HIPAA guidelines give specific recommendations for record security and these must be followed.

The importance of having a practical, consistent format for the organization of the medical chart cannot be underestimated. The medical record basically "tells the story" of the patient's journey through the treatment program, and it should be able to be "read" by the surveyor with little or no direction from staff. Clearly labeled chart tab dividers that separate elements of the chart are commonly used. A system for alerting providers to the presence of any known allergies should be conspicuous. An alert sticker can be placed on the outside of the chart, with the specific allergies listed on the inside cover, in line with health information privacy requirements.

The chart review is not intended to be a draconian process. It is a practical review of treatment records, looking for the elements necessary to accomplish the assessment, complete evaluation, and appropriate treatment of the patient with pain. Obtaining informed consent and permission to release medical records to outside entities, and establishing goals for treatment with the patient are required elements for any successful program.

Several accreditation standards cannot usually be answered in the clinical records, but can be resolved through the examination of other materials. Specialized treatment equipment and all necessary emergency equipment need to be regularly checked and certified by the appropriate state or local authority. Documentation of the certifications may be kept in an easily accessible log book.

The 510k documents for certain medical devices must also be on file. Documentation that staff has the ongoing training necessary to operate the equipment is necessary (this may be accomplished through training logs and training certificates kept in personnel files).

The final general clinical standard that is applicable to all pain programs addresses the need for the facility to be utilizing some type of outcomes measurement strategy. As this is such an important topic, it is covered thoroughly below.

CLASSIFICATION-SPECIFIC ACCREDITATION STANDARDS

The unique standards for each of the distinct classification types of pain programs are now discussed. To explain the need for the *classification-specific standards* a review of the AAPM organizational history regarding accreditation is in order.

Many years ago the leadership of the AAPM decided to offer program accreditation to all types and sizes of pain programs using different designations depending on the type and scope of services offered. It was determined not to be in the interest of the field of pain management, or to the patients served, to exclude any program that was interested in becoming accredited. Instead of accrediting only the larger university- and hospital-based programs, the AAPM developed a methodology to allow all pain programs to apply for accreditation, whether they were inpatient or outpatient in focus, large or small, or involved just a single practitioner, syndrome, or treatment modality. To meet the diverse needs of the AAPM membership and to be able to provide patient safeguards through the accreditation process, six types of pain programs were identified: major comprehensive multidisciplinary, comprehensive, small and network multidisciplinary, and syndrome and modality oriented (International Association for the Study of Pain, 1990). IASP, definitions for pain center classifications are somewhat different from those of the AAPM.)

Each classification of pain program had specific standards developed. The most detailed standards were written for the three largest and most complex types of programs. For the smaller, less-formalized programs, realistic standards were written to motivate solo practitioners and practitioners in syndrome- or modality-oriented programs to address the multidisciplinary needs of patients. A detailed definition of each type of program classification follows.

- Major comprehensive multidisciplinary pain program: Manages various types of painful conditions, conducts education/research programs, and involves a minimum of six disciplines operating within the same organization.

- Comprehensive multidisciplinary pain program: Manages various types of painful conditions, may conduct educational or research programs, and involves a minimum of four disciplines operating within the same organization.
- Small multidisciplinary pain program: Manages various types of pain conditions and involves a minimum of two disciplines operating within the same organization.
- Network multidisciplinary pain program: Generally involves a solo practitioner or group of clinicians all of the same discipline who manage various types of pain conditions by utilizing a network of closely coordinated independent professionals of varying disciplines.
- Syndrome-oriented pain program: Manages a single type of pain syndrome (e.g., back pain, complex regional pain syndrome, headache, temporomandibular joint dysfunction) utilizing one or more clinicians of the same or different disciplines.
- Modality-oriented pain program: Manages one or more pain syndromes by utilizing a single modality (e.g., acupuncture, biofeedback, counseling, hypnosis, nerve blocks, or transcutaneous electrical nerve stimulation).

Unlike the Commission on Accreditation of Rehabilitation Facilities (2003), which requires that all accredited programs have a board-certified medical director and a psychologist on staff, the AAPM system allows for programs that may be headed by a qualified multidisciplinary pain practitioner from other disciplines. The AAPM will accredit smaller syndrome- or modality-oriented programs as long as the treatment philosophy of the multi/interdisciplinary approach can be shown to be approximated through appropriate consultation and referral.

MAJOR COMPREHENSIVE, COMPREHENSIVE, AND SMALL MULTIDISCIPLINARY CLINICAL ACCREDITATION STANDARDS

Major comprehensive, comprehensive, and small multidisciplinary programs have the same *classification-specific standards*. Organizational requirements address the purpose and business structure of these larger programs. Documentation of the structure of the governing body, usually in the form of a clear organizational chart, is very helpful to the surveyor as he or she needs to quickly grasp the lines of communication and authority that exist. This chart should be made available to key employees as well. Minutes of the governing body's meetings should be kept as well as written policy that describes how authority is delegated throughout the organization. Documentation demonstrating commitment to principles of ethical leadership, how policies are determined, and institutional com-

mitment to high-quality patient care are minimal elements the surveyor will want to ascertain are in place through discussion or viewing of relevant documents. Corporations need to have a written job description for the chief executive officer (CEO) detailing the authority and responsibilities delegated to the CEO by the governing body. The CEO should be evaluated on job performance annually by the governing body.

Documentation of the business operations of the larger multidisciplinary programs needs to show that the financial affairs of the organization are managed on the basis of an annual budget that is approved by the governing body. Evidence of adequate communication between key administrative staff members should be present and may take the form of interoffice memoranda or e-mail, for example.

Clinical operations of large multidisciplinary programs can be complex, but if well-thought-out policies and procedures are in place and are clear to all staff, even the largest programs can operate quite smoothly and efficiently. During the onsite survey, the reviewer will want access to written documentation that identifies a case manager for every client/patient to coordinate true interdisciplinary care. Some programs use a patient-care coordinator instead of a nurse case manager, and of course there is flexibility with this and other of the clinical standards. What is necessary is that the program has an effective way of accomplishing its mission to provide integrated patient care and that this is clear to the reviewer. Chart notes reflecting that all patients are properly oriented to the program need to be in evidence in addition to documentation of a coordinated team-approach to treatment.

Documentation of meetings and case management chart notes indicating how treatment goals are updated and modified by the team and communicated to the patient (with their input and agreement) must be present. Staffings need to take place not less than weekly for clients in daily treatment programs. The case manager is responsible for ensuring that the necessary communication between practitioners takes place, and there needs to be a provider designated to make any final treatment decisions especially when there is disagreement between practitioners about how to proceed. Documentation needs to show that care is coordinated. Case conferences need to address goal setting, discharge planning, ongoing patient care, and modifications to the treatment plan. The tracking and modifying of goals with patient input needs to be obvious in the chart. The case manager (or another designee) is also responsible for ensuring appropriate and timely communication between the program and the patient's employer if necessary, with accurate and timely documentation of these contacts and any work-related goals present in the chart. The final duty of the case manager (or other designee) is to ensure that adequate plans are made for discharge. Follow-up appointments, any home-based services needed, along with recommen-

dations and limitations should be documented and present in the discharge summary.

As mentioned above in the section on *nonclinical* accreditation standards, if a major comprehensive, comprehensive, or small multidisciplinary program utilizes regular consultants or independent contractors to accomplish any treatment components, written agreements between the program director and the consultants/contractors that describe the specific duties and responsibilities of the nonstaff team members should be present. A length of time that the agreement is in effect should be specified so that the agreement can be reviewed and updated regularly. A personnel file should include this agreement, a copy of the consultant/contractor's license to practice, and any other documentation necessary (e.g., Drug Enforcement Administration certificate, pharmacy registration) for practice in addition to evidence of malpractice insurance in adequate amounts. An annual performance review for the independent contractor or consultant will help ensure that high standards of care are being upheld and will alert management when there is a need to consider altering or ending the relationship.

NETWORK MULTIDISCIPLINARY CLINICAL ACCREDITATION STANDARDS

Network multidisciplinary programs involve groups of independent practitioners working together to provide interdisciplinary care. In most instances, leadership for a network multidisciplinary program is provided by a solo-practice clinician. This clinician often carries the dual responsibilities of administration and patient care. It is desirable for network multidisciplinary pain program services to be provided by a coordinated interdisciplinary team; however, it is not required that the program actually employ all of the treatment team members. In most network multidisciplinary pain programs, it is common that the other team members are serving as consultants to, or independent contractors for, the primary practitioner providing care. Hence, the standard regarding personnel management for independent contractors described above applies to this type of program as well.

Organizational and business operation standards for network multidisciplinary and syndrome- or modality-oriented programs are quite similar and are in place to ensure adequate documentation of the governing body or owner/operator's policies and procedures regarding delegation of authority, commitment to ethical leadership, establishment of policy, and maintenance of high quality patient care. The governing body or person should operate with an annual budget, and communication needs to be adequate between the treatment team members and support staff (usually through documented phone contact, e-mail, and interoffice memoranda).

Clinical standards include documentation of patient orientation, and most importantly, there should be at least monthly treatment conferences (weekly, if possible) attended by team members caring for active patients engaged in regular (possibly daily) treatment. As this ideal is not always attainable when practitioners do not work in close proximity with each other, phone contact and other means of communication and records sharing may sometimes have to suffice. Network multidisciplinary programs have to be able to show the reviewer that communication between team members and the documentation of this communication is sufficient to provide truly integrated care. Patients may or may not be involved in the team meetings, and the documentation of the team meetings should be the responsibility of a designated staff member. The chart needs to show that individual case management reflects input from the team members and the patient regarding goal setting, discharge planning, patient education, and the modification of goals as treatment progresses.

SYNDROME- AND MODALITY-ORIENTED CLINICAL ACCREDITATION STANDARDS

Syndrome- or modality-oriented pain programs are also usually operated by a solo practice clinician, carrying the dual responsibilities of administration and patient care. With respect to patient care, the clinician carries the responsibility for obtaining consultations or referrals when services required by the patient are outside the scope of the clinician's training and experience, and for coordinating these referrals and consultations to effect, as much as possible, a multi/interdisciplinary treatment approach. Again, in terms of personnel management, consultant agreements are a critical component for the success of this type of program and allow for owner/operator monitoring and quality control.

The syndrome- and modality-oriented program standards covering organization, business practices, and clinical operations are similar to those discussed in the section above for network multidisciplinary programs. In addition, there needs to be evidence that the primary treatment provider makes the necessary referrals and/or seeks consultation when it is clear from the assessment that the patient will benefit from integrated multidisciplinary pain management services outside the scope of training of the primary provider. There should be close communication between the primary provider and any outside consultants and treating providers. This communication must be evident in the medical record, especially in terms of setting and modifying treatment goals.

OUTCOMES MEASUREMENT AND PERFORMANCE IMPROVEMENT

Defining, measuring, and disseminating relevant treatment outcomes information is something even the smallest pain program must do in order to remain viable in today's health care climate of increased demand for evidence-based practice and cost-containment accountability. Patients, payers, and providers are all stakeholders in the pain management process and are looking for results in terms of the outcomes variables that are important to them. Reduced pain, functional recovery, reduced need for medication, improved quality of life, and patient satisfaction with treatment are important to patients and providers. Providers, employers, and insurance companies are interested in functional rehabilitation (as evidenced by return to work) and containing the cost of treatment (as evidenced by settled disability claims and reduced health care utilization) (Okifuji & Turk, 1998). Every pain management program needs to use outcomes measurement to improve performance and address the needs of stakeholders or risk becoming obsolete as competing providers are able to prove their worth. Both JCAHO and CARF have outcomes measurement requirements for the hospitals and pain programs they accredit. *The Wisconsin Resource Manual* (Gordon, Dahl, & Stevenson, 2000), entitled *Building an Institutional Commitment to Pain Management,* outlines the steps necessary to improve pain management in different types of health care settings based on guidelines published by the Agency for Healthcare Research and Quality (1994) and the American Pain Society (1995).

Because the AAPM accredits different classifications of pain programs, the requirement for outcomes measurement must be realistically assessed in the context of the type of program being reviewed. The goal of adequately assessing treatment success and using the information gained through tracking outcomes to affect treatment quality is best viewed as a being on a continuum ranging from the use of a comprehensive multidimensional outcomes assessment instrument, such as the National Pain Data Bank, which only the larger, comprehensive multidisciplinary pain management programs may have the financial resources and workforce available to employ, to the simple use of a Numerical Rating Scale or Visual Analogue Scale (VAS) of pain intensity obtained whenever the patient is seen or before and after invasive procedures, which even the smallest program can be expected to have minimally in place. The AAPM goal is to help all pain programs raise the bar for quality care through improving and effectively utilizing outcomes assessment tools and techniques. The information gained must be useful to all stakeholders including patients, providers, and payers and be presented in a clear, concise, understandable format.

In spite of the obvious need for outcomes research in order for pain programs to stay in business, the market survey of chronic pain management programs cited above (Marketdata Enterprises, 2003) contained a shocking finding. The number of pain programs that claimed they could document outcomes data declined since 2001

from 67 to 59% in 2003. The authors stated that the main reason for the decline may be due to the increase in number of solo anesthesiologists practicing pain management. Although 87% of true multidisciplinary pain programs could document outcomes in 2003, only 40% of anesthesia-based modality-oriented programs could. This represents a decline from 1999 when fully 77% of all pain programs surveyed reported that they could document outcomes data. This trend must be reversed for the field of pain management to remain at the forefront of the integrated health care movement and to continue in its leadership role for the rest of the health care industry. See Chapter 9 for a more in-depth discussion of the importance of quality assurance and outcomes measurement in pain management.

THE NATIONAL PAIN DATA BANK

In response to the different service delivery models current in the field of pain management, the AAPM has created outcomes measurement tools that can fit the needs of different types of pain programs. Much of the following information appears in the AAPM *Pain Outcomes Profile Instruction Manual* (2004). The AAPM created the National Pain Data Bank (NPDB) outcomes measurement system in the early 1990s, as national policy makers began insisting on the use of standardized outcomes measurement approaches to assess the quality of health care. Outcomes measurement was made a requirement for the AAPM Pain Program Accreditation in 1992, and by the end of 2002 the NPDB had collected data from approximately 100 pain management programs and tracked more than 13,000 patients. The purpose of the data bank was to provide comparison benchmarks for successful treatment outcomes that could be used by the solo practitioner as well as by the large multidisciplinary treatment program. The NPDB became an important tool in helping pain management programs comply with pain outcomes measurement standards imposed by national accrediting agencies (Cole, 2000).

The NPDB measurement system consists of three separate questionnaires that a patient completes at intake, discharge, and follow-up. In addition to subscale and total scores, narrative reports may be generated at intake giving a summary description of the patient's pattern of responding on crucial dimensions of the pain experience including pain intensity, functional status, and emotional health. These are three domains recognized as crucial in determining outcomes by the IASP. Other important outcomes data such as disability status, medical resource utilization, patient satisfaction, diagnosis, and treatment modalities used are included in the NPDB questionnaires, making it a complete outcomes measurement system. Subscribing pain programs collect data and submit the data on diskette to the AAPM. Quarterly reports are generated comparing

the performance of programs that are similar in size and in the scope of treatments offered.

With the help of Applied Measurement Professionals, the University of California at San Diego, and the Department of Veterans Affairs, several reliability and validity studies were carried out demonstrating adequate psychometric properties of select subscales of the NPDB questionnaires (Clark & Gironda, 2000; Gironda, Azzarello, & Clark, 2002). One drawback to the use of the NPDB is its length. Some smaller pain programs and solo practitioners have found it challenging to allocate the staff for its proper administration, while others have been limited by budgetary constraints. Use of the NPDB was mandatory for Pain Program Accreditation in the past; however, it is no longer required. Accredited programs may create their own outcomes measurement systems. The NPDB remains a helpful tool for larger pain programs and institutions dedicated to clinical research. A modified, somewhat shorter, Web-based version of the NPDB may be available in the future. As discussed above, the decline in the number of practitioners who are incorporating outcomes measures in their pain practices may be due to a lack of clinically useful, validated, brief outcomes measures. The AAPM responded to the need for a brief measure by continuing to work with psychologists at the Tampa Veteran's Hospital.

THE PAIN OUTCOMES PROFILE

Further psychometric analysis of items from the NPDB allowed Drs. Clark, Gironda, and Young, Jr., at the Tampa Veteran's Hospital, to determine which ones had the greatest psychometric strength. They eliminated weaker items and added several new questions to create a brief pain outcomes measurement instrument that the AAPM (2004) has published under the name "Pain Outcomes Profile" (POP). The Veteran's Hospital version is called the Pain Outcomes Questionnaire–VA Short Form.

The POP is a 23-item self-report questionnaire that uses 11-point, 0 to 10, numerical rating scales to assess a number of relevant dimensions in the patient's pain experience. The POP assesses three domains of a patient's pain experience: pain perception, perceived physical impairment due to pain, and several aspects of emotional functioning. These domains are assessed using two pain intensity scales, three self-report of functional impairment scales, and two scales that address self-reported emotional functioning (seven scales total).

The POP includes 19 items that are identical to the primary pain outcomes items that appear on the POQ–VA Short Form. However, the POP contains two numerical rating scales to assess the patient's experience of pain intensity *right now* and *pain on the average during the last week*. The POQ–VA Short Form contains only one rating of *pain intensity on average during the last week*.

The POP includes the *pain right now* item as it is believed to have clinical utility. Also, in finalizing the POP, the order of the items on the instrument was rearranged so that questions from the different content scales appear in a counterbalanced fashion.

There are three scales in the domain of perceived functional impairment due to pain: Mobility, Activities of Daily Living (ADLs), and Vitality. The Mobility scale contains four items that rate a patient's perception of pain-related interference with the ability to walk, carry or handle everyday objects, and climb stairs, and whether pain requires the use of assistive devices (e.g., a walking aid or wheelchair). ADLs are assessed with four items that inquire about pain-related interference with the ability to bathe, dress, use the bathroom, and manage personal grooming. The patient's subjective feeling of a lack of Vitality is assessed with three items rating the ability to perform physical activities, feelings of overall energy, and strength and endurance. Self-reported emotional functioning is assessed with two scales. The Negative Affect scale contains five items asking the patient to rate the degree to which pain affects self-esteem, feelings of depression, feelings of anxiety, ability to concentrate, and feelings of subjective tension. The Fear scale contains two items that rate how much worry is experienced about reinjury due to increasing activity and feelings of safety exercising.

The POP can be quickly scored and a cumulative patient scoring record can be placed in the chart. This form allows for tracking of POP scale scores across repeated administrations of the measure (e.g., at intake, several times during active treatment, at discharge).

Although not a complete outcomes measurement system, the POP does provide for the assessment of seven core functional pain outcomes domains that are of interest to patients, providers, and payers. Other important outcomes that should be assessed include patient satisfaction, disability/litigation status, and medical resource utilization.

POP scores and scores on these other important outcomes variables can be placed into a computer database. Program staff should be able to perform at least basic tabulations of scores from the beginning to the end of treatment. Benchmarking outcomes against its own previous performance can at least give a pain program a sense of whether quality improvement is occurring over time.

Clark, Gironda, and Young (2003) trace the development of the final brief pain outcomes questionnaire in the 5-year, cooperative VA–AAPM project that originated with the NPDB long forms. They conclude that the new instrument is reliable, valid, and clinically useful in evaluating the effectiveness of treatment for veterans experiencing chronic noncancer pain. When comparing results from the POQ–VA Short Form and the POP for research purposes, it is important to examine only the 19 items that

the two instruments share. Additional research needs to be completed to validate the measure in different populations of patients with various types of pain diagnoses. The future of multidisciplinary pain management depends on the ability to provide the best combination of treatments for the proper duration and intensity to obtain the most cost-effective results with the appropriate patients (Chapman, 2000). The AAPM is currently partnering with several independent pain programs across the country, gathering data to further document the psychometric properties of the POP, to establish norms with different patient samples, and to help programs using the POP document and publish treatment successes. Also, the POP has been translated into Spanish and is available for field-testing and research with a Spanish-speaking population.

With the coming shift toward a "person-centered" health system (Foundation for Accountability, 2003), we hope the 21st century will see a much better educated public taking a greater role in health care decisions, practicing more effective health maintenance behaviors, and gaining a better understanding of health care financing. As patients become savvier in terms of managing their personal health information, they will begin to demand access to quality ratings of different treatment modalities based on evidence for all health conditions, not just chronic or acute pain. Somewhat akin to how *Consumer Reports* magazine publishes ratings and information regarding quality of all kinds of products for the general public, agencies responsible for maintaining standards in health care (such as the Agency for Healthcare Research and Quality) may eventually publish treatment success/cost-effectiveness information designed for the general public concerning treatments for many illnesses and disease conditions. To put it more bluntly, the need and demand for outcomes data for pain management programs of all stripes will not go away anytime soon! If anything, the need to appropriately disseminate quality information will only increase, and this information will need to be presented in different formats for different consumer groups (e.g., the lay public, payers, and health care professionals). Performance improvement and clinical outcomes research should go hand in hand. Pain practitioners need to design performance improvement projects that will lead to publication of articles in peer-reviewed journals so that the evidence base for successful multidisciplinary pain management can continue to grow. These articles can then be summarized in language appropriate for the general public and be published in relevant consumer health publications. Funding for these activities will no doubt be problematic, but strategic research partnerships between membership organizations such as the AAPM and its accredited programs may lead the way.

STEPS TO GAINING AAPM PAIN PROGRAM ACCREDITATION

A PPA brochure, manual order form, and articles describing the standards can be found on the AAPM Web site at www.aapainmanage.org. Once the decision is made to become accredited (after the program has been in operation for at least 6 months), the program director/manager completes the self-assessment found in the manual to see which areas of business, clinical, or personnel operations meet the AAPM standards already and which need to be improved before submitting the application. Facilities are encouraged to contact the Pain Program Accreditation Director with any questions or concerns during the application process for clarification. The mission of the AAPM is to come alongside each program and help the program to raise the bar for quality pain management through the consultative accreditation process. The application and self-assessment are submitted (in duplicate) with the appropriate fees along with the required program documents (also in duplicate). These consist of the patient history and physical exam forms used, consent for treatment forms (invasive procedure and/or general treatment), program description, mission statement, patient education materials and program brochures, code of ethics and bill of patient rights (both of which can be easily adapted from the AAPM documents), release of information forms, current research protocols (if any), and copies of outcome measurement and patient satisfaction tools. Resumes or curriculum vitae for all licensed professionals and clerical or support staff members that have patient contact are also requested.

Once the completed application and supporting documents have been received and processed, a surveyor is selected by the Pain Program Accreditation Director, usually near the facility in terms of geographical area. The AAPM has a highly skilled group of accomplished clinician–surveyors whose goal it is to provide expert consultative services during the 1-day review. The surveyor examines all program documents, previous accreditation reports, and resumes before the actual onsite review, thus saving valuable consultation time.

Each pain program accredited by the AAPM must pass all of the *general standards* and one of the sets of *classification-specific standards*. The period of accreditation is for 3 years if all of the standards for accreditation are met. If there are any standards not found to be in compliance, remediation is attempted immediately to bring the program into compliance. If this cannot be accomplished fairly quickly, these programs are likely to receive a 1-year provisional status. To then become fully accredited for 3 years, these provisional programs must have a second (abbreviated) onsite survey and demonstrate full compliance with the accreditation standards. Over the years that the AAPM PPA service has been available, revisions of the pain program standards and changes in the specific items surveyors are to note during their visits to pain programs have improved the overall accreditation process. The process of accreditation has become much more objective. Along with practitioner credentialing and outcomes measurement, program accreditation provides pain practitioners with another link in the "quality" pain management chain.

FUTURE CHANGES AND ADDITIONS TO PPA STANDARDS

The AAPM accreditation manual is periodically updated and revised in response to advancements in the field of pain management and new legal and ethical requirements that arise. Some areas for future revision may include

- Critical incident reporting-medication errors, equipment-related and other patient or staff injuries, incidents of workplace violence, etc.
- Corporate compliance
- Consumer involvement in performance improvement and outcomes measurement activities
- Better dissemination of outcomes data and incorporation of data into patient education materials
- Internet service security and accessibility standards
- Grievance policies for clients
- Background checks for personnel
- External financial audits
- Risk management policies and procedures

THE VALUE OF PAIN PROGRAM ACCREDITATION

Voluntary accreditation through the AAPM demonstrates to peers, payers, and patients that the pain program has submitted to rigorous scrutiny of its policies and procedures, clinical, business, and personnel practices; has met peer-established quality standards; and is committed to excellent patient care and continuous performance improvement.

In addition to the invaluable consultation that takes place during the survey process, all accredited pain programs receive an engraved plaque for display in the facility and use of the AAPM accredited pain program logo for marketing efforts. Each facility is listed on the AAPM Web site with a detailed program description and photographs of the facility and staff. The AAPM receives many calls per week directly from patients seeking treatment, and while not able to provide direct referrals, AAPM staff does direct people to its Web site to view listings of accredited pain programs and credentialed members. A link

directly to the accredited facility's own Web site can also be created if appropriate. If requested, a press release printed on AAPM letterhead will be provided to any accredited program. Programs are invited to submit updated information to the Pain Program Accreditation Director for periodic new press releases. Assistance creating clinical forms, policies, and procedures and for choosing outcomes measures is also freely given.

Future services include the availability of the Pain Outcomes Profile Plus, a computer version of the POP that gives the user instant access to individual patient data graphically displayed, which can be transferred to statistical analysis software for program-wide outcomes assessment. This computer software will also include a module that will enable physicians to document controlled substance prescribing and relevant patient treatment parameters. Other future services may include an Internet forum for accredited program staff members to provide a mechanism for networking and the sharing of information to improve pain management practices, a periodic e-newsletter for program directors/managers and staff, policies and procedures manuals (general or tailored to an individual pain program's needs), topical Web-based articles addressing such issues as practitioner burnout and patient drug-seeking behavior, downloadable examples of excellent chart documents (e.g., discharge summaries), and marketing assistance such as downloadable patient information and education brochures that increase consumer understanding regarding the benefits of seeking treatment at an AAPM-accredited facility.

The AAPM remains committed to being an invaluable resource to multidisciplinary pain practitioners and seeks to be responsive to its members' needs. Contact AAPM at 13947 Mono Way, Suite A, Sonora, CA 95370, (209) 533-9744, to learn more about the many services and tools available to multidisciplinary pain practitioners including accreditation, credentialing, education, and outcomes measurement, and to have your questions and concerns addressed.

Starting a Pain Clinic

Clayton A. Varga, MD

DEVELOPMENT CHECKLIST

1. Ask: Am I sure I want to do this?
2. Identify a leader: Am I qualified?
3. Select the clinic structure.
4. Assess the need.
5. Develop the business plan.
6. Research financial options.
7. Select the participating professionals.
8. Hire support and administrative personnel.
9. Select the site.
10. Determine equipment needs.
11. Develop the marketing plan.
12. Plan billing and collections procedures.
13. Develop a capitated contract.
14. Acquire an existing clinic.

ARE YOU SURE YOU WANT TO DO THIS?

The formation of any business requires a great deal of forethought and an investment of time, energy, and money to be successful. Starting a pain clinic is no exception. Individuals who wish to engage in the business of pain should ask themselves the following questions: Am I completely committed to the success of the business? Am I willing to be the effective leader of the business? If not, do I have someone to fulfill this function? Do I recognize that the financial aspects of the clinic require as much attention and expertise as the practice aspects? If the answer to any of these questions is no, then all further efforts will most likely be wasted.

IDENTIFY A LEADER

Ask yourself: Am I qualified by education and temperament to start and run a pain clinic? Do I possess the specialized clinical background necessary to develop and implement the needed structure for evaluation and treatment of patients in a multidisciplinary setting? Am I able to participate in the development of contracts and marketing plans and oversee administrative decisions? If you are unable to fulfill these requirements, then it is necessary to secure the participation of one or more individuals who can before proceeding to the next step.

SELECTION OF CLINIC STRUCTURE

Having made the decision to move forward, the desired clinic structure must be selected. Practice types and accompanying brief descriptions are as follows:

1. Single modality: A single practitioner (e.g., neurologist, acupuncturist, chiropractor) seeing and treating patients without regular input from other practitioners.
2. Multimodality: Practitioners of different specialties, treating patients in a similar location without regular, structured discussion of the patients by all practitioners.
3. Multidisciplinary: Practitioners of multiple different specialties, including a minimum of one representative from each of the following fields: physician, physical therapy, and psychology. Often present are occupational therapy, acupuncture, nursing, and chiropractic. The members of the clinic have made a commitment to

attend regular patient conferences and to provide integrated care of the patient.

The applicability of each item discussed in this chapter will largely depend on the clinic model developed. The less complex the model, the less important certain aspects of the development process become. However, even the simplest single-modality model would benefit from following most of the steps in the development checklist.

The more complex the structure and the greater the number of participants, the more time, energy, and money will be required to take the business from concept to a fully operational entity. The remainder of this chapter is directed toward a multidisciplinary pain clinic that has a full-time medical director and provides, as a minimum, physical therapy and psychology services and may well offer nursing, occupational therapy, and acupuncture services.

ASSESSMENT OF NEED

Once a preferred structure for the clinic has been selected, then an assessment of need must take place. The purpose of the assessment of need is to determine the demand for the product. It determines if the clinic, in the geographic area to be served, can reasonably expect to draw enough patients to pay all debt and still produce a profit. The assessment should take into account the following:

1. What is the size of the population served (i.e., what is the catchment area)?
2. What is the willingness of physicians within the catchment area to refer patients for the services you are providing?
3. Who is the competition? Are similar facilities already present?
4. What percentage of the population is served by health maintenance organizations (HMOs), preferred provider organizations (PPOs), or independent practice associations (IPAs)? What will be your ability to gain access to those patients?
5. Can you develop a relationship with an existing health care provider who will guarantee patient referrals prior to beginning operations?

The first step is to define your likely catchment area. This represents the geographic boundaries from which you can reasonably expect to draw patients. In an urban or suburban environment, this usually represents a distance of 15 to at most 30 miles from the business. Obviously, there will be regional variation in the size of the catchment area, depending on the proximity of the clinic to major transportation arteries and traffic patterns and the perceived excellence of the clinic. Once defined, the population within the catchment area should be estimated. While no hard and fast rules exist, if the catchment area has a population of less than 100,000, its ability to support a true multidisciplinary clinic or center is questionable.

Competing service providers need to be evaluated. If one or several high-quality providers already exist in the proposed catchment area, and if they have excess capacity, then concrete reasons for believing that you can capture a large enough portion of the market share to survive must be identified before business start-up. In such a situation, contracts with a PPO or IPA to be the sole provider for pain management services and verbal assurances of appropriate patient referrals from independent physicians should be obtained prior to entering the marketplace.

Talk to local HMO, PPO, and IPA administrators. Assess your ability to draw patients from these ranks. Meet with attorneys, caseworkers, and insurance carriers who are involved locally in the workers' compensation system and assess how many referrals are likely from these sources.

Having done the above, estimate the total number of monthly referrals you expect from all sources. If enough patients are forthcoming to support the business, then development of a detailed business plan becomes the next step. If patient referrals appear to be insufficient, then it is wise to explore other sources of patient referral before proceeding. If, after further exploration, more patients are not forthcoming, it is probably best to rethink your proposed catchment area, moving to one with a more favorable referral pattern.

THE BUSINESS PLAN

If, based on the assessment of need, it is likely that the business will be profitable in the selected catchment area, then a detailed business plan is developed. The purpose of the plan is to secure on paper a description of the components of the operation and a schedule of their implementation. This should occur prior to spending the first dollar on the program.

The business plan has two major components. The first is a narrative that contains a brief description of the business, in which the purpose and structure of the business are outlined. Included is a description of the personnel involved, the function each fulfills, an outline of the marketing plan, and a general description of the facility requirements. The narrative section should briefly address each of the following components:

1. The purpose of the business
2. The market niche served by the business
3. The personnel involved and the function of each
4. Facility requirements
5. Outline of the marketing plan
6. Plan for dissolution of the business

The second portion of the business plan is done as a spreadsheet. It can be prepared by hand using a large ledger sheet or more easily by using one of a number of commercially available electronic spreadsheets (e.g., Excel®).

A sample business plan for a hospital-based multidisciplinary clinic that provides primarily outpatient services is shown in Table 103.1. The business plan estimates fixed and variable costs, revenues, and the amount of start-up capital needed to begin the business and keep it running until the revenue stream produces a profit. Total cost is simply the summation of the individual cost estimates. The sample spreadsheet in Table 103.1 lists most of the individual cost estimates that are required for a multidisciplinary clinic. Each expenditure is estimated on a month-by-month basis for at least 1 year and entered into the spreadsheet. This produces a time estimate of how long it will take to generate a profit and estimates the revenue position of the business at any point along the time line.

The cost estimate should be as detailed as possible. It is possible to accurately predict almost all of the costs, especially fixed costs, when doing the business plan. This is in contrast to revenue estimation, which will be, at best, a rough guess. Nailing down the cost projections as accurately as possible will, in turn, allow for the greatest possible accuracy in predicting the net revenue estimate.

It is best to shift as much of the cost as possible from fixed to variable. This minimizes expenses when revenue is low. Several examples of doing this are hiring personnel on part-time or flexible-time schedules, increasing hours as patient load increases, and having billing and collection done by an outside service, with cost based on a percentage of collections.

Obtaining the revenue estimate requires developing an approximate charge per patient. If the clinic is based on one or several structured programs, in which each patient participates in a relatively uniform program for a predetermined length of time, then average charges are easy to estimate. If the clinic structure is such that revenue generation is spread over a wide range of activities, then generating an average charge per patient is more difficult. In this situation, it is necessary to develop multiple average patient charges and estimate what portion of the total predicted patient flow falls into each group.

Subtracting total cost from total revenue yields the predicted financial position of the business at any point along the time line. It is wise to do estimates using best guess, worst case, and best case revenue projection scenarios. If you are prepared to survive the worst case scenario, then the business should succeed.

FINANCING

The business plan will project the necessary capital required for business formation and development. The most common cause of a new business failure is under-capitalization. It is important to generate at least as much capital as is required based on the business plan. It is also wise to have a credit line available for emergencies. Once capitalization requirements have been determined, options for obtaining the capital must be explored. Numerous financing possibilities exist. Those most commonly employed are as follows:

1. Joint venture: This almost always consists of a limited partnership. The limited partnership consists of both limited and general partners. The general partners oversee the business formation and development and have a greater degree of legal responsibility should the enterprise fail. Limited partners invest money into the partnership but are passive in the business formation and development. Their losses are limited to their investments.

    An example of a joint venture is as follows: The director of the proposed facility develops a detailed business plan. A lawyer is hired to prepare a joint venture agreement, wherein the director is the general partner and the individuals supplying the money are limited partners. The director oversees the development and daily running of the business, for which he or she receives a portion of the profits generated by the business. The director may also receive monies generated via professional activities carried out at the business. The remaining profits are disbursed to the limited partners.

2. Borrowing of money by one or several individuals from conventional lending sources (i.e., a practice loan).

3. Utilization of personal capital to begin the business.

SELECTION OF PARTICIPATING PROFESSIONALS

The type of clinic or operating structure chosen will determine the professional components of the clinic. The quality of the professional personnel will be one of, if not the most important determinants of success. Careful thought must be given to this topic. Not only must the professionals be well trained in their own disciplines, but they must understand the fundamental difference between practicing in a unidimensional office versus a multidisciplinary setting. They must be willing to make what are often perceived as personal sacrifices to make the system work and to regularly attend patient conference meetings and provide input in those meetings in a useful fashion. They must understand the need to promote the clinic as an entity, as well as themselves as individuals, and be willing to defer

[a] Employee benefits calculated at 28% (e.g., medical/dental/workers' compensation insurance/FICA/FWH labor costs will vary, depending upon urban location).

[b] Medical director and psychologists can be paid on a 1099 basis, assuming IRS criteria are met.

[c] Physical therapist's employee benefits 30%.

[d] This individual could function in a marketing capacity in addition to nursing/social work duties.

[e] Federal taxes in first year will be based on the NOI plus capitalized investment not written off in first year.

[f] Capital expenses and office rent could be what joint venture partners might provide for an equity interest in the clinic business. Note that both capital investment and business start-up are paid back in the first year of operation.

[g] Net operating income in the first year is a function of how quickly the marketing strategy/plan can tap into the clinic's catchment referral sources such HMOs, IPAs, personal injury attorneys, and workers' compensation caseworkers/attorneys.

at times to other members of the team in the treatment of any particular patient. Many physicians and other professionals are not suited by character to function easily in such an environment and, despite any academic or other professional qualifications, are best excluded from the multidisciplinary setting. When selecting clinical members for the team, consideration of board certification in pain management should not be overlooked.

SUPPORT PERSONNEL

Personnel to perform all of the nonpatient care activities are obviously necessary for the business to function. These areas include billing and collections, reception, ordering of supplies, scheduling, transcription, and paying bills, to name a few. These individuals should already have been taken into consideration as part of the business plan. All of these people need not be hired at the beginning of the business. It is preferable to keep start-up fixed costs as lean as possible. Even a multidisciplinary center can easily start with a single support person if time-consuming tasks, such as billing and transcription, are subcontracted to outside firms. This plan has the advantage of changing a fixed cost to a variable cost, which will be much cheaper when patient volume is low. As patient volume rises, these functions can easily be transferred in-house at such time as it becomes financially advantageous to do so.

If one individual is initially hired, then this person should be told that he or she is expected to be a jack-of-all-trades. This individual should also be someone who can become the office manager as other employees are put in place. The author believes that it is cheaper to hire one well-paid, highly motivated employee than two poorly paid, poorly motivated employees. As the business matures, additional employees can be added as need dictates.

SITE SELECTION

Having decided on both the general geographic location and the specific structure of the clinic, it is possible to begin specific site selection. If a joint venture with a hospital has been undertaken, then the hospital may have unused space that can serve as the clinic site. This has several advantages. It serves to bind the interests of the hospital and the clinic. It provides the clinic with some instant name recognition, if the hospital name is incorporated into the clinic name, and it may help speed referrals to the clinic from members of the hospital medical staff. It also allows easy proximity between inpatient and outpatient care, if both are provided. The hospital may allow the space to be used in exchange for equity in the business, thus limiting operational costs.

If an off-hospital site is selected, then several factors need to be taken into consideration: proximity to other doctors' offices, ease of access to the likely patient base, cost per square foot, the ability of the site to be tailored to your needs, and the ability to expand into adjacent space in the future without having to relocate.

How much and what type of space will be needed will be determined by the clinic structure. Office rental cost represents one of the largest fixed expenses. The clinic structure should be well planned to maximally utilize each square foot of space. Initially, some, if not all, of the professional participants will have other practice locations. It is less expensive to time-share offices between practitioners, and it is unusual for all individuals to be seeing patients at the same time.

EQUIPMENT

Equipment used in a multidisciplinary pain clinic will depend on the clinic structure. If the clinic site is within a hospital, often all of the diagnostic, occupational and physical therapy, and procedural (nerve block, laboratory testing, radiologic, and operating) equipment and facilities are already available. Supplying a site with the ability to see patients for medical and psychological evaluation, basic physical therapy treatment, minor office procedures (such as certain types of nerve blocks), relaxation training, biofeedback, and group as well as individual psychotherapy will require an expenditure of $100,000 to $150,000. This includes the purchase of furniture, exam and treatment tables, office and medical supplies, biofeedback equipment, fax, computers, photocopy equipment, and a phone system.

MARKETING

It is important to have an overall marketing plan that extends for a period of several years. This should take into consideration how much money is to be allocated to marketing efforts and what types of advertising and other promotional projects will be undertaken. It is not possible to be all things to all people. The marketing plan needs to reflect the market niche and present a consistent message.

Marketing medical services is a complicated and sometimes delicate job. Ethical standards regarding medical marketing vary regionally, and knowledge of local standards is crucial prior to beginning the marketing program. Being the first to employ a specific type of advertising in an area (e.g., radio commercials) can have a negative impact with referring physicians. However, certain techniques (discussed below) can be used in any environment.

Announcements and brochures should be sent to referring physicians, workers' compensation caseworkers, and attorneys. These should be mailed shortly after opening the practice. The announcement should be mailed first, with the brochure to follow 1 to 2 months later. This

reinforces your message and is more effective than sending both at the same time.

Taking the time to personally contact and talk to local physicians, workers' compensation caseworkers, and lawyers is important in building referral patterns. PPOs, IPAs, and HMOs control a majority of the patient population in many areas. The clinic director must take the time to educate and negotiate with these groups to secure appropriate patient referral.

Lectures and community forums are useful tools for educating referring physicians as well as potential patients not only about the problem of pain, but also about your business. Professionally prepared stationery, the development of a logo, and production of a newsletter are all effective means of advertising. The clinic's listing in the local phone directory should be easily visible. Radio, television, and print media all offer opportunities for exposure. These represent expensive and potentially sensitive areas of advertising for which local ethos should be considered and professional marketing help engaged.

A presence on the Internet by individual health care providers is becoming progressively more common and in the near future will become ubiquitous. A basic Web site can be developed and hosted by a good commercial Web development company relatively inexpensively. This provides an excellent avenue for continuous marketing exposure and a way for patients, providers, and third party referral sources to access information about your program at their convenience. A basic site would include information about yourself and any other service providers in your practice; your location including directions, office hours, and phone numbers; and a description of the services provided. More detailed sites can also include information about specific procedures performed by you or your colleagues including photographs or even short video segments, hot links to other complementary Web sites, and informational databases. Your Web address should be included on your business cards and all other promotional materials and activities. The author recommends dealing with an experienced Web development and hosting service. Consider starting with a basic Web page that allows for some scalability. This way you can add features or increase the complexity of the site without losing your investment in the initial development.

Advertising and promotion make physicians and patients aware of the services the clinic provides. They do not replace the need to provide concerned, compassionate, and effective care. If the office is disorganized, the receptionist curt, or physicians and therapists chronically late, no amount of advertising can overcome the bad will spread by irate patients and referring physicians.

BILLING AND COLLECTIONS

Even the best conceived and instituted treatment program will not succeed if efficient billing/collections operations are not instituted from day one. Billing and collections can be done internally or subcontracted. This decision should be made while formulating the business plan. The billing system should be in place before the first patient is seen.

A number of local and nationwide medical billing services are available and usually charge between 6 and 10% of collections. Interview several and consider not only the cost, but also the comprehensiveness of the service rendered. Look for a company that has some expertise in billing for a similar entity or is willing to invest the start-up time to learn the peculiarities of the field. Billing externally can significantly reduce capital investment at the time of business start-up and help to reduce fixed costs at a time when cash flow will be slow.

If billing is done internally, the appropriate software, hardware, and support forms to carry out the task must be purchased. It is important to hire someone with previous billing experience to make the system work. There are numerous companies that sell medical billing systems, with a large range of capabilities. Billing, collection, scheduling, accounting, and payroll functions are all available. Software and hardware can be purchased separately or as a complete system. Prices range from $1,000 to $50,000 or more, depending on the system.

DEVELOPING A CAPITATED CONTRACT

Payment for pain management services has transitioned from a fee-for-service only model to a capitated model in some environments. The extent to which this has already occurred varies dramatically from region to region. In some large metropolitan areas, the market share of managed care exceeds 80%. In other areas, managed care penetration is almost non-existent. Managed care in the form of HMOs has stalled in its growth beginning in the late 1990s and in fact has retracted to a small extent in the Western United States and has contracted significantly in many other areas of the country. Market-driven national healthcare reform has shifted to the PPO model with price control being exerted through benefit limitation, higher out-of-pocket expenses for the insured, and further erosion of payment to physicians. This shift will most likely continue at least into the near future, absent any other national or regional political agenda. It is necessary in some geographic locations for the successful provider of pain management to understand the differences between fee-for-service and capitated reimbursement models and to be able to negotiate a good capitated contract.

In a capitated contract, the clinic receives a payment each month based on the number of members covered by the contract and the rate per member (the per member per month, or PMPM, rate). If the contract covers 50,000 members at a rate of $0.40 PMPM, then the payment would be $20,000 a month. This is independent of the

actual number of patient visits, supplies used, or resources consumed in a particular month. If the cost of service delivery for the month was $15,000, then a $5,000 profit would be realized. Obviously, if the cost to deliver care under the contract was in excess of $20,000 for the month, then a loss would be incurred.

To be able to develop a price structure that makes sense, the following information should be obtained and analyzed:

1. The utilization rate for the current procedural terminology (CPT) codes covered under the contract for the most recent 12-month period for the population in question.
2. Your actual reimbursement for each CPT code by insurance type. The most important, of course, is the reimbursement from the entity with which you are negotiating, if you have previous claims experience with that entity.
3. Knowledge of the range of cap rates for similar contracts in your immediate or similar geographic areas.

The above information will allow you to develop a PMPM rate that will maintain profitability. You should develop a PMPM rate based on your own analysis of prior utilization. Then check this against other contracts as a safety check. Obviously, rates can vary extensively depending on which CPT codes are covered by the contract.

It is important to build the following safeguards into the contract:

1. Input into if not direct control over utilization. If you accept the risk of fixed payments, then you must be able to control utilization to help mitigate that risk.
2. Renegotiation of the contract if actual utilization significantly exceeds projected utilization.

It is important to have in place a system to monitor utilization prior to beginning the contract. Utilization information, along with expense information, will be needed to determine the profitability of the contract. It is important to monitor this closely and move to renegotiate unprofitable contracts quickly.

ACQUIRING AN EXISTING CLINIC

Acquisition of an existing practice or clinic provides an alternative to starting a clinic anew. Over the last two decades the number of pain clinics and the number of trained providers have increased phenomenally. As some providers mature to the point of retirement, they must choose an exit strategy and some of these individuals, and small groups will conclude that a sale of the practice or clinic is the best strategy.

Acquisition of an existing clinic does offer some advantages over starting a clinic from the very beginning and may be the best way to enter into an already saturated market. It provides an opportunity to obtain referrals and establish contracts quickly and provides historical financial information that can be evaluated and valued in an objective way. However, one should be aware of the numerous pitfalls that exist in the purchase of any business entity and these include but are in no way are limited to the emergence of unforeseen liabilities such as lawsuits attached to the entity after the deal closes, the inability to maintain existing contracts or referral patterns, and overvaluation of the accounts receivable. It is mandatory to seek professional financial and legal assistance in the evaluation, appraisal, and deal negotiation. A number of good texts exist and a good overview can be obtained by reading Krallinger (1997).

Going Insurance Free

Thomas J. Romano, MD, PhD

PROLOGUE

"Physician Shortage Predicted to Spread" was one of the headlines on the front page of the January 5, 2004, issue of *American Medical News* (Elliott, 2004). Sadly, doctors have been dissatisfied with the "system" for many years. Loss of autonomy, increasing malpractice premiums, and declining reimbursement top the list of reasons for this state of affairs.

Before I severed all ties with third-party payers in the mid-1990s, I was about to contribute to this practitioner shortage. My ability to provide quality care to my patients was being threatened by ever-increasing distraction and interference from clerks, bureaucrats, and other paper pushers who wanted to influence how I treated my patients. This sad refrain ran the gamut from their insistence on my prescribing generic drugs over brand name medications to when I must discharge a patient from the hospital. Stresses mounted. The cost of malpractice insurance skyrocketed. Overhead crept inexorably higher. Worst of all, respect for patient and practitioner alike diminished significantly. There seemed to be no end in sight to mounting pressures and plummeting satisfaction with my practice situation. In short, I had had enough. I decided that I would either have to change my profession or take charge of my medical practice — and my life. I identified the problem and took steps to solve it. This is how and why I did it. Perhaps you should consider this course of action if you no longer find joy and satisfaction with your practice.

INTRODUCTION

In a previous edition of this textbook, the chapter on this topic was written by Dr. Christopher Brown (Brown,

2002). In his comprehensive, practical, and inspirational writing Dr. Brown put forth a strategy for achieving an insurance-free practice. Rather than try to do the impossible, that is improve on Dr. Brown's chapter, I will endeavor to describe what I believe to be the important issues regarding the present health care reimbursement process, briefly set forth the evolution of my practice to a pure fee-for-service one, and describe why I believe the best method of practice is a fee-for-service one not only for the good of the practitioner but also in order to get the most effective treatment for the individual patient. However, while an insurance-free practice may work for some practitioners, it may not suit your situation.

My intention in writing this chapter is not to try to convince the readers to change the way they run their practices. Rather, it is to present an alternative to the "system" — one that I have found not only appealing for a variety of reasons but one that allows me the freedom and flexibility to best evaluate and treat my patients. I stress the word "my" because it is I who has the moral, legal, and ethical responsibility and accountability for their care. I alone — not the third parties — am in the best position to care for my patients. Why listen to reviewers who have not even met my patient? Why allow nonprofessionals (i.e., chair-bound "paper pushers," clerks, etc.) to set professional fees? Why kowtow to so-called "peer-reviewers" when you know you can do a better job? Why let third parties dictate the way you practice? It is *your* practice! They are *your* patients! If a professional license is required by the state for an individual to lawfully practice, how is it that third parties dictate how patients are treated? Make no mistake about it — nonprofessionals make practice decisions all the time. I am not responsible for law enforcement casting a blind eye to the routine

commitment of such felonies, but I am responsible for how I treat my patients.

If you are truly happy and satisfied with your present practice situation, there is no need to read on. However, if you are sick and tired of ever-decreasing autonomy and steadily declining reimbursement, this chapter may be of benefit. Remember, it is your life; it is your practice; they are your patients! Strive to practice for mutual benefit of patient and practitioner. What other entity deserves consideration?

THE ABUSED CLINICIAN

When asked by a patient what to do in an abusive situation, the clinician is most likely to respond with the advice that one should get away from that situation as quickly as possible and to take control over his or her life. For example, if a woman is married to a man who is a binge drinker and suffers physical and verbal abuse whenever her spouse gets drunk, that woman should not suffer the abuse; she should take control of her life and get herself into a situation where further abuse is not likely to occur. It really doesn't matter whether the abuse occurs on a weekly basis or a monthly basis, whether the husband is a good provider, or whether he pleads and begs for forgiveness. One must judge a person by his acts, not only his words and there can only be reconciliation if there is true remorse and no further abusive behavior.

It is my contention that the relationship between third-party payers, whether the clinician is dealing with Medicare, Medicaid, HMOs, PPOs, etc., is such a situation. The individual abused is the clinician. The abuser is the third party. That is not to say that every interaction between the clinician and the third party is one in which the clinician is harmed. In fact if that were true, no one would deal with third-party payers. Rather the interaction between the third-party payers and clinicians often results in a reimbursement check or a promise for prompt payment. I contend that the actions of third-party payers are perfidious and disrespectful toward clinicians. Furthermore, I do not believe that they will reform. Thus, I have nothing to do with them. I don't submit claims to them; I don't speak with them over the telephone; I don't send them medical records without prior authorization from the patient and payment for said records in advance; I ignore their suggestions regarding the treatment of my patients; I practice medicine as if they did not exist. This seems like a radical step, but wasn't that the way medicine was practiced for untold millennia up until about a generation ago? It works for me. I am happier. My overhead is lower. I try to keep it simple. The patient comes to me for help. I provide advice and help to the best of my ability without influence from third parties. Because I have the moral, ethical, and legal obligation to provide the best care I can

for my patient, I reserve the right to manage the patient the best way I know how. It's that simple.

This chapter is presented in several sections. The first section deals with my own practice and my journey to my present position. The second section points out the various and sundry injustices and pitfalls that abound in today's practice climate, and the third section deals with how any pain practitioner can establish a practice free from third-party influence. However, I must warn you at the outset that not everyone can do this. If you are mediocre, you may need to belong to an HMO or deal with other managed care because many patients make their decision regarding their health care entities based on finances. If you don't keep up and you have nothing different to offer from other practitioners in your community, it may be best to remain "in the pack" instead of striking out on your own. However, if you have excellent skills and believe, as I do, that "guidelines" may not take into account the unique needs of each individual patient, then going insurance free may be for you.

MY JOURNEY

Before I put out my shingle and announced to the world that I was opening a medical practice, I made sure I got good training. Not only did I graduate from an excellent medical school (New York University School of Medicine), I also took a very demanding but incredibly rewarding internship and residency program at Bellevue Hospital/University Hospital in New York City, following that up with a rheumatology fellowship at Barnes Hospital/Washington University in St. Louis Missouri. By the time I opened my practice in 1982 I had gone to school 27 years, 15 years after high school! I had become board-certified in internal medicine and was to become board-certified in rheumatology a few months after opening my practice. I resolved to keep up and regularly went to the rheumatology grand rounds at the University of Pittsburgh, which at that time was headed by Gerald Rodman, a true giant in the field. I resolved to do the best I could to take care of my patients, which included not only keeping up with the medical literature but going to conferences and learning as much as I could about their conditions — often chronic, almost always painful ones. I also quickly obtained staff privileges at four of the local hospitals admitting patients and also doing consultations when asked. In short, I believed I was quite well prepared to care for patients in the private practice setting. Little did I realize that it was not going to be so simple.

In my first year of practice I pretty much dealt with every third-party payer in the area. I was quite naive about the business aspects of the practice but learned quickly. However, learning can be painful, and it happened to be just that for me. After my first year in practice, my collection rate was approximately 50%. This was quite dis-

turbing and I tried to remedy the situation. One of the problems was that one of the local health insurance carriers did not reimburse for trigger point injections! I negotiated with them and told them that trigger point injections were, in fact, good general medical practice. The insurance company responded with a request for documentation of my assertion. This I did by sending them photocopies of journal articles and textbook chapters from numerous sources including Janet Travell, David Simons, and others. After submitting the documentation, which clearly showed that trigger point injections were a generally accepted mode of medical treatment, I was still not reimbursed for them! I thought this quite odd in that documentation had been requested, I provided said documentation, and having done so, rightfully expected that the problem would be rectified. That was not to be the case. I still did not get reimbursed for the injections. Needless to say, I decided not to renew my contract with that carrier. "Fool me once, shame on you; fool me twice, shame on me." That was 1983.

In 1984 Medicare started doing very strange things. It required that physicians, not patients, submit claims for reimbursement. This shifted the burden from the patient to the physician. I had to hire another secretary to keep up with the paperwork. At that time there were only two categories with which a physician could deal with Medicare. The first was called a "participating physician." As such a physician, a doctor would basically accept assignment from Medicare. The doctor could charge whatever he wanted but Medicare would reimburse at whatever rate it wished. The other category was "nonparticipating." To be a "nonparticipating physician," the doctor would not accept assignment from Medicare but could only bill up to a certain amount predetermined by the Medicare carrier. I thought this was also quite strange. How could one deal with an entity and not participate with that entity? It seemed that the term "nonparticipating" could not apply to the situation in which a clinician was, in fact, participating, albeit at a different level. This was another lapse of logic which I again found curious. However, I was still naive and trusted "the system," so I plodded on.

I joined a local IPA/HMO around that time. I had no burning desire to do so. It would seem that I succumbed to peer pressure. Many of the primary care physicians in the area told me that they wanted to refer patients to me but because I was not on the panel of the IPA's participating providers they could not do so. Thus, I signed a contract with the local IPA/HMO with the understanding that although I would get around 85% of my fee in payment, I would make the medical decisions without interference. Needless to say, I severed ties with that entity in 1988 because of disagreements over many of their policies. I did not think that their policies were fair, and I saw that things were quickly going from bad to worse. So, I decided to get out of that situation.

Having opened my practice in 1982, I immediately started doing clinical research regarding patients I was seeing and their response to various treatments. At that time there was very little literature on fibromyalgia syndrome (FS), and because I was seeing a lot of patients with FS, I decided to make observations regarding their presentation, diagnosis, treatment, comorbid conditions, etc. I noticed that many of these patients developed fibromyalgia as a result of a traumatic event. I looked into this as well and eventually published my results in the *State Medical Journal* (Romano, 1990). Other studies followed (Romano, 1998; Romano & Govindan, 1996). I first testified in court in a post-traumatic fibromyalgia case around 1987. The patient had been referred by a family doctor, but eventually I learned that she was represented by an attorney. The patient prevailed in the lawsuit and I started getting referrals from attorneys who had clients involved in motor vehicle accidents, workplace injuries, etc., and who were not responding well to treatment. Many such patients had myofascial pain syndromes and/or fibromyalgia, which had not been recognized and therefore went untreated.

As I started getting more and more patients who had suffered trauma and was also treating patients with various other problems such as systemic lupus erythematosus, rheumatoid arthritis, and Wegener's granulomatosis, I came to the realization that I needed to spend more and more time with each patient because of the nature of these patients' extremely severe and complex problems. This was becoming more and more difficult because my attention would constantly be diverted from direct patient care by messages and inquiries, which I believed were nonsensical at best and downright dangerous at worst. For example, the pressure placed on physicians to discharge patients from the hospital after they had been in the hospital a set number of days or weeks can obviously be very dangerous in that no two patients are alike and response to treatment can vary tremendously. Two experiences in my own practice immediately come to mind.

When asked by a claims reviewer when a certain patient was going to be discharged from the hospital I gave the answer, "When the patient is better." The clerk on the other end of the phone line had the audacity to tell an attending physician whose patient's health and life hung in the balance, "That's not good enough!" How absurd! I quickly responded, "It's good enough for me and that's what counts!" I took pleasure in ending the telephone conversation so abruptly. Now mind you, phone calls like these would regularly interrupt my day, breaking my concentration, and otherwise being extremely annoying and unproductive. In fact, they are probably counterproductive in that it would now take me more time to focus on the patients I had in my office, their unique problems, and their particular difficulties. Another strange interaction that I had over the telephone was with someone who claimed to be a

doctor reviewing the case of a patient I had in the hospital who suffered from a very dangerous medical condition. After speaking to this reviewer for about 5 minutes, I got the impression that he could not understand what I was telling him. My explanation to this doctor/reviewer went something like this: "This man has Wegener's granulomatosis! He was near death when I admitted him to the hospital. He is recovering now but has a long way to go." After a few moments of silence the voice on the other end of the telephone asked the question, "What is Wegener's granulomatosis?" *O tempura! O mores!*

The ground was made even more fertile for my having nothing to do with third-party payers when I received a notice from Nationwide Insurance Company in January of 1991 that, as the Medicare carrier for West Virginia and Ohio at that time, it had decided to lower the amount of money I could charge for services to Medicare recipients. It is important to note that that entity was not announcing to me that it was unilaterally decreasing benefits to Medicare recipients, but rather was telling me how much money I could charge in my office for the treatment of my patients for whom I took responsibility. I thought about it for a bit and decided that if my name was on the door, and I alone would make my office policy including how much I would charge, what my hours would be, etc. I resigned from Medicare the following day.

At that time it was illegal for a physician in the United States to treat a patient covered by Medicare Part B (the outpatient portion, Part A being the inpatient portion) privately. That is, any interaction between a Medicare recipient and a physician had to be reported to Medicare, which then controlled what moneys could be reimbursed to the physician if the physician was participating, or controlled how much money a physician could charge if the physician were "nonparticipating." Using the following logic, I had no choice but to no longer see Medicare patients. "I am in private practice; Medicare prevents its recipients from seeing doctors in private practice; ergo I can no longer see Medicare patients at all." I had to tell my Medicare patients that I could no longer take care of them and that they would have to get rheumatological care elsewhere. I was more than happy to see them privately but that was illegal.

This egregious situation was changed in 1998 by an act of Congress. Now, if a physician elects to "opt out," he or she could see Medicare patients legally, that is, on a one-to-one basis without interference from that governmental entity. However, this was not an ideal situation because the patients could not get reimbursed for any of the moneys they spent seeing me. This strategy was clearly meant to discourage patients from going out of "the system" to seek medical care privately from a doctor who elected to "opt out." It would have certainly been much fairer for the benefit to be given to the patient to be used wherever he or she wished to use it. Thus, the patient

could pay my fee, submit my bill to the government, and be paid whatever it would pay for that particular service whether it be for a Medicare provider or not. However, that is not the case. In order for me to "opt out," I had to notify the Social Security Administration, renew my "opt out" status every 2 years, and have patients sign a disclaimer in which they acknowledge that I do not deal with Medicare and that they would have to pay my fees out of their own pocket.

As each individual health insurance company became more and more incompatible with my office policy, I would simply sever my relationship with that carrier. By 1995, I was totally insurance free. I do not regret that decision. I have more control over my life. I no longer have to hire clerks to deal with insurance companies. I make decisions based on what I believe to be correct, and I have far more time to spend with each individual patient because I am no longer distracted by having to deal with third-party payers.

However, being "insurance free" is challenging in that I have to keep up and be able to offer treatment that is "cutting edge." Furthermore, I tend to see more difficult patients in that I have become in some cases the doctor "of last resort." Many individuals have gone to the practitioners "on the list" of providers that are preferred by their insurance companies. Not satisfied with the care they received from those "in the system," they sought me out. I pledge to each and every one of them on the initial visit that because they are employing me, I have undivided loyalty to them, not caring what some clerk or reviewer has to say about their care. I pray each day that I can be worthy of their trust and confidence in me, but of one thing I am certain, no one will interfere with their care if I have anything to say about it. I have an obligation to my patient, to my profession, and ultimately to myself. Of course, I have to be mindful of the local, state, and federal laws, medical board rules, and professional ethical codes, but these offer general rules and guidelines, not the intrusive micromanagement that characterizes interaction with third parties.

THIRD-PARTY PITFALLS

American medical care has evolved over the past 200 years. For most of that time medical care was fee for service. The patient would go to the doctor (or the doctor did a house call), the doctor would do what he could for that patient, and payment would be made. The payment could be in currency, but often it was whatever the patient could bring to the office. Barter was not an uncommon practice. Since the end of World War II and particularly since the Medicare program was established in 1965, more and more Americans have been covered by some sort of third-party reimbursement for their health care. This evolution has been reviewed exhaustively by Starr (1982).

Although there are various different types of third-party reimbursement systems, they have many things in common. For example, none of the reviewers for these organizations has ever met the patient. They have never sat down face to face with the patient to get an idea of what the chief complaint is, the history of the patient's illness, or the patient's past medical history. Furthermore, they have never done a review of systems, personally asked about drug allergies, and the like. Why is this important?

It is important for several reasons. First, an experienced clinician is able not only to take a history and record that history but also to get an impression regarding the patient, especially by observing body language, acknowledging cultural differences and the like. No third-party payer can ever do this. Furthermore, third parties make decisions based on population data as opposed to what is necessary for the individual patient. In their defense, they have no other way of assessing a patient but by making note of the patient's diagnosis and then making decisions regarding an individual patient using population studies. This process is inherently flawed in that it does not take into account the individual problem that any one particular patient has. While the insurer/third-party payer deals with populations; the pain practitioner deals with individuals. All clinicians know that each of their patients is unique and no mere formula or statistical construct can capture the essence of their particular predicaments. Stephen Jay Gould, the eminent biologist and geologist, wrote in describing his own medical problems, "I am not a measure of central tendency, either mean or median. I am one single human being … and I want a best assessment of my own chances — for I have personal decisions to make and my business cannot be dictated by abstract averages." (Gould, 1997, p. 49).

Just about every reader of this chapter has experienced being told by some third-party reviewer that the average length of stay or the average treatment duration is of a certain length. Reimbursement will not be made for any more than that particular number of days or weeks. Some go further and state that it is not medically necessary that a particular patient receive treatment past a certain date or time. When the clinician who is observing the patient face to face continues treatment because it is necessary from a medical point of view, the clinician is routinely insulted by the third-party payer with such terms as "not cost-effective," "overutilizing," and "exceeds what is allowable." It would be much more honest were the third parties to state that they simply do not wish to pay for the care or that that particular care is not covered in the contract. Instead of doing this, they maintain that they are paying for necessary care except that the care being rendered is unnecessary — according to them! How could they possibly know? They have not examined the patient nor do they take responsibility for the care (or lack of it) rendered. This all-too-common practice of denial and

delay has been called "third party rape" (Shealy, 1993). Sound extreme? Read on.

The Medicare program is yet another practitioner of this Orwellian "Doublespeak." Up until 1998 a practitioner evaluating and treating a patient covered by Medicare would be considered either "participating" or "nonparticipating." Basically the former meant that the practitioner in question would accept assignment on all claims. The latter term represented a policy whereby Medicare could dictate to any practitioners who do not wish to accept assignment exactly how much they could charge. This Medicare policy was not about how much Medicare would pay but about what the practitioner in private practice could actually charge! Naturally, practitioners who did not accept assignment still had to abide by all the other Medicare rules and regulations. How is this nonparticipating? One is just participating on a different level. By thus corrupting the English language communication becomes even more difficult.

The Medicare regulations themselves are almost impossible to understand. However, should one be in violation, one is subject to penalties, which include fines and, if the government invokes the False Claims Act, criminal penalties including incarceration. In 1998, it was possible to "opt out" of Medicare altogether and still treat Medicare recipients. Prior to that date, it was illegal for a practitioner in the United States to have a private contract for medical services with a Medicare recipient. The transaction had to be monitored by Medicare even if the practitioner and the patient wanted to have a private agreement. Clearly this violates the civil rights of both patient and practitioner but it was not until 1998 that this situation changed for the better. I have "opted out" and have renewed my opt-out every 2 years. It doesn't matter what insurance my patients have. That is their business. My job is to take care of them to the best of my ability.

It is important for my patients to understand that in medical school I was actually taught the correct way to make mistakes. Obviously, we were encouraged to be extremely careful and not to make errors, but if errors were going to be made, there was actually a way to make them! In training I was taught to make type I (alpha) errors. A type one error is one where the practitioner assumes something is the case but it turns out not to be. For example, a patient presents with chest pain. The practitioner assumes it is extremely serious, possibly a pulmonary embolism or heart attack, but it ends up after the appropriate workup and observation that a much more benign condition exists. Many patients are admitted to coronary care units only to be told that they had chest wall pain or gastrointestinal problems. I don't see anything wrong with that. It is simply the careful and prudent practice of medicine. On the other hand, an error a practitioner must strive to avoid is a type II (beta) error. A type II error is one in which the practitioner assumes something is not

present but it actually is present. An example of that would be a patient presenting with chest pain is given an antacid for heartburn, and on the way home from the hospital the patient dies of a massive coronary event. In short, type I errors are consistent with good medical practice, whereas type II errors are not. For discussion of the statistical ramifications of these types of errors, I refer the reader to one of many standard mathematical texts that deal with statistics (Anderson, Sweeney, & Williams, 1986, p. 331).

Let's apply this train of thought to the third-party payers. How often are patients discouraged from going to emergency rooms because their problem was not life threatening and thus it would not be covered? How often are practitioners browbeaten into discharging patients from the hospital against their better judgment, the theory being that the patient probably would get along fine at home anyway? Dealing with third parties leads one to make type II errors; remembering what our teachers taught us leads us to make type I errors. Type I errors may seem more costly in the short term, but I submit if one weighs the cost of human suffering and the very tangible price tag of a funeral or an extended hospital stay because of a misdiagnosis that, indeed, the practitioner who tends to commit type I errors may actually be truly "cost-effective."

Perhaps what irks me the most about managed care organizations is that their decisions often make no sense. Furthermore, their statements are rarely backed up by facts and figures that can be verified by the practitioner. One of the myths espoused by third-party payers is that the cost of medical care in this country is far too high and costs need to be contained. I will grant you that the cost of medical care has exceeded the rate of inflation for many years, but I'm not so certain that this is a bad thing. Why not let individual people decide how to spend their own money? Even if one agrees with such statements and agrees to provide less care for patients and get less in the way of reimbursement for themselves, shouldn't the "belt tightening" extend to the third-party payers themselves?

I find it offensive that I am told I have to accept less money for my services. I read that the CEOs of managed care organizations routinely make seven-figure incomes. This has been a subject of a letter to the editor entitled "Managed Care Is Based on a Lie." (Romano, 1999). Several years ago it was reported that CEOs of U.S. health maintenance organizations made on the average $2 million annually. The highest earner for the year 1997 earned $30.7 million — and that excludes stock options! (Jacob, 1997). How is it that executives for a managed care company or any company for that matter would be worth tens of millions of dollars? The only logical conclusion is that they must either make that amount of money for the company or save that company a similar amount of money. How do managed care executives save money for their company? Most likely it is by rationing services or encouraging practitioners to engage in such cost-saving measures

as prescribing only generic drugs on a restrictive formulary, discharging patients from the hospital after very short stays, discouraging patients from going to the emergency room in off hours, profiling practitioners, and/or rewarding or punishing them based on performance, etc. (*American Medical News,* 2002).

Naturally the schemes listed above are not described by third-party payers in such language. Euphemisms abound. Generic equivalents are touted to be of the same quality except they are cheaper. In fact, in many pharmacies one sees generic drugs described as "quality generic preparations" or "quality generic equivalents." It has been my experience that, as a rule, generic preparations are not as potent as their brand name counterparts. Regardless, the choice of what medication a patient should have should be one made by the physician and patient, not by an insurance clerk. Patients who suffer from chronic, painful conditions often are quite complex requiring a multidisciplinary/interdisciplinary approach for proper treatment. As a practitioner I do not believe that it is my job to look out for the financial health of an insurance company or governmental agency. I am ethically, morally, and legally bound to do the best I can to take care of my patient. In my opinion that includes avoidance of interference from third-party carriers. In fact, I truly believe that it is a conflict of interest for practitioners to deal with these carriers, including Medicare (Romano, 1993). The third parties constantly pressure practitioners to limit care and put patients at risk while pontificating about "cost-effectiveness" and "utilization." Give me a break! I am better off without them. You also may be.

GOING INSURANCE FREE

The eminent attorney Gerry Spence described many Americans as being trapped in "a complex web of corporate and governmental behemoths." He calls large corporations the "New Slave Master" and describes in his book, *Give Me Liberty,* how these entities seek to dominate and control individuals (Spence, 1998). *Give Me Liberty* does not deal with the practice of medicine, nor does it comment on the specifics of corporate health care policy including utilization and reimbursement. Attorney Spence discusses work in general and how a worker should be dealt with (i.e., in a fair and evenhanded way). However, pain practitioners would be wise in considering his arguments. For example he espouses the concept of a "union of one." In his words, "The new and most powerful union of all will be a union of one — one man, one woman, one worker with special skills, an inquiring mind, and an independent attitude, his creativity intact, his love of life blooming" (Spence, 1998, p. 178). While not necessarily meaning to, he is addressing all dedicated and erudite pain practitioners. He goes on to write, "He will enter a place of work voluntarily to do a job for a price, his price.… He will cherish his freedom,

which is his security. He cannot be lured into the trap. The master cannot own him. This one man belongs to the union of one, is owned by no one, and represents only himself (Spence, 1998, p. 178).

I urge all of you to consider his words. When I read his book, published in 1998, I realized that I had become a "union of one" about 3 years previously. I decided to blaze my own trail in search of fulfillment and happiness. I did not start out that way. I had learned that dealing with third parties was becoming an ever-increasing cause of tension, anger, and frustration. The less I had to do with them, the better my life got. Maybe there is a better way for you too.

HOW TO BEGIN

Dr. Brown (2002) outlines some strategies to become insurance free. He stresses that practitioners must not accept failure, must set their own goals, and then must create a practice environment that is compatible with their temperament and skills. He stresses the establishment of good communication skills, creation of workable systems, and the development of a USP (Unique Service Position). The USP is what makes your practice different from other practices. I agree with his assessment and suggestions. I have a few of my own. First of all, be the best you can be. Get the best training, keep up in your field, and never give up your desire to do the best job for each and every patient. Do not compromise when it comes to quality care! If you are mediocre, then you may need to deal with third parties to survive. If you are excellent, why settle for low pay and incessant hassles? Market yourself as an expert in pain management. If you have superior skills and more to offer, do not hesitate to say so. Be flexible. If this means changing your office hours or getting involved in medical-legal cases, then so be it. Isn't your freedom worth it? Make it clear to patients that your loyalty is to them and them alone without any consideration given to third parties. Keep in mind that the patient has chosen you for his or her treatment. Divided loyalty will never become a problem when the patient and practitioner both share a common goal — getting the patient better. Make sure you spend sufficient time with each patient, answering all questions posed in an unhurried manner. The practitioner will get more satisfaction from each encounter, and the patient will appreciate that the practitioner really cares about the patient as a person. Medical care can be a very cold and depersonalized experience when the practitioner is harried, resentful, and overworked. All the more so if the practitioner sees himself or herself as a small cog in a monstrous corporate wheel.

Above all, view yourself as a truly independent practitioner who practices for the good of your patients. Do not be distracted by ridiculous "guidelines" or absurd requests. Do not allow your services to be undervalued. Recognize that it is not your responsibility to finance your patients' health care nor is it your obligation to convince third parties to fulfill their contractual obligations to patients. If you are prosperous and fulfilled, you can take better care of your patients. It's your life; it's your practice; it's your decision.

Some, albeit a few, practitioners have decided to strictly limit their involvement with third parties or end their participation altogether (Corona, 1998; Norbut, 2003). They have said, "Enough" (Ward, 1989)! Where do you stand?

AMERICAN ACADEMY OF PAIN MANAGEMENT

Code

of Ethics   1

Preamble

The American Academy of Pain Management recognizes the many facets and problems that pain patients experience. For this reason, the American Academy of Pain Management endorses and reaffirms the benefit of the interdisciplinary and multidisciplinary commitment which professionals from a variety of disciplines can make to the field of pain management.

The conduct of the individual credentialed by the American Academy of Pain Management shall be consistent with all applicable local, state and federal regulations, and with codes of conduct as established by the credentialed individual's primary discipline. Individuals who are credentialed by the American Academy of Pain Management are committed to increasing their knowledge of the mechanisms of pain and its respondent behavior. Every effort will be made to safeguard the health and welfare of patients who seek the services of the practitioners credentialed by the American Academy of Pain Management.

Professional Conduct by Specialty

The credentialed individuals are obligated to maintain their skill competency such that it conforms to the standards of conduct both to the individual's community, practice and discipline. The treatment of pain and the implementation of a patient's plan require that the therapeutic effort be multidisciplinary and/or interdisciplinary. Credentialed individuals will conduct their professional behavior so that it facilitates the services of all team members for the maximum benefit of the patient.

Responsibility

The credentialed individual shall be responsible to determine that standards are applied evenly and fairly to all individuals who receive services. Individuals who are employed by an institution, agency or clinic have the responsibility to be alert for institutional pressure which may be counter to the best interest of the patient and shall make every effort to improve those conditions.

Credentialed individuals provide thorough documentation and timely feedback to members of the team, employers, carriers and other interested parties in order to assure coordinated, managed care. All reports will be objective and based upon an independent professional opinion within the credentialed individual's expertise. Credentialed individuals will provide only those services for which the individual is competent and qualified to perform. Credentialed individuals will refrain from providing services which are counter to the ethical standards of their discipline or which would be a violation of standards established by applicable regulatory boards governing service to pain patients.

Confidentiality

Credentialed practitioners are obligated to safeguard information obtained in the course of their involvement with their patients. Information acquired during the scope of practice may routinely be released only with the patient's written permission. In emergency situations when there exists a clear and imminent danger to the health, safety or welfare of the patient or to others, or when such release is required by a court order or subpoena, a practitioner may release relevant medical information without the patient's written permission. Individuals who seek the services of

AMERICAN ACADEMY OF PAIN MANAGEMENT

Code

of Ethics   2

credentialed practitioners shall be advised that in some jurisdictions insurance companies, managed care organizations and regulatory boards may have access to collected information, test results, and opinions. Patients have the privilege, to the extent that it is feasible and practical, and when there are no legal or clinical contraindications, to see their medical records at a mutually convenient time for the patient and the practitioner.

Education, Training and Competence

Credentialed practitioners shall maintain high standards of professional competence. They shall recognize the limits of their skills and the scope of their licensure. They shall offer services consistent with the standards of their profession.

Credentialed individuals have an obligation to accurately represent and disclose their training, education, and experience to the public. Credentialed practitioners shall engage in continuing education. This will minimally include 100 hours of relevant education in pain management and/or their primary discipline every four years. Credentialed practitioners recognize that the field of pain management is rapidly developing so shall be open to consider and evaluate new approaches and procedures for the management of pain. Credentialed practitioners shall refrain from procedures and treatments that may result in harm to a patient without first considering the alternatives to such therapies. Credentialed practitioners shall seek to employ treatments and services which may achieve the greatest benefit with the fewest associated risks whenever possible.

Credentialed practitioners shall obtain consultations with other providers when indicated, and inform the patient of the likely risks inherent to the proposed approaches, procedures or treatments.

Business Procedures

Credentialed practitioners will abide by all prevailing community standards. They will adhere to all local, state and federal laws regulating business practice. Competitive advertising must be honest, factual, and accurate. Such advertising must avoid making exaggerated claims.

Credentialed practitioners shall not enter into arrangements in which fees are split or exchanged, or where a conflict of interest or undue influence about services rendered would exist.

Credentialed practitioners shall engage in behavior that conforms to high standards of ethical, legal and moral behavior. Credentialed practitioners shall never engage in sexual contact with their patients.

Research

Credentialed practitioners may engage in research concerning the management of pain. In doing so, they shall have the safety of their subjects as a priority. Investigations shall be consistent with the traditions and practices of the credentialed practitioner's discipline. Credit shall be given to all individuals who participate in a research study, but only those who actually participated in the design, study implementation, data analysis of the outcome or the manuscript preparation shall be listed as authors.

AMERICAN ACADEMY OF PAIN MANAGEMENT

Patient's

Bill of Rights

The American Academy of Pain Management endorses a Patient's Bill of Rights. It is an expectation that compliance with the Patient's Bill of Rights can contribute to an effective program for the patient. A modification of the American Hospital Association's statement on a Patient's Bill of Rights has been incorporated as part of the framework of the American Academy of Pain Management.

The modifications consist of the following:

1. The patient has the right to considerate and respectful care.

2. The patient has the right to obtain from their credentialed practitioner complete and current information concerning the diagnosis, proposed treatment, and expected prognosis in terms that the patient may reasonably be expected to understand. When it is not advisable to give such information to the patient, the information should be made available to an appropriate person (medical proxy) on the patient's behalf.

3. The patient has the right to receive the necessary information for medical decision making and the granting of informed consent from the treating credentialed practitioner prior to the start of any procedure or treatment. This information shall include at the minimum: the expected procedure or treatment to be used, who will perform the procedure or treatment, what are the likely benefits from the procedure or treatment, what alternatives exist if any, what are the likely risks from the procedure or treatment, what may occur if no treatment is undertaken, and length of probable duration of incapacitation if any is expected.

4. The patient has the right to refuse any and all treatment to the extent permitted by law, and to be informed of any medical consequences of this action.

5. The patient has the right to every consideration of privacy concerning the medical care provided except when there is an imminent risk to the individual or others, or when the practitioner is ordered by a court to breach confidentiality.

6. The patient has the right to be advised if the practitioner, agency, or facility propose to engage in any form of human experimentation affecting the care or treatment provided. The patient has the right to refuse to participate in research projects or to withdraw continued consent to participate without repercussions.

7. The patient has the right to examine and receive an explanation of the bill for professional services rendered.

All pain management activities are to be provided with an overriding concern for the patient, and above all, with the recognition of the patient's dignity as a human being.

American Academy of Pain Management Credentialing

The American Academy of Pain Management (the Academy) is a non-profit organization that serves a broad range of clinicians who treat people with pain. Founded in 1988, the Academy has approximately 6,000 members and is the largest interdisciplinary pain organization in the United States. The Academy believes that effective pain management can be achieved through cooperation, shared knowledge, and the collective wisdom of healthcare professionals from many disciplines.

The American Academy of Pain Management has established and continues to monitor a national credentialing process in interdisciplinary pain management. The purpose of credentialing is to promote professional accountability and visibility, to identify those pain practitioners who have met specific professional standards, to advance cooperation among the various specialties that treat individuals suffering pain, and to encourage continued professional growth and development of pain practitioners and the field of pain management. The Academy offers three levels of credentialing to clinicians: Diplomate, Fellow, and Clinical Associate. The Academy maintains a registry (posted on the website www.aapainmanage.org) of individuals who have voluntarily sought and obtained credentialing in interdisciplinary pain management.

The Credentialing Examination has been developed to objectively measure the knowledge and skills required for successful performance as an interdisciplinary pain management practitioner. The examination content has been developed by the Academy's examination committee, consisting of interdisciplinary experts in pain management.

Everyone takes the same examination. The examination is based on a comprehensive analysis of the knowledge necessary to do interdisciplinary pain management. The job analysis is conducted by the Academy's testing company on a regular basis. The Credentialing Examination is monitored consistently for content validity and updated for timeliness. It is designed to ensure a minimum level of competence among interdisciplinary pain practitioners, to create a better awareness among the public of the nature and purpose of pain management, and to create guidelines for the safe and effective practice of pain management.

When applying for credentialing, applicants must submit three professional letters of reference, a copy of their professional licenses, official academic transcripts related to their professional practice, application form, and curriculum vitae. The Credential Review Committee evaluates this material to determine credential eligibility. Once Credential Eligible, the candidate must successfully pass the Credentialing Examination to become officially "Credentialed." Individuals who become credentialed receive a registered certificate, a listing in the Registry of Pain Practitioners on the Academy's website, notice of conferences with reduced fees, and periodic educational publications.

The Academy presently publishes the quarterly magazine, *The Pain Practitioner*, which contains hands-on information regarding pain management and the quarterly peer-reviewed journal, *American Journal of Pain Management*. The American Academy of Pain Management is the only interdisciplinary pain management credentialing body.

An application packet is available by contacting the American Academy of Pain Management, 13947 Mono Way #A, Sonora, CA 95370, (209) 533-9744, or by going to the Website: www.aapainmanage.org.

American Academy of Pain Management

ABOUT THE AMERICAN ACADEMY OF PAIN MANAGEMENT

The American Academy of Pain Management (the Academy) is a non-profit organization that serves a broad range of clinicians who treat people with pain through education, setting standards of care, and advocacy. Founded in 1988, the Academy has approximately 6,000 members and is the largest interdisciplinary pain organization in the United States. The Academy believes that effective pain management can be achieved through cooperation, shared knowledge, and the collective wisdom of healthcare professionals from many disciplines.

MEMBERSHIP

Benefits of membership include:

- Access to credentialing program
- Quality publications (see below)
- A listing in the searchable database of the Academy's website
- Networking opportunities with thousands of clinicians
- Professional development through Continuing Education Department
- Reduced registration rates for the Academy's Annual Clinical Meeting

The cost of membership is $195 annually. Student membership is $50.

OVERVIEW OF ACADEMY PROGRAMS, SERVICES, AND PRODUCTS

ANNUAL CLINICAL MEETING

Held each year in September, the Academy's Annual Clinical Meeting is an inclusive gathering of pain management clinicians, from a variety of disciplines and medical traditions, who join together in the spirit of cooperation to learn and share ideas about ways to improve care for those who live with pain. This information-rich meeting offers opportunities for attendees to:

- Attend sessions focusing basic science and the most current advances in pain management.
- Listen to presentations by internationally renowned experts.
- Network with thought leaders and up to 1,000 forward-thinking pain management clinicians.
- Earn CME/CEU/CE credit in many disciplines.

CREDENTIALING

The American Academy of Pain Management has established a national credentialing process in interdisciplinary pain management. The purpose of credentialing is to promote professional accountability and visibility, to identify those pain practitioners who have met specific professional standards, to advance cooperation among the various specialties that treat individuals suffering pain, and to encourage continued professional growth and development of pain practitioners and the field of pain management. The Academy offers three levels of credentialing: Diplomate, Fellow, and Clinical Associate. The registry is posted on the Website www.aapainmanage.org.

PUBLICATIONS

The Academy publishes a peer-reviewed, quarterly journal, *The American Journal of Pain Management*, which offers clinical research information in a multidisciplinary format; and *The Pain Practitioner*, a quarterly magazine that features useful clinical articles, information on pain policies, prescribing information, and up-to-date pain news. In September 2005, the Academy will launch *Currents*, a monthly e-newsletter.

The Academy's best-selling multidisciplinary textbook, *Weiner's Pain Management: A Practical Guide for Clinicians* (7th edition) offers a comprehensive overview of interdisciplinary pain management.

WEBSITE

The award-winning Academy Website offers information about the Academy and its educational programs, products, and services, updates on critical pain management issues and topics, a database of pain clinicians, and links to other organizations and resources.

CONTINUING EDUCATION

The Academy is approved by ACCME to provide category 1 MD credit. The Academy is also approved to provide continuing education by the American Psychological Association (APA), the American Dental Association (ADA), the National Board for Certified Counselors (NBCC), American Association of Nurse Anesthetists (AANA), the American Podiatric Medical Association (CPME), and others (contact the Academy for the complete list). The Academy also provides continuing education to nurses and pharmacists in cooperation with the University of the Pacific School of Pharmacy and Health Services and to chiropractors in association with Cleveland Chiropractic College

PAIN PROGRAM ACCREDITATION

Pain Program Accreditation is a voluntary process that gives pain management programs an opportunity to demonstrate compliance with peer-reviewed quality treatment standards established by pain practitioners. The Academy has a long history of accrediting pain programs based on published standards and onsite review. A broad cross-section of pain programs is eligible for accreditation.

OUTCOMES MEASUREMENT TOOLS

Pain Outcomes Profile

The Pain Outcomes Profile (POP) is a brief, reliable, and clinically useful self-report questionnaire that allows the practitioner to track pain and functional variables across treatment. A computer software version of the POP is in development and there is a Spanish translation available.

National Pain Data Bank

The purpose of the National Pain Data Bank is to collect information about patient demographics, history, pain profile, functional status, quality of life and daily living, return to work, treatment satisfaction, and cost of care. A quarterly report of the data is sent to all participating programs. Participating programs have found this data useful in determining treatment outcomes, in creating more cost-effective treatment protocols and marketing strategies, and in working with third-party payers.

University of Integrated Studies

The University of Integrated Studies offers Master of Arts and Doctor of Philosophy degrees in Pain Studies through a distance learning format. Visit the University's Web site at www.univintegratedstudies.edu to learn more about this exciting offering. The Academy is approved by the State of California to operate a degree-granting university. For more information contact:
