In recent years, scientists have provided elucidation of the mechanisms of action of cannabis and THC, the primary psychoactive component, with the discovery of an endogenous cannabinoid (endocannabinoid) ligand, arachidonylethanolamide, nicknamed anandamide, from the Sanskrit word *ananda,* or "bliss" (Barinaga, 1992; Devane et al., 1992; Marx, 1990; Matsuda, Lolait, Brownstein, Young, & Bonner, 1990). Anandamide inhibits cyclic AMP mediated through G protein coupling in target cells, which cluster in nociceptive areas of the CNS (Herkenham, 1993). Early testing of its pharmacological action and behavioral activity indicate similarity to THC (Fride & Mechoulam, 1993), although anandamide differs from THC in some respects. Pertwee (1997) has examined the pharmacology of cannabinoid receptors in detail. CB_1 receptors are mainly confined to the CNS, while CB_2 receptors are found in the periphery, often in conjunction with immune mechanisms.

Further research has elucidated analgesic mechanisms of cannabinoids, which will be examined system by system.

Cannabinoids and Serotonergic Systems

Serotonergic mechanisms are implicated in many pain conditions, especially migraine and cluster headaches. THC reduces serotonin release from the platelets of human migraineurs (Volfe, Dvilansky, & Nathan, 1985). Cannabis has been observed to stimulate 5-HT synthesis, its brain content, decrease its synaptosomal uptake, while stimulating its release (Spadone, 1991). Anandamide and other cannabinoid agonists inhibit rat serotonin type 3 (5-HT$_3$) receptors (Fan, 1995) that mediate emetic and pain responses. The recent advent of alosetron, a 5-HT$_3$ blocker employed in treatment of irritable bowel syndrome (Letter, 2000), would seem to support claims of the efficacy of cannabis in that disorder on the basis of this mechanism.

Recently, Boger and his group have demonstrated an 89% relative potentiation of the 5-HT$_{1A}$ receptor response, and a 36% inhibition of the 5-HT$_{2A}$ receptor response by anandamide (Boger, Patterson, & Jin, 1998). Similar effects by THC are likely, supporting efficacy for cannabinoids in acute symptomatic migraine treatment due to agonistic activity at 5-HT$_{1A}$ or 5-HT$_{1D}$, and in prophylactic treatment of chronic headache due to antagonistic activity at 5-HT$_{2A}$ (Peroutka, 1990a, b).

Kimura et al. (Kimura, Ohta, Watanabe, Yoshimura, & Yamamoto, 1998) showed that high concentrations of anandamide decreased serotonin and ketanserin binding (a 5-HT$_{2A}$ antagonist). 11-OH-delta 8-THC and 11-oxo-delta 8-THC metabolites of cannabis were also observed to modify serotonin receptor binding.

Ultimately, this author and colleagues have shown that essential oil components of cannabis demonstrate potent serotonin receptor activity (E. B. Russo, Macarah, Todd, Medora, & Parker, 2000) that supports putative synergism with THC in the modulation of analgesia. Similarly, CBD seems to harbor similar activity that would help to explain prophylactic benefits of cannabis in migraine (Hall et al., 2004).

Dopaminergic Systems

The importance of dopaminergic mechanisms in treatment of migraine and other types of pain has received recent emphasis (Peroutka, 1997). However, existing neuroleptics are significantly sedating. Ferri et al. (Ferri, Cavicchini, Romualdi, Speroni, & Murari, 1986) were able to demonstrate that 6-hydroxydopamine, which causes degeneration of catecholamine terminals, was able to block THC antinociception. In a review article (Mechoulam, Fride, & Di Marzo, 1998, p. 12), a number of studies were reviewed as demonstrating that cannabimimetic drugs cause "inhibition of the dopaminergic nigrostriatal system."

Müller-Vahl and her colleagues cited Mailleux (Mailleux & Vanderhaeghen, 1992) in their discussion of cannabinoid interactions with the dopaminergic system (Müller-Vahl, Kolbe, Schneider, & Emrich, 1998) stating, "Cannabinoid receptors were found to be co-localized both with dopamine D$_1$ receptors on striatonigral dynorphin/substance-P-containing neurones and with dopamine D$_2$ receptors on striatopallidal enkephalinergic neurones" (p. 504).

Carta et al. demonstrated that antinociceptive effects of THC are mediated by CB$_1$ and dopamine D$_2$ receptors, and that combination of the agents improved analgesic effects in rats (Carta, Gessa, & Nava, 1999).

Inflammatory Mechanisms

Modern authors (S. Burstein, 1992; A. T. Evans, Formukong, & Evans, 1987; Formukong, Evans, & Evans, 1988, 1989) have examined the relationship between cannabinoids and inflammation. McPartland (2001a) provides an excellent summary and analysis of the subject.

Burstein et al. demonstrated that THC and other cannabinoids inhibit prostaglandin E$_2$ synthesis (S. Burstein, Levin, & Varanelli, 1973). In 1979, experiments showed that smoked cannabis reduced platelet aggregation (Schaefer, Brackett, Gunn, & Dubowski, 1979).

In 1981, cannabichromene was demonstrated to be a more effective anti-inflammatory agent than phenylbutazone in carrageenan-induced rat paw edema and the erythrocyte membrane stabilization method (Turner & ElSohly, 1981). The authors stated, "The activity of cannabichromene through the oral route, its safety and its lack of behavioral-type (psychotomimetic) activity characteristic of THC(I) indicate its therapeutic potential for the treatment of inflammatory diseases" (pp. 288S–289S).

Evans stated (1991, p. S65), "Experiments involving oral administration of THC suggested that THC was 20 times more potent than aspirin and twice as potent as hydrocortisone." Cannabidiol (CBD) functioned as a dual cyclooxygenase and lipoxygenase inhibitor in various assays.

Klein noted that THC had variable effects on tumor necrosis factor (TNF-α) production depending on the cells and culture system selected (Klein, Friedman, & Specter, 1998).

In 1998, Jaggar et al. issued two reports addressing visceral and inflammatory pain in rats (Jaggar, Hasnie, Sellaturay, & Rice, 1998; Jaggar, Sellaturay, & Rice, 1998). The endocannabinoid anandamide, a CB$_1$ ligand, prevented and reduced viscero-visceral hyperreflexia (VVH) in the inflamed bladder. In contrast, palmitylethanolamide, a presumptive endogenous CB$_2$ ligand that accumulates in inflamed tissues and reduces edema by downmodulating mast cells, only reversed VVH once previously established. The authors posited the possibility of development of nonsedating analgesic anti-inflammatory drugs based on CB$_2$ receptor agonism.

In a 1999 review, Fimiani et al. note, "Delta-9-THC blocks the conversion of arachidonic acid into all metabolites derived by cyclooxygenase activity, whereas it stimulates lipoxygenase, resulting in an increase in lipoxygenase products" (p. 27). Clinically, no increased incidence of gastric ulceration was reported in chronic cannabis users (New York [City] Mayor's Committee on Marihuana, Wallace, & Cunningham, 1973; V. D. Rubin & Comitas, 1975; Stefanis, Dornbush, & Fink, 1977). In 1978, cannabis was felt to reduce gastric acidity in humans (Nalin et al., 1978), while another group demonstrated THC to have antiulcer effects in rats (Sofia, Nalepa, Harakal, & Vassar, 1973). In fact, one essential oil sesquiterpene component of cannabis, caryophyllene, has recently been demonstrated to have a gastric cytoprotective effect (Tambe, Tsujiuchi, Honda, Ikeshiro, & Tanaka, 1996).

The above authors (Fimiani et al., 1999) also observed that the morphine-cannabinoid system modulates the eicosanoid cascade and its proinflammatory cytokine activity through induction of nitric oxide synthesis, averting damaging effects on tissues. They state in summary, "Thus, we can surmise cannabinoid-morphine systems are down-regulators of inflammatory processes in an attempt to restore homeostasis" (p. 30).

A recent report has demonstrated the efficacy of oral cannabidiol (CBD), a minimally psychoactive cannabis component, at a dose of 5 mg/kg/day in treating mice against collagen-induced arthritis, a model for human rheumatoid arthritis (Malfait et al., 2000). Benefits were produced through a combination of immunosuppressive effects (diminished CII-specific proliferation and interferon-gamma production) and anti-inflammatory effects (decreased release of tumor necrosis factor by synovial cells).

Cannabis seed also has dietary benefits as an anti-inflammatory agent. It yields linolenic acid, which promotes formation of anti-inflammatory metabolites, and gamma-linolenic acid, which inhibits the formation of proinflammatory products from arachidonate (Conrad, 1997; Haines et al., 2000; Wirtshafter, 1997).

Flavonoid and terpenoid essential oil components of cannabis demonstrate anti-inflammatory effects at physiologically appropriate levels (McPartland & Russo, 2001). Cannflavin A and B inhibited prostaglandin E_2 production in human rheumatoid synovial cells 30 times more potently than aspirin (Barrett, Scutt, & Evans, 1986).

The cannabis flavonoid apigenin has anti-inflammatory actions on interleukin, TNF-α, and carrageenan-induced edema and by inhibition of upregulation of cytokine-induced genes (Gerritsen et al., 1995). Quercetin, another flavonoid in cannabis, serves as an antioxidant, and inhibits hydrogen peroxide–mediated nuclear factor (NF)-kappa B activity (Musonda & Chipman, 1998). Burstein et al. have demonstrated eugenol to be a potent prostaglandin inhibitor (S. Burstein, Varanelli, & Slade,

1975). Subsequently, both the alpha-pinene and caryophyllene components of cannabis have proved to demonstrate anti-inflammatory activity in the rat hindpaw edema model (S. Martin et al., 1993).

Cannabinoid Interactions with Opiates and Endogenous Opioids

THC experimentally increases beta-endorphin levels (Wiegant, Sweep, & Nir, 1987). Depletion of endorphins has been measured in the cerebral spinal fluid of migraineurs during attacks (Fettes, Gawel, Kuzniak, & Edmeads, 1985) and theoretically contributes to migraine effects such as hyperalgesia and photophobia. Early exposure to THC in rat pups boosted adult levels of beta-endorphins in specific brain areas (Kumar et al., 1990).

Mailleux and Vanderhaeghen (1994) have also demonstrated that THC regulates substance P and enkephalin mRNA levels in the basal ganglia. Manzanares et al. (1998) have shown THC is able promote increases in beta-endorphin in rats. Meng and his group demonstrated that THC is involved in an analgesic brainstem circuit in the rostral ventromedial medulla that interacts with opiate pathways (Meng, Manning, Martin, & Fields, 1998).

Cichewicz and her group examined the enhancement of opioid antinociception by oral THC in rodents (Cichewicz, Martin, Smith, & Welch, 1999). THC (20 mg/kg) preceding morphine rendered it significantly more analgesic with an ED_{50} dropping from 28.8 to 13.1 mg/kg. For codeine, the ED_{50} dropped phenomenally from 139.9 to 5.9 mg/kg, with enhancement also noted for oxymorphone, hydromorphone, methadone, diacetylmorphine (heroin), and meperidine. This THC enhancement was decreased by naloxone, but not by other opiate-blockers, suggesting an effect on μ-opioid receptors.

In a subsequent study, Cichewicz, Haller, and Welch (2001) demonstrated that continued low doses of THC and morphine in mice produce no behavioral tolerance to the opioid, and that the combination circumvented the expected downregulation of opioid receptor protein in the mouse midbrain observed in tolerant animals. Extension of this work (Cichewicz & McCarthy, 2003) demonstrated that oral doses of THC with either morphine or codeine produced synergistic increases in analgesia.

Perhaps the most exciting development from this group surrounds the suggestion that THC blocks opiate withdrawal effects and prevents the development of opiate tolerance (Cichewicz & Welch, 2003). Such tolerance in chronic opioid-treated mice was circumvented with nonanalgetic doses of oral THC, while THC also significantly reduced naloxone-precipitated withdrawal effects in such mice. Substantiation is thus provided for 19th century claims of utility of cannabis in treatment of opiate addiction, suggesting a new indication for clinical trials.

Finally, Cichewicz presented findings indicating that late administration of THC will restore opioid analgesic effects after low doses or ones that had previously worn off (Cichewicz, Rubo, & Welch, 2003), thus scientifically verifying the anecdotal reports of cannabis-opiate alternation from the 19th century.

Welch and Eads (1999) note cannabinoid-induced analgesia produced antinociception through spinal dynorphin release with synergistic effects with opiates. They state, however, "THC, in comparison to the morphine derivatives, has a greater therapeutic range" (p. 188).

Many analgesic effects of cannabinoids cannot be reproduced by opiates, however, particularly in cases of neuropathic pain (Hamann & di Vadi, 1999). Nicolodi (1998) examined opiate aggravation of migraine. Manzanares (Manzanares et al., 1999) cited that chronic cannabinoid administration could similarly promote hypothalamic production of beta-endorphin.

Strangman and Walker (1999) demonstrated that a cannabinoid antagonist was able to decrease wind-up in spinal nociceptive neurons producing hyperalgesia and allodynia in chronic pain states. A similar group (Walker et al., 1999) showed that cannabinoids selectively affect nociceptive neurons in the spinal cord and ventroposterolateral nucleus of the thalamus in a manner that promotes antinociception without anesthesia. In all, seven sites in the CNS involved in pain processing produced effects after microinjections of cannabinoids, effecting a circuit that mediates the descending pain suppressing effects of opiates.

Cannabinoids and the Periaqueductal Gray Area

In 1996, researchers demonstrated antinociceptive effects of delta-9-THC and other cannabinoids in the periaqueductal gray (PAG) matter in rats (Lichtman, Cook, & Martin, 1996). The PAG is a putative migraine generator area (Goadsby & Gundlach, 1991; Raskin, 1988) and has received a lengthy analysis (Behbehani, 1995) citing its importance in the processes of ascending and descending pain pathways. A detailed review of effects of the PAG and cannabinoids in migraine is contained in Russo (E. B. Russo, 2001a).

Manzanares (Manzanares et al., 1998) suggested that cannabinoid-mediated antinociception in the PAG is produced by activation of endogenous opioids, supported by the fact that subchronic THC administration elevates proenkephalin gene expression in the area.

Walker, Huang, Strangman, Tsou, and Sanudo-Pena (1999) demonstrated that electrical stimulation of PAG in the rat stimulated anandamide release and CB_1 receptor-mediated analgesia. The system seemed to be tonically active, and cannabinoid antagonists produced hyperalgesia. The authors posited that this cannabinoid-modulated

pain system would support the prospect of approaches with cannabinoids to opiate-resistant syndromes.

NMDA and Glutamate

A trigeminovascular system, which has long been implicated as subserving pain, inflammatory and vascular effects, has again been reviewed (E. B. Russo, 2001a).

In 1996, Shen et al. elucidated basic mechanism of cannabinoids in glutamatergic systems (Shen, Piser, Seybold, & Thayer, 1996). Through G protein coupling, cannabinoid receptors inhibit voltage-gated calcium channels, and activate potassium channels to produce presynaptic inhibition of glutamate release. Subsequently, it has been shown (Shen & Thayer, 1999) that THC is a partial agonist acting presynaptically via CB_1 to modulate glutamatergic transmission through a reduction without blockade.

Hampson and colleagues demonstrated a 30 to 40% reduction in delta-calcium-NMDA responses by THC (Hampson, Bornheim et al., 1998), which was eliminated by a cannabinoid antagonist. THC and CBD components of cannabis act as neuroprotective antioxidants against glutamate neurotoxicity and cell death mediated via NMDA, AMPA, and kainate receptors (Hampson, Grimaldi, Axelrod, & Wink, 1998). Effects are independent of cannabinoid receptors. The natural cannabinoids were more potent in their antioxidant effects than either alpha-tocopherol or ascorbate.

Italian researchers Nicolodi and Sicuteri have recently elucidated the role of NMDA antagonists in eliminating hyperalgesia in migraine, chronic daily headache, fibromyalgia, and possibly other mechanisms of chronic pain (Nicolodi & Sicuteri, 1995, 1998; Nicolodi, Del Bianco, & Sicuteri, 1997; Nicolodi, Volpe, & Sicuteri, 1998). Gabapentin and ketamine were suggested as tools to block this system and provide amelioration. Given the above observations and relationships, it is logical that prolonged use of THC prophylactically may exert similar benefits, as was espoused in cures of chronic daily headache claimed in the 19th century with regular use of extract of Indian hemp (Mackenzie, 1887).

This concept is bolstered by examination of another series of articles by Richardson and her group. One study examined peripheral mechanisms (Richardson, Kilo, & Hargreaves, 1998), wherein cannabinoids acted on CB_1 to reduce hyperalgesia and inflammation via inhibition of neurosecretion of calcitonin gene-related peptide (CGRP) in capsaicin-activated nerve terminals.

At the spinal level, her group noted an antihyperalgesic effect of cannabinoids (Richardson, Aanonsen, & Hargreaves, 1998a), mediated by the CB_1 receptor. Additionally, experimental cannabinoid receptor blockade induced a glutamate-dependent hyperalgesia, suggesting a tonic activity of cannabinoids in averting such a development. The authors suggested the clinical use of cannabinoids in

disorders, "characterized by primary afferent barrage" (p. 152). An increased potency of cannabinoids observed in hyperalgesia "may mean that there are dosages of cannabinoids that would be effective as antihyperalgesic agents but sub-threshold for the untoward psychomimetic effects" (p. 152). This is akin to Dixon's observations of patients able to return to work after having treated their headaches with a few inhalations of cannabis (Dixon, 1899).

Elaborating on these themes, Richardson noted that a decrease in lumbar cannabinoid receptor numbers correlated with hyperalgesia (Richardson, Aanonsen, & Hargreaves, 1998b) and could provide an etiology for certain chronic pain states, especially those unresponsive to opiates.

In another study (Li et al., 1999), the synthetic cannabinoid agonist WIN 55,212-2 was employed to block capsaicin-induced hyperalgesia in rat paws much as has been observed for THC in formalin treatment. Ko and Woods (1999) examined local THC administration and its activity on capsaicin-induced pain in rhesus monkeys. THC effectively reduced pain, which was blocked by a CB_1 antagonist and was effective at a parenteral dose that produced no behavioral change or sedation.

Maneuf, Nash, Crossman, and Brotchie (1996) examined similar issues at higher CNS levels and were able to show a tonic activation of the cannabinoid system serving to reduce GABA uptake in the globus pallidus.

These tonic endocannabinoid systems subserving analgesic pathways are strongly suggestive that certain pain disorders long conceived as at least partially "psychogenic," including migraine, fibromyalgia, idiopathic bowel syndrome, complex regional pain syndromes, and others may be attributable to a "clinical endocannabinoid deficiency" (CECD). This concept is explored elsewhere in depth (E. B. Russo, 2004a).

Synergism and the Entourage Effect

Palmitylethanolamide (PEA) is another endogenous cannabinoid with analgesic effects, released from a phospholipid in conjunction with anandamide (Calignano, La Rana, Giuffrida, & Piomelli, 1998). In ensemble, the two substances effect a 100-fold synergism on CB_1 type peripheral receptors in cutaneous tissues.

Endocannabinoids and their inactive metabolites combine to boost physiological responses (the "entourage effect"; Mechoulam & Ben-Shabat, 1999). Given the likely contributions of cannabis flavonoids and essential oils to therapeutic effects on mood, inflammation, and pain reviewed in McPartland and Russo (2001), one may readily accept Mechoulam's quotation (Mechoulam & Ben-Shabat, 1999, p. 136): "This type of synergism may play a role in the widely held (but not experimentally based) view that in some cases plants are better drugs than the natural products isolated from them."

PRACTICAL APPLICATION OF CANNABINOIDS TO ANALGESIA

MARINOL (DRONABINOL): PROS AND CONS

Marinol,® developed by Unimed Pharmaceuticals, is a synthetically derived THC dissolved in sesame oil. It is available in capsules of 2.5, 5, and 10 mg and is marketed in the United States, Canada, Australia, and some areas in Europe (Grotenhermen, 2001a). Until 1999, Marinol was a Schedule II drug in the United States with close scrutiny to its usage, which was restricted to indications of AIDS-associated anorexia and cancer chemotherapy. After safety studies revealed a low potential for abuse or diversion (Calhoun, Galloway, & Smith, 1998), dronabinol was "down-scheduled" to Schedule III in 1999, allowing refill prescriptions for up to 6 months, and its "off-label" administration for any indication.

Clinicians have used Marinol only to a limited degree. Its bioavailability is only 25 to 30% of an equivalent smoked dose of THC (Association, 1997). Additional problems include the first pass effect of hepatic metabolism, which results in the production of a possibly more psychoactive metabolite 11-hydroxy-THC, and its considerable cost, which may exceed U.S. $600 per month for the lowest dosage of 2.5 mg TID. Considerable anecdotal data supports preference by patients of herbal cannabis over dronabinol (Grinspoon & Bakalar, 1997; E. B. Russo et al., 2002).

Reports of dronabinol use in painful clinical conditions are few, but it has had some variable success in migraine prophylaxis (Mikuriya, 1997; E. Russo, 1998; E. B. Russo, 2001a).

Maurer et al. demonstrated efficacy of analgesia of 5 mg per oris THC to 50 mg codeine in treatment of pain in a young paraplegic patient after removal of a spinal tumor (Maurer, Henn, Dittrich, & Hofmann, 1990). However, THC also limited spasticity whereas codeine and placebo did not.

Holdcroft et al. (1997) were able to demonstrate an analgesic benefit ($p < 0.001$) of THC 50 mg per day in five split doses in a patient with relapsing familial Mediterranean fever in a double-blind, placebo-controlled trial.

NABILONE

Nabilone is a synthetic cannabinoid said to be pharmacologically similar to THC, but more potent, less apt to produce euphoria, and possessing lower "abuse potential" (Association, 1997). It is produced by Eli Lilly Company as Cesamet® and is available in the United Kingdom, Canada, Australia, and certain countries in Europe (Grotenhermen, 2001a) as an agent for nausea in chemotherapy. Some scattered reports have noted benefit on spasticity in multiple sclerosis (MS) and effects on dyskinesias.

Lethal toxicity in dogs has been noted with chronic use (Mechoulam & Feigenbaum, 1987).

A group in the United Kingdom recently assessed analgesic effects of nabilone in patients including some with neuropathic pain (Notcutt, Price, & Chapman, 1997). Side effects of drowsiness and dysphoria were troubling. Several patients claimed improved pain relief and fewer side effects with smoked cannabis and preferred it to this legal alternative. Nabilone's cost was also estimated to be 10 times higher than cannabis even at black market rates.

LEVONANTRADOL

Levonantradol is a synthetic cannabinoid developed by Pfizer. In 1981, levonantradol was studied in double-blind fashion versus placebo with single intramuscular exposures in acute postoperative or trauma pain (Jain, Ryan, McMahon, & Smith, 1981). Various doses were analgesic for up to 6 hours compared with placebo ($P < 0.05$), but no dose–response effect was evident, and side effects were prominent with levonantradol (57 vs. 12.5%), including prominent drowsiness with less degrees of dry mouth, dizziness, "weird dreams," mild hallucinations, and anxiety. These adverse events were labeled "unacceptable" according to the British Medical Association (Association, 1997).

AJULEMIC ACID (CT3)

Ajulemic acid is a synthetic derived from delta-8-THC that does not bind to cannabinoid receptors. CT3 was developed by Atlantic Pharmaceuticals. It has shown analgesic and anti-inflammatory properties in animal models without COX-1 inhibition side effects (S. H. Burstein, 2000, 2001). It has shown strong analgesic and anti-inflammatory properties in animal models of arthritis without COX-1 inhibition side effects such as ulcer production, and is in advanced clinical trials (S. H. Burstein 2000, 2001). Ajulemic acid binds to the peroxisome proliferator-activated receptor gamma, part of the nuclear receptor superfamily involved in inflammatory processes (Liu, Li, Burstein, Zurier, & Chen, 2003), and also suppresses human monocyte interleukin-1beta production *in vitro* (Zurier, Rossetti, Burstein, & Bidinger, 2003). Ajulemic acid may represent a valuable addition to cannabinoid pharmaceuticals used for anti-inflammatory and analgesic effects.

DEXANABINOL (HU-211)

Dexanabinol is a synthetic cannabinoid agent developed at Hebrew University from Δ^8-THC. It is a nonpsychoactive enantiomer of the extremely potent cannabis agonist, HU-210 (Pop, 2000). It has several interesting properties including antioxidant and anti-inflammatory effects, as well as suppression of TNF-α production. Additionally,

it reduced damage in experimental focal ischemia, as may be associated with closed head injury (Lavie, Teichner, Shohami, Ovadia, & Leker, 2001). In one human Phase II clinical trial of 67 patients with closed-head injury, dexanabinol reduced intracranial pressure and perfusion significantly with few adverse events (Knoller et al., 2002). Improvements in clinical outcome scales were seen after 3 and 6 months, but were relatively subtle.

Dexanabinol is currently in Phase III clinical trials. Parenteral injection of dexanabinol is required.

HU-308

HU-308 is another agent emerging from the research of Raphael Mechoulam's laboratories in Israel. It is a synthetic and specific CB_2 agonist demonstrating no cannabinoid behavioral effects in laboratory animals (Hanus et al., 1999). Its pharmacological properties include inhibition of forskolin-stimulated cyclic AMP production, blood pressure reduction, inhibition of defecation, and production of peripheral analgesia with anti-inflammatory effects. An important therapeutic role for HU-308 as a peripherally acting agent may eventuate on further testing.

CANNABIS PROPER

Use of cannabis for pain conditions is extensive in the United States and some European nations. A survey of patients attending the Oakland Cannabis Buyers' Club revealed (Gieringer, 2001):

> By far the largest category of patients interviewed by Mikuriya use cannabis for analgesia to treat conditions including: migraines and neuralgias; arthritis and rheumatism; spinal, skeletal and back disorders due to injury, deformity, or degenerative disease; inflammatory gastrointestinal disorders, and a host of miscellaneous diseases.

Analysis of the totals revealed that at least 1,133 of 2,480 patients or 46% sought cannabis for analgesia in treatment of chronic pain conditions.

Cannabis is traditionally employed therapeutically by smoking, ingestion, or vaporization. Each has advantages and disadvantages. Grotenhermen has produced an excellent summary of "Practical Hints" (Grotenhermen, 2001b), as have Brazis and Mathre (1997). Dosing of therapeutic cannabis must be titrated to the patient's need. In general, 5 mg of THC represents a threshold dose for noticeable effects in the average adult. While tolerance to cardiovascular effects (tachycardia) and psychoactive effects ("high") are achieved after some days to weeks of chronic usage, observed clinical and "anecdotal" reports support retention of analgesic efficacy over the long term. Occasionally, upward dose titration is necessary, as is true for any agent.

Allergies to cannabis are rare, although some may experience rhinitis symptoms, particularly when exposed to the smoke of the unrefined product.

More severe psychiatric conditions present a relative contraindication to use of cannabis, while many milder emotional afflictions may benefit from the drug (Grinspoon & Bakalar, 1997; Grinspoon, Bakalar, & Russo, 2005; E. B. Russo, 2001c). Although concerns have been raised about subtle neuropsychological sequelae in children born to mothers employing cannabis in pregnancy, other studies have shown no significant abnormalities (Dreher, 1997). Certainly, no mutagenic or teratogenic potential has been demonstrated in humans (E. Russo, 2002b).

Concerns about our youth employing cannabis are often well intentioned. However, there is some evidence that very young children may be relatively resistant to its psychoactive properties. A research group in Israel examined the antiemetic effects of delta-8-tetrahydrocannabinol (a natural isomer) in a series of children undergoing chemotherapy (Abrahamov & Mechoulam, 1995). Excellent efficacy and tolerance was observed at doses that would be expected to produce significant psychoactivity in adults. People employing cannabis therapeutically must be warned of the usual caveats assigned to any potentially sedative drug: due care with operation of machinery, motor vehicles, etc.

Acute overdosages of cannabis are self-limited, and most frequently consist of panic reactions. These are uniquely sensitive to reassurance ("talking down") and are quite unusual once a patient becomes familiar with the drug. Cannabis has a unique distinction of safety over four millennia of analgesic usage: No credible deaths due to direct toxicity of cannabis have ever been documented in the medical literature. An extremely detailed review of chronic cannabis effects in a medical context is available (E. B. Russo et al., 2002).

Some cannabis–drug interactions are apparent, but are few in number or consequence. Additive sedative effects with other agents, including alcohol, may be observed. Similarly, however, additive or synergistic antiemetic and analgesic benefits may accrue when combining dopamine agonist neuroleptics and cannabis (Carta et al., 1999). Cannabis may accelerate metabolism of theophylline, while slowing that of barbiturates. Anticholinergic-induced tachycardia may be accentuated by cannabis, while this effect is countered by beta-blockers (Grotenhermen, 2001b). Indomethacin seems to reduce slightly the psychoactive and tachycardic effects of cannabis (Perez-Reyes, Burstein, White, McDonald, & Hicks, 1991). As discussed above, synergistic analgesic benefits may accrue with concomitant usage of cannabis and opioids (Cichewicz et al., 1999; Hare, 1887).

Crude cannabis contains most of its THC in the form of delta-9-THC acids that must be decarboxylated by heating to be activated. This occurs automatically when can-

nabis is smoked, whereas herbal cannabis that is employed orally should be heated to 200 to 210°C for 5 minutes prior to ingestion (Brenneisen, 1984).

Contrary to political opinion in the United States, *average* cannabis potency has varied little over the last three decades (ElSohly et al., 2000; Mikuriya & Aldrich, 1988). It is true that the *maximum* potency has increased through applied genetics, cultivation, and harvesting techniques. This goal is achieved through production of clonal cultivation of the preferred female plants and maximization of the yield of unsterilized flowering tops known as *sinsemilla* (Spanish for "without seed"). In this manner a concentration of stalked trichomes where THC and therapeutic terpenoids are produced is effected. Resultant yields of THC may exceed 20% by weight. This is potentially advantageous, particularly if smoked, because a therapeutic dosage of THC is obtained with fewer inhalations, thereby decreasing lung exposure to tars and potential carcinogens.

A considerable concentration of THC, other cannabinoids, and terpenoids may also be achieved through some simple processing of crude dried cannabis. Techniques for sieving or washing of cannabis to isolate the trichomes to produce hashish are well described (Clarke, 1998; Rosenthal, Gieringer, & Mikuriya, 1997), and may produce potential yields of 40 to 60% THC. Clarke demonstrates a simple method of rolling the resultant powdery material into a joint of pure hashish, termed "smoking the snake" (Clarke, 1998), providing a relatively very pure product for inhalation.

Cultivation techniques are beyond the scope of this review, but are freely available through a variety of guidebooks (Clarke, 1981; Rosenthal et al., 1997), magazines such as *Cannabis Culture* or *High Times,* or via the Internet to those who live in jurisdictions where this endeavor is legal. Outdoor, indoor, or hydroponic techniques are possible. Recent reviews outline good agricultural practice in cultivation of cannabis (Anonymous, 2003), its husbandry for medical usage in an industrial setting (Potter, 2004; E. B. Russo, 2003), and a primer on cannabis genetics (E. P. de Meijer et al., 2003). Emphasis should focus on potent medicinal strains, scrupulous organic cultivation of female plants, clonal selection and augmentation, and appropriate processing, all combined with best available techniques of harm reduction.

Oral Use of Cannabis

A variety of issues attend this mode of cannabis administration. The most important one concerns bioavailability. Oral absorption of cannabinoids is slow and erratic at best, often requiring 30 to 120 minutes. In HIV-positive or chemotherapy patients and in acute migraine, nausea and emesis may preclude oral usage altogether. Additionally, oral THC is subject to the "first pass effect" of hepatic

metabolism yielding 11-hydroxy-THC, which may be more psychoactive than THC itself. Thus, some patients clearly become "too high" even on low doses of medicine, such as 2.5 mg of THC as dronabinol.

Advantages of oral usage are its avoidance of lung exposure in those who are immunosuppressed or have impaired pulmonary function, and its prolonged half-life. This may be of advantage for nocturnal complaints where sedation is less of an issue.

Grotenhermen suggests dose titration beginning with 2.5 mg of oral THC bid with increases as needed and tolerated (Grotenhermen, 2001b). For cannabis of 5% THC content, this would represent 50 mg of herb per dose. For 10% THC cannabis, only 25 mg of plant material would be required. Most painful clinical conditions require tid dosing of cannabis.

THC, CBD, and terpenoids are all highly lipophilic. Gastrointestinal absorption is markedly enhanced by inclusion of lipids in the cooked preparations. Traditional Indian cannabis cookery makes good use of *ghee,* or clarified butter. When cannabis tea is employed, added cream will enhance clinical benefits. Therapeutic tincture extraction in alcohol is also possible.

Smoked Cannabis

Techniques of smoking cannabis are legion, and include marijuana cigarettes ("joint," "reefer," etc.), pipes, waterpipes ("hookahs"), bongs etc. Pharmacodynamically, smoking might seem a reasonable administration of clinical cannabis, but for its attendant pulmonary sequelae, lack of standardization, risks of intoxication, and illegality in most jurisdictions (E. B. Russo et al., 2002). Clinical effects are noted within seconds to minutes after smoking. Inhalation avoids the first pass effect that hampers oral use and allows effective dosage titration. Doses as low as 5 mg of THC equivalent may provide relief of clinical symptoms, while anecdotal evidence claims the ability to continue work or study with unimpaired effectiveness. When symptoms return, repeat dosage may be achieved quickly and easily. Overdosage is possibly avoidable.

In chronic usage of smoked cannabis, isolated cases of upper airway carcinogenesis have been noted (Tashkin, 2001). Precancerous cytological changes in the airways of heavy cannabis smokers have been observed via bronchoscopy but do not seem to lead to emphysematous deterioration (Tashkin, Simmons, Sherrill, & Coulson, 1997). There still has never been a documented case of a pulmonary malignancy in a cannabis-only smoker. That not withstanding, smoked cannabis is unlikely to be a vehicle that can achieve FDA approval as a prescription medicine, due to the irritant effects, lack of standardization, quality control, and similar issues herein discussed.

The "amotivational syndrome" has been largely relegated to the dustbin of drug war propaganda (Zimmer & Morgan, 1997). In fact, the interested reader may wish to seek out three rare books of the past generation on chronic usage that are remarkable for their careful documentation of the few distinguishing features between chronic cannabis smokers and age-matched controls (Carter, Coggins, Doughty, University of Florida Center for Latin American Studies, & National Institute on Drug Abuse, 1976; V. D. Rubin & Comitas, 1975; Stefanis et al., 1977). These are hardly ever mentioned in alarmist reviews of the dangers of cannabis.

Some old myths die hard. Traditional smoking techniques in the United States make prolonged holding of a marijuana "toke" *de rigueur.* From a dose–response standpoint, this is unnecessary. Inhaled THC is well absorbed after a very brief interval, and subjective high and serum THC levels do not increase beyond a maximum 10-second inhalation (Azorlosa, Greenwald, & Stitzer, 1995). Furthermore, prolonged breath holding under pressure increases the potential for hypoxia or pneumothorax (Tashkin, 2001).

Contamination of herbal cannabis by pesticides, herbicides, and bacterial or fungal agents is possible and may represent a threat to the smoker, especially immunosuppressed patients (McPartland, 2001b; McPartland & Pruitt, 1997; Tashkin, 2001). Scrupulous cultivation techniques avoid some of these issues. McPartland recommends pasteurization of herbal cannabis by heating in an oven of 150°C for 5 minutes (McPartland, 2001b).

Waterpipes and bongs are popular techniques for cooling smoke. While they may reduce particulate matter as well, THC content and pharmaceutical efficiency also seem to be compromised (Gieringer, 1996a, b). Surprisingly, the unfiltered "joint" seems to represent a relatively efficient means for conventional smoking, although use of hashish in a pipe (without tobacco) was not examined.

Vaporizers for Cannabis Administration

Vaporization of herbal cannabis may allow THC and terpenoid components below the flash point of the leaf, thereby reducing exposure to smoke, tar, and carcinogens. The technology has been hampered in its development by paraphernalia laws. Initial investigations of available second-generation devices were quite disappointing in their results (Gieringer, 1996a, b), but additional studies with the Volcano® vaporizer are more promising (E. B. Russo & Stortz, 2003). In a recent assay of the device, there was reasonable preservation of available THC, and a reduction, *but not elimination,* of potential carcinogens down to 5% of yield (Gieringer, St. Laurent, & Goodrich, 2004). A clinical trial of the Volcano vs. smoked cannabis was approved by the FDA in late 2003.

Rectal Administration

Suppository preparations of cannabis were employed in the 19th century and may be an acceptable alternative route of administration for some conditions. The first pass effect is largely avoided, although the ability for close dose titration is lost. THC suppositories as a hemisuccinate have proved to be twice as bioavailable as oral THC (Brenneisen, Egli, ElSohly, Henn, & Spiess, 1996; Broom, Sufka, ElSohly, & Ross, 2001; ElSohly et al., 1991; Mattes, Engelman, Shaw, & ElSohly, 1994). No studies have examined use of this preparation with respect to analgesia, but one might expect comparison with dronabinol at least with regard to the spectrum of activity. Synergistic combinations of cannabis components may be more valuable. Additionally, suppositories are not a popular method of drug delivery in the United States.

Transdermal Administration

The American Cancer Society has received a large grant to examine the use of a THC skin patch. Limited pharmacokinetic data are currently available to ascertain whether transdermal THC administration is a viable option (Brenneisen, 2001; Challapalli & Stinchcomb, 2002), but results to date have fallen far short of goals. Additionally, the gradient required to drive THC through the skin necessitates a large residual would remain in the patch that could represent a danger of diversion.

Sublingual/Oro-Mucosal Tincture of Cannabis

The oro-mucosal method of administration was first used in the 19th century, wherein Marshall described symptoms of cannabis intoxication after 45 minutes, as opposed to 4 hours after oral ingestion of a cannabis extract (Marshall, 1897). It has been under investigation by GW Pharmaceuticals in the United Kingdom employing combinations of specific strains of cannabis that are rich in THC or CBD. Terpenoids and other minor components that may be important to therapeutic effects of cannabis are retained in this fashion (Whittle & Guy, 2001; Whittle, Guy, & Robson, 2001). Dose-metered sublingual/oromucosal sprays are currently in Phase I to III clinical trials for a variety of indications, and approval as a prescription medicine for Sativex®, a whole cannabis extract with equal proportions of THC and CBD, was confirmed for central neuropathic pain in multiple sclerosis in Canada in 2005, and is expected for other indications in the United Kingdom, European Union, and British Commonwealth nations subsequently.

Further data on the raising of the plant material through application of Mendelian genetics are available (E. de Meijer, 2004; E. P. de Meijer et al., 2003), as is further information on its organic husbandry (Potter, 2003; E. B. Russo, 2003), processing with supercritical carbon dioxide extraction and production of cannabis-based medicine extracts (CBME; E. B. Russo, 2003; Whittle & Guy, 2003; Whittle, Guy, & Robson, 2003).

Phase I pharmacokinetic data on the material are available (Guy & Flint, 2003; Guy & Robson, 2003a, b). Clinical studies support good bioavailability, patient tolerance, and clinical effects. A Phase II clinical study in England with 24 patients with MS and intractable pain was performed as a consecutive series of double-blind, randomized, placebo-controlled single-patient cross-over trials with oro-mucosal CBME (Wade, Robson, House, Makela, & Aram, 2003). Pain scores on visual analogue scales were significantly improved over placebo with both high THC and high CBD CBME. Subjectively, spasm was significantly improved with high THC and THC:CBD fixed ratio extracts. Spasticity was also subjectively improved with the high THC CBME. All three extracts significantly improved objective measures of spasticity, while the high THC and THC:CBD fixed ratio CBME significantly improved objective measures of spasm (all improvements were $P < 0.05$).

In 34 patients with intractable pain in England (Notcutt et al., 2004), 7 experienced substantial improvement over best available conventional treatment with CBME, 13 moderate, and 8 some benefit. Many extended the range of their activities of daily living with acceptable levels of adverse effects.

Preliminary results of four Phase III clinical trials of CBME by GW Pharmaceuticals have revealed highly significant benefits ($P < 0.01$) in neuropathic pain in MS, pain and sleep disturbance in MS and other neurological diseases, multiple symptoms in MS, and neuropathic pain in brachial plexus injury. Most patients attained good symptomatic control with minimal side effects. Results are available online at http://www.gwpharm.com/news_pres_05_nov_02.html.

Aerosol THC Preparations

Cannabis has a long history of use in asthma, even as a smoked preparation. A pure THC aerosol has been attempted numerous times in the past. Physical and delivery issues have been challenging, but more interestingly, pure THC seems to have an irritating and even bronchoconstrictive effect when employed in isolation (Tashkin et al., 1977). This author believes that anti-inflammatory effects of concomitant terpenoid and flavonoid administration are necessary for full effects and tolerance in pursuit of the pulmonary route. Further research is under way by GW Pharmaceuticals, Inhale Therapeutic Systems, and possibly others. Preliminary Phase I data from GW Pharmaceuticals indicate that very rapid effects within seconds to minutes are produced, comparable with those from smoking cannabis (Guy & Flint, 2003). Although this rapid onset is not necessary for most chronic pain condition treatments, it may be of value in paroxysmal disorders

such as treatment of trigeminal neuralgia, or for break-through pain or spasm.

Guidelines for the Practice of Interventional Techniques

Laxmaiah Manchikanti, MD, Vijay Singh, MD, Andrea M. Trescot, MD,
Timothy R. Deer, MD, and Mark V. Boswell, MD, PhD

INTRODUCTION

Guidelines for the practice of interventional pain management are statements developed to assist physician and patient decisions about appropriate health care related to chronic pain.[1–4] These recommendations are professionally derived for practices in the diagnosis and treatment of chronic or persistent pain.

These guidelines do not constitute inflexible treatment recommendations. It is recommended that a provider establish a plan of care on a case-by-case basis, taking into account an individual patient's medical condition and the physician's experience. Based on an individual patient's needs, treatment different from that outlined here may be warranted. Each practice should develop their policies considering their needs. This document may be used as a template.

These guidelines have not been approved or endorsed by any agency or organization. Individual carriers including third-party payers, Medicare, and Medicaid operate under their own coverage, utilization, and local medical review policies. Thus, while each practice may have separate guidelines, it is always prudent to check with payors to make certain that guidelines correlate. However, the information from these guidelines may assist in providing an appropriate rationale for appeals, etc.

EVALUATION AND MEDICAL NECESSITY

Appropriate history, physical examination, and medical decision making comprise the initial evaluation of a patient's presenting symptoms. A patient's evaluation should not only meet the required medical criteria but also pertinent regulatory requirements.[5–9] The guidelines of the Centers for Medicare and Medicaid, formerly the Health Care Financing Administration, provide various criteria for five levels of service. The three crucial components of evaluation and management services are history, physical examination, and medical decision making. Other components include counseling, coordination of care, nature of presenting problem, and time.

HISTORY

The history includes

- Chief complaint
- History of present illness
- Review of systems
- Past, family, and/or social history

Chief Complaint

The chief complaint is a concise statement describing the symptom, problem, condition, diagnosis, or other factor that is the reason for the encounter; it is usually stated in the patient's words.

History of Present Illness

The history of present illness is a chronological description of the development of the patient's present illness

from the first sign and/or symptom. It includes the following elements:

- Location
- Quality
- Severity
- Duration
- Timing
- Context
- Modifying factors
- Associated signs and symptoms

Review of Systems

The review of systems is an inventory of body systems obtained through a series of questions seeking to identify signs and/or symptoms that the patient may be experiencing or has experienced.

Past, Family, and/or Social History

Past, family, and/or social history consists of a review of the past history of the patient including past experiences, illnesses, operations, injuries, and treatment; family history, including a review of medical events in the patient's family, hereditary diseases, and other factors; and social history, appropriate for age, reflecting past and current activities.

Past history in interventional pain medicine includes history of past pain problems and motor vehicle, occupational, or non-occupational injuries; history of headache, neck pain, upper-extremity pain, pain in the upper or mid back or chest wall, pain in the lower back or lower extremities, and pain in joints; and disorders such as arthritis, fibromyalgia, or systemic lupus erythematosus.

Family history includes history of pain problems in the family, degenerative disorders, familial disorders, drug dependency, alcoholism, or drug abuse; and psychological disorders such as depression, anxiety, schizophrenia, suicidal tendencies, etc. Family history of medical problems is also important.

Social history includes environmental information such as education, marital status, children, habits, hobbies, and occupational history, whenever available.

PHYSICAL EXAMINATION

Physical examination in interventional pain medicine involves general, musculoskeletal, and neurological examination.

Examination of other systems, specifically cardiovascular, lymphatic, skin, eyes, and cranial nerves is recommended, based on the presenting symptomatology.

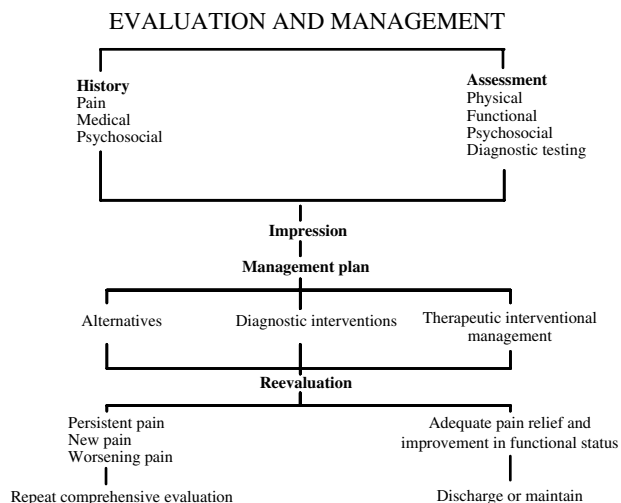
EVALUATION AND MANAGEMENT


FIGURE 57.1 Suggested algorithm for comprehensive evaluation and management of chronic pain. From Evidence-based practice guidelines for interventional techniques in the management of chronic spinal pain, by L. Manchikanti et al. (2003), *Pain Physician, 6,* 3–80. Reproduced with permission of the authors and the American Society of Interventional Pain Physicians (ASIPP).

MEDICAL DECISION MAKING

Medical decision making refers to the complexity of establishing a diagnosis and/or selecting a management option as measured by three components:

1. Diagnosis/management options with a number of possible diagnoses and/or the number of management options
2. Review of records/investigations, with number and/or complexity of medical records, diagnostic tests, and other information that must be obtained, reviewed, and analyzed
3. Risk(s) of significant complications, morbidity, and mortality, as well as comorbidities associated with the patient's presenting problem(s), the diagnostic procedure(s), and/or the possible management options

Psychological evaluation, laboratory evaluation, imaging techniques, electromyography, and nerve conduction and somatosensory evoked potentials are also an extension of the evaluation process. It is beyond the scope of these guidelines to discuss these assessment techniques.

Appropriate history and physical examination with the assistance of other evaluations should direct a physician to formulate a provisional diagnosis. A suggested algorithm for comprehensive evaluation and management of chronic pain is illustrated in Figure 57.1.

MEDICAL NECESSITY DOCUMENTATION

The following criteria should be considered carefully in performing interventional techniques:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to less invasive modalities of treatment except in acute situations such as acute disc herniation, herpes zoster and postherpetic neuralgia, reflex sympathetic dystrophy, and intractable pain secondary to carcinoma
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as severe spinal stenosis resulting in intraspinal obstruction, infection, or predominantly psychogenic pain
   - Responsiveness to prior interventions with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

INTERVENTIONAL TECHNIQUES

The overall benefit of various types of injection techniques includes pain relief outlasting by days, weeks, or months the relatively short duration of pharmacologic action of the local anesthetics and other agents used.[1-4,10] Clear-cut explanations for these benefits are not currently available. It is believed that neural blockade alters or interrupts nociceptive input, reflex mechanisms of the afferent limb, self-sustaining activity of the neuron pools and neuraxis, and the pattern of central neuronal activities. The explanations are based in part on the pharmacological and physical actions of local anesthetics, corticosteroids, and other agents. It is also believed that local anesthetics interrupt the pain–spasm cycle and reverberating nociceptor transmission, whereas corticosteroids reduce inflammation either by inhibiting the synthesis or release of a number of proinflammatory substances. Various modes of action of corticosteroids include membrane stabilization, inhibition of neural peptide synthesis or action, blockade of phospholipase A_2 activity, prolonged suppression of ongoing neuronal discharge, suppression of sensitization of dorsal horn neurons, and reversible local anesthetic effect. In addition, local anesthetics have been shown to produce prolonged dampening of C-fiber activity.[10]

Physical effects include clearing adhesions or inflammatory exudates from the vicinity of the nerve root sleeve. The scientific basis of some of these concepts, at least in part, is proven for spinal pain management with epidural injections of betamethasone and intravenous methylprednisolone.

DIAGNOSTIC INTERVENTIONAL TECHNIQUES

Diagnostic blockade of a structure with a nerve supply that can generate pain can be performed to test the hypothesis that the target structure is a source of the patient's pain. Testing the hypothesis by provoking pain in any structure is an unreliable criterion except in provocative discography. Although neurodiagnostics of the involved nerve pathways have proven valuable, the relief of pain is the essential criterion in almost all structures, including analgesic discography in the cervical spine, the only deviation being lumbar discs. If the pain is not relieved, the source may be in another structural component of the spine similar to the one tested such as a different facet joint or a different nerve root or some other structure. Thus, precision diagnostic injections directed toward specific spinal pathology are potentially powerful tools for diagnosis of chronic spinal pain, but are often technically challenging.[11,12] Identifying the specific pathology responsible for pain is often difficult, leading to frustrated patients and clinicians. Nevertheless, these injections may be safely performed by properly trained anesthesiologists, physiatrists, neurologists, radiologists, spine surgeons, and physicians from other related specialties who take the time to learn the basis for, and perfect, the application of these techniques.

When the source of pain is more than one structure or multiple levels, it is not expected that all the pain will be relieved. For example, there may be painful facet joints bilaterally at a given segmental level, in which case anesthetizing the left joint should relieve the left side, but not the right side; there may be pain from two consecutive joints on one side, in which case anesthetizing the lower joint alone may relieve only the lower half of the pain; or there may be more than one structure involved, such as pain contributed by discs and facet joints or facet joints and nerves.

True-positive responses are secured by performing controlled blocks. Ideally, this should be in the form of placebo injections of normal saline, but logistical and/or ethical considerations prohibit the use of normal saline in conventional practice.

Rationale

The rationale for diagnostic neural blockade in the management of spinal pain stems from the fact that in the absence of disc herniation and neurological deficit clinical

TABLE 57.1
Profile of Commonly Used Epidural Steroids

| Drug | Equivalent Dose | Epidural Dose | Anti-Inflammatory Potency | Sodium Retention Capacity | Duration of Adrenal Suppression | | |
					IM	Single Epidural	Three Epidurals
Hydrocortisone	20 mg	N/A	1	1	N/A	N/A	N/A
Depo-methylprednisolone (Depo-Medrol®)	4 mg	40–80 mg	5	0.5	1–6 weeks	1–3 weeks	N/A
Triamcinolone diacetate (Aristocort®)	4 mg	25–50 mg	5	0	1–2 weeks	1–5 weeks	N/A
Triamcinolone acetonide (Kenalog®)	4 mg	40–80 mg	5	0	2–6 weeks	N/A	2–3 months
Betamethasone (Celestone Soluspan®)	0.6 mg	6–12 mg	25	0	1–2 weeks	N/A	N/A

features and imaging or neurophysiologic studies do not permit the accurate diagnosis of the causation of spinal pain in the majority of patients. Further rationale is based on the recurring facts showing the overall rate of inaccurate or incomplete diagnosis in patients referred to pain treatment centers as ranging from 40 to 67%, the incidence of psychogenic pain to be only 1 in 3,000 patients, and the presence of organic origin of the pain mistakenly branded as psychosomatic in 98% of cases.[13,14] Finally, chronic low back pain is a diagnostic dilemma in 85% of patients, even in experienced hands with all the available technology.[11,12,15,16] Structural basis of spinal pain has been well established.[17–22] It has been determined that utilizing alternative means of diagnosis, including precision diagnostic blocks in cases where there is a lack of definitive diagnostic radiologic or electrophysiologic criteria, can enable an examiner to identify the source of pain in the majority of patients, thus reducing the proportion of patients who cannot be given a definite diagnosis from 85 to 30% or even as low as 15%.[4,11,12,20,21]

THERAPEUTIC INTERVENTIONAL TECHNIQUES

The rationale for therapeutic interventional techniques in the spine is based on several considerations: the cardinal source of chronic spinal pain, namely, discs and joints, is accessible to neural blockade; removal or correction of structural abnormalities of the spine may fail to cure and may even worsen painful conditions; degenerative processes of the spine and the origin of spinal pain are complex; and the effectiveness of a large variety of therapeutic interventions in managing chronic spinal pain has not been demonstrated conclusively. It has been shown that there is no conclusive evidence supporting the effectiveness of numerous conservative modalities used in managing chronic low back pain, including drug therapy, manipula-

tion, back schools, electromyographic biofeedback therapy, exercise therapy, traction and orthoses, behavioral/cognitive/relaxation therapy, and transcutaneous electrical nerve stimulation. There are a multitude of interventional techniques in the management of chronic pain, including not only neural blockade but also minimally invasive surgical procedures such as peripheral nerve blocks, trigger-point injections, epidural injections, facet joint injections, sympathetic blocks, neuroablation techniques, intradiscal thermal therapy, disc decompression, morphine pump implantation, and spinal cord stimulation.

DELIVERY

There is no consensus among interventional pain management specialists with regards to type, dosage, frequency, total number of injections, or other interventions, yet significant attention in the literature seems to be focused on the complications attributed to the use of epidural steroids in the entire arena of interventional pain management. Thus, various limitations of interventional techniques, specifically neural blockade, have arisen from basically false impressions. Based on the available literature and scientific application, the most commonly used formulations of long-acting steroids (see Table 57.1), which include methylprednisolone (Depo-Medrol®), triamcinolone diacetate (Aristocort®), triamcinolone acetonide (Kenalog®), and betamethasone acetate and phosphate mixture (Celestone Soluspan®), appear to be safe and effective.[10] Based on the present literature, it appears that if repeated within 2 weeks, betamethasone probably would be the best choice in avoiding side effects; whereas if treatment is carried out at 6-week intervals or longer, any one of the four formulations would be safe and effective.

Frequency and total number of injections or interventions are a key issue, although controversial and rarely

addressed. Some authors recommend one injection for diagnostic as well as therapeutic purposes; others advocate three injections in a series irrespective of the patient's progress or lack thereof; still others suggest three injections followed by a repeat course of three injections after 3-, 6-, or 12-month intervals; and, finally, there are some who propose an unlimited number of injections with no established goals or parameters. Limitation of 3 mg/kg of body weight of steroid or 210 mg per year in an average person and a lifetime dose of 420 mg of steroid, equivalent to methylprednisolone, also have been advocated. While some investigators recommend one injection and do not repeat if there has been no response to the first, others recommend one or two more injections in the absence of response to the first injection. Some authors have reported good pain relief in previously unresponsive patients after an additional one or two injections. Similarly, some have believed that more than three injections do not result in additional improvement,[23] whereas others have reported the use of 6 to 10 injections if they are of benefit, however, not to exceed 3 if they are not beneficial.[24,25] Such descriptions for other interventional techniques have been extrapolated from the limitations described for epidural steroid injections, even though there is no scientific basis or justification for such an extrapolation, as the techniques and type and dosage drugs are vastly different. It also has been shown in a multitude of publications that relief following multiple injections or interventions demonstrated a staircase-type phenomenon, even though it reached a plateau after three to four interventions.

AN ALGORITHMIC APPROACH

In the changing paradigm of modern medicine, with its major focus on evidence-based medicine, interventional pain physicians are forced to learn and practice evidence-based interventional pain management. The necessary ingredients to provide evidence-based care include the following:

- Precise definition of the problem/diagnosis
- Research of best evidence
- Critical appraisal of the evidence
- Consideration of the evidence and its implications, in the context of the patient's condition, circumstances, and values

Even though a basic understanding of these ingredients may appear not only easy, but simple, developing expertise with the incorporation of evidence, and meticulous application of evidence to a patient's situation, is difficult and time-consuming. Thus, an algorithmic approach, if developed properly, may assist a physician in the clinical practice of interventional pain management.

We have developed an algorithmic approach based on the structural basis of spinal pain, moderate to strong evidence of diagnostic techniques available in arriving at a structural diagnosis of spinal pain (not available by means of radiological evaluation, physical examination, and electrodiagnostic testing), and employing effective interventional techniques available in managing chronic spinal pain. Consensus was used in the absence of evidence. Figure 57.2 and Figure 57.3 describe proposed algorithmic approaches for diagnosis and management of chronic low back pain, whereas Figure 57.4 describes a proposed algorithmic approach for diagnosis of chronic neck pain.

EPIDURAL INJECTIONS[26–53]

DESCRIPTION

Spinal pain generates from multiple structures in the spine with a nerve supply capable of causing pain similar to that seen in clinically normal volunteers, and that are susceptible to diseases or injuries that are known to be painful. Certain conditions may not be detectable using currently available technology or biochemical studies. However, for a structure to be implicated, it should have been shown to be a source of pain in patients, using diagnostic techniques of known reliability and validity. The structures responsible for pain in the spine include the intervertebral discs, spinal cord, nerve roots, facet joints, ligaments, muscles, and sacroiliac joints.

One of the most common structures responsible for pain in the spine is the intervertebral disc. Even though disc herniation is seen only in a small number of patients, degeneration of the disc resulting in primary discogenic pain is seen much more commonly. In contrast to a ruptured disc with pain arising from the nerve root, in discogenic pain a disc with or without internal disruption is implicated rather than the nerve root.

Postlaminectomy syndrome, or pain following operative procedures of the spine, sometimes also known as failed management syndrome, is becoming a common entity in modern medicine. It is estimated that 20 to 30% of spinal surgeries, occasionally up to as high as 60%, may not be successful as a result of the surgery being either inadequate, incorrect, or unnecessary; but also it may result following a well-indicated and well-performed surgical procedure. Even in cases of successful surgery, pain and subsequent disability have returned after variable periods of 6 months to 20 years. However, surgical results are extremely poor in patients after a failed surgical procedure. Other spinal conditions include various degenerative disorders such as spinal stenosis, spondylolysis, spondylolisthesis, degenerative scoliosis, idiopathic vertebrogenic sclerosis, diffuse idiopathic spinal hyperostosis, and segmental instability. Degenerative conditions other

than disc disruption and facet arthritis may contribute to approximately 5 to 10% of spinal pain.

CURRENT PROCEDURAL TERMINOLOGY (CPT) CODES

- 62310 Injection, single, not including neurolytic substances, with or without contrast of diagnostic or therapeutic substance(s); epidural or subarachnoid; cervical or thoracic
- 62311 Injection, single, not including neurolytic substances, with or without contrast of diagnostic or therapeutic substance(s); epidural or subarachnoid; lumbar, sacral (caudal)
- 62318 Catheter placement, continuous infusion for intermittent bolus; epidural or subarachnoid; cervical or thoracic
- 62319 Catheter placement, continuous infusion for intermittent bolus; epidural, lumbar, sacral (caudal)
- 64479 Cervical/thoracic transforaminal epidural, single level
- 64480 Cervical/thoracic transforaminal epidural, each additional level
- 64483 Transforaminal epidural; lumbar or sacral, single level
- 64484 Transforaminal epidural; lumbar or sacral, each additional level

- 72275 Epidurography, radiological supervision and interpretation
- 76005 Fluoroscopic guidance and localization of needle or catheter tip for spine or paraspinous diagnostic or therapeutic injection procedures (epidural, transforaminal epidural, subarachnoid, paravertebral facet joint, paravertebral facet joint nerve, or sacroiliac joint), including neurolytic agent destruction

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully when performing epidural injections:

1. Complete initial evaluation including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to less invasive modalities of treatments except in acute situations such as acute disc herniation, herpes zoster and postherpetic neuralgia, reflex sympa-

thetic dystrophy, and intractable pain secondary to carcinoma

- Pain and disability of moderate to severe degree
- No evidence of contraindications such as severe spinal stenosis resulting in intraspinal obstruction, infection, or predominantly psychogenic pain
- Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
- Repeating interventions only upon return of pain and deterioration in functional status

ICD-9[1] CODES THAT SUPPORT MEDICAL NECESSITY

1. Postlaminectomy syndrome: 722.81 cervical, 722.82 thoracic, 722.83, lumbosacral
2. Disc displacement without myelopathy (disc herniation, radiculitis, disc extrusion, disc protrusion, disc prolapse, discogenic syndrome): 722.0 cervical, 722.11 thoracic, 722.10 lumbosacral
3. Disc displacement with myelopathy: 722.71 cervical, 722.72 thoracic, 722.73 lumbosacral
4. Degeneration of intervertebral disc (includes narrowing of disc space): 722.4 cervical, 722.51 thoracic, 722.52 lumbosacral
5. Radiculitis: 723.4 cervical, 724.4 thoracic, 724.4 lumbosacral
6. Spinal stenosis: 723.0 cervical, 724.04 thoracic, 724.02 lumbosacral
7. Spondylosis with myelopathy: 721.1 cervical, 721.41 thoracic, 721.42 lumbosacral
8. Closed fracture of spine: 805.0 cervical, 805.2 thoracic, 805.4 lumbar, 805.6 sacral
9. Congenital spondylolysis: 756.11 cervical, 756.11 thoracic, 756.11 lumbosacral
10. Acquired/degenerative spondylolysis or acquired spondylolisthesis: 738.4 cervical, 738.4 thoracic, 738.4 lumbosacral
11. Congenital spondylolisthesis: 756.12 cervical, 756.12 thoracic, 756.12 lumbosacral
12. Coccygodynia: 724.79
13. Sciatica: 724.3
14. Complex regional pain syndrome (Type I or reflex sympathetic dystrophy): 337.20 reflex sympathetic dystrophy unspecified, 337.21 reflex sympathetic dystrophy upper limb, 337.22 reflex sympathetic dystrophy lower limb, 337.29 reflex sympathetic dystrophy other unspecified site

15. Complex regional pain syndrome (Type II or causalgia): 355.9 causalgia, 354.4 causalgia upper limb, 355.71 causalgia lower limb
16. Peripheral neuropathy: 356.4 idiopathic, 356.0 hereditary, 357.2 diabetic, 357.5 alcoholic, 357.6 due to drug
17. Limb pain: 353.6 phantom limb pain, 997.60 stump pain, 997.61 neuroma of amputation stump, 342.0 hemiplegia–flaccid, 342.1 hemiplegia–spastic
18. Postherpetic neuralgia: 053.10 with unspecified nerve system complication, 053.13 postherpetic polyneuropathy
19. Pain syndromes secondary to neoplasm 141.0–239.9
20. Vascular ischemic pain 440.22

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic phase, a patient may receive injections at intervals of no shorter than 1 week or preferably, 2 weeks, except for blockade in cancer pain or when a continuous administration of local anesthetic is employed for reflex sympathetic dystrophy.
- In the therapeutic phase (after the diagnostic phase is completed), the frequency of interventional techniques should be 2 months or longer between each injection, provided that at least ≥50% relief is obtained for 6 to 8 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week and preferably 2 weeks for most types of blocks. The therapeutic frequency must remain at least 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely.
- In the diagnostic phase, the number of injections should be limited to no more than two times except for reflex sympathetic dystrophy, in which case three times is reasonable.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times.
- Under unusual circumstances with a recurrent injury, carcinoma, or reflex sympathetic dystrophy, blocks may be repeated at intervals of 6 weeks after diagnosis/stabilization in the treatment phase.
- Total number of interventions are applied separately for each region.

---

[1] *International Classification of Diseases,* Ninth Revision.

COMBINATIONS OF BLOCKS/INTERVENTIONS

It may be essential to combine, in certain circumstances, more than one block. This may include an epidural for the cervical region and facet-joint blocks for the lumbar region, or epidural and facet-joint blocks for the same region in the case of identification of pain generators from both sources.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for epidural injections.

It is preferable to perform interlaminar epidural injections (CPT 62310, 62311) in interventional pain management under fluoroscopy. It is mandatory to perform transforaminals under fluoroscopy. If interlaminar or caudal epidurals are performed without fluoroscopy, response to the first epidural injection must always be documented. If the response to the first injection is inadequate either in quality (level of pain relief ≤ 50%) or quantity (less than 1 week), the next treatment must be performed under fluoroscopy.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

FACET JOINT BLOCKS[11,12–21,54–77]

DESCRIPTION

Spinal pain generates from multiple structures in the spine with a nerve supply capable of causing pain similar to that seen in clinically normal volunteers; these structures are susceptible to diseases or injuries that are known to be painful. Certain conditions may not be detectable using currently available technology or biochemical studies. However, for a structure to be implicated, it should have been shown to be a source of pain in patients, using diagnostic techniques of known reliability and validity. The structures responsible for pain in the spine include the intervertebral discs, spinal cord, nerve roots, facet joints, ligaments, and muscles.

Disc herniation, strained muscles, and torn ligaments have been attributed in the past to be the cause of most spinal pain. However, in the neck and upper extremities, upper and mid back, or low back and lower extremities; disorders of the spinal joints, which include facet joints, have been implicated more commonly than disc herniation, attributing some 50% of spinal pain to these joints. Facet joints were described as a potential source of low back pain as early as 1911, 20 years earlier than ruptured discs. The existence of lumbar facet joint pain is supported by a preponderance of scientific evidence, even though a few detractors have disputed this. The prevalence of facet joint pain in patients with chronic spinal pain has been established as 15 to 45% in low back pain, 42 to 48% in chronic thoracic pain, and 54 to 67% in neck pain, utilizing controlled diagnostic blocks, based on type of setting and population studied.

In managing low back pain, local anesthetic injection into the facet joints or interruption of the nerve supply to the facet joints has been accepted as the standard for diagnosis of facet joint pain. Because a single joint is innervated by at least two medial branches, two adjacent levels should always be blocked.

If the pain is relieved, the joint may be considered to be the source of pain. However, false-positive responses, which may be seen in 27 to 63% in cervical spine, 45 to 58% in thoracic spine, and 17 to 47% in lumbar spine of the patients, must be ruled out.

- All the patient's pain need not be relieved, for it is possible that a patient may have several sources of pain.
- Comparative local anesthetic blocks, should be administered so that the same joint is anesthetized on two separate occasions, but using local anesthetics with different durations of action or placebo blocks.
- A true-positive response confirms that the joint is the source of the pain, with a confidence of 85%.

It is recognized that it may be necessary to provide additional blocks such as selective nerve root or selective epidural blocks and disc injections in conjunction with facet-joint blocks. It is also recognized that multiple levels of facet-joint blocks may be performed in one setting, either in the same region or in multiple regions, more commonly than not.

Multiple blocks are provided only with proper evaluation to determine pain generator(s). Once a structure is proved to be negative, no interventions must be directed at that structure.

Therapeutic facet joint blocks are based on the outcome of a diagnostic facet-joint block, with the patient obtaining sufficient relief for a meaningful period of time; but when pain recurs, a repeat block using a small dose of local anesthetic and steroid provides longer-lasting relief (4 to 8 weeks).

If facet joint pain is present in conjunction with radiculopathy, both ailments should be managed.

CURRENT PROCEDURAL TERMINOLOGY (CPT) CODES

- 64470 Cervical paravertebral facet joint nerve block, single level
- 64472 Injection, cervical facet joint nerve block, each additional level

- 64475 Injection, lumbar facet joint nerve block, single level
- 64476 Injection, lumbar facet joint nerve block, each additional level
- 76005 Fluoroscopic guidance and localization of needle or catheter tip for spine or paraspinous diagnostic or therapeutic injection procedures (epidural, transforaminal epidural, subarachnoid, paravertebral facet joint, paravertebral facet joint nerve, or sacroiliac joint), including neurolytic agent destruction

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully when performing facet blocks:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem
   - Nonresponsiveness to less invasive modalities of treatments except in acute situations such as acute disc herniation, herpes zoster and postherpetic neuralgia, reflex sympathetic dystrophy, and intractable pain secondary to carcinoma
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
   - Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Spondylosis without myelopathy, dorsal arthritis, osteoarthritis, and spondyloarthritis (facet-joint arthropathy): 721.0 cervical, 721.2 thoracic, 721.3 lumbar, and 721.7 traumatic spondylopathy
2. Spondylolysis: 756.11 congenital, 738.4 acquired
3. Spondylolisthesis: 756.12 congenital, 738.4 acquired

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.

- In the therapeutic phase (after the stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least ≥50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or preferably 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely. AdminaStar Federal of Kentucky and Indiana limits to a total of six blocks per year, per region.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks for a period of 1 year per region.
- Under unusual circumstances with a recurrent injury or cervicogenic headache, blocks may be repeated at intervals of 6 weeks after stabilization in the treatment phase.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for facet joint injections as described above.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

Facet joint blocks must always be performed under fluoroscopy.

MEDIAL BRANCH NEUROTOMY[54-86]

DESCRIPTION

Spinal pain generates from multiple structures in the spine with a nerve supply capable of causing pain similar to that seen in clinically normal volunteers; these structures are susceptible to diseases or injuries that are known to be painful. Certain conditions may not be detectable using currently available technology or biochemical studies. However, for a structure to be implicated, it should have been shown to be a source of pain in patients, using diagnostic techniques of known reliability and validity. The structures responsible for pain in the spine include the intervertebral discs, spinal cord, nerve roots, facet joints, ligaments, and muscles.

Even though disc herniation, strained muscles, and torn ligaments have been attributed in the past to be the cause of most spinal pain in the neck and upper extremities, the upper and mid back, or the low back and lower extremities, disorders of the spinal joints, which include facet joints, have been implicated more commonly than disc herniation, attributing some 50% of spinal pain to these joints. Facet joints were described as a potential source of low back pain as early as 1911, 20 years earlier than ruptured discs. The existence of lumbar facet joint pain is supported by a preponderance of scientific evidence, even though a few detractors have disputed this. The prevalence of facet joint pain in patients with chronic spinal pain has been established as 15 to 45% in low back pain, 42 to 48% in chronic thoracic pain, and 54 to 67% in neck pain utilizing controlled diagnostic blocks.

Facet joint denervation is based on the outcome of a diagnostic facet joint block, with the patient obtaining sufficient relief for a meaningful period of time; but, when pain recurs, a repeat block using a small dose of local anesthetic and steroid does not provide longer-lasting relief. This is performed either by injecting neurolytic substance or by denervation utilizing radiofrequency thermoneurolysis or cryoneurolysis.

If facet joint pain is present in conjunction with radiculopathy, both ailments should be managed.

CPT Codes

- 64626 Destruction by neurolytic agent, paravertebral facet joint nerve; cervical or thoracic, single level
- 64627 Destruction by neurolytic agent, paravertebral facet joint nerve; cervical or thoracic, each additional level
- 64622 Destruction by neurolytic agent, paravertebral facet joint nerve; lumbar or sacral, single level
- 64623 Destruction by neurolytic agent, paravertebral facet joint nerve; lumbar or sacral, each additional level
- 76005 Fluoroscopic guidance and localization of needle or catheter tip for spine or paraspinous diagnostic or therapeutic injection procedures (epidural, transforaminal epidural, subarachnoid, paravertebral facet joint, paravertebral facet joint nerve, or sacroiliac joint), including neurolytic agent destruction

Indications and Medical Necessity

The following criteria should be considered carefully in performing facet neurolytic blocks:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem
   - Nonresponsiveness to less invasive modalities of treatments except in acute situations such as acute disc herniation, herpes zoster and postherpetic neuralgia, reflex sympathetic dystrophy, and intractable pain secondary to carcinoma
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
   - Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status
4. Confirmation of facet joint pain with double diagnostic blocks

ICD-9 Codes That Support Medical Necessity

1. Spondylosis without myelopathy, dorsal arthritis, osteoarthritis, and spondyloarthritis (*facet-joint arthropathy*): 721.0 cervical, 721.2 thoracic, 721.3 lumbar, and 721.7 traumatic spondylopathy
2. Spondylolysis: 756.11 congenital, 738.4 acquired
3. Spondylolisthesis: 756.12 congenital, 738.4 acquired

Frequency and Number of Interventions

- The frequency should be limited to 3 months or longer between each injection, provided that at least ≥50% relief is obtained for 10 weeks. However, if the neurotomy is applied for different regions, it can be performed at intervals of no sooner than 1 month. The therapeutic frequency must remain at 3 months for each region. AdminaStar Federal of Kentucky and Indiana (www.astar-federal.com/anthem/affiliates/adminastar) limits to a total of two neurotomies per year.
- The interventional procedures should be repeated only as necessary judging by the medical necessity criteria.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for the diagnosis of facet joint pain and neurolytic blocks.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

Medial branch neurotomy must always be performed under fluoroscopy.

PERCUTANEOUS LYSIS OF EPIDURAL ADHESIONS[1,87–96]

DESCRIPTION

Postlaminectomy syndrome or pain following operative procedures of the spine, sometimes known as failed management syndrome, is becoming a common entity in modern medicine. It is estimated that 20 to 30% of spinal surgeries, occasionally up to as high as 40%, may not be successful as a result of the surgery being inadequate, incorrect, or unnecessary, or may result following a well-indicated and well-performed surgical procedure. Even in cases of successful surgery, pain and subsequent disability have returned after variable periods of from 6 months to 20 years. In these cases, scar tissue development, destabilization of the spinal joints, and recurrent or repeat disc herniation may be responsible for continued pain problems. However, surgical results are extremely poor in patients after a failed surgical procedure. Epidural fibrosis may also develop without surgery.

Percutaneous nonendoscopic adhesiolysis and injection of hypertonic saline in the lumbar spine, its utilization, and its studies have been reasonable and acceptable. This modality of treatment appears to be reasonable in the management of refractory low back pain secondary to failed back surgery, disc disruption, and multilevel degenerative arthritis, even though there are a few detractors.

Percutaneous epidural adhesiolysis is also indicated for patients suffering with refractory low back pain secondary to a multitude of causes, including postlumbar laminectomy syndrome, lumbar epidural fibrosis, spinal stenosis and multilevel disc disruption, or multilevel degenerative arthritis. However, this should only be used after the failure of the conservative modalities of treatment, including caudal and transforaminal epidural injections.

CPT CODES

- 62263 Percutaneous lysis of epidural adhesions using solution injection, e.g., hypertonic saline, enzyme, or mechanical means, e.g., catheter, including radiologic localization (includes con-

trast when administered), multiple adhesiolysis sessions; 2 or more days
- 62264 Percutaneous lysis of epidural adhesions using solution injection, e.g., hypertonic saline, enzyme, or mechanical means, e.g., catheter, including radiologic localization (includes contrast when administered); 1 day

Note: Epidurography (CPT 72275) and fluoroscopic guidance (CPT 76005) are component codes of CPT 62263 and 62264.

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing lysis of epidural adhesions:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem
   - Presence of facet joints has been ruled out by clinical evaluation or diagnostic controlled facet joint blocks
   - Non-responsiveness to less invasive modalities of treatments including fluoroscopically directed caudal, interlaminar, or transforaminal epidural steroid injections
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
   - Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Postlaminectomy syndrome: 722.81 cervical, 722.82 thoracic, 722.83 lumbosacral
2. Epidural fibrosis: 349.2
3. Disc displacement with myelopathy: 722.71 cervical, 722.72 thoracic, 722.73 lumbosacral
4. Disc displacement without myelopathy (disc herniation, radiculitis, disc extrusion, disc protrusion, disc prolapse, discogenic syndrome): 722.0 cervical, 722.11 thoracic, 722.10, lumbosacral

5. Degeneration of intervertebral disc (includes narrowing of disc space): 722.4 cervical, 722.51 thoracic, 722.52 lumbosacral

FREQUENCY AND NUMBER OF INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 4 weeks.
- In the treatment or therapeutic phase, the number of procedures should be limited to:
  - With a 3-day protocol, two interventions per year
  - With a 1-day protocol, a maximum of four interventions per year.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for lysis of epidural adhesions.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

SPINAL ENDOSCOPIC ADHESIOLYSIS[1,97–105]

DESCRIPTION

Spinal endoscopy with epidural adhesiolysis is an invasive but important treatment modality in managing chronic low back pain that is nonresponsive to other modalities of treatment, including percutaneous spring guided adhesiolysis and transforaminal epidural injection(s).

Low back pain is the most common ailment in the modern era, burdening approximately 15 to 39% of the population with serious financial and social consequences, and ranking first among musculoskeletal disorders. Multiple investigators have shown that as many as 79% of patients continue to suffer with chronic or recurrent low back pain 1 year after its onset. Among various causes of low back pain, postlumbar laminectomy syndrome is increasingly recognized as a cause. It is estimated that 5 to 40% of lumbar surgeries result in failed back surgery syndrome, with some statistics showing failure rates reaching as high as 68%. Postlumbar laminectomy syndrome may result from surgery that may have been inadequate, incorrect, or unnecessary, but it may also result following a well-indicated and well-performed surgical intervention or without surgery. Endoscopic adhesiolysis is based on the premise that the three-dimensional visualization of the contents of the epidural space provides the operator with the ability to steer the catheter toward structures of interest, allowing the examination of a specific nerve root and its pathology, lysis of adhesions, and target-specific injection of a drug(s).

The purpose of spinal or epidural endoscopy is to directly visualize the contents of the epidural space, lyse the adhesions, and directly apply drugs, thus assuring delivery of high concentrations of injected drugs to the target areas. Thus, spinal endoscopy with lysis of adhesions incorporates multiple therapeutic goals into one treatment, similar to percutaneous lysis of adhesions with a spring-guided catheter, with added advantages of direct visualization of the epidural space and its contents, a three-dimensional view, and increased steerability of endoscopic equipment with a fiber-optic catheter. Nomenclature used to describe this procedure includes *spinal canal endoscopy, spinal epiduroscopy, myeloscopy, spinal or lumbar epiduroscopy,* and *endoscopic adhesiolysis.*

Percutaneous epidural endoscopic adhesiolysis is also indicated for patients suffering with refractory low back pain secondary to a multitude of causes, including postlumbar laminectomy syndrome, lumbar epidural fibrosis, and multilevel disc disruption, or multilevel degenerative arthritis. However, this should only be used after the failure of conservative modalities of treatments, as well as other interventional procedures, including caudal and transforaminal epidural steroid injections and percutaneous lysis of adhesions.

CPT CODE

1. 0027T Endoscopic lysis of epidural adhesions with direct visualization using mechanical means, e.g., spinal endoscopic catheter system, or solution injection, e.g., normal saline, including radiologic localization and epidurography, which retained its approval even though EBI opposed the code.

Note: Epidurography (CPT 72275) and fluoroscopic guidance (CPT 76005) are component codes of CPT 0027T.

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing lysis of epidural adhesions:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem without facet joint arthropathy
   - Nonresponsiveness to other invasive modalities of treatments including fluoroscopically directed epidurals and percutaneous adhesiolysis

- Pain and disability of moderate to severe degree
- No evidence of contraindications such as severe spinal stenosis resulting in intraspinal obstruction, infection, or predominantly psychogenic pain
- Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
- Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 Codes That Support Medical Necessity

1. Postlaminectomy syndrome: 722.83 lumbosacral
2. Epidural fibrosis: 349.2
3. Disc displacement with myelopathy: 722.73 lumbosacral
4. Disc displacement without myelopathy (disc herniation, radiculitis, disc extrusion, disc protrusion, disc prolapse, discogenic syndrome): 722.10 lumbosacral
5. Degeneration of intervertebral disc (includes narrowing of disc space): 722.52 lumbosacral

Frequency and Number of Injections or Interventions

- Spinal endoscopy with adhesiolysis may not be repeated within 6 months after the procedure.

Documentation Requirements

The patient's medical record must contain documentation that fully supports the medical necessity for lysis of epidural adhesions.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

PROVOCATIVE DISCOGRAPHY[106–116]

Description

Disc herniation, strained muscles, and torn ligaments have been attributed in the past as the cause of most spinal pain, in the neck and upper extremities, the upper and mid back, or the low back and lower extremities. However, disc herniation is seen only in a small number of patients, whereas degeneration of the disc resulting in primary discogenic pain is seen much more commonly. In contrast to a ruptured disc having pain arising from the nerve root, in discogenic pain a disc with or without internal disruption is implicated rather than the nerve root.

Even though riddled with controversy, disc stimulation is used quite frequently for diagnosis of discogenic syndrome, as well as a precursor to surgical intervention such as fusion. Stringent standards of practice have been established to ensure that the results of discography are not polluted by false-positive responses.

CPT Codes

- 62290 Injection procedure for discography, each level; lumbar
- 62291 Injection procedure for discography, each level; cervical or thoracic
- 72285 Discography, cervical or thoracic, radiological supervision and interpretation
- 72295 Discography, lumbar, radiological supervision and interpretation
- 76003 Fluoroscopic guidance for needle placement

Note: 76003 should not be used with discography interpretation codes CPT 72285 and CPT 72295. CPT 76005 is a component code of discography.

Indications and Medical Necessity

The following criteria should be considered carefully in performing disc interventions:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
4. Indications for discography:
   - Unremitting spinal pain, with or without extremity pain, of greater than 4 months' duration
   - The pain has been unresponsive to all appropriate methods of conservative therapy including fluoroscopically directed epidural steroid injections
   - Before discography, the patient should have undergone investigations with other modalities which have failed to explain the source of pain; such modalities should include, but not be limited to, computed tomography (CT) scanning, magnetic resonance imaging (MRI) scanning, and/or myelography. In

these circumstances, discography may be the only study capable of providing a diagnosis or permitting a precise description of the internal anatomy of the disc.

- To rule out secondary internal disc disruption or recurrent herniation in the postoperative patient
- To determine the number of levels to include in a spine fusion
- To determine the primary symptom-producing level when annular denervation (via thermocoagulation with an intradiscal catheter or a radiofrequency probe) is contemplated

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Disc displacement without myelopathy (disc herniation, radiculitis, extrusion, protrusion, prolapse, discogenic syndrome): 722.0 cervical, 722.11 thoracic, 722.10 lumbosacral
2. Degeneration of intervertebral disc including narrowing of disc space: 722.4 cervical, 722.51 thoracic, 722.52 lumbosacral

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for discography.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

SYMPATHETIC BLOCKS[3,4,117–127]

DESCRIPTION

The evolution of the nomenclature, conceptual understanding, and management of complex regional pain syndrome, formerly known as reflex sympathetic dystrophy and causalgia, has been dynamic. *Reflex sympathetic dystrophy, causalgia, sympathetically maintained pain, sympathetically independent pain*, and *complex regional pain syndrome* encompass some of the commonly used nomenclature. As per the International Association for the Study of Pain Committee on Taxonomy, to satisfy the diagnosis of complex regional pain syndrome Type I (reflex sympathetic dystrophy), the clinical findings include regional pain, sensory changes, e.g., allodynia, abnormalities of temperature, abnormal pseudomotor activity, edema, and an abnormal skin color that occurs after a noxious event. Complex regional pain syndrome Type II, or causalgia, includes all of the above-described features, in addition to a peripheral nerve lesion. However, the pathophysiology of these syndromes is poorly understood.

Sympathetically maintained pain, by definition, is eliminated by an anesthetic blockade of the sympathetic efferents that serve the painful area. Similarly, neuropathic pain, which is similar to reflex sympathetic dystrophy, however, represents various heterogeneous conditions, which can be explained neither by one single etiology nor by a particular anatomical lesion.

Visceral pain also may be caused by sympathetic overactivity. Temporary relief of abdominal visceral pain can therefore be obtained by blockade of the celiac plexus or lumbar or thoracic sympathetic chain.

In addition to the above conditions, sympathetic blockade may also be used for treatment of other painful conditions, including vascular ischemic pain, phantom limb pain, herpes zoster, postherpetic neuralgia, facial pain of unknown origin, neuropathic pain, pain secondary to carcinoma, headache, and other painful conditions, which may not be differentiated.

Numerous modalities of treatments include sympathetic ganglion blocks, intravenous regional blocks, physical therapy, administration of a host of pharmacological agents, behavioral interventions, and surgical interventions with either sympathetectomy or radiofrequency neurotomy.

CPT CODES

- 64505 Injection, anesthetic agent; sphenopalatine ganglion block
- 64510 Injection, anesthetic agent; stellate ganglion (cervical sympathetic)
- 64517 Injection, anesthetic agent; superior hypogastric plexus block
- 64520 Injection, anesthetic agent; lumbar or thoracic (paravertebral sympathetic)
- 64530 Injection, anesthetic agent; celiac plexus, with or without radiological monitoring
- 64680 Destruction by neurolytic agent; with or without radiologic monitoring; celiac plexus
- 64681 Destruction by neurolytic agent; with or without radiologic monitoring; superior hypogastric plexus
- 76003 Fluoroscopic guidance for needle placement

Note: A physician may use modifier 22 with sphenopalatine ganglion code, stellate ganglion code, or thoracic or lumbar paravertebral sympathetic code if neurolysis is performed.

INDICATIONS AND MEDICAL NECESSITY

Sympathetic blocks are indicated and are considered appropriate to confirm the diagnosis of sympathetically maintained pain. The following criteria should be considered carefully in performing sympathetic blocks:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity:
   - Suspected organic problem
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
   - Responsiveness to prior interventions with improvement in physical and functional status to proceed with repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks except for cancer pain or when a continuous administration of local anesthetic for sympathetic block is employed. However, the total number of injections in the stabilization phase should be limited to four to six per year.
- In the treatment or therapeutic phase, that is, after the stabilization phase, the frequency of sympathetic blocks should be limited to 6 weeks or longer between each injection, provided that at least >50% relief is obtained for 4 to 6 weeks.

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Complex regional pain syndrome Type I (reflex sympathetic dystrophy) and Type II (causalgia):
   - 337.20 reflex sympathetic dystrophy unspecified, 337.21 reflex sympathy dystrophy upper limb, 337.22 reflex sympathetic dystrophy lower limb, 337.29 reflex sympathetic dystrophy other unspecified site
   - 355.9 causalgia, 354.4 causalgia upper limb, 355.71 causalgia lower limb
2. Peripheral neuropathy: 356.4 idiopathic, 356.0 hereditary, 357.2 diabetic, 357.5 alcoholic, 357.6 due to drug
3. Limb pain: 353.6 phantom limb pain, 997.60 stump pain, 997.61 neuroma of amputation stump, 342.0 hemiplegia–flaccid, 342.1 hemiplegia–spastic

4. Plexus lesions: 353.0 thoracic outlet syndrome, 353.1 lumbar plexus lesions
5. Postherpetic neuralgia: 053.10 with unspecified nerve system complication, 053.11 geniculate herpes zoster, 053.12 postherpetic trigeminal neuralgia, 053.13 postherpetic polyneuropathy, 053.19 other, 053.12 herpes zoster dermatitis of upper eyelid, 053.21 herpes zoster keratoconjunctivitis, 053.22 herpes zoster iridocyclitis, 053.29 other ophthalmic complications
6. Pain syndromes secondary to neoplasm: 141.0 to 239.9
7. Chronic pancreatitis
8. Abdominal pain
9. Pelvic pain
10. Vascular ischemic pain
11. Headache: 346.01 intractable migraine with aura, 346.11 intractable migraine without aura, 346.21 intractable cluster, 346.20 nonintractable cluster, 346.9 unspecified migraine

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for sympathetic blocks.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

INTERCOSTAL NERVE BLOCKS AND NEUROLYSIS[128]

DESCRIPTION

Intercostal/chest wall pain usually results from irritation or inflammation of the intercostal nerve, which may result from, but is not limited to, trauma, rib fracture, cancer, injury from a thoracotomy incision, osteoarthritis or degenerative arthritis of the thoracic spine, herpes zoster or postherpetic neuralgia, compression fracture of vertebrae, sternal fracture, injury to the nerve trunk, compression of nerves, or nerve-root lesions. This type of pain can be managed with either an intercostal nerve block or neurolysis (via radiofrequency ablation, cryoablation, or injection of a neurolytic agent such as phenol).

CPT CODES

- 64420 Injection, anesthetic agent; intercostal nerve, single
- 64421 Intercostal nerves, multiple, regional block
- 64620 Destruction by neurolytic agent; intercostal nerve

- 76003 Fluoroscopic guidance for needle placement

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully when performing either intercostal nerve blocks or intercostal neurolysis:

1. Complete initial evaluation including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or pain of predominantly psychogenic origin
   - Responsiveness to prior interventions, with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Herpes zoster, with unspecified nervous system complication: 053.10
2. Postherpetic polyneuropathy: 053.13
3. Pain syndromes secondary to neuroplasm: 114.02 to 239.9
4. Malignant neoplasm of ribs, sternum, and clavicle: 170.3
5. Secondary malignant neoplasm of other specified sites, bone and bone marrow: 198.5
6. Benign neoplasm of ribs, sternum, and clavicle: 213.3
7. Thoracic root lesions, not elsewhere classified (intercostal neuritis): 353.3
8. Other nerve root and plexus disorders: 353.8
9. Unspecified nerve root and plexus disorder: 353.9
10. Pathologic fracture of other specified site: 733.19
11. Fracture of rib(s) closed: 807.00
12. Of rib(s) open: 807.1
13. Of sternum, closed: 807.2
14. Of sternum, open: 807.3
15. Flail chest: 807.4

16. Injury to other nerve(s) of trunk, excluding shoulder and pelvis girdles, other specified nerve(s) of trunk: 954.8

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after the stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least >50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks, and four times for interventions such as radiofrequency thermoneurolysis, and cryoneurolysis, for a period of 1 year.

CODING GUIDELINES

For multiple levels of neurolytic blocks for additional levels, CPT 64620-51 may be used. For fluoroscopic guidance, CPT 76003 may be used.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for intercostal nerve blocks and neurolysis.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

SACROILIAC JOINT INJECTIONS

DESCRIPTION

The sacroiliac joint includes a joint capsule, synovial fluid, and hyaline cartilage on the sacral side and fibrocartilage on the iliac side. The sacroiliac joint possesses

widespread neural innervation, anatomic variability, and unique biomechanical properties. Now there is evidence that the sacroiliac joint is a source of mechanical low back and lower extremity pain. Provocative injections and arthrography have described sacroiliac joint pain referral patterns in asymptomatic volunteers, predicted symptomatic sacroiliac joints in patients with suspected lumbar discogenic or facet joint pain, described morphologic futures of sacroiliac joint capsule, and defined contrast extravasation patterns on sacroiliac joint arthrography and post-arthrography CT in subjects with low back or groin pain.

Sacroiliac joint block may be diagnostic or therapeutic. In the diagnostic sacroiliac joint block, an anesthetic agent is introduced into the sacroiliac joint under fluoroscopic guidance. At least 75% resolution of the patient's pain over the ipsilateral sacroiliac joint is considered diagnostic of pain emanating from the sacroiliac joint. Incidence of sacroiliac joint pain has been highly variable.

CPT CODES

- 27096 Injection procedure for sacroiliac joint, arthrography, and/or anesthetic/steroid
- 73542 Radiologic examination, sacroiliac joint arthrography, radiological supervision and interpretation
- 76005 Fluoroscopic guidance and localization of needle or catheter tip for spine or paraspinous diagnostic or therapeutic injection procedures (epidural, transforaminal epidural, subarachnoid, paravertebral facet joint, paravertebral facet joint nerve, or sacroiliac joint), including neurolytic agent destruction

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing sacroiliac joint blocks:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or predominantly psychogenic pain

- Responsiveness to prior interventions with improvement in physical and functional status for repeat blocks or other interventions
- Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODE THAT SUPPORTS MEDICAL NECESSITY

- Sacroiliitis: 720.2

FREQUENCY AND NUMBER OF INTERVENTIONS

- In the diagnostic phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the therapeutic phase (after stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least ≥50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or preferably 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four times per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks for a period of 1 year.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for sacroiliac joint injections.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

TRIGEMINAL NERVE BLOCKS[146–151]

DESCRIPTION

Trigeminal nerve block with local anesthetic and steroid is used in managing pain of trigeminal neuralgia or cancer pain when pharmacological measures fail.

CPT CODES

- 64400 Injection, anesthetic agent; trigeminal nerve, any division or branch

- 64600 Destruction by neurolytic agent, trigeminal nerve; supraorbital, infraorbital, mental, or inferior alveolar branch
- 64605 Destruction by neurolytic agent, trigeminal nerve; second and third branches at foramen ovale
- 64610 Destruction by neurolytic agent, trigeminal nerve; second and third division branches at foramen ovale under radiological monitoring
- 76003 Fluoroscopic guidance for needle placement

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least 50% relief is obtained for 6 to 8 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks, and four times for interventions such as radiofrequency thermoneurolysis, and cryoneurolysis, for a period of 1 year.

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Trigeminal neuralgia: 350.1
2. Atypical facial pain: 350.2
3. Trigeminal neuralgia, specified: 350.8
4. Trigeminal neuralgia, unspecified: 350.9
5. Postherpetic trigeminal neuralgia: 053.12

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for trigeminal nerve blocks and neurolytic procedures.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

SUPRASCAPULAR NERVE BLOCKS[3,152]

DESCRIPTION

Pain secondary to irritation or inflammation of the suprascapular nerve may be caused by multiple variants such as soft tissue trauma, arthritis, cysts, or lesions. The irritation of the suprascapular nerve is manifested with pain in the distribution of the shoulder and shoulder–girdle area. This may be associated with weakness of the supraspinatus and infraspinatus muscles. Weakness of these muscles may be diagnosed by weakness of abduction of the shoulder, as well as lateral rotation.

A suprascapular nerve block, which results in relief of pain, can confirm the diagnosis of suprascapular neuritis. This may be followed by injection of depo-steroids.

CPT CODES

- 64418 Suprascapular nerve block
- 76003 Fluoroscopic guidance for needle placement

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing either intercostal nerve blocks or intercostal neurolysis:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or pain of predominantly psychogenic origin
   - Responsiveness to prior interventions, with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Brachial neuritis or radiculitis: 723.4

2. Degeneration of cervical intervertebral disc, including narrowing of disc space: 722.4

3 Cervical disc displacement without myelopathy (disc herniation, radiculitis, disc extrusion, disc protrusion, disc prolapse, discogenic syndrome): 722.0

4. Frozen shoulder: 726.0

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least 50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time provided all procedures are performed safely.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four times per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks and four times for interventions such as radiofrequency thermoneurolysis, and cryoneurolysis for a period of 1 year.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for suprascapular nerve block.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

GREATER OCCIPITAL NERVE BLOCKS

DESCRIPTION

Cervicogenic headache may result from cervical facet joint syndrome, cervical spinal disease, or occipital neuritis. Cervicogenic headache may be caused by either arthritis of the facet joints or whiplash syndrome causing facet joint mediated pain or irritation of the greater occipital nerve. Rarely, the greater occipital nerve may be entrapped; however, more commonly it is inflamed.

A diagnostic block or greater occipital nerve can confirm the clinical impression of occipital neuralgia. Headaches secondary to occipital neuralgia are either unilateral or bilateral. They may be constant or intermittent. Headaches may be radiating behind the ear or to the face. Therapeutically, injection of local anesthetic with or without steroids along the greater occipital nerve in its course also may provide relief which may be long-lasting in some cases, particularly if chronic muscle spasm is present and in conjunction with other modalities of treatments, including physical therapy and an exercise program.

CPT CODES

- 64405 Greater occipital nerve block
- 76003 Fluoroscopic guidance for needle placement

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing either intercostal nerve blocks or intercostal neurolysis:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or pain of predominantly psychogenic origin
   - Responsiveness to prior interventions, with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Occipital neuritis: 729.2
2. Cervical spondylosis or cervical facet joint arthropathy: 721.0
3. Cervical intervertebral disc disease: 722.4

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after the stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least 50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely.
- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria and these should be limited to a maximum of six times for local anesthetic and steroid blocks and four times for interventions such as radiofrequency thermoneurolysis, and cryoneurolysis for a period of 1 year.
- Under unusual circumstances with a recurrent injury or cervicogenic headache, blocks may be repeated at intervals of 6 weeks after stabilization in the treatment phase.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for occipital nerve blocks.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

PERIPHERAL NERVE BLOCKS[2,154]

DESCRIPTION

Peripheral nerve blocks may be performed to manage pain emanating from irritation or inflammation of peripheral nerve(s). If response to a peripheral nerve block with local anesthetic is significant and predictable, a peripheral neurolytic block may be performed, either by injection of neurolytic agent or cryoablation.

CPT CODES

- 64450 Peripheral nerve block
- 64640 Peripheral neurolytic block
- 76003 Fluoroscopic guidance for needle placement

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing either intercostal nerve blocks or intercostal neurolysis:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or pain of predominantly psychogenic origin
   - Responsiveness to prior interventions with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

Codes describing peripheral neuritis are considered to support medical necessity.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for peripheral nerve blocks or neurolysis as it is covered by Medicare as described above.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after the stabilization is completed), the frequency

should be 2 months or longer between each injection, provided that at least 50% relief is obtained for 6 weeks. However, if the neural blockade is applied for different regions, it can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time, provided all procedures are performed safely.

- In the diagnostic or stabilization phase, the number of injections should be limited to no more than four per year.
- In the treatment or therapeutic phase, the interventional procedures should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks and four times for neurolytic blocks for a period of 1 year.

TRIGGER POINT INJECTIONS[2,155–164]

DESCRIPTION

Myofascial pain syndrome, which is a regional muscle pain disorder accompanied by trigger points, appears to be a common phenomenon in multiple regions, specifically in the cervical spine. In the head and neck region, it is believed that myofascial pain syndrome can manifest not only with mechanical symptoms in the neck, but also as headache, tinnitus, shoulder pain, temporomandibular joint pain, eye symptoms, and torticollis. However, there is absolutely no epidemiologic data on the prevalence of myofascial pain in the neck. The authors, exploring the role of trigger points and myofascial pain in whiplash injuries, believe that the theory of trigger points lacks demonstrated internal validity. Formal studies also have shown that myofascial experts have difficulty agreeing on the presence of a trigger point, which is the cardinal feature of regional myofascial pain syndrome. In addition to this, it has been shown that, topographically, trigger points of the neck overlie the cervical facet joints, and it has been reported that pain patterns of cervical trigger points are identical to those of referred pain from the facet joints.

Similar to the cervical spine, the most common diagnosis for low back pain is acute or chronic lumbosacral strain or sprain; however, the scientific evidence for low back pain of muscle origin is not overwhelming.

Myofascial trigger points are self-sustaining, hyperirritative foci that may occur in any skeletal muscle in response to strain produced by acute or chronic overload. Classically, these trigger points produce a referred-pain pattern characteristic for that individual muscle. Thus,

each pattern becomes part of a single muscle myofascial pain syndrome. To successfully treat chronic myofascial pain syndrome, each single muscle syndrome needs to be identified, along with every perpetuating factor.

As there is no laboratory or imaging test available for establishing or confirming the diagnosis of trigger points, diagnosis mainly depends on detailed history and specific musculoskeletal examination. Some of the cardinal features of trigger points are as follows:

1. Distribution pattern of the pain consistent with the referral pattern of trigger points that are described in the literature
2. The presence of trigger points with focal tenderness with a specific referral pattern of pain
3. A palpable taut band of muscle in which the trigger point is located
4. Reproduction of referred-pain pattern upon stimulation of the trigger point

CPT CODES

- 20552 Injection, single or multiple trigger point(s), one or two muscle groups
- 20553 Injection, single or multiple trigger point(s), three or more muscle groups

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing trigger point injections:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to conservative modalities of treatments
   - Pain and disability of moderate to severe degree
   - No evidence of contraindications such as infection or pain of predominantly psychogenic origin
   - Responsiveness to prior interventions with improvement in physical and functional status for repeat blocks or other interventions
   - Repeating interventions only upon return of pain and deterioration in functional status

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Myalgia and myositis, unspecified: 729.1
2. Rheumatism, unspecified, and fibrositis: 729.0

FREQUENCY AND NUMBER OF INJECTIONS OR INTERVENTIONS

- In the diagnostic or stabilization phase, a patient may receive injections at intervals of no sooner than 1 week or, preferably, 2 weeks.
- In the treatment or therapeutic phase (after the stabilization is completed), the frequency should be 2 months or longer between each injection, provided that at least 50% relief is obtained for 6 weeks. However, if the neural blockade and/or injections are applied for different regions, it/they can be performed at intervals of no sooner than 1 week or, preferably, 2 weeks for most types of blocks. The therapeutic frequency must remain at 2 months for each region. It is further suggested that all regions be treated at the same time provided all procedures are performed safely.
- In the diagnostic or stabilization phase, the number of trigger point injections should be limited to no more than four times per year.
- In the treatment or therapeutic phase, the trigger point injections should be repeated only as necessary judging by the medical necessity criteria, and these should be limited to a maximum of six times for local anesthetic and steroid blocks.

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for trigger point injections.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

SPINAL CORD STIMULATORS[1–4,165–179]

DESCRIPTION

Spinal cord or epidural stimulation involves an electric field, and a specified waveform, pulse width, and rate, and is reported to diminish pain intensity in select cases of chronic neurogenic pain. In spinal cord stimulation used to treat chronic neurogenic pain, most typically dorsal or sensory fibers of the spinal cord are stimulated. Spinal cord stimulation is indicated for the treatment of a number of conditions that are intractable and nonresponsive to many of the other modalities of treatments. The neurostimulator electrodes used for this purpose are implanted percutaneously in the epidural space through a special needle. Some patients may need an open procedure requiring a laminectomy to place the electrodes.

Prior to placement of the permanent electrodes, trial electrodes are placed and stimulation is carried out with an external stimulator. The trial period may be extended up to 4 weeks if necessary. If, during the trial period, it is determined that the spinal cord stimulation is not effective or is not acceptable to the patient, the electrodes may be removed. However, if the trial has been successful, a spinal neurostimulator and pulse generator are inserted subcutaneously and connected to the electrodes already in place or to new electrodes.

In some cases, neurostimulator electrodes migrate or move from the area that needs to be stimulated, in which case the electrodes require realignment. Additionally, in very few cases, electrodes may need to be removed if the patient cannot tolerate the electrodes, the spinal cord stimulation becomes ineffective after a period of time, or the leads and/or the impulse generator become infected.

CPT CODES

- 63650 Percutaneous implantation of neurostimulator electrode array, epidural
- 63655 Laminectomy for implantation of neurostimulator electrodes, plate/paddle, epidural
- 63660 Revision or removal of spinal neurostimulator electrode percutaneous array(s) or plate/paddle(s)
- 63685 Incision and subcutaneous placement of spinal neurostimulator pulse generator or receiver, direct or inductive coupling
- 63688 Revision or removal of implanted spinal neurostimulator pulse generator or receiver

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing spinal cord simulation procedures:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Psychological evaluation as necessary
4. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to almost all conservative modalities of treatments, including fluoroscopically directed epidural injections
   - Pain and disability of severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
5. Implantation of the spinal cord stimulator used only as a choice of last resort and after other

treatment modalities have been tried and did not prove to be satisfactory, or these have been judged to be unsuitable or contraindicated for the given patient

6. In addition to the physical, functional, and psychological assessment, which is basic, careful screening and evaluation by a multidisciplinary team prior to implantation, which should include physical and functional as well as psychological evaluation

7. Prior to implantation of the permanent electrodes, demonstrated relief of pain with a temporarily implanted electrode, without deleterious effects

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

1. Postlaminectomy syndrome: 722.81 cervical, 722.82 thoracic, 722.83 lumbosacral

2. Disc displacement without myelopathy (disc herniation, radiculitis, disc extrusion, disc protrusion, disc prolapse, discogenic syndrome): 722.0 cervical, 722.11 thoracic, 722.10 lumbosacral

3. Disc displacement with myelopathy: 722.71 cervical, 722.72 thoracic, 722.73 lumbosacral

4. Epidural fibrosis: 349.2 cervical, 349.2 thoracic, 349.2 lumbosacral

5. Complex regional pain syndrome (Type I or reflex sympathetic dystrophy): 337.20 reflex sympathetic dystrophy unspecified, 337.21 reflex sympathetic dystrophy upper limb, 337.22 reflex sympathetic dystrophy lower limb, 337.29 reflex sympathetic dystrophy other unspecified site

6. Complex regional pain syndrome (Type II or causalgia): 355.9 causalgia, 354.4 causalgia upper limb, 355.71 causalgia lower limb

7. Limb pain: 353.6 phantom limb pain, 997.60 stump pain, 997.61 neuroma of amputation stump, 342.0 hemiplegia–flaccid, 342.1 hemiplegia–spastic

8. Postherpetic neuralgia: 053.10 with unspecified nerve system complication, 053.13 postherpetic polyneuropathy

9. Cauda equina injury: 952.4

10. Chronic arachnoiditis: 322.2

11. Arthrosclerosis of extremities with wrist pain: 440.22

12. Mechanical complications of nervous system device implanted graft: 996.2 (to be used to indicate intolerance of the device by the patient or failure of equipment/loss of effectiveness)

13. Infection and inflammatory reaction due to internal prosthetic device, implant, and graft; due to nervous system device, implant, and graft: 996.63

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for spinal cord stimulators.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

INTRATHECAL INFUSION SYSTEMS[180–191]

DESCRIPTION

Chronic opioid therapy in the treatment of persistent pain of noncancer origin has gained broad acceptance. The multiple routes of administration available to the practitioner are the oral, transdermal, epidural, and intrathecal. This policy addresses intrathecal administration of opioids and other drugs. Opioid agonists produce analgesia at the spinal cord level when administered in the intrathecal or epidural space. This technique may be used for the management of chronic intractable pain when it is not controlled by less invasive techniques, as well as oral narcotics. Intrathecal baclofen is used for the treatment of intractable spasticity of the spine or brain etiology. For intrathecal administration of drugs, a reservoir is inserted subcutaneously; it is attached to the proximal portion of the catheter, which is tunneled beneath the skin.

With the epidural catheterization, preservative-free morphine sulfate, hydromorphone hydrochloride (Dilaudid®, Palladone), Fentanyl, or baclofen can be administered every 8 to 12 hours in the epidural space through an indwelling catheter, which can be placed percutaneously.

CPT CODES

- 62350 Implantation, revision, or repositioning of tunneled intrathecal or epidural catheter, for long-term medication administration via an external pump or implantable reservoir/infusion pump; without laminectomy

- 62351 Implantation, revision, or repositioning of tunneled intrathecal or epidural catheter, for long-term medication administration via an external pump or implantable reservoir/infusion pump; with laminectomy

- 62355 Removal of previously implanted intrathecal or epidural catheter

- 62360 Implantation or replacement of device for intrathecal or epidural drug infusion; subcutaneous reservoir

- 62361 Implantation or replacement of device for intrathecal or epidural drug infusion; non-programmable pump
- 62362 Implantation or replacement of device for intrathecal or epidural drug infusion; programmable pump, including preparation or pump, with or without programming
- 62365 Removal of subcutaneous reservoir or pump, previously implanted for intrathecal or epidural infusion
- 62367 Electronic analysis of programmable, implanted pump for intrathecal or epidural drug infusion (includes evaluation of reservoir status, alarm status, drug prescription status); without reprogramming
- 62368 Electronic analysis of programmable, implanted pump for intrathecal or epidural drug infusion (includes evaluation of reservoir status, alarm status, drug prescription status); with reprogramming
- 62310 Injection, single, epidural or subarachnoid; cervical or thoracic
- 62311 Lumbar, sacral (caudal)
- 62318 Catheter placement, continuous infusion or intermittent bolus; epidural or subarachnoid; cervical or thoracic
- 62319 Lumbar, sacral (caudal)
- 96530 Refilling or maintenance of implantable pump or reservoir for drug delivery, systemic (e.g., intravenous, intra-arterial)

INDICATIONS AND MEDICAL NECESSITY

The following criteria should be considered carefully in performing intrathecal pump placements:

1. Complete initial evaluation, including history and physical examination
2. Physiological and functional assessment, as necessary and feasible
3. Psychological evaluation as necessary
4. Definition of indications and medical necessity, as follows:
   - Suspected organic problem
   - Nonresponsiveness to almost all conservative modalities of treatments, including fluoroscopically directed epidural injections
   - Pain and disability of severe degree
   - No evidence of contraindications such as intraspinal obstruction, infection, or predominantly psychogenic pain
5. Implantation of the morphine pump or epidural catheterization for long-term purposes used only as a choice of last resort and after other treatment modalities have been tried and did

not prove to be satisfactory; or these have been judged to be unsuitable or contraindicated for the given patient
6. In addition to the physical, functional, and psychological assessment, which is basic, careful screening and evaluation by a multidisciplinary team prior to implantation, which should include physical and functional, as well as psychological, evaluation
7. Prior to implantation of the pump, demonstrated relief of pain with subarachnoid or epidural injections of morphine reliably on at least two occasions, without any deleterious effects
8. A patient with the diagnosis of cancer with a likely life expectancy of at least 3 months and unresponsiveness to less invasive medical therapy or that may no longer be the choice of therapy

ICD-9 CODES THAT SUPPORT MEDICAL NECESSITY

For implantation of catheter/pump services:

1. Postherpetic trigeminal neuralgia: 053.12
2. Postherpetic polyneuropathy: 053.13
3. Carcinomas: 141.0 to 239.9
4. Chronic arachnoiditis: 322.2
5. Reflex sympathetic dystrophy: 337.20 to 337.29
6. Unspecified disease of spinal cord: 336.9 (to be used only for the diagnosis of myelopathy)
7. Phantom limb pain: 353.6
8. Causalgia of upper limb: 354.4
9. Causalgia of lower limb: 355.71
10. Postlaminectomy syndrome, cervical region: 722.81
11. Postlaminectomy syndrome, thoracic region: 722.82
12. Postlaminectomy syndrome, lumbar region: 722.83

For removal/revision of catheter/pump services:

1. Other complications of internal (biological) (synthetic): 996.70 due to unspecified device, implant, and graft

DOCUMENTATION REQUIREMENTS

The patient's medical record must contain documentation that fully supports the medical necessity for pump implantation and administration of drugs.

Documentation must also support the frequency and the appropriateness of this procedure, as opposed to alternative forms of therapy.

Evidence for the Use of Interventional Techniques for Chronic Spinal Pain

Laxmaiah Manchikanti, MD, Vijay Singh, MD, and Elmer E. Dunbar, MD

STRUCTURAL BASIS OF CHRONIC SPINAL PAIN

Chronic spinal pain continues to be an epidemic and treatment often remains inadequate.[1–16] The devastating nature of chronic pain, which can destroy the quality of life by eroding the will to live, disturbing sleep and appetite, creating fatigue, and impairing recovery from illness or injury, is not well appreciated.[7–10,16] Consequences may be especially difficult for the elderly patient in chronic pain, resulting in vocational, social, and family discord, which may make the difference between a reasonable quality of life and loss of function and comorbidity.[11–13]

Chronic spinal pain is recognized as a multidimensional problem with both sensory and affective components. The biopsychosocial model, which emerged in the 1980s, views chronic spinal pain as a biopsychosocial phenomenon, in which biological, psychological, and social factors dynamically interact with each other. In the 1990s, the biopsychosocial approach dominated chronic spinal pain management, at least among academicians, with efforts to introduce "psychosocial" approaches.

The concept of psychogenic pain has stimulated controversy in the field of pain medicine, not only regarding its prevalence, but indeed, its very existence.[17] Essentially, psychogenic pain is considered within the context that "since there is nothing wrong with your body, there must be something wrong with you." Some state that the term *psychogenic pain* is fundamentally meaningless.[18]

The diagnosis of psychogenic pain not only fails to provide a valid organic diagnosis, but it also fails to pro-

vide validation of patient symptomatology and complaints. Thus, psychogenic pain also implies it is unreal or illusional. The concept of psychogenic pain is weakened by the fact that its diagnostic signs have been challenged. Gagliese and Katz[18] believe that medically unexplained pain is not a symptom of a psychological disorder and that it is time to abandon thinking that separates mind and body. Thus, the challenge remains for proponents to provide empirical evidence to prove that psychopathology causes pain and, in doing so, to specify the mechanisms by which it is generated.

Modern technology, including magnetic resonance imaging (MRI), computed axial tomographic scanning (CT), neurophysiologic testing, and comprehensive physical examination with psychological evaluation, can identify the cause of low back pain in only 15% of patients in the absence of disc herniation and neurological deficit.[1–3,19] In addition, overall inaccurate or incomplete diagnoses in patients referred to pain treatment centers have been described as ranging from 40 to 67%, and the incidence of psychogenic pain has been shown to be present only in 1 of 3,000 patients, with the presence of pain of organic origin mistakenly branded as psychosomatic in 98% of the cases.[20,21] Psychogenic pain should not be confused with factitious illness and malingering, which are distinct psychiatric disorders.

Providing a structural basis of pain will invalidate the theory that maladaptive psychological processes are primarily responsible for causing regional pain syndromes, and therefore, the assumption that psychological or behavioral interventions are the most logical treatment

modalities. The majority of painful conditions include various types of pain originating from the spine with pain in the neck, upper back, mid back, low back, and upper or lower extremities.

Bogduk[22] postulated that, for any structure to be deemed a cause of back pain: (1) the structure should have a nerve supply; (2) the structure should be capable of causing pain similar to that seen clinically, ideally demonstrated in normal volunteers; (3) the structure should be susceptible to diseases or injuries that are known to be painful; and (4) the structure should have been shown to be a source of pain in patients, using diagnostic techniques of known reliability and validity. The same philosophy may be applied for cervical and thoracic pain.

PATHOPHYSIOLOGIC BASIS

Kuslich et al.[23] identified intervertebral discs, facet joints, ligaments, fascia, muscles, and nerve root dura as tissues capable of causing pain in the low back. Thus, the structures responsible for pain originating in the spine and afflicting the neck, mid back, upper back and low back, upper extremities, and lower extremities may originate from the vertebrae, intervertebral discs, spinal cord, nerve roots, facet joints, ligaments, muscles, and sacroiliac or atlanto-axial and atlanto-occipital joints. However, vertebrae, muscles, and ligaments have not been proved to be common sources of spinal pain. In contrast, facet joint pain, discogenic pain, and sacroiliac joint pain have been proved to be common causes of pain with proven diagnostic techniques.[1,22,24]

Cavanaugh et al.[25] describe how idiopathic low back pain has confounded health care practitioners for decades and how the cellular and neural mechanisms that lead to facet pain, discogenic pain, and sciatica are not well understood. In a series of neurophysiologic and neuroanatomic studies, they show the evidence in support of facet pain, including an extensive distribution of small nerve fibers and endings in the lumbar facet joint, nerves containing substance P, high threshold mechanoreceptors in the facet joint capsule, and sensitization and excitation of nerves in facet joint and surrounding muscle when the nerves were exposed to inflammatory or algesic chemicals. Evidence for pain of disc origin included an extensive distribution of small nerve fibers and free nerve endings in the superficial anulus of the disc, as well as small fibers and free nerve endings in the adjacent longitudinal ligaments. They also described possible mechanisms of sciatica including vigorous and long-lasting excited discharges when dorsal root ganglia were subjected to moderate pressure, excitation of dorsal root fibers when the ganglia were exposed to autologous nucleus pulposus, and excitation and loss of nerve functions in nerve roots exposed to phospholipase A_2. These findings render support for a structural and chemical basis for low back pain.

Pang et al.[26] by applying spinal pain mapping, which is a sequence of well-organized nerve block procedures, analyzed 104 cases in a pain clinic. They prospectively evaluated consecutive adult patients with intractable low back pain (who had failed conservative therapy) of undetermined etiology after medical history, physical examination, x-ray, CT, MRI, EMG/NCV (electromyography/nerve conduction velocity) evaluation of the lumbar spine. By using pain mapping, the source of pain was facet joint(s) in 24%, combined lumbar nerve root and facet disease in 24%, combined facet(s) and sacroiliac joint(s) in 4%, lumbar nerve root irritation in 20%, internal disc disorder in 7%, sacroiliac joint in 6%, and sympathetic dystrophy in 2% of the patients. Pain mapping failed to demonstrate causes of pain in the remaining 13% of the patients. However, Pang et al.[26] used a single block technique with the potential for false-positive results.[1,2,27]

Manchikanti et al.[27] evaluated the relative contributions of various structures in patients with chronic low back pain who had failed to respond to conservative modalities of treatments including physical therapy, chiropractic, and drug therapy. These patients had lack of radiological evidence to indicate disc protrusion or radiculopathy. Utilizing precision diagnostic injections (controlled comparative double diagnostic blocks), they showed that 40% of the patients suffered from facet joint pain, 26% from discogenic pain, 2% from sacroiliac joint pain, and possibly 13% from segmental dural/nerve root pain with no cause identified in 19% of the patients.

INTERVENTIONAL TECHNIQUES

The overall benefit of various types of injection techniques includes pain relief that outlasts by days, weeks, or months the relatively short duration of pharmacologic action of the local anesthetics and other agents used. Clear-cut explanations for these prolonged improvements are not currently available. It is believed that neural blockade alters or interrupts nociceptive input, reflex mechanisms of the afferent limb, self-sustaining activity of the neuron pools and neuraxis, and the pattern of central neuronal activities.[28] Explanations for improvements are based in part on the pharmacological and physical actions of local anesthetics, corticosteroids, and other agents. It is believed that local anesthetics interrupt the pain–spasm cycle and reverberating nociceptor transmission, whereas corticosteroids reduce inflammation either by inhibiting the synthesis or release of a number of proinflammatory substances or by causing a reversible local anesthetic effect.[29–45]

MECHANISM OF ACTION

Various modes of action of corticosteroids include:

- Membrane stabilization
- Inhibition of neural peptide synthesis or action
- Blockade of phospholipase A_2 activity
- Prolonged suppression of ongoing neuronal discharge
- Suppression of sensitization of dorsal horn neurons.

Local anesthetics have been shown to produce prolonged dampening of C-fiber activity.[46–48] Physical effects include clearing adhesions or inflammatory exudates from the vicinity of the nerve root sleeve. The scientific basis of some of these concepts, at least in part, is proved for spinal pain management with epidural injections of betamethasone and intravenous methylprednisolone.[29,33,35–39]

Various mechanisms of benefits for longer periods of time than the duration of the anesthetics used have been described.[40] This phenomenon has been documented in the literature and is regularly observed by clinicians. The mechanisms by which local anesthetics abolish chronic pain for several days when they are effective for a maximum of 4 hours if used for acute or "physiological" pain are not known.[40] Several theories have been suggested. In an essay on the future of local anesthetics,[41] several theories were listed including the sympathetic nervous system.[42] Others[43–45] have speculated that such blocks cause temporary abolition of spontaneous ectopic discharges, resulting in abolition of dynamically maintained central hyperexcitability, as well as reinforcing endogenous G-protein-couple receptor inhibition of N-type voltage-sensitive calcium channels. In addition, the data on glial activation in pathological pain[45] also may cast doubt on the utility of cognitive behavioral therapy and other psychological interventions, while lending new legitimacy to local anesthetic block procedures. Activation of spinal cord glia has been demonstrated in response to a variety of stimuli including tissue injury and infections.[45] The activated glia produces a number of proinflammatory cytokines associated with central sensitization. This activation spreads from cell to cell across "gap junctions," following no particular neuronal pathways or anatomical boundaries. In an editorial on nerve blocks and cognitive therapy, Merskey and Thompson[40] commented:

> It now seems highly likely that "unexplained" regional pain is the result of organic or neurochemical changes; therefore, they are medically explained. Hence, therapeutic modalities that can, even temporarily, reduce neuronal excitability and sympathetic nervous system malfunction may result in just the sort of benefits from local anesthetic blocks documented.… The time is right for renewed interest in nerve block models for the relief of pain. Those models are the ultimate foundation of the truly multidisciplinary pain clinic, and their results encouraged pioneers such as Bonica and Travell to take chronic pain seriously. A look at their work may help to renew some well-established approaches that are currently neglected or out of favor (p. 175).

DIAGNOSTIC INTERVENTIONAL TECHNIQUES

It has been postulated that for any structure to be deemed a cause of back pain, the structure should have been shown to be a source of pain in patients, using diagnostic techniques of known reliability and validity.[49] The diagnostic blockade of a structure with a nerve supply with the ability to generate pain can be performed to test the hypothesis that the target structure is a source of the patient's pain. Evidence-based interventional diagnostic techniques include facet joint blocks, discography, and sacroiliac joint injections. Other techniques including transforaminal epidural or selective nerve root blocks and sympathetic blocks also are used. The descriptions in this chapter are limited to evidence-based techniques.

RATIONALE

The popularity of neural blockade as a diagnostic tool in painful conditions is due to several features.[50] Multiple challenging clinical situations include the characteristics of chronic spinal pain, which are purely subjective. Various painful conditions, in most cases, are inexactly defined with uncertain pathophysiology. Precision diagnostic blocks are used to clarify these challenging clinical situations, in order to determine the pathophysiology of clinical pain, the site of nociception, and the pathway of afferent neural signals. Precise anatomical diagnosis in low back pain has been described not only as elusive, but also as often frustrating for both physicians and patients.[51,52] History, physical examination, and imaging provide limited information.[52]

RELIABILITY AND VALIDITY

Clinical studies of precision diagnostic techniques are variable, not only in quality, but also in quantity. Important considerations include entrance criteria, study size, and the use of controlled subjects. The importance of the false-positive rate (how often patients without a condition will nonetheless have a positive test) and false-negative rate (how often a patient with disease will have a negative test) is extremely crucial because they vary inversely with specificity and sensitivity. Specificity is a relative measure of the prevalence of false-positives, whereas sensitivity is the relative prevalence of false-negative results. The general parameters of accuracy are described as the specificity and sensitivity of the diagnostic test. The most sensitive test will be positive for all cases in which the disease is present. The specificity is greatest when there is a positive test result only when the disease is present. Thus, the ideal

diagnostic test would have a sensitivity of 100% and a specificity of 100%. Placebo response also needs to be taken into consideration. Because none of the tests available in clinical medicine has these ideal features, there is a degree of uncertainty regarding the accuracy of each and every diagnostic test as applied to an individual clinical case. In addition, for many painful conditions, a credible standard to document the disease for comparison with test results is unavailable.

Hildebrandt[53] published an extensive review on the relevance of nerve blocks in treating and diagnosing low back pain. He described zygapophysial joint blocks, sacroiliac joint blocks, disc stimulation, and nerve root blocks. Hildebrandt[53] concluded that the diagnostic use of neural blockade rests on three premises:

1. The pathology causing pain is located in an exact peripheral location, and impulses from this site travel via unique and consistent neural route.
2. Injection of local anesthetic totally abolishes the sensory function of intended nerves and does not affect other nerves.
3. Relief of pain after local anesthetic block is attributable solely to the block of the target afferent neural pathway.

However, the validity of these assumptions is limited by complexities of anatomy, physiology, and psychology of pain perception, and by the effect of local anesthetics on impulse conduction.

In contrast, others[54,55] have concluded that various studies outside imaging have rarely demonstrated clinical utility in assessment of patients with neck and back pain. It was described that diagnostic and treatment devices lacking in scientific rigor included facet blocks, discography, and diagnostic nerve root infiltration, along with other tests including EMG, stress radiographs and flexion and extension x-rays, bone scintigraphy, thermography, diagnostic ultrasound, and temporary external fixation.[55] It is generally described that the accuracy of a diagnostic test is best determined by comparing it with an appropriate reference standard (gold standard) such as biopsy, surgery, autopsy, or long-term follow-up.[56,57] A reference standard allows accurate comparison of a given diagnostic test's capacity to yield positive results when the clinical condition is present and negative results when the clinical condition is not present. Thus, a gold standard or reference standard facilitates accurate determination of the specificity and sensitivity of a test. Tissue confirmation of the presence or absence of a disease at surgery, with a biopsy, or at autopsy, which has served as the accepted gold standard across multiple medical disciplines, is not applicable to interventional pain management. Thus, most pain provocative or relieving tests used to diagnose painful conditions of the spine are more closely related to a phys-

ical examination than to a laboratory test.[58] Stability of the diagnosis over a long period of time with long-term follow-up may also be used as a gold standard.[59] These facts are especially true in the diagnosis of facet joint pain, discogenic pain, and sacroiliac joint pain. Thus, there is no completely reliable gold standard with which to compare the diagnostic test of precision diagnostic injection in conditions where the evaluation is dependent on pain relief or functional improvement as the end point. Consequently, a true calculation of clinical accuracy of these tests may not be possible.

The clinical setting in which the test is performed and the prevalence of the disease in that setting also affect the meaningfulness of the test results. The prevalence refers to the frequency of the disease in the general population and to the population seen in a specific setting where the test is used. When the prevalence is high, there is a higher probability that a positive test result indicates the presence of the disease. Consequently, evaluation of a diagnostic test in a population for which the prevalence is low or absent has either limited meaning or no meaning. Thus, the predictive value of a diagnostic test is a function of the prevalence, sensitivity, and specificity.

Although diagnostic blockade of a structure with a nerve supply that can generate pain can be performed to test the hypothesis that the target structure is the source of the patient's pain,[49,60] testing the hypothesis by provoking pain in any structure is an unreliable criterion except in provocative discography.[61] Thus, relief of pain is the essential criterion in almost all structures. If the pain is not relieved, the source may be in another structural component of the spine similar to the one tested, such as a different facet joint, different nerve root, or some other structure.[49] Ideally, all controlled blocks should include placebo injections of normal saline, but it may be neither logistically feasible nor ethical to use placebo injections of normal saline in conventional practice in each and every patient. In addition, one may be required to perform three blocks of the same structure if a placebo is used. As an alternative, the use of comparative local anesthetic blocks, on two separate occasions, during which the same joint is anesthetized using two local anesthetics with different duration of actions, has been proposed. The use of comparative local anesthetic blocks with facet joint injections has been validated and found to be robust against challenge with placebo.[62, 63]

FACILITIES

The requirements for diagnostic interventional techniques include a sterile operating room or a procedure room, monitoring equipment, radiological equipment, sterile preparation with all the resuscitative equipment, needles, gowns, injectate agents, intravenous fluids, sedative agents, and trained personnel for preparation and moni-

toring of the patients. Minimum requirements include history and physical examination, informed consent, and appropriate documentation of the procedure.

CONTRAINDICATIONS

Contraindications include bacterial infection, possible pregnancy, bleeding diathesis, and anticoagulant therapy. Precautions are warranted in patients with antiplatelet or anticoagulant therapy, diabetes mellitus, and artificial heart valves.

FACET OR ZYGAPOPHYSIAL JOINT BLOCKS

Blocks of a facet or zygapophysial joint can be performed in order to test the hypothesis that the target joint is the source of the patient's pain.[49,60]

RATIONALE

The rationale for using facet joint blocks for diagnosis is based upon the following:

- **Innervation:** Spinal facet joints are well innervated[2,49,60]
- **Sources of pain:**
  Cervical facet joints have been shown to be capable of being a source of neck pain and referred pain in the head or upper limb girdle.
  Thoracic facet joints have been shown to be capable of being a source of thoracic pain and referred pain over the chest wall.
  Lumbar facet joints have been shown to be capable of being a source of low back pain and referred pain in the lower limbs in normal volunteers.
- **Referral patterns:**
  Various patterns of referred pain described for facet joints in the spine are variable and restricted.[64–75]
  Other structures, such as the disc, in the same segment may produce the same pattern of pain.
- **Physical examination:**
  None of the features of physical examination is diagnostic.
  Most maneuvers used in physical examinations are likely to stress several structures simultaneously, especially the discs, muscles, and facet joints, thus failing to provide any reasonable diagnostic criteria.
  Presented evidence thus far has been controversial.[49,60,76–85]
- **History:**
  Demographic features, pain characteristics, and other signs and symptoms may not be corre-

lated with diagnosis of facet joint pain and are unreliable.[49, 60, 76–85]
- **Imaging:**
  There are no valid and reliable means of identifying symptomatic lesions of the facet joint using currently available imaging technologies.[86–95]
  On retrospective review of radiographs of specimens known to have lesions, radiologists could identify lesions in only a small minority of instances,[95] if at all.[87]
  The results of most studies fail to show a correlation between radiologic imaging, including MRI, CT scanning, dynamic bending films, single photon emission computed tomography (SPECT), and radionuclide bone scanning, and facet joint pain.[76,77,86,88–96]

VALIDITY

Controlled diagnostic blocks with two separate local anesthetics (or placebo controlled) are the only means of confirming diagnosis of facet joint pain. The face validity of medial branch blocks has been established by injecting small volumes of local anesthetic onto the target points for these blocks and by determining the spread of contrast medium in posteroanterior and lateral radiographs.[58–61] Construct validity of facet joint blocks is also extremely important, as the placebo effect is the single greatest confounder of diagnostic blocks. Patients are liable to report relief of pain after a diagnostic block for reasons other than the pharmacologic action of the drug administered.[63] Thus, it is essential to know in every individual case whether the response is a true-positive. The theory that testing a patient first with lidocaine and subsequently with bupivacaine provided a means of identifying placebo response has been tested and proved.[62,63]

The specificity of the effect of cervical and lumbar facet joint blocks was demonstrated in controlled trials.[58–61] Provocation response was shown to be unreliable in one study.[61] The false-negative rate of diagnostic facet joint blocks was shown to be 8% due to unrecognized intravascular injection of local anesthetic.[60] Confounding psychological factors showed lack of influence of psychological factors on the validity of comparative controlled diagnostic local anesthetic blocks of facet joints in the lumbar spine.[59] False-positive rates were evaluated in multiple investigations.[27,80,101–113] Reported false-positive rates varied from 27 to 63% in cervical spine, 55 to 58% in thoracic spine, and 22 to 47% in lumbar spine.

PREVALENCE

Based on multiple evaluations, using controlled diagnostic blocks, facet or zygapophysial joints have been implicated

as the source of chronic spinal pain in 15 to 45% of the heterogeneous groups of patients with chronic low back pain,[27,79,80,84,101,102,104,106,107] 42 to 48% of the patients with thoracic pain,[105] and 54 to 67% of the patients with chronic neck pain.[103,104,107,114–16]

Based on a multitude of evaluations, Manchikanti et al.[1] and Boswell et al.[117] conclude that the validity, specificity, and sensitivity of facet joint nerve blocks were strong in the diagnosis of facet joint pain.

SAFETY AND COMPLICATIONS

Safety of facet joint interventions with intra-articular injections and medial branch blocks has been demonstrated. The most common and worrisome complications of facet joint injections or nerve blocks are related to needle placement and drug administration. These complications include dural puncture, spinal cord trauma, infection, intravascular injection, spinal anesthesia, chemical meningitis, neural trauma, pneumothorax, radiation exposure, and hematoma formation.[118–130] Steroid side effects were attributed to the chemistry or to the pharmacology of the steroids.[129,130] Facet capsule rupture also may occur, if large volumes of injectate are used for intra-articular injections.[67]

Vertebral artery damage or entry is a potential risk with cervical facet blockade. Such complications occur more frequently with a lateral intra-articular technique than with blockade of the medial branches because the former technique requires deeper penetration of the needle toward the spinal structures. Local anesthetic leakage out of the joint into spinal canal may cause motor and sensory blockade with its risks and complications. In the cervical spine, third occipital nerve blocks can cause transient ataxia and unsteadiness due to partial blockade of the upper cervical proprioceptive afferents and the righting response.[131] Furthermore, when C3/4, C4/5, or C5/6 facet joint blocks are performed, the phrenic nerve may be compromised, especially if a large volume of local anesthetic is employed.

DISCOGRAPHY

Discography is a diagnostic procedure designed to determine whether a disc is intrinsically painful.

RATIONALE

Formal studies have shown that the discs are innervated and can be a source of pain that has pathomorphologic correlates.[132–151] Biologic basis for lumbar discography has been well established. However, embryologically and morphologically, the cervical discs differ from lumbar discs and do not suffer the same pathology.[152, 153] In addition, there is no evidence that cervical discs suffer

the internal disc disruption widely described in lumbar discs. Thoracic discs with anular tears, intrinsic degeneration, and/or associated vertebral body end plate infractions were painful in approximately 75% of the patients.[154] Cervical discs also have been shown to have prelesions in the anterior anulus, which may be the basis for cervical discogenic pain but they have not been shown to be painful.[155,156]

The rationale is well established for lumbar discography.[152,153,157,158] Discography is helpful in patients with lumbar or leg pain to acquire information about the structure and sensitivity of their lumbar intervertebral discs and to make informed decisions about treatment and modifications of activity. The injected substance in the disc pushes anular fibers aside to form pools of contrast, which indicate the location of fissures.[159] Contrast exiting from the disc indicates tears in the outer wall of the anulus. Extruded contrast may outline fragments of anulus and nucleus outside the disc and adjacent tissues, such as peridural membranes.

Discography was performed in asymptomatic volunteers without spinal pain in cervical spine,[160] thoracic spine,[161] and lumbar spine.[162] It was shown that discographically normal cervical discs were never painful in either symptomatic or asymptomatic groups.[160–162] For many years, disc degeneration was considered as the sole or dominant factor predisposing to spinal pain. However, spinal pain without disc herniation or secondary to involvement of other structures is well known.[22] Even though the mechanism of pain that arises within the disc continues to be poorly understood, it is accepted that damage to the disc can produce pain without consensus on the responsible mechanisms.[22]

VALIDITY

Examination of cadaver discs provided good correlation with which images were compared.[159,163–165] Multiple authors also have investigated the accuracy of discographic and CT/discographic findings based on the ability to demonstrate accurate pathology confirmed at the time of surgery. While many authors[166-171] have demonstrated significant correlation with reliable and accurate diagnosis, some[172,173] have demonstrated poor correlation. In addition, discography was compared with myelography, CT, MRI, and results of surgical and conservative management. CT discography was reported to be more accurate than myelography.[167,168,173–180] On similar grounds, discography was shown to be superior to plain computed tomography.[176,179,181] While comparing the results of discography with MRI, some found discography to be as good as MRI, even though MRI was preferable as it was non-invasive and allowed assessment of more levels with one test with minimal risks of complication and minimal discomfort.[182,183] However, others have identified advan-

tages of discography with pain provocation when MRIs were normal or equivocal.[160,161,184–188] Some have identified its poor sensitivity and specificity.[136–142] Thus, the role of discography in a normal MRI is of questionable value and is not suggested to be performed routinely.

The good correlation between MRI, discography, and high intensity zone (HIZ) related pain have been established by some,[196–200] while others have reported poor correlation and limited value of discography in evaluating the clinical significance of the HIZ and the need for treatment.[201–204] Finally, the relationship of discography to outcomes, including conservative management, minimally invasive surgery, and open procedures also has been controversial.[1,157]

While the accuracy of discography as an imaging test is high, with high specificity and sensitivity for diagnosis of disc degeneration, the question that revolves around discography is whether this test is accurate for the diagnosis of discogenic pain. An integral part of the problem is the lack of an adequate reference or gold standard. Surgical exposure can confirm the presence of disc degeneration or disruption, but it cannot definitely confirm the presence or absence of discogenic pain. However, the results from both surgical and minimally invasive treatment of discogenic pain in patients whose diagnosis was confirmed by discography should provide a reference standard for discogenic pain. Positive results have been provided in multiple publications.

The face validity of discography has been established by injecting small volumes of contrast into the disc and by determining the concordant pain with spread of the contrast medium in posteroanterior and lateral radiographs and/or computed tomography. Construct validity of the discograms is also extremely important, as a false-positive result is the single greatest confounder of diagnostic discography. Patients are liable to report pain after insertion of the needle for reasons other than stimulation of the nociceptors. Thus, it is essential in each and every case for a response to be considered positive, that concordant pain be produced; and for the test to be valid, there must be at least one disc (preferably two) that do not illicit pain upon injection, thereby serving as control discs.[205]

Validity of discography has been established in asymptomatic patients. However, there are no modern normative data that establish that cervical discography is a specific test for cervical discogenic pain.[152] There is also evidence indicating that up to 40% of the positive cervical discograms may be false-positive.[206] Further, it was shown that cervical discography induced neck pain in 50% of the patients with neurological symptoms due to cervical spondylosis but with no neck pain.[207] With thoracic discography, unfamiliar or disconcordant pain was produced in lifelong asymptomatic individuals.[161] Thus, any evidence of value for cervical and thoracic discography is inconclusive at the present time.

In the 1960s, Holt[208, 209] reported a significant number of false-positive (37%) lumbar spine discograms[208] in an asymptomatic prison population;[208] similar findings were reported with cervical spine discograms.[209] Simmons et al.[210] reassessed Holt's data[208] and pointed out that discography as performed by Holt, although appropriate for its time, was quite different from discography as performed in 1988. The necessity for accurate needle tip positioning was proven by Urasaki et al.[211] Walsh et al.,[162] in a carefully controlled series of disc injections in asymptomatic volunteers, showed a 0% false-positive rate refuting the findings of Holt.[208] Studies by Carragee et al.[212–217] have shown a higher rate of false-positives than the study of Walsh et al.[162] However, a multitude of methodological flaws have been pointed out with each of these similarly structured studies.[58,218–221]

Multiple drawbacks described include the technique of disc puncture, interpretation, presence of negative discs, small number of patients, inability to compare pain provocation to clinical or typical pain, post-test and pretest probability, and accuracy of psychological evaluation. Discography is most accurate and useful when the diagnosis of discogenic pain is highly probable, as determined by the history, physical examination, imaging data analyzed, and inability to isolate another source of pain. Manchikanti et al.[220] evaluated 50 patients with discography, of which 25 patients were without somatization disorder and 25 patients were with documented somatization disorder. They concluded that provocative discography provided similar results in patients with or without somatization, with or without depression, with somatization but with or without depression or with other combinations of the psychological triad of somatization disorder, depression, and generalized anxiety disorder. Saal[58] points out that some of the issues raised by Carragee et al.[212–217] may be resolved on the basis that disc stimulation is related to reflex reaction in the groin and lower abdomen; L5/6 disc was innervated by the L1 or L2 spinal nerves; and the sacroiliac joints are dually innervated, including those arising from L1 to L3. Others also have reported psychological influences, perhaps causing false-positive results.[222,223]

INDICATIONS

Much of the controversy about discography has arisen because the results of discography have been used to help decide whether a certain patient should or should not have surgery, even though patients have usually undergone other diagnostic tests, the results of which were either equivocal or nondiagnostic. Thus, discography should be performed only if the patient has failed to respond to adequate attempts of non-operative care, and if diagnostic tests such as MRI have not provided sufficient diagnostic information. Generally, discography should be viewed as

an invasive test to be used to seek abnormalities when results from other tests are equivocal or inconsistent, in a patient with symptoms severe enough to require further evaluation.[157] Thus, specific uses for discography include, but are not limited to,

- Further evaluation of demonstrably abnormal discs to help assess the extent of abnormality or correlation of the abnormality with clinical symptoms (in case of recurrent pain from a previously operated disc or a lateral disc herniation)
- Evaluation of patients with persistent, severe symptoms in whom other diagnostic tests have failed to reveal clear confirmation of a suspected disc as the source of pain
- Assessment of patients who have failed to respond to surgical procedures to determine if there is painful pseudoarthrosis or asymptomatic disc in a posteriorly fused segment, or to evaluate possible recurrent disc herniation
- Assessment of discs before fusion to determine if the discs within the proposed fusion segment are symptomatic and to determine if discs adjacent to this segment are normal
- Assessment of minimally invasive surgical candidates to confirm a contained disc herniation or to investigate contrast distribution pattern before chemonucleolysis or other intradiscal procedures

PREVALENCE

Prevalence of pain due to internal disc disruption was reported as 39% in patients suffering with chronic low back pain.[224] In contrast, primary discogenic pain was reported to be 26% in a sample of 120 patients, but 43% in patients undergoing discography in lumbar spine.[27] However, in another study of patients with intractable low back pain, using spinal pain mapping with nerve blocks, the authors estimated lumbar nerve root involvement in 20% and internal disc disorder in only 7% of the patients.[26]

EVIDENCE

Review of the available evidence regarding discogenic pain[1] shows that the validity for cervical and thoracic discography is limited, whereas the validity for lumbar discography is strong for the diagnosis of discogenic pain.

SAFETY AND COMPLICATIONS

Complications related to discography include infection, neural trauma, intravascular penetration, and spinal cord trauma. Lack of permanent effects secondary to discography has been reported.[225–228] Significant complications

from diagnostic cervical discography procedures occurred in 0.6 to 2.5% of the patients and 0.16 to 1.5% of the cervical disc injections.[229–231] In contrast, in the lumbar spine, overall incidence of discitis has been reported to be 2 to 3%, with an overall complication rate of 13%.[177–181] However, postdiscography discitis represents approximately 30% of all cases of pyogenic discitis and has been reported after almost every type of open and minimally invasive spinal surgical procedure.[236-239] Similar to postoperative vertebral osteomyelitis, postprocedural discitis frequently affects elderly and immunocompromised individuals and is an important cause of postoperative back pain in the patient with a spine disorder. Other reported complications include subdural empyema,[240] pulmonary embolism of nucleus pulposus,[241] herniated cervical disc,[242] quadriplegia,[243] and epidural abscess.[244,245]

Prophylactic intradiscal antibiotic administration may also result in disastrous complications, including death.[246]

SACROILIAC JOINT BLOCKS

The sacroiliac joint is accepted as a potential source of low back and/or buttock pain with or without lower extremity pain. Diagnostic blocks of a sacroiliac joint can be performed in order to test the hypothesis that the sacroiliac joint is the source of the patient's pain. The sacroiliac joint can be anesthetized with intra-articular injection of local anesthetic.

RATIONALE

The rationale for sacroiliac joint blocks for diagnosis is based on the fact that sacroiliac joints have been shown to be capable of being a source of low back pain and referred pain in the lower extremity. There are no definite historical, physical, or radiological features to provide definite diagnosis of sacroiliac joint pain.[247–257] Nevertheless, multiple authors[85,258–260] have advocated a positive predictive value in diagnosing sacroiliac joint pain in patients with positive provocative maneuvers. However, a corroborative history and physical examination may enter into the differential diagnosis of sacroiliac joint pain but cannot make a definitive diagnosis of sacroiliac joint syndrome.[261,262] Many studies have reported on the efficacy of plain films,[263] computed tomography,[255] single photon emission computed tomography,[264] bone scans,[265,266] nuclear imaging,[267–270] and MRI.[271] However, these radiologic studies can only help in assessing anatomic integrity of other possible nociceptive sources that may mimic sacroiliac joint pain, such as the lumbar intervertebral disc. Imaging studies may be helpful in other disorders, which may affect the sacroiliac joint, such as hyperparathyroidism, fracture, Reiter's syndrome, psoriatic arthritis, ankylosing spondylitis, rheumatoid arthritis, and septic sacroiliitis.

VALIDITY

The face validity of sacroiliac joint block has been established by injecting small volumes of local anesthetic with contrast into the target joint and determining the contrast spread in posterior, anterior, and lateral radiographs. Construct validity of sacroiliac joint blocks is also extremely important to avoid the placebo effect. Maigne et al.[248] established that the false-positive rate of single, uncontrolled, sacroiliac joint injections was 20%. False-positive injection may occur with extravasation of anesthetic agent out of the joint secondary to defects in the joint capsule. False-negative results may occur from faulty needle placement, intravascular injection, or inability of the local anesthetic agent to reach the painful portion of the joint due to loculations.

PREVALENCE

Multiple authors have shown sacroiliac joint pain to be 10 to 30% by a single block[26,247] and 10 to 19% by a double-block paradigm.[27,248]

EVIDENCE

The validity of sacroiliac joint diagnostic injections has been established as moderate.[1]

SAFETY AND COMPLICATIONS

Complications of sacroiliac joint injection include infection, trauma to the sciatic nerve, and others related to drug administration. Without fluoroscopy, successful joint injection, as documented with CT, is successful in only 22% of procedures.[272] Notable in the study was epidural spread in 24% of the procedures or foraminal filling in 44% sacroiliac joint injections. Others have demonstrated similar findings.[251,252,273]

THERAPEUTIC INTERVENTIONAL TECHNIQUES

Interventional techniques in the management of chronic spinal pain include neural blockade and minimally invasive surgical procedures ranging from epidural injections, facet joint injections, and neuroablation techniques, to intradiscal thermal therapy, disc decompression, morphine pump implantation, and spinal cord stimulation.

RATIONALE

The rationale for therapeutic interventional techniques in the spine is based on several considerations:

- Cardinal source(s) of chronic spinal pain, namely discs and joints, are accessible to neural blockade

- Removal or correction of structural abnormalities of the spine may fail to cure and may even worsen painful conditions
- Degenerative processes of the spine and the origin of spinal pain are complex
- The effectiveness of a large variety of therapeutic interventions in managing chronic spinal pain has not been demonstrated conclusively

FACILITIES

The requirements for therapeutic interventions include a sterile operating room or procedure room, monitoring equipment, radiological equipment, special equipment based on technique, sterile preparation with all the resuscitative equipment, needles, gowns, injectate agents, intravenous fluids, sedative agents, and trained personnel for preparation and monitoring of the patients. Minimum requirements include history and physical examination, informed consent, appropriate documentation of the procedure.

CONTRAINDICATIONS

Contraindications include bacterial infection, possible pregnancy, bleeding diathesis, and anticoagulant therapy. Precautions are warranted in patients with anticoagulant or antiplatelet therapy, diabetes mellitus, or artificial heart valves.

FACET JOINT INTERVENTIONS

A preponderance of evidence supports the existence of facet joint pain;[1–3,22–27,49,58–81,84–86,88,97–117,274–315] however, there are also a few detractors.[316–318] Facet joint pain may be managed by either intra-articular injections, medical branch blocks, or neurolysis of medial branches. An extensive, evidence-based review[1] considered relief with intra-articular injections or medial branch blocks as short term if it was documented for less than 3 months and long-term if it was documented for longer than 3 months. Relief with medial branch neurotomy was considered short-term if it was less than 6 months and long-term it if was longer than 6 months.

INTRA-ARTICULAR BLOCKS

Therapeutic benefit has been reported with the injection of corticosteroids, local anesthetics, or normal saline into the facet joints. The literature describing the effectiveness of these interventions is abundant. However, no systematic reviews have been performed. Five randomized clinical trials offer data on the use of intra-articular injections in the spine.[274–278] Controlled and uncontrolled clinical studies that evaluated the long-term relief of back and leg pain from intra-articular facet joint injections are abundant.

The well-controlled trials of both Carette et al.[274] and Barnsley et al.[275] were described as negative by the

authors. Manchikanti et al.[1] concluded that only one randomized trial by Carette et al.[274] was considered positive in contrast to the second randomized trial by Barnsley et al.,[275] which was negative. Among the nonrandomized trials, positive results were noted for short-term relief in all the studies; however, long-term relief was noted only in three of the five studies.[94,283–286,315]

Manchikanti et al.[1] concluded that the evidence of intra-articular injections of local anesthetics and steroids from randomized trials, complemented with that of nonrandomized trials (prospective and retrospective evaluations), provided moderate evidence of short-term relief and limited evidence of long-term relief of chronic neck and low back pain.

Medial Branch Blocks

Medial branch blocks have been extensively used for diagnostic and prognostic purposes with limited use for therapeutic purposes. The therapeutic role of medial branch blocks was evaluated in three randomized clinical trials[276,277,291] and five nonrandomized clinical trials.[97,101,319–321]

Based on the review of the current studies, it appears that the evidence of medial branch blocks is strong for short-term relief and moderate for long-term relief of pain of facet joint origin.

Medial Branch Neurotomy

Percutaneous radiofrequency neurotomy of medial branches is a procedure that offers temporary relief of pain by denaturing the nerves that innervate the painful joint. However, the pain returns when the axons regenerate. This return of pain can be managed by repeating the procedure and reinstating the relief.[297] Radiofrequency neurotomy is a neurolytic technique.

There have been three systematic reviews of medial branch neurotomy.[322–324] Two[322,324] of the three reviews were marred with inappropriate methodology and inaccurate conclusions. Manchikanti et al.[323] also evaluated the medial branch neurotomy in the management of chronic spinal pain. This review used inclusion/exclusion criteria and search strategy, and followed key domains in rating quality of systematic reviews as described by the Agency for Healthcare Research and Quality (AHRQ).[325]

Manchikanti et al.[1,323] concluded that the evidence for radiofrequency neurotomy of medial branches was strong for short-term relief (less than 6 months) and moderate for long-term relief (6 months or longer) of chronic spinal pain of facet joint origin.

Safety and Complications

Potential side effects with radiofrequency denervation include painful cutaneous dysesthesias, increased pain due to neuritis or neurogenic inflammation, anesthesia dolo-rosa, cutaneous hyperesthesia, pneumothorax, and deafferentation pain.

EPIDURAL INJECTIONS

Epidural injection of corticosteroids is one of the commonly used interventions in managing chronic spinal pain.[1–3,327,328] Several approaches are available to access the lumbar epidural space: caudal, interlaminar, and transforaminal. Epidural administration of corticosteroids is one of the subjects most studied in interventional pain management with the most systematic reviews available.

Numerous systematic reviews of effectiveness of epidural steroid injections have reached contradictory conclusions, mostly negative and a few positive.[1–3,327–338]

Epidural injections may be performed by three approaches. There are substantial differences between the three approaches.[1–3,327,328]

- The interlaminar entry is directed more closely to the assumed site of pathology, requiring less volume than the caudal route.
- The caudal entry is relatively easily achieved, with minimal risk of inadvertent dural puncture.
- The transforaminal approach is target specific with smallest volume in fulfilling the aim of reaching the primary site of pathology, namely, ventrolateral epidural space.

Disadvantages of the caudal approach include[1–3,327,346–367]

- Requirement of substantial volume of fluid
- Dilution of the injectate
- Extra-epidural placement of the needle
- Increased risk for intravascular placement of the needle

Disadvantages of interlaminar approach include[1–3,325,326,346–367]

- Dilution of the injectate
- Extra-epidural placement of the needle
- Intravascular placement of the needle
- Preferential cranial flow of the solution
- Preferential posterior flow of the solution
- Difficult placement (with increased risk) in postsurgical patients
- Difficult placement below L4/5 interspace
- Deviation of needle to nondependent side
- Dural puncture
- Trauma to spinal cord

Disadvantages of the transforaminal approach include[1–3,327,328,368–380]

- Intraneural injection
- Neural trauma
- Technical difficulty in presence of fusion and/or hardware
- Intravascular injection
- Spinal cord trauma

Due to the inherent variations, differences, advantages, and disadvantages applicable to each technique (including the effectiveness and outcomes), caudal epidural injections, interlaminar (cervical, thoracic, and lumbar) epidural injections, and transforaminal (cervical, thoracic, and lumbosacral) epidural injections are considered separate entities within epidural injections and are discussed as such below.

Manchikanti et al.[1] and Boswell et al.,[328] after considering a multitude of systematic reviews, along with randomized, as well as nonrandomized trials for each category, namely, interlaminar, caudal, and transforaminal epidural injections, considered short-term effect as significant relief of less than 3 months and long-term effect as 3 months or longer.

Caudal Epidural Injections

There was only one systematic review[328] and one evidence-based review[1] evaluating caudal epidural injections. There were nine studies either randomized or double blind,[381–389] three prospective trials,[390–392] and many retrospective evaluations[1–3] examining the effectiveness of caudal epidural injections.

Boswell et al.[328] and Manchikanti et al.[1] included eight randomized or double-blind trials, of which five were positive for short-term relief and five were positive for long-term relief with multiple injections.[381,382,386–388] Further, all prospective trials[390–392] and all (four) retrospective trials[1] were positive for short-term and long-term relief with multiple injections.

The combined evidence of caudal epidural steroid injections with randomized trials and nonrandomized trials (prospective and retrospective trials) is strong for short-term relief and moderate for long-term relief.

Interlaminar Epidural Injections

Multiple systematic reviews provided contradictory and confusing opinions. Further, most of the systematic reviews utilized combined caudal and interlaminar epidural steroid injections, thus, no reasonable conclusions may be drawn from these systematic reviews, and their conclusions may not be applied in clinical practice settings. However, studies in the literature evaluating the effectiveness of interlaminar epidural injections, specifically the lumbar epidural injections, are extensive. Multiple evaluations included 16 randomized or double-blind trials,[393–408]

eight non-randomized prospective trials, and multiple other observational trials.[1,409–417]

Of the 16 randomized trials, 10 included an evaluation, 7 were positive for short-term relief, whereas only 3 were positive for long-term relief. Numerous nonrandomized trials, both prospective and retrospective, reported good results in 18 to 90% of patients receiving cervical or lumbar interlaminar epidural steroid injections.

Among the three prospective trials included for evaluation, one was positive, one was indeterminate, and one was negative. Boswell et al.[328] and Manchikanti et al.[1] concluded that the evidence for the overall effectiveness of interlaminar epidural steroid injections in managing chronic low back pain was moderate for short-term relief and limited for long-term relief. There was no evidence of effectiveness of interlaminar epidural steroids in managing spinal stenosis.[410,411] Further, multiple evaluations[412–414] failed to identify predictive factors in administration of interlaminar epidural steroid injections.

Transforaminal Epidural Injections

Transforaminal epidural injections have emerged recently as a target-specific modality of treatment for management of spinal pain. Review of the literature showed seven randomized trials,[405,417–423] nine prospective evaluations,[409,412–415,424–431] one prospective evaluation of change in disc herniation,[432] and multiple retrospective reports.[1,433–435]

Manchikanti et al.[1] and Boswell et al.[328] synthesized the evidence with inclusion of multiple evaluations, all of them showing positive short-term and long-term effectiveness of transforaminal epidural steroids in managing nerve root pain. Based on all the evidence, transforaminal epidural injections provide strong evidence for short-term relief and moderate evidence for long-term relief. Their effectiveness in postlumbar laminectomy syndrome and disc extrusions was inconclusive.

Safety and Complications

The most common and worrisome complications of caudal, interlaminar, and transforaminal epidural injections are of two types: those related to the needle placement, and those related to drug administration. Complications include dural puncture, spinal cord trauma, infection, hematoma formation, abscess formation, subdural injection, intracranial air injection, epidural lipomatosis, pneumothorax, nerve damage, headache, death, brain damage, increased intracranial pressure, intravascular injection, vascular injury, cerebral vascular or pulmonary embolus, and effects of steroids.[1–3,129,130,368–380,433–486] Spinal cord trauma and spinal cord or epidural hematoma formation are catastrophic complications that are rarely seen following interventional procedures in the cervical spine, thoracic spine, or upper lumbar spine.[357–361] There are growing

concerns about the potential risk of unintended intravascular injections that occur during the performance of transforaminal epidural steroid injections. Disastrous, but apparently rare injuries have occurred, which may be due to injection of particulate steroid into spinal arteries that enter the spinal canal adjacent to exiting nerve roots.[369–380] Complications have been reported with cervical and lumbar transforaminal injections.

Side effects related to the administration of steroids are generally attributed either to the chemistry or to the pharmacology of the steroids. The major theoretical complications of corticosteroid administration include suppression of pituitary-adrenal axis, hypercorticism, Cushing's syndrome, osteoporosis, avascular necrosis of bone, steroid myopathy, epidural lipomatosis, weight gain, fluid retention, and hyperglycemia.[1–3,129,474–486] However, evaluation of the effect of neuraxial steroids on weight and bone mass density noted no significant difference in patients undergoing various types of interventional techniques with or without steroids.[130] The most commonly used steroids in neural blockade in the United States, methylprednisolone acetate, triamcinolone acetonide, and betamethasone acetate and phosphate mixture, have all been shown to be safe at epidural therapeutic doses in both clinical and experimental studies.[1–3,129]

ADHESIOLYSIS

The purpose of epidural lysis of adhesions is to eliminate deleterious effects of scar formation, which can physically prevent direct application of drugs to nerves or other tissues to treat chronic back pain. The goal of percutaneous lysis of epidural adhesions is to assure delivery of high concentrations of injected drugs to the target areas. Epidural lysis of adhesions and direct deposition of corticosteroids in the spinal canal are also achieved with a three-dimensional view provided by epiduroscopy or spinal endoscopy.

PERCUTANEOUS ADHESIOLYSIS

Manchikanti et al.[1] in their evaluation, considered duration of relief of less than 3 months as short-term and longer than 3 months as long-term, for percutaneous adhesiolysis. In contrast, for spinal endoscopic adhesiolysis, 6 months of relief was considered short-term and longer than 6 months was considered long-term.

In the evidence synthesis for percutaneous epidural adhesiolysis using a spring-guided catheter with or without hypertonic saline neurolysis to evaluate the clinical effectiveness, three randomized controlled trials[487–489] and multiple nonrandomized evaluations[490–493] were included. Thus, it appears that evidence for effectiveness of percutaneous adhesiolysis is strong for short-term and moderate for long-term relief with repeat interventions.

SPINAL ENDOSCOPIC ADHESIOLYSIS

Evidence synthesis for spinal endoscopy included one randomized, double-blind trial,[494,495] two prospective evaluations,[496,497] and two retrospective evaluations[493,498] showing strong evidence for short-term relief (less than 6 months) and moderate for long-term relief (greater than 6 months).

SAFETY AND COMPLICATIONS

The most common and worrisome complications of adhesiolysis and spinal endoscopy with lysis of adhesions are related to dural puncture, spinal cord compression, catheter shearing, infection, steroids, hypertonic saline, hyaluronidase, instrumentation with endoscope, and administration of high volumes of fluids potentially resulting in excessive epidural hydrostatic pressures. Hypertonic saline injected into the subarachnoid space has been reported to cause cardiac arrhythmias, myelopathy, paralysis, and loss of sphincter control.[499] Aldrete, Zapata, & Ghaly,[500] in a case report, attributed incidences of arachnoiditis following epidural adhesiolysis with hypertonic saline to subarachnoid leakage of hypertonic saline. However, there were multiple variations in the technique and injection of hypertonic saline, (intraoperatively or injecting in spite of subarachnoid blockade), which may be responsible for these complications. While there are multiple reports with experience of hypertonic saline solution, there are no controlled reports of potential adverse effects.[501–505]

Another specific complication of percutaneous epidural adhesiolysis is related to catheter shearing and its retention in the epidural space.[506] Additionally, a troublesome complication is that of excessive intraspinal pressure development with its potential to affect both local and distant profusion, and resulting in visual changes and even blindness. Even though the incidence is rare, it appears that this would be much higher with spinal endoscopic procedures with a combination of high volumes of fluid and generation of high hydrostatic pressures.[507] It is also possible with catheter-based adhesiolysis if excessive amounts of fluids are injected rapidly.

Spinal cord trauma or spinal cord or epidural hematoma formation is a catastrophic complication possible with both catheter-based or endoscopic adhesiolysis, however, more so with endoscopic adhesiolysis. But, there are no such case reports in the literature. Understanding fluoroscopic imaging is crucial to avoid disastrous complications.[508]

INTRADISCAL THERAPIES

Commensurate with our improved ability to identify painful discs and image spinal anatomy are the advances achieved in the treatment of spinal disorders.[509] During

the past few decades, numerous authors have reported on percutaneously administered minimally invasive spinal surgery techniques to manage discogenic pain. Procedures investigated have been chymopapain injection to achieve nucleolysis, percutaneous disc decompression with nucleotomy using coblation technology (nucleoplasty), and intradiscal electrothermal therapy (IDET). Manchikanti et al.[1] defined relief of 6 months or less as short-term, whereas long-term was over 6 months.

INTRADISCAL ELECTROTHERMAL THERAPY

IDET intervention is applicable solely for the patient with axial symptoms and is not indicated for radicular pain.[509] IDET is performed by introducing a flexible catheter, containing a resistive coil, into the disc. IDET has been shown to provide precision temperature control.[510–512]

The present evidence for intradiscal electrothermal therapy appears to be controversial with limited evidence for short-term as well as long-term relief.[510,512–516]

Safety and Complications

Infrequent complications were reported, including catheter breakage in 19 of 35,000 catheters used (0.05%) and six nerve root injuries; there were six cases of post-IDET disc herniation at the treated level transpiring 2 to 12 months post-treatment in 1,675 patients.[517] Two separate case reports of cauda equina syndrome have been reported.[518,519]

PERCUTANEOUS DISC DECOMPRESSION

Percutaneous disc decompression (PDD) with nucleoplasty (coblation technology) is performed with radiofrequency energy, used to dissolve nuclear material through molecular dissociation.[520–522] It is believed that this reduced volume of disc material results in reduced intradiscal pressure. Bipolar radiofrequency coagulation further denatures proteoglycans, changing the internal environment of the affected nucleus pulposus, which showed changes in intradiscal pressure following coblation. The present evidence for PDD is limited.

Safety and Complications

Safety and complications are expected to be similar to those for discography and IDET, even though none have been reported thus far.

IMPLANTABLE THERAPIES

Spinal cord stimulation systems and implantable intrathecal devices are frequently used in managing chronic intractable pain.[523,524]

SPINAL CORD STIMULATION

The mechanism of action of spinal cord stimulation is not completely understood. However, recent research has given us insight into effects occurring at the local and supraspinal levels, and through dorsal horn interneuron and neurochemical mechanisms.[525,526]

There have been multiple reviews evaluating the effectiveness of spinal cord stimulation in low back and lower extremity pain,[1,527] along with a few prospective controlled trials.[528–530] Based on this, it appears that the evidence for spinal cord stimulation in properly selected population with neuropathic pain is moderate for long-term relief (longer than 6 months).

Safety and Complications

Complications with spinal cord stimulation range from simple, easily correctable problems, such as lack of appropriate paraesthesia coverage, to devastating complications such as paralysis, nerve injury, and death.[529–533]

IMPLANTABLE INTRATHECAL DRUG ADMINISTRATION SYSTEMS

Spinal administration of opioid and non-opioid medication has been increasingly advocated for those patients who fail to achieve pain relief or experience undue side effects with oral opioid regimens.[534]

With inclusion of multiple trials,[535–542] in the evidence synthesis, there is moderate evidence indicating the long-term effectiveness of intrathecal infusion systems (longer than 6 months).

Safety and Complications

The complication rate appears to average about 20%. The most common immediate problems include postdural puncture headache, infection, nausea, urinary retention, and pruritus. Long-term complications seen post-implant include catheter and pump failure. The high rate of device-related complications identified in the literature is certainly concerning from a patient safety and cost-effectiveness perspective. Catheter complication rates tend to range from 10 to 40% with pump complications somewhat lower. The incidence of granuloma based on reporting to the FDA and device manufacturers appears to be less than 1%.[543] Commonly reported drug-related complications include pedal edema and hormonal changes leading to decreased libido and sexual dysfunction.

Psychological Evaluation in Interventional Pain Practice

Jeffrey W. Janata, PhD

INTRODUCTION

Two phenomena currently characterize the field of pain medicine. First is the dramatic rise of interventional pain practice. Invasive, nonsurgical procedures are playing an increasingly prominent role in the treatment of chronic pain.[1] Simultaneously, research points out how psychologically and behaviorally complex are the patients who present to pain physicians. Recent informal studies indicate that an alarming proportion of patients in carefully managed practices are abusing narcotics or other substances and are escaping routine detection.[2] Depression as a consequence of chronic pain is considered normative.[3] Demoralization and passivity typically characterize this population, which increases the implicit demand on physicians to provide cures. Physicians, and particularly their staffs, complain of the high incidence of personality disorders in their practices. The physicians who care for people with chronic pain often find themselves feeling overwhelmed and at a loss regarding how to provide compassionate care while developing and protecting their practices and finding a sense of satisfaction in their work.

This chapter is written with the intention of aiding clinicians in identifying strategies used to elucidate psychological and behavioral factors, which contribute to and are consequent of chronic pain, particularly for patients who may be candidates for interventional pain procedures.

Comprehensive evaluation of people experiencing chronic pain definitionally includes assessment of the behavioral and social factors that contribute to the subjective experience of pain. This is distinct from the assess-

ment of psychiatric pathology, which may constitute a comorbid condition, in the case, for example, of a patient presenting with chronic pain who incidentally carries a diagnosis of schizophrenia, which is otherwise well controlled on antipsychotic medication.

SOURCES OF EVALUATIVE INFORMATION

Psychological and behavioral information can come from a variety of sources each informing clinicians in unique ways.

CLINICAL INTERVIEW AND PATIENT QUESTIONNAIRES

The clinical interview can be a rich source of information and often provides the initial indication that a more comprehensive psychological evaluation is indicated.[4,5] Experienced clinicians follow a general interview outline to ensure obtaining a complete picture but not so rigidly as to get in the way of hearing the patient's story.[6] Table 59.1 provides a suggested outline for the clinical interview, which can be paralleled in a questionnaire given to patients to complete in advance of their initial appointment or in the waiting room.

PAIN

The clinical interview (and questionnaire) should always begin with the complaints that bring the patient to the

TABLE 59.1
Outline of the Clinical Interview and Waiting Room Questionnaire

1. Pain
   a. Pattern and distribution, including pain drawing
   b. Pain rating: best, worst, average levels
   c. Qualitative pain perception: adjectival descriptions of pain
   d. Activities, events, interventions that increase, decrease pain
   e. Coping with pain: the patient's adaptive and maladaptive strategies
2. Pain History
   a. Precipitating event
   b. Duration
   c. Treatment history: Physicians consulted, diagnostic procedures, medications (prescribing physician, dosage, response), interventional procedures (physician, response)
   d. Patient's understanding, beliefs about his/her pain, diagnosis and prognosis
3. General medical history and status
   a. Medical and surgical history
   b. Medications for conditions other than pain
   c. Physical status: height, current weight and weight history, sleep patterns
   d. Sexual function
   e. Nicotine, caffeine use
   f. Substance use: history, any treatment, family history, CAGE* questions
4. Financial and legal history
   a. Pursuit of disability, family history of disability
   b. Pending litigation, family history of litigation
   c. Current sources of financial support
5. Educational and occupational history
   a. Educational history
   b. Occupational history
   c. Perceived future occupational opportunity
6. Psychosocial information
   a. Behavioral observation, how the patient expresses pain verbally and physically, obtained from staff waiting room observation and during interview
   b. Mental status examination
   c. Psychological, psychiatric history: personal and family
   d. Family and marital status and history
   e. Impact of pain on personal functioning, degree of independence, dependence
   f. Impact of pain on family functioning
   g. Daily activity, description of typical day

*1. C: Have you ever felt that you should **Cut down** on your drinking?
 2. A: Have people **Annoyed** you by criticizing your drinking?
 3. G: Have you ever felt bad or **Guilty** about your drinking?
 4. E: Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover? (**Eye-opener**)

Interpretation:
Answering yes to two questions is a strong indication for alcoholism. Answering yes to three questions confirms alcoholism.

office. Patients typically want to be able to provide a narrative of their pain experience and history, which can be full of emotion, attribution, and expectation and "present the thread necessary to weave the facts of the clinician's evaluation into the fabric of pain".[7] Pain drawings can provide valuable information about the patient's experience of pain. Pain ratings often indicate not only perception of the intensity of pain but also provide clues about the patient's cognitive set. For example, it is not uncommon that patients are better able to describe what makes pain worse than what helps to decrease pain. This helps define a negative cognitive set on the part of the person in pain, symptomatic of the situational depression that is so commonly seen in chronic pain presentations[8] and provides the clinician an early opportunity to help the patient recalibrate his or her sense of the topography of pain intensity through the day.

PAIN HISTORY

Pain history provides the patient's perspective on causes of pain and the types of interventions used to date. This again gives the clinician a view of the patient's emotional response to the circumstances surrounding the onset of pain and to prior attempts by physicians to alleviate the pain. A careful examination of pain medications used and the patient's response to those medications helps to begin the process of understanding the patient's expectations of relief provided by medications and the potential evolving dependence on those medications. Behavior indicative of physical tolerance, psychological dependence, and addiction deserves careful attention.[9,10] Addiction is defined by a pervasive preoccupation with obtaining a substance, use or misuse despite negative consequences to the patient, and an increased risk that illegal means will be employed (e.g., prescription forgery or alteration) or illegal substances sought to satisfy the patient's craving. Addiction has been likened to experiencing a "hole in the soul" (T. Parran, personal communication) that only the substance of choice can fill. By contrast, pseudo-addiction is an iatrogenic condition created when a beneficial medication is provided in inadequate doses or with unnecessarily rigid restrictions on the part of the prescribing physician. An example of the latter condition might be the physician who provides prescription refills only every 30 days to the day to a patient whose work requires frequent travel. What appears to be drug-seeking behavior may in fact be reasonable relief-seeking.

GENERAL MEDICAL INFORMATION

Obtaining general medical information helps complete the medical context in which painful conditions reside. It also provides the first opportunity to observe any vegetative signs of depression in chronic pain. Recent his-

tory of weight loss or gain may be symptomatic of depression, and sleep disturbance is among the most common complaints of patients experiencing pain. While patients may report that sleep is disturbed by virtue of the difficulty they face in finding comfortable sleeping positions, sleep disturbance may represent another of the vegetative signs of affective disorder. Sexual function is often overlooked in medical history-taking and yet to ignore patients' concerns about the quality of their sex lives is to avoid an important aspect of their experience. Sexual function can be impaired by pain itself and by medications used to manage pain, particularly the selective serotonin reuptake inhibitors (SSRI) class of antidepressants. Decreased sexual drive can be symptomatic of depression, and sexual difficulties can contribute to marital distress. Use of substances represents a critical line of inquiry, particularly given the aforementioned high rate of undetected substance abuse in the chronic pain population. Embedding the CAGE questions[11] in a questionnaire can provide clinicians important clues regarding the risk of misuse of analgesics.

FINANCIAL AND LEGAL HISTORY

The financial and legal portions of the interview are often overlooked in clinical practice. Clinicians are as likely to experience discomfort when asking about patient finances as when inquiring about sexual function. However, the patient's financial status and concerns about financial security can set the context for anticipatory anxiety, thereby increasing the urgency with which a cure is demanded of the physician. Pursuing legal aspects of the patient's presentation is equally critical. A patient intent on seeking disability has different expectations of medical care than does one who is intent on return to occupational function, yet this intention is often difficult to detect. Inquiry both in questionnaire and interview form may increase the likelihood that clinicians have an accurate sense of the patient's motivation. Finally, asking simply whether a patient has contacted or retained an attorney can open an important line of inquiry.

EDUCATIONAL AND OCCUPATIONAL HISTORY

Educational and occupational history provides a sense of premorbid functioning and may set the stage for inquiry about the patient's anxiety about the future. A patient employed historically as a laborer presenting with chronic low back pain is entitled to considerably greater anxiety about future employability than one who has a long history of stable white collar employment.

PSYCHOSOCIAL INFORMATION

The psychosocial section completes the interview process and indications already obtained of psychological diffi-

culty can be more fully pursued. In addition to asking about previous psychological diagnosis and treatment, obtaining family history of psychopathology is also helpful in determining possible genetic risk. The history can aid, for instance, in establishing that a biological risk of depression exists in addition to a situational depressive response to pain. The degree of patient stability in marital and familial relationships, along with employment stability, can provide initial indications of possible personality disorders, defined by the DSM IV[12] as persistent, maladaptive patterns of behavior affecting cognition, affect, interpersonal function, and/or impulse control. Personality disorders influence how one relates to others and are expressed frequently in the interpersonal relationship that a patient develops with his or her physician and staff. Because personality disorders are developmentally present as early as adolescence, these long-term patterns of dysfunction are likely to be present prior to the onset of pain. However, the distress accompanying pain can amplify the symptoms of personality disorders.[13,14]

Mood evaluation is central to the comprehensive evaluation of pain. In addition to the vegetative signs of affective disorders, chronic pain routinely and predictably precipitates emotional responses such as anger, irritability, and agitation. As pain persists despite ameliorative efforts, patients can become demoralized and experience *learned helplessness* characterized by passivity and increased dependence. *Locus of control* is a psychological construct that describes a continuum from internal to external. Internal locus of control suggests an individual who relies primarily on internal resources to manage life stresses, while external locus of control describes one who relies primarily on resources outside his or her own control. Patients with long histories of pain inevitably have learned from their own failed attempts at managing pain and increasingly depend on external strategies. Eventually, this can create a pattern of overreliance on physicians, procedures, and medications. A pattern of passivity and evidence of external locus of control provides clues to the clinician that intervention strategies should be paired with, or even made conditional upon, evidence of the patient's engaging in self-managed efforts.

The mood assessment should also explore suicidality and impulsivity. Depression is the strongest correlate of suicidal ideation and behavior. Impulsivity, often expressed in a history of substance misuse, helps establish risk for impulsive misuse of medications. Finally, clinicians prescribing narcotics and antidepressants (particularly tricyclics) need to be aware that another correlate of suicidal behavior is access to lethal means.

Observations about a patient's demeanor and personal interactions while in the office may provide insight regarding the patient's cognitive state. However, a mental status examination should be included in the interview to provide

more specific information about memory and cognition, particularly if traumatic brain injury is suspected.

Inquiry into a patient's typical day can be revelatory. Evidence of the impact of pain on personal and family function, on physical activity and functional capacity, and on quality of life can be revealed and explored further as indicated.

The interview and waiting room questionnaires can generate a rich, initial source of data, setting the stage for determining whether additional psychological evaluation is indicated. Moreover, these data help to determine what particular consultative questions are being asked of a pain-informed psychologist or psychiatrist. Establishing a comprehensive psychological understanding of the patient in chronic pain often is aided by the process of *convergent validation*, in which history, observations, patterns of behavior and assessment results coalesce to create a more valid and reliable diagnostic and prognostic picture than any of these means alone can provide. The high probability of psychological and behavioral distress in the chronic pain population argues for routine inclusion of psychological opinion in comprehensive, team-based assessment of pain.

PSYCHOLOGICAL ASSESSMENT

Formal psychological assessment employs instruments that have been thoroughly researched and provide established reliability and validity. *Reliability* refers to the capacity of an instrument to provide the same data over time. Scales have established reliability coefficients that quantify this capacity for stable measurement. *Validity* measures indicate the degree to which an instrument measures what it purports to measure.

PERSONALITY

Although the search for the pain-prone personality has been roughly as fruitful as the search for the Holy Grail,[15] personality issues specific to particular individuals can be revelatory. The utility of personality testing per se continues to be debated,[16] yet the potential for describing one's general psychological status, detecting prognostic behavioral information, and the reliance of the medicolegal system on personality testing preserve an important role for personality assessment.

The Minnesota Multiphasic Personality Inventory (MMPI-2)[17] is a widely used and highly validated general measure of personality. Among its strengths is the use of validity scales that provide a profile of test-taking set. The MMPI's capacity to estimate whether an examinee provided a valid self-description, tried to appear healthy, or tried to appear unhealthy can be beneficial to clinicians. The 10 primary clinical scales and a host of subscales and research scales help explain the prominence of the MMPI

in personality testing. Computer scoring provides scale scores and a brief, initial interpretive narrative. The test comprises 576 true–false questions, so the time it takes a patient to complete the test is significant. Clinicians need to weigh the cost in patient time against the possible diagnostic benefits of MMPI administration.

The Symptom Checklist-90 (SCL-90-R)[18] comprises 90 items describing both physical and psychological symptoms. Each item is scored using a five-point scale representing the degree to which a particular symptom was bothersome to the patient in the past week. Nine clinical scales are derived, estimating, for example, obsessive-compulsive tendencies, somatization, depression, and anxiety. Like the MMPI, the SCL-90-R has been widely used in pain populations.

The Millon Behavioral Health Inventory (MBHI)[19] was designed to assess personality function in medical populations. The instrument is a 150-item scale, deriving 20 clinical scales: eight scales assessing styles of relating to providers, six that assess stressors, and six that assess probable response to illness. Advantages of the MBHI include having fewer items than the MMPI, its items having low somatic content, and the instrument having been validated in a medical (rather than psychiatric) population.

MOOD

The relationship between mood and pain has been well established.[20,21] The experience of pain has been associated with vegetative symptoms (e.g., sleep disturbance, weight changes), affective symptoms (e.g., demoralization, irritability, anger), and cognitive symptoms (e.g., concentration, attention). Several instruments have been found to be useful in the assessment of mood.

The Beck Depression Inventory (BDI-2)[22] has been extensively used in pain populations.[23,24] It is brief and well validated, consisting of 21 items each with four possible answers. Easily scored in the office, the BDI provides clinicians with information in cognitive-affective as well as somatic-performance domains. The Beck provides a well-accepted criterion for psychological distress that has been used frequently in studies of chronic pain.[25]

The Center for Epidemiological Studies-Depression Scale (CES-D)[26] was designed as an alternative to the BDI, arising out of a concern that the somatic content on the BDI might artificially inflate estimation of depression in medical populations.[27] One study suggests that the CES-D was somewhat more sensitive to changes in the severity of depression than the BDI,[28] which may reflect its deemphasis of somatic content.

The Profile of Mood States (POMS)[29] provides an assessment of six mood states (tension–anxiety, anger–hostility, depression–dejection, vigor–activity, fatigue–inertia, and confusion–bewilderment). The

POMS is being employed in an increasing number of pain treatment studies.[30,31]

MEASURES OF PHYSICAL FUNCTIONING

Pain-specific, health quality of life measures quantify the degree to which pain interferes with daily functioning. A series of studies has demonstrated that pain and function are only modestly correlated,[32] however, which argues for the inclusion of measures of function in pain assessment.

The SF-36 Health Survey[33] is a widely used general measure of health-related quality of life. The instrument provides an eight-scale profile of functional health scores, along with indices of physical and mental health. Although much used in the surveys of general health, its utility in pain populations has been tempered by concern that it may lack adequate sensitivity to change in pain populations.[28]

The Sickness Impact Profile[34] assesses perception of general health and, as such, is not specific to pain. However, scales derived, such as ambulation, mobility, body care, and social activity, may be useful in some pain subtypes in which a patient's perception of his or her level of disability is in question.

The Multidimensional Pain Inventory (MPI)[35] more specifically assesses pain and function using 56 items scored on a seven-point scale. Nine clinical scales are derived, including particularly interference of pain on physical functioning. Other scales include ratings of pain severity, life control, affective distress, social support, punishing and distracting responses from others, and a measure of activity level. The MPI assigns the probability that a patient falls into one of three profiles: dysfunctional, interpersonally distressed, or active coper.

The Brief Pain Inventory (BPI)[36] measures intensity of pain and interference of pain, including interference with sleep, a clinically significant concern. The inventory is well validated and reliable and has been used in a variety of painful conditions.

Additional instruments of note include the Oswesty Low Back Pain Disability Questionnaire;[37] the Coping Strategies Questionnaire,[38] used to evaluate how patients are coping with pain (e.g., catastrophizing, praying, reinterpreting pain sensations); the Pain Cognitions Questionnaire,[39] which assesses patient beliefs and expectations about pain and its treatment; and the Pain Disability Index,[40] which provides disability evaluation of seven areas of function.

SCREENING FOR USE OF INVASIVE PROCEDURES

Most clinicians are in agreement with the use of psychological exclusion criteria when considering use of interventional procedures, particularly spinal cord stimulators, which can inform clinical thinking when considering the use of narcotics as well. Nelson, Kennington, Novy et al.[41] have proposed the following criteria:

1. Active psychosis. With evidence of delusions, hallucinations, or somatic preoccupation, the validity of pain complaints must be suspect. However, patients who are well controlled on antipsychotic medications, who are not currently or recently psychotic, may be candidates for interventional procedures if carefully psychiatrically monitored.

2. Major depression, untreated or poorly treated. Patients with severe mood disturbance may, as a consequence, experience intensification of pain or be at risk for responding poorly to treatment. Moreover, the relationship between mood and pain is likely bidirectional; failure to isolate and aggressively treat significant mood disturbance puts clinicians at risk for underappreciating that pain report is inflated and maintained by depression. Significant sleep disturbance should also indicate pretreatment prior to considering pain intervention. It should be emphasized that depression is a normal consequence of pain and does not preclude adequate response to treatment; it is the severity of depression that is at issue.

3. Active suicidal ideation or behavior. Suicidal thoughts, preoccupations, intentions, or plans require psychological or psychiatric intervention before pain treatment can be considered. Suicidal patients cannot reliably participate in the process of treatment and are at risk to respond to failed treatment with a fatal solution to pain.

4. Active homicidal thinking or behavior. Patients who are preoccupied with thoughts of violence or who have a history of difficulty controlling violent impulses are considered too unstable to engage in treatment. Rarely are such individuals candidates for spinal cord stimulation at any point, given the difficulty achieving adequate psychological stabilization. This poor prognosis should inform clinical use of other pain interventions as well.

5. Untreated or poorly treated substance abuse or addiction. A patient with drug-seeking behavior cannot be relied on to adhere to a medication or treatment regimen. Moreover, addicts are at risk to pursue medicinal narcotics over street drugs, given relative purity, low cost, and diminished legal risk. Clinicians should refer patients with alcohol or drug addiction for evaluation and treatment and reconsider such patients for inter-

vention only after a minimum of 3 months of appropriate control of substance use.

6. Somatization or somatoform disorder. These diagnoses carry the risk that the patient will be preoccupied with physical complaints that are unsupported by or exceed evidence obtained in diagnostic evaluations. The dilemma here, of course, is that pain mechanisms in many conditions are not well understood. What may appear to be a non-organic complaint may originate with an undetected or undetectable physical cause. Referral to a psychologist or psychiatrist who is familiar with the somatoform disorders can help to clarify this complex issue.

7. Unresolved compensation or litigation issues. Active disability pursuit or involvement in a lawsuit can create a significant disincentive for patients to report positive response to treatment. This should not suggest that every patient on disability or pursuing legal remedy is a poor candidate for interventional pain treatment, only that the influence of these contingencies should be carefully examined.

8. Lack of adequate social support. To be successful, pain treatment and rehabilitative efforts require the daily practical and psychological support of family members or friends. Our experience suggests that social support is an important prognostic indicator.

9. Serious cognitive deficits. When reason, judgment, or memory are significantly impaired, a patient cannot be expected to actively partner with a treating physician or team in participating in treatment or reliably reporting pain symptoms.

10. Inadequate self-efficacy. Self-efficacy,[42] or the perception that a person has in him or her the ability to effect behavior change, predicts response to treatment and may mediate the relationship between pain and disability.[43] As noted earlier, patients who overrely on external strategies to try to control pain are disinclined to actively engage in the behavior change efforts that are the necessary companions to pain interventions.

ASSESSMENT OF OUTCOME

Dworkin, Turk, and colleagues[31] have advocated the standardized use of behavioral measures to assess the outcome of pain treatment. The Initiative on Methods, Measurement and Pain Assessment in Clinical Trials (IMMPACT) convened 35 specialists representing academics, patient advocates, governmental institutions, and the pharmaceutical industry to recommend core outcome measures for pain treatment trials. Included in their recommendations was the routine use of (1) pain intensity ratings (using a 0 to 10 numerical rating); (2) measures of physical functioning, such as the Brief Pain Inventory or the Multidimensional Pain Inventory Interference Scale; (3) measures of emotional function, specifying either the Beck Depression Inventory or the Profile of Mood States; (4) ratings of overall improvement as estimated by the Patient Global Impression of Change scale; (5) comprehensive review of history and symptoms, with particular emphasis on prospective assessment of predictable adverse or stressful events that appear contribute to pain exacerbation; and (6) comprehensive documentation of treatment adherence and reasons for discontinuation of a treatment trial.

Especially in the field of pain, where long-term benefits of particular treatment strategies have not been demonstrated, the kind of standardization that IMMPACT calls for is more than justified. As pain management and interventional strategies evolve and develop, the use of standard sets of outcome measures can aid in the process of developing research protocols, provide comparability across treatment types and settings, and create a basis for determining which treatment outcomes constitute clinically meaningful differences.[44]

Epidural Steroid Injections

W. David Leak, MD

INTRODUCTION

Epidural injection of corticosteroids is commonly used for managing chronic spinal pain and other painful conditions. Several approaches are available to access the lumbar epidural space: caudal, interlaminar, and transforaminal. The mechanisms of action of epidural injections are not well understood, but it is believed that neural blockade alters or interrupts nociceptive or neuropathic mechanisms. Explanations for improvement are based in part on the pharmacological and physical actions of local anesthetics, corticosteroids, and other agents. Effects may occur at spinal roots, dorsal root ganglia, and the dorsal horn. It is probable that the steroid component of the injection has an anti-inflammatory component, although there may be effects on neural excitability as well.

The placement of chemicals for diagnostic, prognostic, and therapeutic purposes in the epidural space is widely practiced and published. More than 1,817 references were cited in 2004, up from 447 in 2000, in the National Library of Medicine, using the search phrase "epidural injection." The search for the keyword "epidural" yielded 20,471 citations in 2000. The search in 2004 produced 25,607 references.

Approximately 140 citations referenced transforaminal epidural injections. The advent of sensitive and specific electrophysiological diagnostic testing and the standard application of fluoroscopy make precision needle localization the most practical approach for epidural injections for advanced practitioners of interventional pain management. The use of epidural injections, although a useful clinical tool, is underappreciated and thus undervalued relative to associated risk.

Key clinical pearl: Transforaminal epidural injections may be used as a diagnostic, prognostic, or therapeutic tool. Current literature affirms that transforaminal epidural injection is neither experimental nor investigational.

HISTORICAL BACKGROUND

Clinical reports of the earliest use of epidural anesthesia were credited to James Corning. Corning used intraspinal cocaine on a human with "spinal weakness and seminal incontinence." These were classified as neurological illnesses. The results were reported in the fall of 1885 in the *New York Medical Journal*. European urologists Cathelin and Sicard of France documented epidural placement via the sacral route in the early 1900s. Epidural injection to treat sciatica was described by Viner in 1925. Edwards and Hingson reported continuous caudal epidural anesthesia in 1942 (Kafiluddi & Hahn, 2000). Interventional procedures can be partitioned into three major purposes: (1) diagnostic, (2) prognostic, and (3) therapeutic.

Historically, epidural steroid injections were viewed as therapeutic, applied in many cases to treat sciatica. Epidural injection with various agents may be diagnostic. Injection of epidural steroids yielding relief suggests inflammatory disease. Injection of epidural local anesthetics for lower extremity pain relief that lasts well beyond the duration of the local anesthetic suggests neuropathic or autonomic dysfunction. Should pain return after a short duration of relief (hours, days, weeks), the procedure is prognostic for future interventions. If pain relief is prolonged after the diagnostic injection, the procedure is therapeutic.

Key clinical pearl: Epidural injection and infusion are neither new nor investigational.

ANATOMY

The epidural space is confined to the cranial and spinal canal. The most common reference is the space between the walls of the vertebral canal and the dura mater of the spinal cord (Stedman, 1999). It extends from the most cephalad aspect of the cranium surrounding the brain with compartmental interruption at the foramen magnum. In the spinal canal, it extends caudally to the sacrococcygeal junction. Thus, epidural therapies and pathology may occur from the cranium to the caudal canal.

Accessing the epidural space in the spinal column had been traditionally taught as a "blind technique," palpating vertebral spinous processes and advancing the needle using proprioceptive feedback. Numerous terms have been used to describe the sensations one should appreciate during various phases of this "blind procedure." The terms include words such as *give, pop, release,* and *loss of resistance*. When taught by experts, an appreciation of these mystical sensations can be regarded as universal truths that guarantee proper procedural performance. The subcutaneous fascial planes and intervertebral ligaments have give, will pop, release, and lose resistance but may direct a needle far away from the epidural space.

The advent of fluoroscopic guidance for spinal injection procedures has revealed that massive amounts of misinformation existed relative to the anatomy, proprioception, and behavior of infusions into the epidural space. When compared with fluoroscopy, vertebral interspaces (specifically the L3–4) could not be identified using conventional anatomy surface landmarks in patients in the prone position. Clinicians and researchers have published prospective studies demonstrating the essential need for fluoroscopy when performing epidural blocks for painful diseases (Bogduk, Aprill, & Derby, 1995; Manchikanti & Bakhit, 1999). White (White, Derby, & Wynne, 1980) noted a missed target rate of 25% using blind techniques for epidurals. The traditional teachings suggested that the spread of injection solutions in the epidural space could be calculated. Teaching that the volume of an anesthetic solution would cover predictable anatomic areas has been proved erroneous by numerous clinical reports (Bogduk et al., 1995).

A recent review by Boswell et al. (2005) concluded that there is strong evidence for transforaminal epidural steroid injections in managing lumbar nerve root pain. Evidence for caudal epidural steroid injections in managing lumbar radicular pain also was strong. Evidence for other conditions was either limited or inconclusive.

THE WORK-UP

Although mastery of anatomy for execution of the epidural injection is required, the most important components of the procedure are performing it correctly, for the right reasons. Guidelines regarding technical aspects of the procedure and clinical indications are available (Boswell et al., 2003, 2005).

Patient history and physical examination should generate substantial subjective and objective evidence to support the need for the procedure. The impressions and plan should be consistent with the history and physical examination. Avoidance of being the "itinerant surgeon" is of paramount importance. A patient may be referred for a series of epidural injections for back pain or sciatica. The performance of a transient palliative procedure may result in masking or delaying the diagnosis of cancer, exacerbating undiagnosed diabetes, propagation of discitis, worsening of osteomyelitis, all of which are preventable. Thus, a review of records, history, and relevant laboratory and radiographic studies, and physical examination constitute the minimum standard prior to performance of the procedure.

Precise diagnosis is important, as the transforaminal epidural has become the most appropriate injection of choice. An appropriate medical evaluation prior to injection is medically indicated and necessary. The application of electrophysiological studies to evaluate the status of sensory, vasomotor, thermal, and/or sudomotor activity of specific nerve roots may provide additional useful diagnostic information.

The specific components of the medical evaluation should include the following.

HISTORY

1. Chief complaint
2. History of present illness (include other work-ups and treatment for the current problem)
3. Past medical and surgical history (e.g., age is an important factor in the work-up of complaints of low-back pain from a 20-year-old subject)
4. Social history (e.g., work, smoking, substance abuse, and secondary gain factors should be explored)
5. Family history (rheumatoid disease, coagulopathy, cancer, etc.)
6. Allergies and specific reactions and where the events are documented:
   a. Beware of patients who are allergic to "all nonsteroidal anti-inflammatory drugs"
   b. Supplementation of pain relief with scheduled drugs must be based on appropriate medical evaluation

c. When total classes of nondependency producing agents are reported without any health care professional's objective documentation, consider allergy testing

7. Medication history (a copy of pharmacy printouts from the previous 12 months is recommended)

8. Review of systems

PHYSICAL EXAMINATION

1. Vital signs:
   a. They will change in association with performance of epidurals.
   b. Noxious stimulation associated with traumatic introduction of a trochar into an already hyperalgesic area may produce a clinically significant changes in hemodynamics.
   c. A patient rendered "normotensive" by antihypertensive agents may be volume deficient and suffer physiologic consequences from epidural infusions and associated vasodilation.

2. Cardiovascular exam:
   a. Mortality associated with epidural injections in the face of uncompensated aortic stenosis is a preventable circumstance. The epidural may cause vasodilatation that may not be adequately compensated for in an individual with severe aortic stenosis, resulting in profound hypotension.

3. Neurologic exam:
   a. Sensory, motor, and reflex findings should be documented prior to commencing a procedure with the capacity to cause neurologic damage.

4. Musculoskeletal exam:
   a. Tenderness pre- and postprocedure
   b. Noxious range of motion
   c. Pain-alleviating range of motion
   d. Documentation of range of motion

5. Integument:
   a. Infectious lesions of the skin in the path of the epidural are direct contraindications to performing the procedure.
   b. Psoriatic lesions should not be traversed if in the path of an epidural injection.
   c. Displacing keratinotic and possibly nonsterile tissue into the epidural space may be hazardous.
   d. Bruises may suggest coagulation problems: epidural hematomas are associated with severe morbidity and mortality.

LABORATORY

1. Complete blood count (CBC):
   a. Evidence of infection or, more important, absence of infection should be documented.
   b. Leukopenia may identify risk of serious infection.
   c. Anemia may become clinically significant with required volume expansion.
   d. Thrombocytopenia may result in insufficient clotting.

2. Coagulation profile:
   a. Prolonged bleeding times may result in bleeding and anemia.
   b. Prolonged coagulation times may result in paralyzing intraspinal hematomas.

3. Electrolytes and blood tests as clinically indicated:
   a. Glucose may have dangerous fluxes in susceptible individuals, such as those with diabetes, when epidural steroids are administered.

4. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP):
   a. Inflammatory processes, both infectious and noninfectious, may yield elevated ESR and CRP. Elevated studies should prompt additional testing.
   b. The CRP can be followed to determine whether the inflammation is progressive, because it responds very quickly to circulating pyrogens and complement complexes.

5. Urinalysis may be helpful:
   a. Urinalysis provides a broad snapshot of endocrine, immune, and metabolic functions.
   b. Infectious processes revealed in the urine are a relative contraindication to epidural injection.

RADIOGRAPHIC STUDIES

1. Plain radiographs:
   a. The target region must be imaged in the anterior/posterior and lateral views to eliminate the presence of anatomic anomalies that may create complications in an otherwise uncomplicated procedure.
   b. Spina bifida should be known prior to needle introduction.
   c. Hypertrophic spinous processes and facets may impede successful injection.
   d. Calcification of interspinous ligaments may complicate a midline approach.

2. Nuclear medicine scans:
   a. Primary metastatic oncologic disease may be revealed.
   b. Discitis or osteomyelitis may be discovered.
3. Computerized axial tomography (CT):
   a. Depending on the history and physical examination, a CT scan may be indicated.
   b. With a history of cancer, a CT or MRI is necessary to visualize potential metastatic or recrudescent disease.
4. Magnetic resonance imaging (MRI):
   a. Prior to embarking on an invasive therapeutic trial, comprehensive information concerning soft tissue structures of the spine should be known.

Electrophysiologic Studies

1. Somatosensory evoked potentials (SSEP):
   a. Measures sensory (the pain) aspects of nerve function
2. Nerve conduction velocities and electromyography (NCV/EMG) to evaluate for conduction abnormalities and denervation
3. Selective tissue conductance (STC):
   a. A direct measure of autonomic dysfunction that responds instantly to change
   b. Evaluates changes in sudomotor and vasomotor activity

Note that overlapping abnormalities in three electrophysiological studies direct the clinician to a more focused work-up. Objective data reflect the presence or absence of nociception. The STC, cold pressor, and SSEP studies allow the physician to quantify physiologic improvements brought about through therapeutic intervention.

Invasive and non-invasive modalities are associated with side effects and complications. Interventions are associated with expected benefits as well as risks. The possibilities of bleeding, infection, intravascular injection, adverse reactions, and neurological damage are notable complications. Clinical reports of complications including paralysis and death have been associated with transforaminal epidural injection.

The diagnosis must be specific and match the procedural plan. Transforaminal epidural injections have been used clinically as a localization procedure for chemoneuroloysis. The procedure has been part of the treatment paradigm in predicting the probability of success of spinal cord stimulator implantation. Transforaminal epidural injections appear to be more therapeutic in late inflammatory conditions than diffuse intervertebral epidural injections. Postlaminectomy patients experiencing post lumbar puncture cephalgia can have successful epidural blood patches safely performed via the bilateral transforaminal approach. Unlike interlaminar epidural injections, there is no expert opinion supporting nonfluoroscopically guided needle placement using the transforaminal approach.

The term "rule out" negates a diagnosis and leads to third-party rejection of the procedural claim. The cancellation of the work-up may be included in the denial as the impression was reduced to "rule out." The Center for Medicare and Medicaid Services (CMS), formerly the Healthcare Finance Administration (HCFA), the administrative and regulatory body for Medicare, requires that the documentation for epidural injection meet their criteria for diagnosis and treatment, prior to issuing reimbursement. Each state has published polices administered by the Medicare contracting administrative company. The policies are known as local Medicare review policies (LMRPs). Appropriate *International Diagnosis of Coding, 9th edition* (ICD-9) and *Current Procedural Terminology* (CPT) codes supporting the performance of epidural injections are provided in Chapter 57 by Manchikanti et al. entitled, "Guidelines for Practice of Interventional Techniques" in this volume.

Giving a disease a name does not necessarily prove that that is what the patient has; thus, objective criteria should be used when possible. The U.S. health care culture may contain numerous third-party administrative encumbrances. The administrative information request for documentation can be overcome with proper radiographs, laboratory, and electrophysiology studies. Objective evidence of motor, sensory, or autonomic function allows the practitioner to practice evidence-based medicine. The known hazards of the procedure mandate the laboratory assessment.

PHARMACOLOGY

Numerous agents are used for epidural injections. Agents include, but are not limited to,

1. Saline
2. Local anesthetics
3. Steroids
4. Alpha-2-adrenergic agonists
5. Neurolytics

Below is a description of the two classes of agents most frequently injected into the epidural space — steroids and local anesthetics.

Steroids

Methylprednisolone acetate is an anti-inflammatory steroid with glucocorticoid properties, formulated for intramuscular, intrasynovial, soft tissue, or intralesional injections. It is available in three strengths: 20 mg/ml, 40 mg/ml, and 80 mg/ml.

Preparations of triamcinolone are preferred by some because the formulation may be less prone to clumping when suspended in local anesthetic solution. Clumping is worrisome because of the risk of unintentional intravascular injection and spinal cord injury from embolization of particulate steroid. However, there are few studies supporting the use of one depo-steroid preparation over another.

Prolonged use of corticosteroids may produce posterior subcapsular cataracts or glaucoma with possible damage to the optic nerves and may enhance the establishment of secondary ocular infections due to fungi or viruses. Avascular necrosis has been reported with a wide variety of doses and durations of recurrent exposures to steroids.

The appropriate number of injections is a clinical decision, and guidelines are available to aid the clinician (see Chapter 57 of this volume). In addition, one should follow electrolytes, glucose, weight, CBCs, and manufacturer recommendations for diagnosing and management of toxicity when using these agents. Methylprednisolone is indicated for many inflammatory diseases. However, the indication for intraspinal injections is an off-label use of the steroid preparations. The Food and Drug Administration updated its position on "Off-Label" and "Investigational Use of Marketed Drugs, Biologics, and Medical Devices" in 1998 (see http://www.fda.gov/oc/ohrt/irbs/offlabel.html).

LOCAL ANESTHETICS

Local anesthetics block the conduction of nerve impulses, by increasing the threshold for electrical excitation in the nerve, by slowing the propagation of the nerve impulse, and by reducing the rate of rise of the action potential. Systemic absorption of local anesthetics can produce effects on the cardiovascular and central nervous systems. However, at blood concentrations achieved with usual therapeutic doses, changes in cardiac conduction, excitability, refractoriness, contractility, and peripheral vascular resistance are minimal. On the other hand, toxic blood concentrations can depress cardiac conduction and excitability, which may lead to atrioventricular block, ventricular arrhythmias, and cardiac arrest. Myocardial contractility is depressed and peripheral vasodilation occurs, leading to decreased cardiac output and arterial blood pressure. Incremental dosing is necessary with blind injection. Fluoroscopy with contrast reduces the incidence of adverse reactions associated with injection of local anesthetics.

TECHNICAL CONSIDERATIONS

Interlaminar epidural injections performed with fluoroscopic guidance and injection of non-ionic contrast such as iohexol help ensure proper needle placement and flow of injectate. Fluoroscopy confirms that needle placement is adjacent to the presumed site of nerve root irritation.

FIGURE 60.1 Interlaminar epidural steroid injection in a patient with spinal stenosis. A right paramedian epidural was performed using the loss of resistance technique. Fluoroscopy was helpful to guide and confirm proper needle placement. Note the hourglass appearance of the non-ionic contrast in the epidural space. The S1 nerve root opacified.

The procedure may involve using the "loss of resistance" technique, in conjunction with visual confirmation of needle position by fluoroscopy. After proper needle position is obtained, confirmation of epidural drug flow is confirmed with injection of contrast agent (Figure 60.1).

The transforaminal epidural steroid injection technique, as described in detail by Derby (Derby, Bogduk, & Kine, 1993), allows more precise placement of the epidural needle, without damaging the target nerve root. Typically, needle placement is at the anterior and superior aspect of the intervertebral foramen, at the 6 o'clock position of the pedicle on anteroposterior view (Figure 60.2). This localizes the tip of the needle above and lateral to the nerve root, adjacent to the dorsal root ganglion. Optimal position should allow flow of injectate to the anterior epidural space, adjacent to the intervertebral disc (Figure 60.3).

Precision diagnostic and therapeutic injections are possible with the transforaminal technique. However, dural puncture or subdural injection, which may traumatize the nerve root or dorsal root ganglion, should be avoided. Intravascular injection must be meticulously avoided, to prevent unintentional intravascular embolization of particulate steroid, which could compromise blood flow to the spinal cord (Figure 60.4 a and b).

COMPLICATIONS

Informed consent is critical as complications do occur. Patients should be asked to make decisions that a reasonable person would make, if placed in a similar circum-

FIGURE 60.2 Transforaminal epidural steroid injection. Needle placement at the L5 intervertebral foramen outlines the nerve root with extension of iohexol contrast to the adjacent intracanal spinal dura. There is no evidence of intrathecal or intravascular uptake.
FIGURE 60.3 Transforaminal epidural steroid injection; lateral view. Needles placed at L4, L5, and S1. Iohexol contrast is seen to outline the anterior epidural space.

FIGURE 60.4 (a) Intravascular transforaminal injection. The epidural needle is positioned appropriately at the L3 intervertebral foramen. Iohexol injection opacified a blood vessel adjacent to the foramen. Intravascular contrast is seen to enter the spinal canal through the foramen. The needle was repositioned with a subsequent normal epidurogram and the steroid injection was completed without complication. (b) Needle repositioned after intravascular injection. The transforaminal epidural needle was repositioned slightly, and the subsequent injection was satisfactory.

stance as the patient. Guarantees and assurances should not be promised, but failure of expectation constitutes a perceived breach of contract. Do not say, "This will definitely take all your pain away, and there is no risk of anything bad happening to you." The following components should be included in the informed consent and thought process for treating complications:

1. The patient should be aware of the nature (invasive vs. noninvasive) of the procedure.
2. The patient should be aware of the purpose (diagnostic, prognostic, or therapeutic) of the procedure.
3. The patient should be aware of the alternatives to the procedure (e.g., behavioral, pharmacological, physiotherapy, less-invasive procedures).
4. The patient should be aware of the course of the disease without the procedure (e.g., remain the same with unacceptable pain, get worse relative to pain and physiologic dysfunction).
5. The patient should be aware of the risk of the procedure. This is the predominant issue relative to informed consent in liability cases. The consent as a whole is important, but lack of disclosure of salient risks is often an important point of contention. The following is a brief list of possible complications that should be disclosed when seeking consent for epidural procedures:

a. Bleeding (perioperative CBC and vital signs)

b. Infection (perioperative CBC and vital signs)

c. Adverse reactions to drugs (monitoring, perioperative CBC, and vital signs)

d. Allergic reactions to materials used (monitoring, perioperative CBC, and vital signs)

e. Injury to organs/organ systems (monitoring, perioperative CBC, and vital signs)

f. Pain not be relieved (monitoring, pain rating scales, vital signs, SSEPs, and STCs)

g. May need further procedures

h. Paralysis (monitoring with emphasis on neurological function, pain rating scales), e.g., intravascular injections of particulate medications

i. Headache (monitoring, vital signs, CBC, electrolytes, bed rest, fluid, caffeine, adrenocorticotropic hormone, dural repair)

j. Numbness (CBC, monitoring with emphasis on neurological function, pain rating scales, vital signs, SSEPs, and STCs)

k. Weakness (CBC, monitoring with emphasis on neurological function, pain rating scales, vital signs, SSEPs, and STCs)

l. Bladder dysfunction (monitoring with emphasis on urological function, pain rating scales, vital signs, SSEPs, and STCs)

SUMMARY

The clinical benefits of indicated epidural injections in properly selected patients are positive. The agents commonly used are frequently applied in an off-label but widely published and acceptable manner.

Knowledge of radiographic anatomy, pharmacology, physiology, and medical management of perioperative comorbid diseases is critical. Equal importance must be placed on early recognition of complications by appropriate monitoring and patient follow-up.

The procedure can be performed safely by properly trained physicians, but must always be respected for its capacity cause injury. The development of additional agents that may be effective in long-term pain relief makes epidural injection one of the most valuable current and future skills in the physician's repertoire.

Sympathetic Neural Blockade in the Evaluation and Treatment of Pain

Steven D. Waldman, MD, JD

INTRODUCTION

The role of the sympathetic nervous system as a factor in a variety of painful conditions in humans has been a part of conventional medical wisdom for over 100 years. Early interest in the role of the sympathetic nervous system as part of the pain puzzle was limited primarily to its role as an anatomic pathway to carry the pain impulses to the brain in a manner analogous to the somatic nervous system. The unique anatomic nature of the sympathetic nervous system relative to the better anatomically defined somatic nervous system doomed this line of inquiry to raising more questions than were ultimately answered. It took the landmark work of Melzak and Wall and their gate control theory to move the prosaic thinking of the nerve as simply a wire to carry a pain message from a receptor to the brain to allow early pain clinicians such as Alon Winne to more clearly delineate the role of the sympathetic nervous system as a unique contributor to the evolution and continuation of pain in humans. As our specialty began to understand the unique way that the sympathetic nervous system interacted at both the peripheral and spinal cord levels, many of the things we were observing clinically begin to make sense, and for the first time, the specialty could put forth a rational explanation of how interruption of the sympathetic nervous system could provide prolonged pain relief. The advent of computerized tomography and magnetic resonance imaging further advanced our understanding of the structure and functional anatomy sympathetic nervous system in health and disease, enabling refinement of the techniques described below to allow for improved safety and efficacy. This chapter provides the reader with an overview of the current clinical thinking on the uses and abuses of sympathetic neural blockade in the treatment of pain.

STELLATE GANGLION BLOCK: ANTERIOR APPROACH

INDICATIONS

Stellate ganglion block is indicated in the treatment of acute herpes zoster in the distribution of the trigeminal nerve and cervical and upper thoracic dermatomes as well as frostbite and acute vascular insufficiency of the face and upper extremities. Stellate ganglion block is also indicated in the treatment of reflex sympathetic dystrophy of the face, neck, upper extremity, and upper thorax, and Raynaud's syndrome of the upper extremities, as well as sympathetically mediated pain of malignant origin. There are clinical reports to suggest that stellate ganglion blocks may also be useful in the acute palliation of some atypical vascular headaches.

CLINICALLY RELEVANT ANATOMY

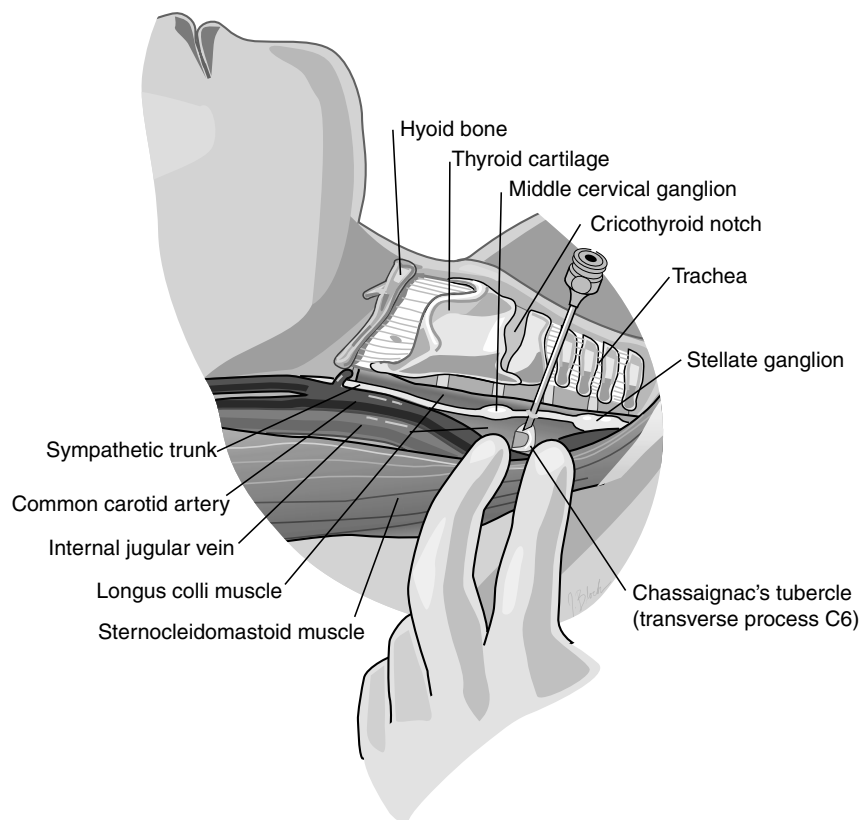
The stellate ganglion is located on the anterior surface of the longus colli muscle. This muscle lies just anterior to the transverse processes of the seventh cervical and first thoracic vertebrae. The stellate ganglion is made up of the fused portion of the seventh cervical and first thoracic sympathetic ganglia. The stellate ganglion lies anterome-


FIGURE 61.1 Technique for stellate ganglion block.

dial to the vertebral artery and is medial to the common carotid artery and jugular vein. The stellate ganglion is lateral to the trachea and esophagus.

TECHNIQUE

The patient is placed in the supine position with the cervical spine in neutral position, and 7 to 10 mL of local anesthetic without preservative is drawn into a 12-mL sterile syringe. For disease processes that have a component of inflammation, such as acute herpes zoster, or disease processes with associated edema, such as reflex sympathetic dystrophy, 80 mg of methylprednisolone is added for the first block and 40 mg of methylprednisolone is added for subsequent blocks.

The medial edge of the sternocleidomastoid muscle is identified at the level of the cricothyroid notch (C6). The sternocleidomastoid muscle is then displaced laterally with two fingers, and the tissues overlying the transverse process of C6 (Chassaignac's tubercle) are compressed. The pulsations of the carotid artery are then identified under the palpating fingers (Figure 61.1). The skin medial to the carotid pulsation is prepared with antiseptic solution, and a 22-gauge, 1.5-inch needle is advanced until contact is made with the transverse process of C6 (Figure 61.2). If bony contact is not made with needle insertion to a depth of 1 inch, the needle is probably between the transverse processes of C6 and C7. If this occurs, the needle should be withdrawn and reinserted with a more cephalad trajectory. After bony contact is made, the needle is then withdrawn approximately 2 mm to bring the needle tip out of the body of the longus colli muscle. Careful aspiration is carried out, and 7 to 10 mL of solution is then injected (Figure 61.3).

SIDE EFFECTS AND COMPLICATIONS

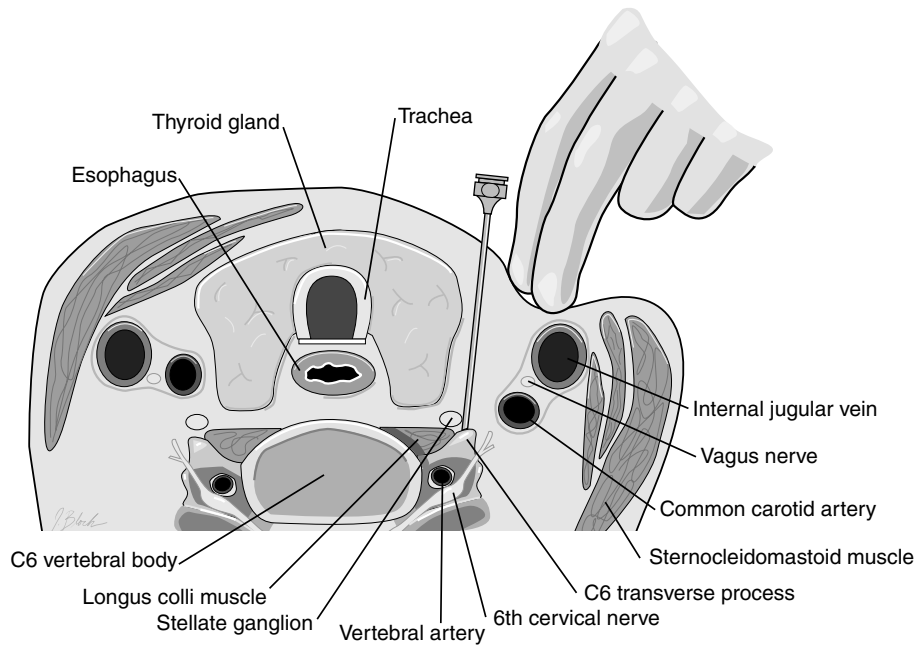
This anatomic region is highly vascular, and because of the proximity of major vessels, the pain specialist should carefully observe the patient for signs of local anesthetic toxicity during injection. This vascularity and proximity to major blood vessels also give rise to an increased incidence of post-block ecchymosis and hematoma formation, and the patient should be warned of such. In spite of the vascularity of this anatomic region, this technique can safely be performed in the presence of anticoagulation by using a 25- or 27-gauge needle, albeit at increased risk of hematoma, if the clinical situation dictates a favorable risk-to-benefit ratio. These complications can be decreased if manual pressure is applied to the area of the block immediately after injection. Application of cold packs for 20-minute periods after the block will also decrease the amount of post-procedure pain and bleeding the patient may experience.


FIGURE 61.2 Technique for stellate ganglion block. Cross-sectional view.

FIGURE 61.3 Stellate ganglion block. Fluoroscopic view.

Because of the proximity to the spinal column and its contents, it is also possible to inadvertently inject the local anesthetic solution into the epidural, subdural, or subarachnoid space. At this level, even small amounts of local anesthetic placed into the subarachnoid space may result in a total spinal anesthetic. If needle placement is too inferior, pneumothorax is possible, because the dome of the lung lies at the level of the C7–T1 interspace.

Additional side effects associated with stellate ganglion block include inadvertent block of the recurrent laryngeal nerve with associated hoarseness and dysphagia and the sensation that there is a lump in the throat when swallowing. Horner's syndrome occurs when the superior cervical sympathetic ganglion is also blocked during stellate ganglion block. The patient should be forewarned of

the possibility of these complications prior to stellate ganglion block.

CLINICAL PEARLS

Properly performed stellate ganglion block is a safe and effective technique for treatment of the previously mentioned pain syndromes. Improperly performed, it can be one of the most dangerous regional anesthetic techniques used in pain management. Almost all the complications associated with stellate ganglion block can be avoided if two simple rules are always followed: (1) the C6 level must always be accurately identified and double-checked by identifying the cricothyroid notch; and (2) the needle tip must always make bony contact with the transverse process of C6 before the injection of any drugs. Always forewarn the patient of the potential side effects associated with this technique, as side effects invariably occur.

CELIAC PLEXUS BLOCK: SINGLE-NEEDLE PERIAORTIC TECHNIQUE

INDICATIONS

Pain management specialists began performing celiac plexus block using a single needle after it was recognized that, when using the two-needle transcrural approach to celiac plexus block under computed tomographic guidance, contrast injected via the left-sided needle would spread around the aorta, obviating the need for injection through the second needle. The use of a single needle decreases needle-related complications as well as the pain

associated with the procedure. The single-needle periaortic approach to celiac plexus block has the added advantage over the classic two-needle retrocrural technique in that the single needle is placed in the precrural space, thus avoiding the higher incidence of neurologic complications associated with retrocrural needle placement.

Celiac plexus block using the single-needle periaortic approach with local anesthetic is indicated as a diagnostic maneuver to determine whether flank, retroperitoneal, or upper abdominal pain is sympathetically mediated via the celiac plexus. Daily celiac plexus block with local anesthetic is also useful in the palliation of pain secondary to acute pancreatitis and other acute pain syndromes subserved by the celiac plexus. Early implementation of celiac plexus block with local anesthetic, steroids, or both markedly reduces the morbidity and mortality associated with acute pancreatitis. Single-needle periaortic celiac plexus block is also used to palliate the acute pain of arterial embolization of the liver for cancer therapy as well as to treat the pain of abdominal "angina" associated with visceral arterial insufficiency. Single-needle periaortic celiac plexus block with local anesthetic may also be used prognostically prior to celiac plexus neurolysis.

Neurolysis of the celiac plexus via the single-needle periaortic approach with alcohol or phenol is indicated to treat pain secondary to malignancies of the retroperitoneum and upper abdomen. This approach may also be useful in some chronic benign abdominal pain syndromes, including chronic pancreatitis, in carefully selected patients.

CLINICALLY RELEVANT ANATOMY

The sympathetic innervation of the abdominal viscera originates in the anterolateral horn of the spinal cord. Preganglionic fibers from T5–T12 exit the spinal cord in conjunction with the ventral roots to join the white communicating rami on their way to the sympathetic chain. Rather than synapsing with the sympathetic chain, these preganglionic fibers pass through it to ultimately synapse on the celiac ganglia. The greater, lesser, and least splanchnic nerves provide the major preganglionic contribution to the celiac plexus. The greater splanchnic nerve has its origin from the T5–T10 spinal roots. The nerve travels along the thoracic paravertebral border through the crus of the diaphragm into the abdominal cavity, ending on the celiac ganglion of its respective side. The lesser splanchnic nerve arises from the T10–T11 roots and passes with the greater nerve to end at the celiac ganglion. The least splanchnic nerve arises from the T11–T12 spinal roots and passes through the diaphragm to the celiac ganglion.

Interpatient anatomic variability of the celiac ganglia is significant, but the following generalizations can be drawn from anatomic studies of the celiac ganglia. The number of ganglia vary from one to five and range in

diameter from 0.5 to 4.5 cm. The ganglia lie anterior and anterolateral to the aorta. The ganglia located on the left are uniformly more inferior than their right-sided counterparts by as much as a vertebral level, but both groups of ganglia lie below the level of the celiac artery. The ganglia usually lie approximately at the level of the first lumbar vertebra.

Postganglionic fibers radiate from the celiac ganglia to follow the course of the blood vessels to innervate the abdominal viscera. These organs include much of the distal esophagus, stomach, duodenum, small intestine, ascending and proximal transverse colon, adrenal glands, pancreas, spleen, liver, and biliary system. It is these postganglionic fibers, the fibers arising from the preganglionic splanchnic nerves, and the celiac ganglion that make up the celiac plexus. The diaphragm separates the thorax from the abdominal cavity while still permitting the passage of the thoracoabdominal structures, including the aorta, vena cava, and splanchnic nerves. The diaphragmatic crura are bilateral structures that arise from the anterolateral surfaces of the upper two or three lumbar vertebrae and discs. The crura of the diaphragm serve as a barrier to effectively separate the splanchnic nerves from the celiac ganglia and plexus below.

The celiac plexus is anterior to the crus of the diaphragm. The plexus extends in front of and around the aorta, with the greatest concentration of fibers anterior to the aorta. With the single-needle periaortic approach to celiac plexus block, the needle is placed close to this concentration of plexus fibers. The relationship of the celiac plexus to the surrounding structures is as follows. The aorta lies anterior and slightly to the left of the anterior margin of the vertebral body. The inferior vena cava lies to the right, with the kidneys posterolateral to the great vessels. The pancreas lies anterior to the celiac plexus. All of these structures lie within the retroperitoneal space.

TECHNIQUE

Pre-block preparation includes the administration of adequate amounts of oral or intravenous fluids to attenuate the hypotension associated with celiac plexus block. Evaluation of the patient for coagulopathy is indicated if the patient has undergone antiblastic therapy or has a history of significant alcohol abuse. If radiographic contrast is to be used, evaluation of the patient's renal status is also indicated.

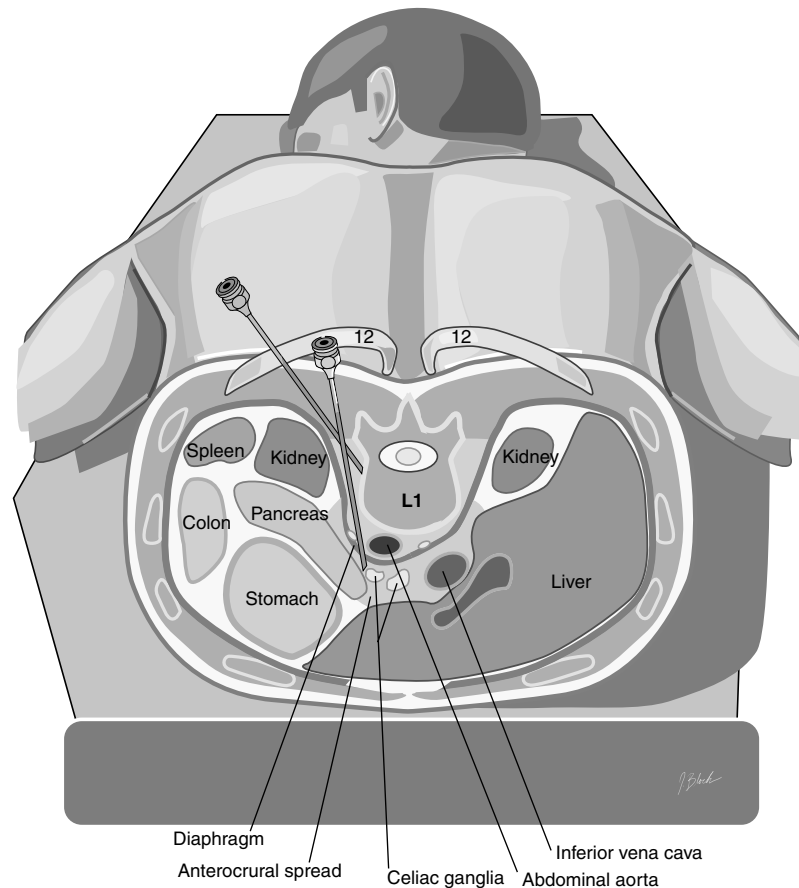
The patient is placed in the prone position with a pillow under the abdomen to flex the thoracolumbar spine. For comfort, the patient's head is turned to the side and the arms are permitted to hang freely off each side of the table. The inferior margins of the 12th ribs are identified and traced to the T12 vertebral body. The spinous process of the L1 vertebral body is then identified and marked with a sterile marker. A point approximately 2.5 inches


FIGURE 61.4 Celiac plexus block. Cross sectional view.

just inferior and lateral to the left side of the transverse process of L1 is identified. The injection site is then prepared with antiseptic solution.

The skin, subcutaneous tissues, and musculature are infiltrated with 1.0% lidocaine at the point of needle entry. A 20-gauge, 13-cm styletted needle is inserted bilaterally through the previously anesthetized area. The needle is initially oriented 45° toward the midline and about 15° cephalad to ensure contact with the L1 vertebral body. Once bone is contacted and the depth noted, the needle is withdrawn to the level of the subcutaneous tissue and redirected less mesiad (about 65° from the midline) so as to "walk off" the lateral surface of the L1 vertebral body (Figure 61.4). The needle is reinserted to the depth at which the vertebral body was first contacted. At this point, if no bone is contacted, the needle is gradually advanced 3 to 4 cm, or until the pulsation emanating from the aorta and transmitted to the advancing needle is noted. If aortic pulsations are noted, the pain specialist may either convert the block into a transaortic celiac plexus technique or note the depth to which the needle has been placed, withdraw the needle into the subcutaneous tissues, and then redirect the needle less mesiad to slide laterally to the aorta. Ultimately, the tip of the needle should be just lateral and anterior to the side of the aorta (Figure 61.5). This periaortic precrural placement decreases the incidence of inadvertent spread of injected solutions onto the lumbar somatic nerve roots.

The stylet of the needle is removed, and the needle hub is inspected for the presence of blood, cerebrospinal fluid, or urine. If radiographic guidance is being used, a small amount of contrast material is injected through the needle, and its spread is observed radiographically. On the fluoroscopic anteroposterior view, contrast is confined primarily to the left of the midline near the L1 vertebral body. A smooth curvilinear shadow can be observed that corresponds to contrast in the pre-aortic space on the lateral view. Alternatively, if computed tomographic guidance is used, contrast should appear periaortic or, if adenopathy or tumor is present, contrast should be confined to the periaortic space to the left of the aorta. If this limitation of spread of contrast occurs, one should consider redirecting the needle more medially to pass through the aorta to place the needle tip just in front of the aorta. If the contrast is entirely retrocrural, the needle should be advanced to the precrural space to avoid any risk of spread of local anesthetic or neurolytic agent posteriorly to the somatic nerve roots.
FIGURE 61.5 Celiac plexus block. Oblique view.

If radiographic guidance is not used, a rapid-onset local anesthetic is used in sufficient concentration to produce motor block (such as 1.5% lidocaine or 3.0% 2-chloroprocaine) prior to administration of neurolytic agents. If the patient experiences no motor or sensory block in the lumbar dermatomes after an adequate time, additional drugs injected through the needles will probably not reach the somatic nerve roots if given in like volumes.

For diagnostic and prognostic block via the single-needle periaortic technique, 12 to 15 mL of 1.0% lidocaine or 3.0% 2-chloroprocaine is administered through the needle. For therapeutic block, 10 to 12 mL of 0.5% bupivacaine is administered through the needle. Because of the potential for local anesthetic toxicity, all local anesthetics should be administered in incremental doses. When treating acute pancreatitis or pain of malignant origin, 80 mg of depot methylprednisolone is advocated for the initial celiac plexus block, with a 40-mg dose given for subsequent blocks.

A 10- to 12-mL volume of absolute alcohol or 6.0% aqueous phenol is injected through the needle for neurolytic block. Alternatively, 25 mL of 50% ethyl alcohol can be injected via the needle. After neurolytic solution is injected, the needle should be flushed with sterile saline solution because there have been anecdotal reports of neu-rolytic solution being tracked posteriorly with the needle as it is withdrawn.

SIDE EFFECTS AND COMPLICATIONS

Because of its proximity to vascular structures, celiac plexus block using the single-needle periaortic approach is contraindicated in patients who are on anticoagulant therapy or suffer from coagulopathy secondary to antiblastic cancer therapies or liver abnormalities associated with ethanol abuse. Intravascular injection of solutions may result in thrombosis of the nutrient vessels to the spinal cord with secondary paraplegia. Local or intra-abdominal infection and sepsis are absolute contraindications to celiac plexus block.

Because blockade of the celiac plexus results in increased bowel motility, this technique should be avoided in patients with bowel obstruction. Post-block diarrhea occurs in approximately 50% of patients. Celiac plexus block should be deferred in patients who suffer from chronic abdominal pain, who are chemically dependent, or who exhibit drug-seeking behavior until these issues have been adequately addressed. Alcohol should not be used as a neurolytic agent in patients on disulfiram therapy for alcohol abuse.

The proximity to the spinal cord, exiting nerve roots, pleura space, and viscera makes it imperative that this procedure be carried out only by those well versed in the regional anatomy and experienced in interventional pain management techniques. Needle placement that is too medial may result in epidural, subdural, or subarachnoid injections or trauma to the spinal cord and exiting nerve roots. Such incorrect needle placement can result in severe neurologic deficits, including paraplegia. Medial needle placement may also result in intradiscal placement and resultant discitis. Because the needle terminus is precrural with the single-needle periaortic approach to celiac plexus block, there is a decreased incidence of neurologic complications, including neurolysis of the lumbar nerve roots with resultant hip flexor weakness and lower extremity numbness, compared with the classic two-needle approach to celiac plexus block.

Given the proximity of the pleural space, pneumothorax after celiac plexus block may occur if the needle is placed too cephalad. Trauma to the thoracic duct with resultant chylothorax may also occur. If the needle is placed too laterally, trauma to the kidneys and ureters is a distinct possibility.

CLINICAL PEARLS

When using the classic two-needle retrocrural approach to celiac plexus block, the needles will almost always be retrocrural in proximity to the splanchnic nerves rather than the celiac ganglia. That is to say that the needles and injected solution will be placed posterior and cephalad to the crura of diaphragm. Computed tomographic and cadaver studies have given rise to the recent suggestion that the classic method of retrocrural block is more likely to produce splanchnic nerve block than blockade of the celiac plexus. This is because this approach does not result in the deposition of injected material around and anterior to the aorta and directly onto the celiac plexus at the level of the L1 vertebral body, as previously thought. Rather, the injectate appears to (1) concentrate posterior to the aorta and in front of and along the side of the L1 vertebral body, where it may anesthetize retroaortic celiac fibers, (2) diffuse cephalad to anesthetize the splanchnic nerve at a site rostral to the origin of the plexus, and (3) only finally encircle the aorta at the site of the celiac plexus when enough drug is injected to transgress the diaphragm by diffusing caudad through the aortic hiatus. Unfortunately, this larger volume of drug is also associated with an increased incidence of blockade of the lumbar somatic nerve roots.

Radiographic guidance, especially computed tomographic guidance, offers the pain specialist an added margin of safety during neurolytic celiac plexus block via the single-needle periaortic approach and hence should be used routinely unless the patient's clinical status requires that celiac plexus block be performed at the bedside. Given the increased incidence of damage to the lumbar nerve roots due to the retrocrural placement of needles with the classic two-needle technique, the transcrural, single needle periaortic, or transaortic approaches to celiac plexus block should be preferred.

Most pain specialists report a lower success rate when using celiac plexus block to treat chronic benign abdominal pain than when treating abdominal pain of malignant origin. Patients with chronic benign abdominal pain should be tapered off narcotic analgesics prior to consideration of celiac plexus neurolysis. It should be noted that the phrenic nerve also transmits nociceptive information from the upper abdominal viscera. This information is perceived as poorly localized pain referred to the supraclavicular region; this source of pain should be considered in all patients suffering from upper abdominal pain.

LUMBAR SYMPATHETIC GANGLION BLOCK

INDICATIONS

Lumbar sympathetic ganglion block is useful in the evaluation and management of sympathetically mediated pain of the kidneys, ureters, genitalia, and lower extremity. Included in this category are phantom limb pain, reflex sympathetic dystrophy, causalgia, and a variety of peripheral neuropathies. Lumbar sympathetic ganglion block is also useful in the palliation of pain secondary to vascular insufficiency of the lower extremity, including pain secondary to frostbite, atherosclerosis, Buerger's disease, and arteritis secondary to collagen vascular disease, and in maximizing blood flow after vascular procedures on the lower extremities. Lumbar sympathetic ganglion block with local anesthetic can be used as a diagnostic tool when performing differential neural blockade on an anatomic basis in the evaluation of flank, pelvic, and lower extremity pain. If destruction of the lumbar sympathetic chain is being considered, this technique is useful as a prognostic indicator of the degree of pain relief that the patient may experience. Lumbar sympathetic ganglion block with local anesthetic is also useful in the treatment of acute herpes zoster and postherpetic neuralgia involving the lumbar and sacral dermatomes. Destruction of the lumbar sympathetic chain is indicated for the palliation of pain syndromes that have responded to lumbar sympathetic blockade with local anesthetic.

CLINICALLY RELEVANT ANATOMY

The preganglionic fibers of the lumbar sympathetics exit the intervertebral foramina along with the lumbar paravertebral nerves. After exiting the intervertebral foramen, the lumbar paravertebral nerve gives off a recurrent branch that loops back through the foramen to provide innervation

to the spinal ligaments, meninges, and its respective vertebra. The upper lumbar paravertebral nerve also interfaces with the lumbar sympathetic chain via the myelinated preganglionic fibers of the white rami communicantes. All five of the lumbar nerves interface with the unmyelinated postganglionic fibers of the gray rami communicantes. At the level of the lumbar sympathetic ganglia, preganglionic and postganglionic fibers synapse. Additionally, some of the postganglionic fibers return to their respective somatic nerves via the gray rami communicantes. Other lumbar sympathetic postganglionic fibers travel to the aortic and hypogastric plexus and course up and down the sympathetic trunk to terminate in distant ganglia.

In many patients, the first and second lumbar ganglia are fused. These ganglia and the remainder of the lumbar chain and ganglia lie at the anterolateral margin of the lumbar vertebral bodies. The peritoneal cavity lies lateral and anterior to the lumbar sympathetic chain. Given the proximity of the lumbar somatic nerves to the lumbar sympathetic chain, the potential exists for both neural pathways to be blocked when performing blockade of the lumbar sympathetic ganglion.

TECHNIQUE

The patient is placed in the prone position with a pillow under the abdomen to gently flex the lumbar spine. The spinous process of the vertebra just above the nerve to be blocked is palpated. At a point just below and 3 inches lateral to the spinous process, the skin is prepared with antiseptic solution. A 22-gauge, 3.5-inch needle is attached to a 12-mL syringe and is advanced at a 35° to 45° angle to the skin, aiming for the lateral aspect of the vertebral body. The needle should impinge on bone after being advanced approximately 2 inches. If the needle comes into contact with bone at a shallower depth, it has probably impinged on the transverse process. If this occurs, the needle should be directed in a slightly more cephalad trajectory to pass above the transverse process to impinge on the lateral aspect of the vertebral body. After bony contact is made with the vertebral body, the needle is withdrawn into the subcutaneous tissues and redirected at a slightly steeper angle and walked off the lateral margin of the vertebral body. As soon as bony contact is lost, the needle is slowly advanced approximately 0.5 inch deeper (Figure 61.6). Given the proximity of the lumbar sympathetic chain to the somatic nerve, a paresthesia in the distribution of the corresponding lumbar paravertebral nerve may be elicited. If this occurs, the needle should be withdrawn and redirected slightly more cephalad. The needle is then again slowly advanced until it passes the lateral border of the vertebral body. The needle should ultimately rest at the anterior lateral margin of the vertebral body (Figure 61.7). If fluoroscopy is used,

a small amount of contrast medium may be added to the local anesthetic (Figure 61.8). The contrast medium should appear just anterior to the vertebral body on the lateral view and just lateral to the vertebral body on the PA view. If computed tomographic guidance is used, the contrast can be seen surrounding the sympathetic chain, anterolateral to the vertebral body. Once the needle is in position and careful aspiration reveals no blood or cerebrospinal fluid, 12 to 15 mL of 1.0% preservative-free lidocaine is injected.

SIDE EFFECTS AND COMPLICATIONS

The proximity to the spinal cord and exiting nerve roots makes it imperative that this procedure be carried out only by those well versed in the regional anatomy and experienced in performing interventional pain management techniques. Given the proximity of the peritoneal cavity, damage to the abdominal viscera during lumbar sympathetic ganglion block is a distinct possibility. The incidence of this complication will be decreased if care is taken to place the needle just beyond the anterolateral margin vertebral body. Needle placement too medial may result in epidural, subdural, or subarachnoid injections or trauma to the intervertebral disc, spinal cord, and exiting nerve roots. Although uncommon, infection remains an ever-present possibility, especially in the immunocompromised patient with cancer. Early detection of infection, including discitis, is crucial to avoid potentially life-threatening sequelae.

CLINICAL PEARLS

Lumbar sympathetic ganglion block is a simple technique that can produce dramatic relief for patients suffering from the previously mentioned pain complaints. Neurolytic block with small quantities of absolute alcohol or phenol in glycerin, or by cryoneurolysis or radiofrequency lesioning, has been shown to provide long-term relief for patients suffering from sympathetically maintained pain that has been relieved with local anesthetic. As mentioned earlier, the proximity of the lumbar sympathetic chain to the neuraxis and pleural space makes careful attention to technique mandatory.

HYPOGASTRIC PLEXUS BLOCK: SINGLE-NEEDLE TECHNIQUE

INDICATIONS

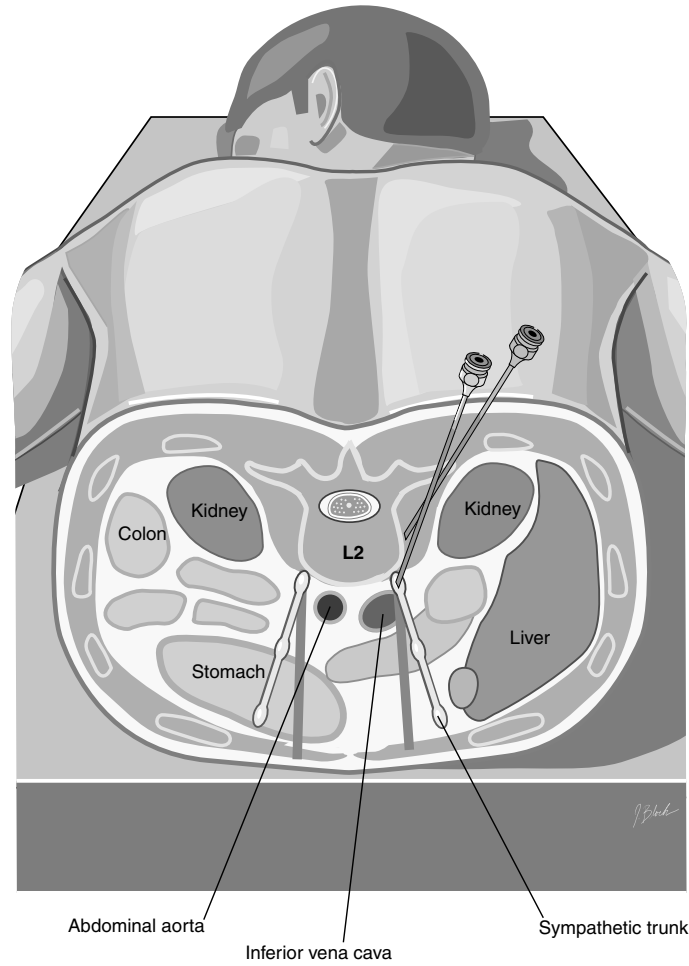
Hypogastric plexus block with the single-needle technique is useful in the evaluation and management of sympathetically mediated pain of the pelvic viscera. Included in this category is pain secondary to malignancy, endometriosis, reflex sympathetic dystrophy, causalgia, proctalgia fugax, and radiation enteritis. Hypogastric plexus block is also


FIGURE 61.6 Diagram for lumbar sympathetic block.

FIGURE 61.7 Needle placement for lumbar sympathetic block. Fluoroscopic view. (Courtesy of Milton Landers, D.O.)
FIGURE 61.8 Needle placement for lumbar sympathetic block. Fluoroscopic view demonstrating proper contrast spread along the vertebral column. (Courtesy of Milton Landers, D.O.)

useful in the palliation of tenesmus secondary to radiation therapy to the rectum. Hypogastric plexus block with local anesthetic can be used as a diagnostic tool when performing differential neural blockade on an anatomic basis in the evaluation of pelvic and rectal pain. If destruction of the hypogastric plexus is being considered, this technique is useful as a prognostic indicator of the degree of pain relief that the patient may experience. Hypogastric plexus block with local anesthetic is also useful in the treatment of acute herpes zoster and postherpetic neuralgia involving the sacral dermatomes. Destruction of the hypogastric plexus is indicated for the palliation of pain syndromes that have temporarily responded to blockade of the hypogastric plexus with local anesthetic and have not been controlled with more conservative measures.

CLINICALLY RELEVANT ANATOMY

In the context of neural blockade, the hypogastric plexus can simply be thought of as a continuation of the lumbar sympathetic chain that can be blocked in a manner analogous to lumbar sympathetic nerve block. The preganglionic fibers of the hypogastric plexus find their origin primarily in the lower thoracic and upper lumbar region of the spinal cord. These preganglionic fibers interface with the lumbar sympathetic chain via the white communicantes. Postganglionic fibers exit the lumbar sympathetic chain and, together with fibers from the parasympathetic sacral ganglion, make up the superior hypogastric plexus. The superior hypogastric plexus lies in front of L4 as a coalescence of fibers. As these fibers descend, at a level of L5, they begin to divide into the hypogastric nerves following in close proximity the iliac vessels. As the hypogastric nerves continue their lateral and inferior course, they are accessible for neural blockade as they pass in front of the L5–S1 interspace. The hypogastric nerves pass downward from this point, following the concave curve of the sacrum and passing on each side of the rectum to form the inferior hypogastric plexus. These nerves continue their downward course along each side of the bladder to provide innervation to the pelvic viscera and vasculature.

TECHNIQUE

Blind Technique

The patient is placed in the prone position with a pillow placed under the lower abdomen to gently flex the lumbar spine and maximize the space between the transverse process of L5 and the sacral alae. The L4–L5 interspace is located by identifying the iliac crests and finding the interspace at that level. The skin at this level is prepared with antiseptic solution. A point 6 cm from the midline at this level is identified, and the skin and subcutaneous tissues are anesthetized with 1.0% lidocaine. A 20-gauge, 13-cm needle is then inserted through the previously anesthetized

area and directed approximately 30° caudad and 30° mesiad toward the anterolateral portion of the L5–S1 interspace. If the transverse process of L5 is encountered, the needle is withdrawn and redirected slightly more caudad. If the vertebral body of L5 is encountered, the needle is withdrawn and redirected slightly more lateral until, in a manner analogous to lumbar sympathetic block, the needle is walked off the anterolateral aspect of the vertebral body.

A 5-mL glass syringe filled with preservative-free saline is then attached to the needle. The needle is then slowly advanced into the prevertebral space while maintaining constant pressure on the plunger of the syringe in a manner analogous to the loss-of-resistance technique used for identification of the epidural space. A "pop" and loss of resistance will be felt as the needle pierces the anterior fascia of the psoas muscle and enters the prevertebral space (Figure 61.9). After careful aspiration for blood, cerebrospinal fluid, and urine, 10 mL of 1.0% preservative-free lidocaine is slowly injected in incremental doses while observing the patient closely for signs of local anesthetic toxicity. If there is believed to be an inflammatory component to the pain, the local anesthetic is combined with 80 mg of methylprednisolone and is injected in incremental doses. Subsequent daily nerve blocks are carried out in a similar manner, substituting 40 mg of methylprednisolone for the initial 80-mg dose. The needle is then removed, and an ice pack is placed on the injection site to decrease post-block bleeding and pain.

Computed Tomographic Guided Technique

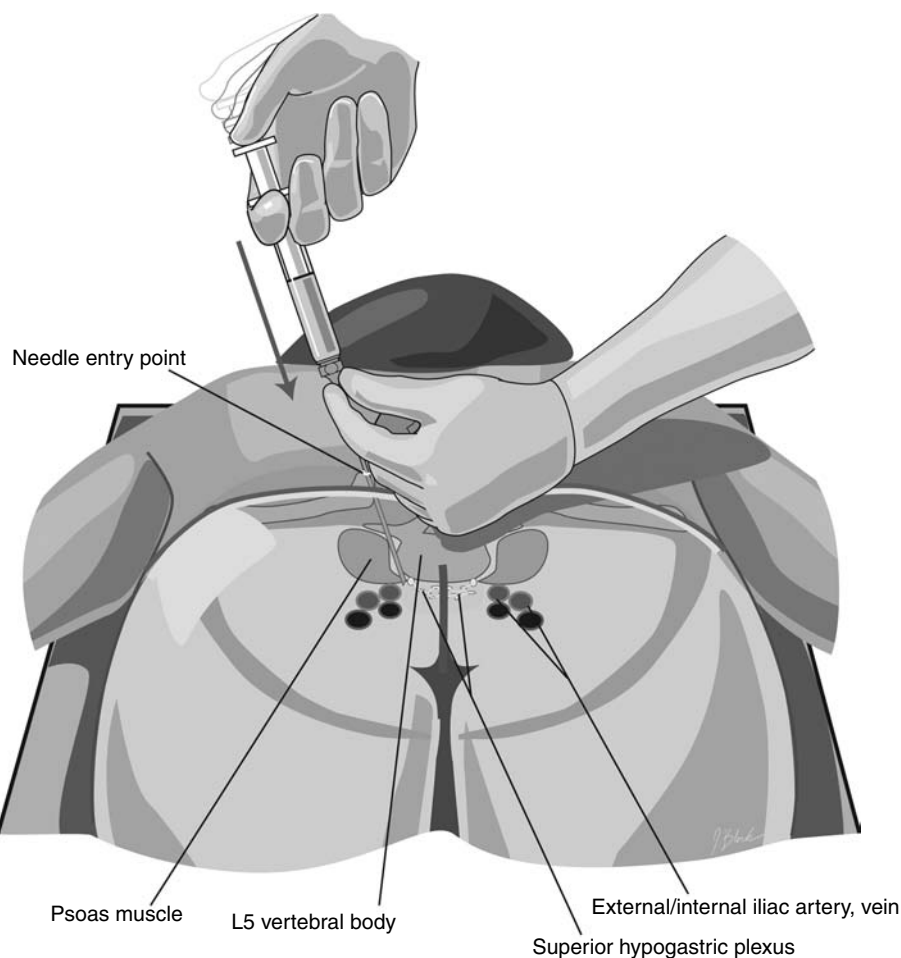
The patient is placed in the prone position on the computed tomography gantry with a pillow placed under the lower abdomen to gently flex the lumbar spine and maximize the space between the transverse process of L5 and the sacral alae. A computed tomography scout film of the lumbar spine is taken, and the L4–L5 interspace is identified. The skin overlaying the L4–L5 interspace is prepared with antiseptic solution, and sterile drapes are placed. At a point approximately 6 cm from midline, the skin and subcutaneous tissues are anesthetized with 1% lidocaine using a 25-gauge, 3.8-cm needle. A 20-gauge, 13-cm needle is then inserted through the previously anesthetized area and directed approximately 30° caudad and 30° mesiad toward the anterolateral portion of the L5–S1 interspace. If the transverse process of L5 is encountered, the needle is withdrawn and redirected slightly more caudad. If the vertebral body of L5 is encountered, the needle is withdrawn and redirected slightly more lateral and walked off the anterolateral aspect of the vertebral body in a manner analogous to lumbar sympathetic block. A 5-mL glass syringe filled with preservative-free saline is then attached to the needle. The needle is then slowly advanced into the prevertebral space while maintaining constant pressure on the plunger of the syringe. A "pop"


FIGURE 61.9 Diagram showing superior hypogastric plexus block.

and loss of resistance will be felt as the needle pierces the anterior fascia of the psoas muscle. After careful aspiration, 2 to 3 mL of water-soluble contrast medium is injected through the needle and a computed tomography scan is taken to confirm current retroperitoneal needle placement. Because of contralateral spread of the contrast medium in the prevertebral space, it is often unnecessary to place a second needle as is advocated by some pain specialists. A total volume of 10 mL of 1.0% preservative-free lidocaine is then injected in divided doses after careful aspiration for blood, cerebrospinal fluid, and urine. If adequate pain relief is obtained, incremental doses of absolute alcohol or 6.5% aqueous phenol may be injected in a similar manner after it is ascertained that the patient is experiencing no untoward bowel or bladder effects from blockade of the hypogastric plexus.

SIDE EFFECTS AND COMPLICATIONS

The proximity of the hypogastric nerves to the iliac vessels means that the potential for bleeding or inadvertent intravascular injection remains a distinct possibility. The relationship of the cauda equina and exiting nerve roots makes

it imperative that this procedure be carried out only by those well versed in the regional anatomy and experienced in performing lumbar sympathetic nerve block. Given the proximity of the pelvic cavity, damage to the pelvic viscera including the ureters during hypogastric plexus block is a distinct possibility. The incidence of this complication will be decreased if care is taken to place the needle just beyond the anterolateral margin of the L5–S1 interspace. Needle placement too medial may result in epidural, subdural, or subarachnoid injections or trauma to the intervertebral disc, spinal cord, and exiting nerve roots. Although uncommon, infection remains an ever-present possibility, especially in the immunocompromised patient with cancer. Early detection of infection, including discitis, is crucial to avoid potentially life-threatening sequelae.

CLINICAL PEARLS

Hypogastric plexus block is a simple technique that can produce dramatic relief for patients suffering from the previously mentioned pain complaints. Neurolytic block with small quantities of absolute alcohol or phenol in glycerin or by cryoneurolysis or radiofrequency lesioning

has been shown to provide long-term relief for patients suffering from sympathetically maintained pain that has been relieved with local anesthetic. As with the celiac plexus and lumbar sympathetic nerve blocks, the proximity of the sympathetic nerves to vascular structures mandates repeated careful aspiration and vigilance for signs of unrecognized intravascular injection. Computed tomographic guidance allows visualization of the major blood vessels and their relationship to the needle, which is a significant advance over blind or fluoroscopically guided techniques. As mentioned earlier, the proximity of the hypogastric plexus to the neuraxis and pelvic viscera makes careful attention to technique mandatory.

GANGLION OF WALTHER (IMPAR) BLOCK

INDICATIONS

Ganglion of Walther (also known as the ganglion impar) block is useful in the evaluation and management of sympathetically mediated pain of the perineum, rectum, and genitalia. This technique has been used primarily in the treatment of pain secondary to malignancy, although theoretical applications for benign pain syndromes including pain secondary to endometriosis, reflex sympathetic dystrophy, causalgia, proctalgia fugax, and radiation enteritis can be considered if the pain has failed to respond to more conservative therapies. Ganglion of Walther block with local anesthetic can be used as a diagnostic tool when performing differential neural blockade on an anatomic basis in the evaluation of pelvic and rectal pain. If destruction of the ganglion of Walther is being considered, this technique is useful as a prognostic indicator of the degree of pain relief that the patient may experience. Destruction of the ganglion of Walther is indicated for the palliation of pain syndromes that have temporarily responded to blockade of the ganglion with local anesthetic and have not been controlled with more conservative measures.

CLINICALLY RELEVANT ANATOMY

In the context of neural blockade, the ganglion of Walther can simply be thought of as the terminal coalescence of the sympathetic chain. The ganglion of Walther lies in front of the sacrococcygeal junction and is amenable to blockade at this level. The ganglion receives fibers from the lumbar and sacral portions of the sympathetic and parasympathetic nervous system and provides sympathetic innervation to portions of the pelvic viscera and genitalia.

TECHNIQUE

Blind Technique

The patient is placed in the jackknife position to facilitate access to the inferior margin of the gluteal cleft. The midline is identified, and the skin just below the tip of the coccyx that overlies the anococcygeal ligament is prepared with antiseptic solution. The skin and subcutaneous tissues at this point are anesthetized with 1.0% lidocaine. A 3.5-inch spinal needle is then bent at a point 1 inch from its hub to a 30° angle to allow placement of the needle tip in proximity to the anterior aspect of the sacrococcygeal junction. The needle may be bent again at a point 2 inches from the hub to accommodate those patients with an exaggerated coccygeal curve to allow placement of the needle tip to rest against the sacrococcygeal junction.

The bent needle is then placed through the previously anesthetized area and is advanced until the needle tip impinges on the anterior surface of the sacrococcygeal junction (Figure 61.10 and Figure 61.11). However, fluoroscopic visualization is advocated, and contrast injection can be used to confirm proper needle placement (Figure 61.12). After careful aspiration for blood, cerebrospinal fluid, and urine, 3 mL of 1.0% preservative-free lidocaine is slowly injected in incremental doses. If there is believed to be an inflammatory component to the pain, the local anesthetic is combined with 80 mg of methylprednisolone and is injected in incremental doses. Subsequent daily nerve blocks are carried out in a similar manner, substituting 40 mg of methylprednisolone for the initial 80-mg dose. The needle is then removed, and an ice pack is placed on the injection site to decrease post-block bleeding and pain.

Computer Tomographic Guided Technique

The patient is placed in the prone position on the computed tomography gantry with a pillow placed under the pelvis to facilitate access to the inferior gluteal cleft. A computed tomography scout film is taken, and the sacrococcygeal junction and the tip of the coccyx are identified. The midline is also identified, and the skin just below the tip of the coccyx that overlies the anococcygeal ligament is prepared with antiseptic solution. The skin and subcutaneous tissues at this point are anesthetized with 1.0% lidocaine. A 3.5-inch spinal needle is then bent at a point 1 inch from its hub to a 30° angle to allow placement of the needle tip in proximity to the anterior aspect of the sacrococcygeal junction. The needle may be bent again at a point 2 inches from the hub to accommodate patients with an exaggerated coccygeal curve to allow the needle tip to rest against the anterior sacrococcygeal junction.

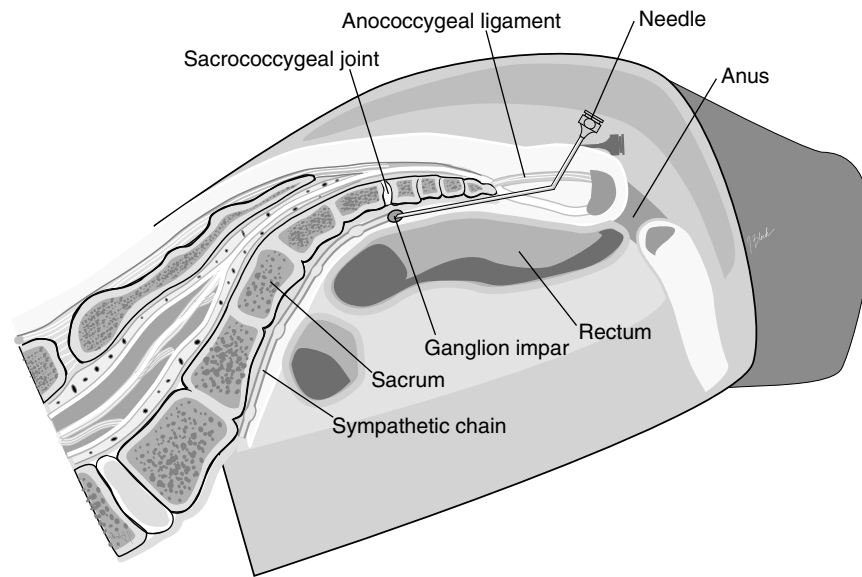
The needle is then placed through the previously anesthetized area and is advanced until the needle tip impinges on the anterior surface of the sacrococcygeal junction. After careful aspiration for blood, cerebrospinal fluid, and urine, 2 to 3 mL of water-soluble contrast medium is injected through the needle and a computed tomography scan is taken to confirm the spread of contrast medium just anterior to the sacrococcygeal junction. After correct needle placement is confirmed, a total volume of 3 mL of


FIGURE 61.10 Diagram showing ganglion impar block. Lateral view.

FIGURE 61.11 Needle placement for ganglion impar block. Lateral fluoroscopic view.

FIGURE 61.12 Needle placement for ganglion impar block. Lateral fluoroscopic view with contrast injection.

1.0% preservative-free lidocaine is injected in divided doses after careful aspiration for blood, cerebrospinal fluid, and urine. If adequate pain relief is obtained, incremental doses of absolute alcohol or 6.5% aqueous phenol may be injected in a similar manner after it is ascertained that the patient is experiencing no untoward bowel or bladder effects from local anesthetic blockade of the ganglion of Walther. The needle is then removed, and an ice pack is placed on the injection site to decrease post-block bleeding and pain.

SIDE EFFECTS AND COMPLICATIONS

The proximity of the ganglion of Walther to the rectum makes perforation and tracking of contaminants back through the needle track during needle removal a distinct possibility. Infection and fistula formation, especially in those patients who are immunocompromised or have received radiation therapy to the perineum, can represent a devastating and potentially life-threatening complication to this block. The relationship of the cauda equina and exiting sacral nerve roots makes it imperative that this procedure be carried out only by those well versed in the regional anatomy and experienced in performing interventional pain management techniques.

CLINICAL PEARLS

Ganglion of Walther block is a straightforward technique that can produce dramatic relief for patients suffering from

the previously mentioned pain complaints. Given the localized nature of this neural structure when compared with the superior hypogastric plexus, neurolytic block with small quantities of absolute alcohol or phenol in glycerin or by cryoneurolysis or radiofrequency lesioning may be a reasonable choice over superior hypogastric plexus block, at least insofar as bowel and bladder dysfunction is concerned. Destruction of the ganglion of Walther has been shown to provide long-term relief for patients suffering from sympathetically maintained pain that has been relieved with local anesthetic. Computed tomographic guidance allows visualization of the regional anatomy and the relationship of the rectum to the needle. This is a significant advance over blind or fluoroscopically guided techniques.

ACKNOWLEDGMENTS

The author thanks colleague and friend Milton Landers, D.O., Ph.D., for the use of several radiographs used in the preparation of this chapter.

Pain Management with Regenerative Injection Therapy

*Felix S. Linetsky, MD, Richard Derby, MD, Rafael Miguel, MD,
Lloyd Saberski, MD, and Michael Stanton-Hicks, MD*

INTRODUCTION

The purpose of this chapter is to provide pain management clinicians with a review of the pertinent literature and clinical and anatomic considerations in relation to an interventional regenerative treatment for chronic musculoskeletal pain.

Connective tissues are ubiquitous throughout the body. Structurally and biomechanically, they represent a heterogeneous group with variations in collagen orientation cross-linking, shape, cell properties, and presence of synovial lining. They constitute the essence of the musculoskeletal system.

A large variety of functions depend on the proper homeostasis of connective tissue. For example, without the storage and release of energy in connective tissue during locomotion, much higher energy expenditure would be required (Bannister et al., 1995; Dorman, 1992). Conversely, many dysfunctional and painful syndromes may arise from pathologic conditions of the connective tissue.

The injury occurs when the internal or external forces exceed the threshold of failure for the specific connective tissue. This may be in the form of a ruptured or strained ligament, tendon, fascia, or a bone fracture, or a disrupted disc.

Pain arising from connective tissue pathology, such as posttraumatic changes in the intervertebral disc, ligaments, tendons, aponeuroses, fasciae, sacroiliac, and zygapophyseal joint capsular ligaments, is often difficult to differentiate based solely on clinical presentation. Individ-ual variations in innervation further complicate the differential diagnosis. Left untreated, post-traumatic and overuse injuries of ligaments and tendons can linger indefinitely, leading to the progression of degenerative changes, loss of function, deconditioning, and perpetuation of disability and chronic pain (Bogduk et al., 1996a, b; Dreyfuss, 1997; Hackett, 1958, 1991; Merskey & Bogduk, 1994; Shuman, 1958; Steindler et al., 1938).

Interventional regenerative modalities for painful musculoskeletal pathologies have been described for more than two millennia. For example, the technique of collagen thermomodulation, now known as thermocapsulorraphy, was originally described by Hippocrates, who performed thermocoagulation of the anteroinferior capsule for treatment of recurrent shoulder dislocations "with red hot slender irons" (Dorman et al., 1991; Shuman, 1958). It is currently recognized that sufficient thermomodulation of collagen can be achieved with lower temperatures to stimulate a proliferative and regenerative/reparative response. This concept has led to the development of intradiscal electrothermal (IDET) procedures, currently used with the intent to achieve nuclear shrinkage, seal annular fissures, and thermocoagulate nociceptors (Derby et al., 1998; Saal et al., 1998a, b).

The coexistence of physical and chemical methods is well demonstrated in the contemporary practice of dermatology and plastic surgery, where chemical (carbolic acid/phenol) and laser-induced facial peels are used for regeneration and rejuvenation by chemo- and thermomodulation of the skin collagen.

Regenerative injection therapy (RIT), also known as prolotherapy or sclerotherapy, is one of the long-practiced methods of pain management. It was originally described by Celsus for treatment of hydroceles, with injections of saltpeter (Hoch, 1939; Linetsky, 1999a). From inception to date, the general principles of injection techniques and differential diagnosis employed in RIT are those advocated by American Academy of Pain Management, American Society of Interventional Pain Physicians, International Spinal Injection Society, and the International Association for the Study of Pain (Aprill et al., 1990; Bogduk, 1982, 1986, 1988, 1996, 1997; Bogduk et al., 1996b; Bonica, 1990; Derby, 2002; Manchikanti, 2002; Merskey & Bogduk, 1994; Steindler, 1938). The difference is that painful chronic tissue bed pathology is the primary target for differential diagnosis and therapeutic application of RIT. Response to the blocks and nerve supply to the tissue are continuously taken into account during procedure. Differential diagnosis encompasses a wide variety of painful tissue including large synovial joints with their components and extends beyond the spinal segmental innervation (Cyriax, 1969, 1982; Dorman, 1993; Dorman et al., 1991; Hackett et al., 1991; Linetsky et al., 2002a, b, c; Ombregt et al., 1995; Waldman, 1998).

Application of RIT for low back pain has been described in numerous textbooks and articles; comparable, adequate applications for cervical and thoracic pain are lacking. We choose to emphasize cervicothoracic pain problems treated with RIT in this chapter (Cyriax, 1969, 1982; Dorman et al., 1991, 1993; Hackett, 1991; Ombregt et al., 1995).

ETYMOLOGY OF SOME TERMINOLOGY

Biegeleisen (1984) first used the term "sclerotherapy" in 1936. *Sclero* is derived from the word *skleros* (Greek, hard). Hackett (1958) felt that sclerotherapy implied scar formation; therefore, he coined the term "prolotherapy" and defined it as "the rehabilitation of an incompetent structure by the generation of new cellular tissue" (derived from the word *proli,* Latin, offspring). "Proliferate": to produce new cells in rapid succession. Proliferation, however, is an integral attribute of a malignant, unsuppressed growth. Moreover, with advances in basic science and the contemporary understanding of the healing process, contemporary exponents prefer RIT because it is recognized that regeneration extends beyond the proliferative stage. On a cellular level, RIT induces chemomodulation of collagen through repetitive stimulation of the inflammatory and proliferative phases in a sophisticated process of tissue regeneration and repair, mediated by numerous growth factors leading to the restoration of tensile strength, elasticity, increased mass, and load-bearing capacity of the affected connective tissue (Klein et al., 1989; Liu et al., 1983; Maynard et al., 1985; Ongley et al., 1987). These

capabilities make RIT a specific treatment for chronic, degenerative, painful conditions such as enthesopathy, tendinosis, and ligament laxity, in place of commonly used steroid injections and denervation procedures (Klein & Eek, 1997; Reeves, 1995).

LOCAL ANESTHETICS IN DIAGNOSIS OF MUSCULOSKELETAL PATHOLOGY: BRIEF HISTORY

In 1930, Leriche introduced the application of procaine for differential diagnosis and treatment of ligament and tendon injuries of the ankle and other joints at their fibro-osseous insertions. In 1934, Soto-Hall and Haldeman reported on the benefits of procaine injections in the diagnosis and treatment of painful shoulders. Subsequently in 1938, they published a study on diagnosis and treatment of painful sacroiliac dysfunctions with procaine injections. After infiltration of the posterior sacroiliac ligaments, interspinous ligaments at L4–5 and L5–S1 levels, and zygapophyseal joint capsules with procaine, they observed a marked relaxation of spastic musculature. They added the routine use of sacroiliac joint manipulations, establishing manipulation of axial joints under local anesthesia (Haldeman et al., 1938).

In 1938, Steindler and Luck made a significant contribution to currently validated approaches in the diagnosis and treatment of low back pain based on procaine injections. The authors pointed out that posterior divisions of the spinal nerves provide the sensory supply to the musculature; tendons; supraspinous, interspinous, iliolumbar, sacroiliac, sacrotuberous, and sacrospinous ligaments; and origins and insertions of aponeurosis of tensor fascia lata, gluteal muscles, and thoracolumbar fascia. They proposed and postulated that five criteria must be met to prove that a causal relationship exists between the structure and pain symptoms (Table 62.1).

Subsequently, in 1948, Hirsch demonstrated relief from sciatica following intradiscal injection of procaine (Hirsch, 1948).

TABLE 62.1
Radiating/Referral Pain Postulates

1. Contact with the needle must aggravate the local pain.
2. Contact with the needle must aggravate or elicit the radiation of pain.
3. Procaine infiltration must suppress local tenderness.
4. Procaine infiltration must suppress radiation of pain.
5. Positive leg signs must disappear.

Note: From "Differential Diagnosis of Pain Low in the Back: Allocation of the Source of Pain by the Procaine Hydrochloride Method," by A. Steindler et al., 1938, *Journal of the American Medical Association, 110,* 106–113. Reproduced with permission.

Local anesthetic diagnostic blocks are currently the most reliable and objective confirmation of the precise tissue source of pain and clinical diagnosis (Bonica, 1990; Cousins et al., 1988; Merskey & Bogduk, 1994; Wilkinson, 1992).

HISTORY AND EVOLUTION OF RIT

The rationale for implementing RIT in chronic painful pathology of ligaments and tendons evolved from clinical and histologic research performed for injection treatment of hernias, hydroceles, and varicose veins. The therapeutic action of the newly formed connective tissue was different in each condition. In hernias, the proliferation and subsequent regenerative/reparative response led to fibrotic closure of the defect (Riddle, 1940; Warren, 1881; Watson, 1938). In hydroceles, hypertrophied subserous connective tissue reinforced the capillary walls of serous membrane and prevented further exudate formation (Hoch, 1939; Linetsky, 1999c). The latter mode of action was employed in the treatment of chronic olecranon and pre-patellar bursitis by Poritt in 1931. He drained the fluid from the sac and injected 5% sodium morrhuate. In cases of persistence, he injected a 5% phenol solution into the bursae (Poritt, 1931).

In 1935, Schultz, while searching for a better way to treat painful subluxations of temporomandibular joints (TMJs), conceived the idea that strengthening of the joint capsule by induced ligament fibrosis would lead to capsular contraction and prevent subluxations. Animal experiments were conducted with several solutions. Among those, Sylnasol provided the best outcomes and therefore was chosen for the clinical trials. (Sylnasol-sodium psyllate was an extract of psyllium seed oil produced by Searle Pharmaceutical and discontinued in 1960s.) A clinical study of 30 human subjects after biweekly injections of 0.25 to 0.5 ml Sylnasol demonstrated "entire patient satisfaction." Schultz (1937) concluded that the principle of induced hypertrophy of the articular capsule by injecting a fibrosing agent might be applied to other joints capable of subluxations or recurrent dislocations. He also concluded that Sylnasol was a dependable agent. Injections restored normal joint function and the method was within the scope of treatment of a general practitioner. Twenty years later, Schultz presented the positive results of Sylnasol injections on several hundred patients, successfully cured of painful hypermobility of TMJ (Schultz, 1956). Also in 1937, Gedney reported some details of collateral ligament injections for painful unstable hypermobile knees and posterior sacroiliac ligaments of unstable painful sacroiliac articulations. Small amounts of sclerosant solutions were injected along the entire affected structures. He extended this treatment 6 months later to recurrent shoulder dislocations, acromioclavicular separations, and sternoclavicular subluxations (Gedney, 1937, 1938).

In 1939, Kellgren injected volunteers with hypertonic saline and implicated interspinous ligaments as a significant source of local and referred pain. He published maps of referred pain from deep somatic structures, including interspinous ligaments (Kellgren, 1939).

In 1940, Riddle included a chapter on "The Injection Treatment of Joints" in his text and described the injection treatment of TMJs and shoulders in great detail, giving Schultz the appropriate credit for initiation of this treatment. Shuman described injection treatment of recurrent shoulder dislocations via strengthening of the inferior capsular ligaments with Sylnasol in 1941. Subsequently, in 1949, he adopted the term "sclerotherapy" for this injection modality, modifying it later that year to "joint sclerotherapy" (Shuman, 1949a, 1949b).

In 1945, Bahme published the first retrospective study of 100 patients who improved after injection of Sylnasol to the sacroiliac ligaments. Patients were under his care for an average of 4 months. The average number of injection treatments was five; 80% reported complete resolution of symptoms. He also found these injections to be very helpful in the treatment of unstable ribs, and reported improvement in 12 patients. He described a significant coexistence of painful hypermobile ribs with hypermobile sacroiliac joints, explaining the phenomenon by concomitant functional scoliosis.

By 1944, Lindblom demonstrated radial annular fissures during cadaveric disc injections and later described nucleographic patterns of 15 discs in 13 patients. Thereafter, in 1948, Hirsch relieved sciatic pain with intradiscal injection of procaine. These two articles prompted Gedney, and subsequently Shuman, to explore therapeutic applications of sclerosants for pain related to intervertebral disc (IVD) pathology.

By 1951, Gedney had extended treatment with sclerosant injections to painful degenerative lumbar disc syndromes and described the detailed technique of Sylnasol injections into the lateral annulus of the lumbar disc without fluoroscopic guidance. He reported L4 disc involvement in 95% of cases and a 50% clinical improvement after treatment of this disc alone (Gedney, 1952b). In the treatment of hypermobile sacroiliac joints, he emphasized that the amount of solution and quantity of treatments were highly individual and depended on the patient's response (Gedney, 1952a). In a retrospective study, Gedney (1954b) emphasized the significant statistical coexistence of sacroiliac pathology with IVD pathology at L3, L4, and L5 levels. By 1954, he had completed a prospective study of 100 patients; 65 were initially treated with the injections into the disc, and 35 were initially treated with injections into the posterior sacroiliac ligaments. The latter group required fewer intradiscal injections. Thus, he concluded that in the presence of sacroiliac pain and hypermobility, adequate stabilization of the sacroiliac joint should be achieved in all cases prior to addressing

discogenic pain (Gedney, 1954b). He emphasized the importance of interspinous and iliolumbar ligament injections in the treatment of lumbar spondylolisthesis (Gedney, 1954a).

In 1954, Shuman evaluated the effectiveness of sclerosant injections to the sacroiliac joints, intervertebral discs, spondylolisthesis, zygapophyseal joint capsules, knees, and shoulders in 93 respondents in a retrospective survey. Improvements ranged from 75 to 98%. Only those patients who were able to perform their usual occupations were considered to have positive results. Subsequently, he detailed many aspects of treatment with integration of manipulative techniques, including manipulation under local anesthesia as introduced 20 years earlier by Haldeman and Soto-Hall. Shuman stated that zygapophyseal joint pathology (emphasized by Hackett in 1956) and disc pathology were the more common causes of lower back pain than sacroiliac joint pathology (Shuman, 1958).

Hackett, the inventor of prolotherapy, postulated in 1939 that ligaments were responsible for the majority of back pain (Hackett, 1953). By 1958, he came to the conclusion that tendons at the fibro-osseous junctions were another significant source of chronic pain syndromes (Hackett, 1958). In a retrospective study, he reported on 84 patients with sacroiliac pain treated by sclerosant injections of Sylnasol, five to seven times to each affected area. In this study, 82% reported themselves entirely symptom free for a duration of 6 to 14 years (Hackett & Henderson, 1955). In the initial animal experiments, he demonstrated a 30 to 40% increase in tendon size after injections of Sylnasol (Hackett, 1956; Figure 62.1). Not satisfied with the term "sclerotherapy," because it implied hardening of the tissue and scar formation, Hackett introduced the term "prolotherapy" in 1956. He did this because the results of his experimental study did not support scarring but rather hypertrophy induced by proliferation of connective tissue in a linear fashion (Hackett, 1956). Hackett employed and emphasized the importance of the earlier referenced postulates of Steindler. He confirmed ligament or tendon involvement as pain generators reproducing local and referred pain by "needling" and abolishing the pain by infiltration of local anesthetic prior to injecting the proliferants (Hackett, 1956). He published maps of referred pain from ligaments and tendons, initially of the lumbopelvic region. These were derived from 7,000 injections in more than 1,000 patients treated over 17 years. He subsequently developed maps of the cervicothoracic region (Hackett, 1958; Figure 62.2). Later, he pointed out that loose-jointed individuals have a lesser ability to recuperate from sprains, because of the congenital laxity of their ligaments, and have a predisposition to chronic lingering pain for decades. He emphasized their positive response to prolotherapy (Hackett, 1959a).

In several subsequent publications, Hackett emphasized the common pathogenesis of impaired local circu-
FIGURE 62.1 Paired radiograph of hypertrophied rabbit tendons, fibro-osseous attachment 1 and 3 months after injection of proliferant. Treated tendons are on the right side of each pair, controls on the left. From *Ligament and Tendon Relaxation (Skeletal Disability) — Treated by Prolotherapy (Fibro-Osseous Proliferation)* (3rd ed.), by G. Hackett, 1958, Springfield, IL: Charles C Thomas.

lation in chronic conditions such as neuritis, headaches, whiplash, osteoporosis, bone dystrophy, bronchospasm, and arteriosclerosis. Excess antidromic, sympathetic, and axon reflex stimulation caused local vasodilatation and edema, with a perpetuating vicious cycle of "tendon relaxation," the condition now understood as degenerative changes, enthesopathy, tendinosis, and laxity (Hackett 1959a, 1959b, 1960a, 1960b, 1961, 1966a, 1966b, 1966c, 1967; Hackett et al., 1961, 1962).

Extended subsequent animal experiments with multiple solutions conducted by Hackett revealed that the strongest fibro-osseous proliferations were achieved with Sylnasol, zinc sulfate solutions, and silica oxide suspensions. The strongest acute inflammatory reaction was obtained with Sylnasol and zinc sulfate, followed by silica oxide. Whole blood moderately stimulated fibro-osseous proliferation. Hydrocortisone used alone or in combination with proliferants inhibited proliferation for 3 to 4 weeks. At the fracture sites, proliferants increased callus formation in 3 weeks, whereas when used in combination with steroids, the callus formation was markedly inhibited (Hackett et al., 1961).

Hackett's positive results were initially corroborated by others (Compere et al., 1958; Green, 1956, 1958; Myers, 1961; Neff, 1959). In fact, Myers reported improvement in 82% of patients.

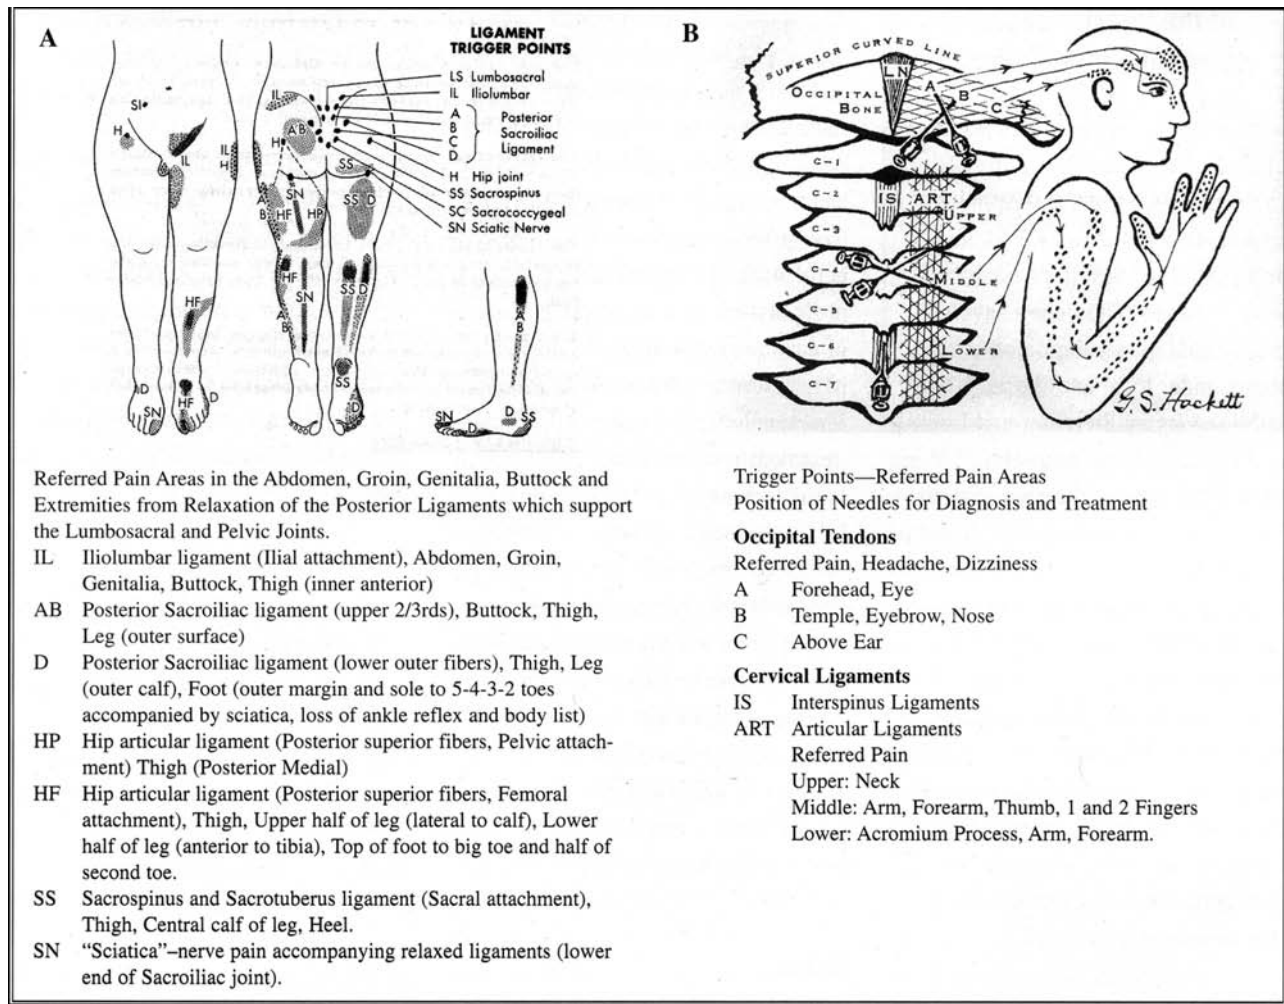
In 1961, Blaschke reported the first prospective study of 42 patients treated with prolotherapy for lower back pain. Of the patients 32 were workers' compensation cases, notoriously the most difficult cases to treat, and 10 were private insurance cases. Complete recovery was achieved in 20 patients observed for 3 years, 13 patients reported no change in their condition, and 9 underwent surgery. The 4 patients with clinical presentation of acute


FIGURE 62.2 Hackett's maps of referred pain from ligaments and tendons. (A) The initial maps of the lumbopelvic region derived from 7,000 injections in more than 1,000 patients treated over 17 years. (B) Subsequent maps were of the cervicothoracic region. From *Ligament and Tendon Relaxation (Skeletal Disability) — Treated by Prolotherapy (Fibro-Osseous Proliferation)* (3rd ed.), by G. Hackett, 1958, Springfield, IL: Charles C Thomas. Reproduced with permission.

herniated disc, in whom prolotherapy was used without hope of success, had better results than any other patients in this study. In three instances of surgical intervention, specimens were obtained from the sites of injections and were reported as "normal fibrous tissue."

A multicenter study (Kayfetz et al., 1963b) was published in 1963. Of 264 patients treated by prolotherapy for headaches, 78% had headaches of traumatic origin, 58% had nontraumatic headaches, and 56% had symptoms of Barre–Lieou syndrome. In addition, 86% had symptoms longer than 1 month and 46% had symptoms longer than 1 year. The traumatic group reported satisfactory results in 79%, with excellent results in 60%. The nontraumatic group reported satisfactory results in 47% and excellent results in 29%. Of 264 cases, 60% of patients were followed for over 1 year and 27% were followed for 3 to 5 years. There were no infections or other complications following prolotherapy.

Kayfetz (1963b) also reported a 5-year follow-up study of 189 cases with whiplash injuries treated by prolotherapy. Of these, 149 cases (79%) were due to automobile accidents, 153 (81%) had associated injuries to the thoracic and lumbar areas, 98 (52%) had an associated Barre–Lieou syndrome, and 55% had symptoms longer than 1 month duration and 21% longer than 1-year duration. A majority of patients received 6 to 30 injections in one setting and were treated on 1 to 10 occasions. Duration of treatment was from 1 to 6 months. Excellent results, in terms of pain, were obtained by 113 (60%), good results by 15 (8%), and fair results by 34 (18%). Some 75% of patients considered themselves cured of pain.

In response to adverse effects published after alleged incidental intrathecal injections of zinc sulfate, experiments were conducted with intrathecal injections of this solution in rabbits (Hunt, 1961; Keplinger et al., 1960; Schneider, 1959). Clinical doses (4 to 5 drops) did not

produce any noticeable effect. Those animals receiving increased doses that produced spinal anesthesia completely recovered after the anesthetic wore off. "It was necessary to use much greater than clinical dosage to induce paraplegia for a few weeks duration, which also cleared up" (Hackett et al., 1961).

In 1967, Coleman brought medicolegal aspects of prolotherapy to the attention of the medical community. He pointed out that Hackett's technique was accepted as a standard of care. It was declared by a California court that a physician treating a patient had deviated from the method as described by Hackett. Conclusion was made that one did not have to follow the method of treatment followed by the majority of the physicians in the community. A physician is permitted to follow a method or a form of treatment followed by a minority of physicians if they are reputable and in good standing. But if physicians vary from the minority method of treatment they do so in violation, just as if they deviated from the generally accepted method of treatment.

The court concluded: "as a matter of law that prolotherapy as a method of treatment cannot be said to be inappropriate or to be malpractice even though it has not been accepted as a common method of treatment by the medical profession generally" (Coleman, 1968, p. 348).

Abroad, positive results with Hackett's method were obtained by Ongley, Cyriax (1969, 1982), Barbor (1964), and Coplans (1972). Barbor presented a study of 153 patients with back pain for up to 20 years duration. Of 153, 111 (74%) of them reported relief to their satisfaction, 17 (11%) failed to improve; 25 (16%) were lost for follow-up, and 31 (23%) required periodic booster injection for relief. The solution utilized was dextrose, phenol, and glycerin (DPG) mixed in proportions of 2 cc DPG to 3 cc local anesthetic.

Cyriax (1969, 1982, 1993) included detailed descriptions of "sclerosant injections" to interspinous and facet joint capsular ligaments of the cervical, thoracic, and lumbar regions in his texts. Further, he described "a clinical blind study of 'sclerosant therapy' presented by Sanford in 1972. Of 100 patients, only 3 were lost for follow-up." The following three solutions were compared: (1) 2 ml DPG sclerosant mixed with 8 ml saline; (2) 10 ml of 0.5% procaine; and (3) 10 ml normal saline. The diluted sclerosant and procaine solutions were almost equally effective, by relieving pain in more than 50% of cases. Procaine and normal saline were equally ineffective by not helping in 50% of cases. Saline solution helped less than a third of patients. The dilution of DPG sclerosant down to 20% of the original strength significantly impaired its proliferant action.

In 1974, Blumenthal reported two cases of migraine headache and one case of cluster headache successfully cured by prolotherapy and a minor modification of Hackett's technique in the treatment of cervicodorsal pain.

By 1976, Leedy had reported a 70% improvement in the condition of 50 patients with low back pain treated with sclerosant injections and followed for 6 years. He also published several descriptive articles of the method (Leedy et al., 1976).

Also in 1976, Vanderschot compared prolotherapy with acupuncture in the treatment of chronic musculoskeletal pain and concluded that prolotherapy has a faster onset of action and longer-lasting pain relief (Vanderschot, 1976a, 1976b).

In 1978, Chase reported up to 70% or better improvement in long-standing cases of painful head, neck/shoulder, and low back syndromes.

Also in 1978, Koudele reported findings of Haws and Willman on histologic changes in human tissue treated up to five times with sclerosant injections for low back pain. The following changes were observed and documented on slides. DPG solution produced early coagulation necrosis, followed by early collagen formation. By 6 months, a small zone of residual inflammatory cells was documented in an area of very dense collagen. In two other specimens treated with DPG, a dense collagen with fibrosis, occluded blood vessels, and a dense whirl of scar was observed.

After injection of a pumice suspension, an area of dense collagen and fibrosis surrounding a "lake" of pumice was documented without foreign body reaction but with a capsule formation (Koudele, 1978).

In 1982, Hirschberg et al. reported a prospective study of 16 patients with the iliolumbar syndrome. Of the patients, 9 were treated with infiltration of lidocaine at the insertion of the posterior iliolumbar ligament to the iliac crest, and 7 were injected with a mixture containing equal amounts of 50% dextrose and 2% xylocaine (a total of 5 cc). Significant recovery was reported by 10 patients. Of the 7 treated with dextrose/xylocaine, 6 recovered, whereas only 4 of the 9 treated with xylocaine recovered.

Liu et al., in a 1983 double-blind study, injected rabbit medial collateral ligaments (MCLs) and demonstrated that repeated injections of 5% sodium morrhuate at the fibroosseous attachments (enthesis) significantly increased its bone–ligament–bone junction strength by 28%, ligament mass by 44%, and thickness by 27%, when compared with saline controls. Morphometric analysis of electron micrographs demonstrated a highly significant increase in the diameter of collagen fibrils in the experimental ligaments vs. controls. These findings confirmed that sodium morrhuate had a significant regenerative influence on dense connective tissue at the insertion sites.

Maynard and co-workers (1985) reported a decrease in collagen fibrils and hydroxyproline content and an overall increase in the mass of tendons in experimental animals injected with sodium morrhuate. The average tendon circumference increased up to 25%.

Ongley et al. (1987) in a double-blind, randomized study of chronic low back pain in 81 subjects, statistically

demonstrated a significant improvement greater than 50% in patients injected with a DPG solution vs. saline. In terms of disability scores, the experimental groups demonstrated a greater improvement than the control group ($p < 0.001$, $p < 0.004$, and $p < 0.001$, respectively; Ongley et al., 1987). Subsequently, Ongley demonstrated a significant statistical improvement in five patients treated for painful instability of the knees with prolotherapy. Ligament stability data was obtained via three-dimensional computerized goniometry, integrated with force measurements (Ongley et al., 1988).

Bourdeau (1988) published a 5-year retrospective survey of patients with low back pain treated with prolotherapy; 17 patients (70%) reported excellent to very good results.

Klein et al. (1989) histologically documented proliferation and regeneration of ligaments in human subjects in response to injections of DPG solution, accompanied by decreased pain and increased range of motion, as documented by computerized inclinometry.

Roosth (1991) described gluteal tendinosis as a distinct clinical entity, and Klein (1991) described the treatment of gluteus medius tendinosis with proliferant injections.

Also in 1991, Schwartz et al. reported a retrospective study of 43 patients with chronic sacroiliac strain who received three series of proliferant injections at biweekly intervals. Improvement was reported by all but 3 patients, and ranged from 95% reported by 20 patients to 66% reported by 4 patients; 10 patients reported recurrence. Schwartz concluded that induced proliferation of collagen and dense connective tissue of the ligament is associated with a reduction of painful subluxations.

Hirschberg et al. (1992) reported positive results in treating iliocostal friction syndrome in elderly individuals with proliferant injections and a soft brace.

Klein et al. (1993) reported a double-blind clinical trial of 79 patients with chronic low back pain who had failed to respond to previous conservative therapy. Subjects were randomly assigned to receive a series of six injections in a double-blind fashion at weekly intervals of either lidocaine/saline or lidocaine/DPG solution into the posterior sacroiliac and interspinous ligaments, fascia, and facet capsules of the low back from L-4 to the sacrum. All patients underwent pretreatment magnetic resonance imaging (MRI) or computed tomography (CT) scans. Patients were evaluated with visual analogue, disability, and pain grid scores, and with objective computerized triaxial tests of lumbar function 6 months following the conclusion of injections. Of the 39 patients randomly assigned to the proliferant group, 30 achieved a 50% or greater decrease in pain or disability scores at 6 months compared with 21 of 40 in the group that received lidocaine/saline ($p = 0.042$). Improvements in visual analogue ($p = 0.056$), disability ($p = 0.068$), and pain grid scores ($p = 0.025$) were greater in the proliferant group.

Massie et al. (1993) reported that it was possible to stimulate fibroplasia in the intervertebral discs with proliferant injections. Also in 1993, Mooney advocated proliferant injections for chronic painful recurrent sacroiliac sprains if the clinician was skilled (Mooney, 1993a, 1993b).

Grayson (1994) reported a case of sterile meningitis after injection of lumbosacral ligaments with proliferating solutions. Matthews (1995) found significant improvement in painful osteoarthritic knees after injection of the ipsilateral sacroiliac ligaments with proliferant solutions. Also in 1995, Reeves pointed out those degenerative changes of enthesopathy may be painful, and prolotherapy with a less aggressive solution such as 12% dextrose with xylocaine is the only type of specific treatment for these pathologic changes of ligaments and tendons.

Eek (1996) reported on the benefit of proliferating injections for intradiscal pain. Klein and Eek have described proliferant injections for low back pain in detail (Klein, 1997).

The clinical anatomy in relation to RIT/prolotherapy for low back pain was reviewed recently. The presence of the connective tissue stocking surrounding various lumbar structures, dictating their function as a single unit in a normal state and the necessity to include multiple segmental and extrasegmental structures in differential diagnosis of low back pain, was emphasized (Linetsky & Willard, 1999; Linetsky et al., 2000).

Subsequently, in March of 2000, Reeves demonstrated in a randomized, double-blind, placebo-controlled study the beneficial effects of 10% dextrose with lidocaine in knee osteoarthritis with anterior cruciate ligament laxity. Goniometric measurements of knee flexion improved by 12.8% ($p = 0.005$) and anterior displacement difference improved by 57% ($p = 0.025$). By 12 months (six injections), the dextrose-treated knees improved in pain (44% decrease), swelling complaints (63% decrease), knee buckling frequency (85% decrease), and flexion range (14° increase). He concluded that proliferant injection with 10% dextrose stimulated growth factors and regeneration and resulted in statistically significant clinical improvements in knee osteoarthritis (Reeves et al., 2000). The history of RIT/prolotherapy from the 1930s through the 1980s was recently reviewed (Linetsky et al., 2000, 2001).

Two recent pilot studies demonstrated significant pain reduction and return to previous levels of activity in patients treated with intradiscal injections of 25% dextrose and combined dextrose-based solutions (Klein et al., 2003; Matthews et al., 2001). Comparison of intradiscal RIT and intradiscal electrothermal therapy (IDET) demonstrated a statistically significant and better results from intradiscal RIT, 47.8% of IDET patients reported improvement while 65.6% of RIT patients reported the same results. Worsening of the conditions was reported by 35.8% of IDET patients and by none of the RIT patients (Derby et al., 2004).

A retrospective study demonstrated a statistically significant improvement in patients treated with phenol-based solution (Wilkinson et al., 2002). An Australian pilot study demonstrated visual analog scale (VAS) scores of back pain improved 60% and VAS scores for leg pain improved 76% after injection of 20% dextrose/xylocaine solution (Yelland et al., 2000). The randomized study by the same senior author comparing 20% dextrose/xylocaine solution and normal saline demonstrated a sustained, statistically significant improvement in a group of patients with chronic low back pain of up to 14 years duration and post-procedural follow-up for 2 years. The role of volume and concentration in the injectate has been brought to light by this study and appears to be much more complex than previously thought; normal saline injected at 3-cc increments (which had never been done by previous investigators) demonstrated significantly positive results (Yelland et al., 2003). Further studies in this direction may provide a better grasp on the indirectly induced stimulation of growth factors in regenerative reparative cascade. Yelland's study also suggests that the volume of injectate may change the concentration of prevailing catabolic interleukin (IL-1) to anabolic interleukin (IL-8). The latter changes have been demonstrated in the injured porcine discs after percutaneous plasma decompression (O'Neill, 2003). A small group of patients improved after intra-articular injection of 25% dextrose or 2.5% phenol into the cervical synovial joints (Linetsky et al., 2004).

To understand the essence of RIT/prolotherapy, it is important to review the basic science related to the healing process, as well as some anatomical and biomechanical properties of connective tissue and clinical anatomy.

INFLAMMATORY-REGENERATIVE/ REPARATIVE RESPONSE AND DEGENERATIVE PATHWAYS

The inflammatory response is intertwined with the regenerative, reparative process. A complex inflammatory reaction induced in vascularized connective tissue by endogenous or exogenous stimuli may lead to two distinct repair pathways. The first is regeneration, which replaces injured cells with the same type of cells; and the second is fibrosis, or the replacement of injured cells with fibrous connective tissue. Often, a combination of both processes contributes to the repair. Initially in both processes a similar pathway takes place with migration of fibroblasts, proliferation, differentiation, and cell–matrix interaction. The last, together with the basement membrane, provides a scaffold for regeneration of preexisting structures (Cotran et al., 1999). Leadbetter (1992) stated, "modulation of these cell matrix responses regardless of the method provides an intriguing challenge" (p. 572). Cell replication is controlled by chemical and growth factors. Chemical factors

may inhibit or stimulate proliferation, whereas growth factors such as cytokines/chemokines, TGF-b1 (transforming growth factor-b1), PDGF (platelet-derived growth factor), FGF (fibroblast growth factor), VEGF (vascular endothelial growth factor), IGF (insulin-like growth factor), CTF (connective tissue growth factor), and NGF (nerve growth factor) stimulate proliferation. The regenerative potential depends on cell type, genetic information, and the size of the defect. In the presence of a large connective tissue defect, fibrotic healing takes place (Cotran et al., 1999; Reeves, 2000).

Under the best circumstances, natural healing restores connective tissue to its preinjury length but only 50 to 75% of its preinjury tensile strength (Leadbetter, 1992; Reeves, 1995). Connective tissues are bradytrophic (their reparative capability is slower than that of muscle or bone). In the presence of repetitive microtrauma, injudicious use of nonsteroidal anti-inflammatory drugs (NSAIDs) and steroid medications, tissue hypoxia, metabolic abnormalities, and other less-defined causes, connective tissue may divert toward a degenerative pathway (Leadbetter, 1992, 1994, 1995; Reeves, 1995, 2000). "A judicious utilization of anti-inflammatory therapy remains useful, albeit adjunctive therapy" (Leadbetter, 1995, p. 402). Biopsies of these tissues demonstrate disorganized collagen, excessive matrix, insufficient elastin, disorganized mesenchymal cells, vascular buds with incomplete lumen, few or absent white blood cells, neovasculogenesis, and neoneurogenesis (Jozsa & Kannus, 1997; Leadbetter, 1994). Degenerative changes in tendons may be hypoxic, mucoid, mixoid, hyaline, calcific, fibrinoid, fatty, fibrocartilaginous and osseous metaplasia, and any combination of the above (Jozsa & Kannus, 1997).

Similar degenerative changes were found in fibromyalgia syndrome with dense foci of rough, frequently hyalinized fibrillar connective tissue. Vascularization occurred at the periphery of these foci, only where thin nervous fibrils and sometimes small paraganglions were seen with severe degenerative changes of the collagen fibers, and marked decrease of fibroblasts. Inflammatory markers were absent (Tuzlukov et al., 1993).

Neoneurogenesis and neovascularization always accompanies the proliferative phase of the healing process and regresses during the contraction phase. Neovascularization has been demonstrated by ultrasound in the injured Achilles tendons (Zanetti et al., 2003). The presence of hyaline cartilage in extruded disc material can suppress neovascularization and subsequent size reduction of herniated mass leading to persistent radiculopathy. Modic types of MRI bone marrow changes are highly suggestive of hyaline cartilage defects at the end plates (Schmid et al., 2004). There is a high correlation between gene defects of COL9A3 and intervertebral disc degeneration, Scheurermann disease, Schmorl's nodules, dorsal annular tears,

end plate degeneration, and hyperintense lesions on sagittal T2-weighted lumbar MRIs (Karppinen et al., 2003).

Repeated eccentric contractions diminish muscle function and increase intramuscular pressure. For example, the intramuscular pressure in the supraspinatus and infraspinatus is four to five times higher than that in the deltoid or trapezius at the same relative load (Ranney, 1997). Edema arising in one muscle compartment secondary to overuse does not spread to adjacent compartments. Prolonged static muscular efforts predispose to edema, which leads to a decrease in perfusion pressure and a subsequent reduction of blood flow with granulocyte plugging of the capillaries and further metabolite accumulation and vasodilatation (Jozsa & Kannus, 1997; Leadbetter, 1994; Ranney, 1997).

Further repeated eccentric contractions are notorious for microtraumas with microruptures at the fibro-osseous junctions, in the mid substance of the ligaments and tendons, or at the myotendinous interface. Repetitive microtrauma with insufficient time for recovery leads to an inadequate regenerative process that turns to a degenerative pathway in tendons, muscles, discs, joint ligaments, and cartilage. Improper posture, in combination with eccentric contractions (such as driving with both hands on a steering wheel or typing on a computer with improperly positioned keyboard and monitor), are the most common examples of eccentric contraction (Jozsa, 1997; Leadbetter, 1992, 1994, 1995; Ranney, 1997; Reeves, 2000).

Impaired circulation at the fibromuscular and fibro-osseous interface eventually leads to impaired intraosseous circulation with diminished venous outflow and increased intraosseous pressure. This, in turn, stimulates intraosseous baroreceptors and contributes to nociception transmitted through fine myelinated and nonmyelinated fibers that accompany nutrient vessels into bone and located in perivascular spaces of Haversian canals. Decreased circulation leads to hypoxia, affects calcium metabolism, and contributes to the progression of osteoarthritis (Bannister, 1995; Hackett, 1959b, 1960a, 1960b, 1961, 1966a, 1966c, 1966d, 1967; Hackett et al., 1961, 1962; Shevelev et al., 2000; Sokov et al., 2000; Zoppi et al., 2000).

There is a high coincidence of degenerative changes in syndesmotic, symphyseal (IVD), and uncovertebral joints of the anterior column with degenerative painful changes in synovial and syndesmotic joints of the posterior column. Communications have been reported between the IVD and costovertebral joints (CVJ) through uncovertebral joints. An S-shaped deformity of zygapophyseal joints invariably accompanies disc degeneration with disc height narrowing throughout cervical, thoracic, and lumbar regions (Giles & Singer, 2000, 2001). Degenerative changes in IVD coincide with degenerative changes in tendinous tissue of the posterior spinal syndesmotic joints, i.e., supraspinous, interspinous, and ligamentum flavum representing themselves with disorganization and quantitative decrease of proteoglycan (PG) bonds, chondrifications, and calcifications. Further degenerated spinal ligaments may be a precursor of IVD protrusions (Yahia et al., 1990).

Neoneurogenesis and neovasculogenesis have been documented in chronic connective tissue pathology. The nerve and vascular tissue ingrowth into diseased intervertebral discs, posterior spinal ligaments, hard niduses of fibromyalgia, together with neuropeptides in the facet joint capsules, have been observed (Ashton et al., 1992; El-Bohy et al., 1988; Freemont et al., 1997; Tuzlukov et al., 1993).

Substance P has been recently identified in chronically painful posterior sacroiliac ligaments, joint capsule, and periarticular adipose tissue. There is a strong possibility that it may be present at chronically painful enthesopathy sites throughout the body (Fortin, Vilensky, & Merkel, 2003).

Insertion pathology of the trunk muscles (enthesopathy) at the fibro-osseous junctions most commonly affects the following sites: occiput, scapulas, spinous processes, especially at the cervicodorsal and thoracolumbar regions; sternum, ribs, posterior lateral and anterior surfaces; iliac crest; and symphysis pubis (Figure 62.3 through Figure 62.9). Histopathologically, the following findings were observed: calcium deposits and mineralization of the fibrocartilaginous zone (Jozsa & Kannus, 1997). A large study examined traumatically ruptured tendons from 891 patients in comparison with 445 tendon specimens obtained from similar local sites in similar age and gender groups of "healthy" individuals who died accidentally. Degenerative changes were well documented in 865 ruptured tendons (97%) and only in 149 control tendons (27%). Similar statistical differences were observed comparing tendons of individuals who died 3 years after quadriplegia and those who died accidentally. Irreversible lipoid degenerations at the muscle tendon junctions were documented as early as 3 months after onset of quadriplegia (Jozsa & Kannus, 1997).

There is a high coincidence of degenerative change in syndesmotic and symphyseal joints of the anterior column and uncovertebral arthroses with degenerative painful changes in synovial and syndesmotic joints of the posterior column. Communications have been reported between the IVD and CVJ through uncovertebral joints. An S-shaped deformity of zygapophyseal joints invariably accompanies disc degeneration with disc height narrowing throughout cervical, thoracic, and lumbar regions (Giles & Singer, 2000, 2001). This makes intra-articular needle placement from the posteroinferior pole difficult even with fluoroscopic guidance. Degenerative changes in IVD correspond with degenerative changes in the posterior spinal syndesmotic joints, i.e., supraspinous, interspinous, and ligamentum flavum, where they are represented by disor-
FIGURE 62.3 Dots represent some of the common enthesopathy areas at the fibro-osseous insertions (enthesis), at the occiput, scapulas, humerus, trochanter, iliac crests, and spinous processes. Dots also represent the most common needle locations during RIT infiltrations. (*Note:* Selected locations are treated at each visit.) From *Atlas of Anatomy* (Vol. 1)*,* by R. D. Sinelnikov, 1972, Moscow: Meditsina. Modified for publication by David M. Paul.

ganization and quantitative decrease of proteoglycan bonds and chondrification (Yahia et al., 1990).

The ability of RIT to regenerate and repair connective tissue has been documented by multiple experimental and clinical studies (Klein et al., 1989; Koudele, 1978; McPheeters et al., 1949; Rice, 1936; Riddle, 1940; Warren, 1881; Yeomans et al; 1939).

SOME ANATOMICAL AND BIOMECHANICAL PROPERTIES OF LIGAMENTS AND TENDONS

Ligaments are dull white, dense connective tissue structures that connect adjacent bones. They may be intra-articular, extra-articular, or capsular. Collagen fibers in ligaments may be parallel, oblique, or spiral. These orientations represent adaptation to specific directions in restriction of joint displacements.

Tendons are glistening white collagenous bands interposed between muscle and bone that transmit tensile forces during muscle contraction. There are considerable variations in shape of fibro-osseous attachments from cylindrical, fan shaped to wide, flat, and ribbon shaped.
FIGURE 62.4 Schematic drawing demonstrates sites of tendon origins and insertions (enthesis) of the vertebral, paravertebral, and peripheral musculature in the cervical, thoracic, and lumbar regions and part of the upper and lower extremities. Clinically significant painful enthesopathies are common at these locations defined by dots. Dots also represent most common locations of needle insertions and infiltration during RIT. (*Note:* Selected locations are treated at each visit.) From *Atlas of Anatomy* (Vol. 1)*,* by R. D. Sinelnikov, 1972, Moscow: Meditsina. Modified for publication by David M. Paul.

The myotendinous junctions have significant structural variations from end to end, to oblique and singular intermuscular fibers. The collagen content of tendons is approximately 30% wet weight, 70% dry weight (Bannister, 1995; Butler et al., 1978).

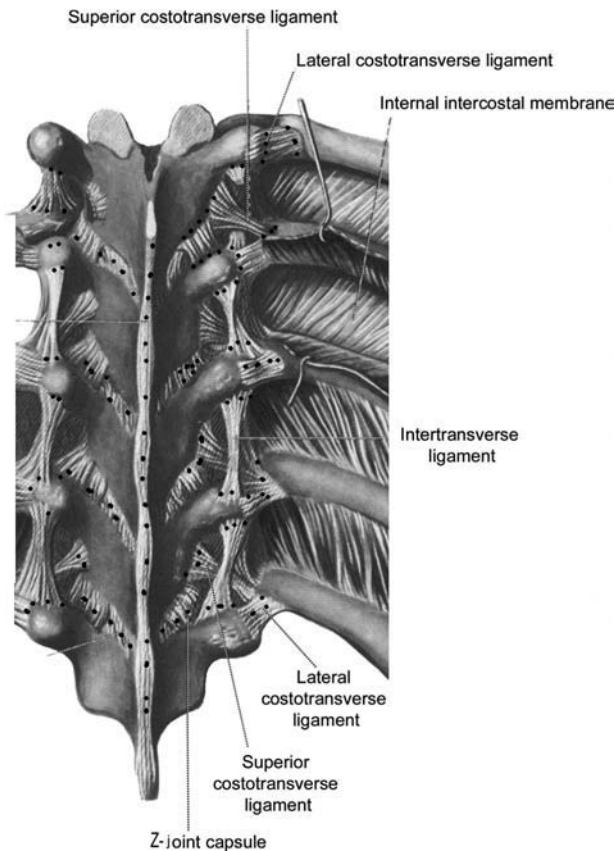
Under a light microscope, ligaments and tendons have a crimped, waveform appearance. This crimp is a planar zigzag pattern that unfolds during initial loading of collagen (Bannister, 1995; Butler et al., 1978). Elongated below 4% of original length, ligaments and tendons return to their original crimped wave appearance; beyond 4% elongation, they lose the elasticity and become permanently laxed. However, in degenerative ligaments, subfailure was reported as early as 1.5% elongation. Laxity of ligaments obviously leads to joint hypermobility. Experi-


FIGURE 62.5 Sites of common posterior thoracic vertebral and paravertebral arthropathies and enthesopathies. Dots also represent the most common needle locations during RIT infiltrations. FIGURE 62.6 Common sites of painful enthesopathies on the anterior thoracic wall, including sternoclavicular, costosternal, interchondral synovial articulations, various syndesmotic joints, and costochondral synchondroses. (*Note:* Selected locations are treated at each visit.) From *Atlas of Anatomy* (Vol. 1)*,* by R. D. Sinelnikov, 1972, Moscow: Meditsina. Modified for publication by David M. Paul.

mental studies have confirmed that the MCL failed more abruptly than either the capsular ligaments or the anterior cruciate ligament (ACL). This happens because the MCL has more parallel fibers with uniformity in length, and therefore, they fail together. The capsular fibers are less organized than the MCL or ACL, and their lengths and orientations vary. Because these fibers are loaded and fail at different times a large joint displacement is needed before capsular failure is complete.

Three principal failure modes exist. The first and most common is ligament failure. The second is a bone avulsion fracture, and the third, the least common, is a shear or cleavage failure at the fibro-osseous interface.

Collagenous tissues are deleteriously affected by inactivity and are favorably influenced by physical activity of an endurance nature. They are also deleteriously affected by NSAIDs and steroid administrations.

In fact, "Administration of even a single dose of corticosteroids directly into ligaments or tendons can have debilitating effects upon their strength. Intra-articular injections of methyl-prednisolone acetate given either

once or at intervals of several months may be less detrimental to ligament or tendon mechanical properties" (Butler et al., 1978).

Tendons are strongly attached to the bones by decussating and perforating Sharpey's fibers. Current understanding of OTJ (osseo tendinous junction, also called enthesis, fibro-osseous junction) is such that the fibers insert to the bone via four zones: tendon zone, fibrocartilage zone, mineralized fibrocartilage zone, and lamellar bone. However, it does not shed much light on the mechanism of tendon avulsion and overuse-induced pathology, as was emphasized by Hackett et al. (1991) and Jozsa and Kannus (1997). The tensile strength of tendons is similar to that of bone and is about half that of steel. A tendon
FIGURE 62.7 Clinically significant painful enthesopathies and arthropathies are common at the locations defined by dots. Dots also represent most common needle locations during RIT infiltrations. with a cross section of 10 mm in diameter can support a load of 600 to 1,000 kg (Bannister, 1995; Butler et al., 1978; Jozsa & Kannus, 1997).

During postnatal development, tendons enlarge by interstitial growth, particularly at the myotendinous junction (also called the fibromuscular interface) where there is a high concentration of fibroblasts. The nerve supplies are largely sensory (Bannister, 1995; Best, 1994; Butler et al., 1978; Jozsa & Kannus, 1997).

GROSS ANATOMY OF CRANIOVERTEBRAL, CERVICAL AND THORACIC REGIONS IN RELATION TO RIT

The shape of a human body and its components is irregularly tubular. This shape is maintained by continuous compartmentalized connective tissue stocking that incor-

porates, interconnects, and supports various ligaments, tendons, fascia, muscles, osseous and neurovascular structures. Collagenous connective tissues, despite slightly different biochemical content, blend at their boundaries and at the osseous structures, functioning as a single unit (Agur, 1991; Bannister, 1995; Linetsky et al., 1999, 2002a, 2002b, 2004; Sinelnikov, 1972; Willard, 2003). This arrangement provides bracing and a hydraulic amplification effect to the muscles, increasing contraction strength in the lumbar region up to 30% (Bogduk, 1997). If only the connective tissues were left in place and all other tissue removed, the shape of a human body would not change.

Movements of the spine and cranium are accomplished through various well-innervated joints, located in the anterior and posterior columns. These joints are syndesmotic, synovial, and symphyseal in nature. Syndesmotic joints of the anterior column are anterior and posterior longitudinal ligaments; anterior and posterior atlanto-occipital membranes; and transverse, apical, and alar ligaments. Symphyseal joints are IVDs and their extensions; unique to the cervical and upper thoracic spine are the so-called uncovertebral joints of Luschka, which are lateral and posteriolateral elevations of the uncinate processes. Synovial joints are atlanto-axial (AA), atlanto-occipital (AO), and CVJ. Syndesmotic joints of the posterior column are posterior atlanto-occipital membrane, supraspinous and interspinous ligaments, ligamentum flavum and nuchae. Synovial joints are costotransverse and zygapophyseal (ZJ). The following joints are indirectly related to the spine: costosternal, interchondral, and sternoclavicular (Agur et al., 1991; Bannister, 1995; Giles & Singer, 2000, 2001; Sinelnikov, 1972).

Segmental innervation of the aforementioned compartments and their contents is provided by the spinal nerves and their respective ventral and dorsal rami (VR, DR). The DRs further divide into medial and lateral branches (MBDR, LBDR) providing innervation to the posterior structures. Anteriorly, spinal segments are innervated by sympathetic fibers (SF); laterally, by gray rami communicantes (GRC); and posteriorly, by the sinuvertebral nerve of Luschka (SN). The extrasegmental communications are widely present on the anterior surface of the spine between the SF, laterally between GRCs and posteriorly between branches of SN (Agur et al., 1991; Bannister, 1995; Bogduk, 1986, 1996; Cramer & Darby 1995; Linetsky et al., 2002a, 2002b, 2004; Willard, 1995).

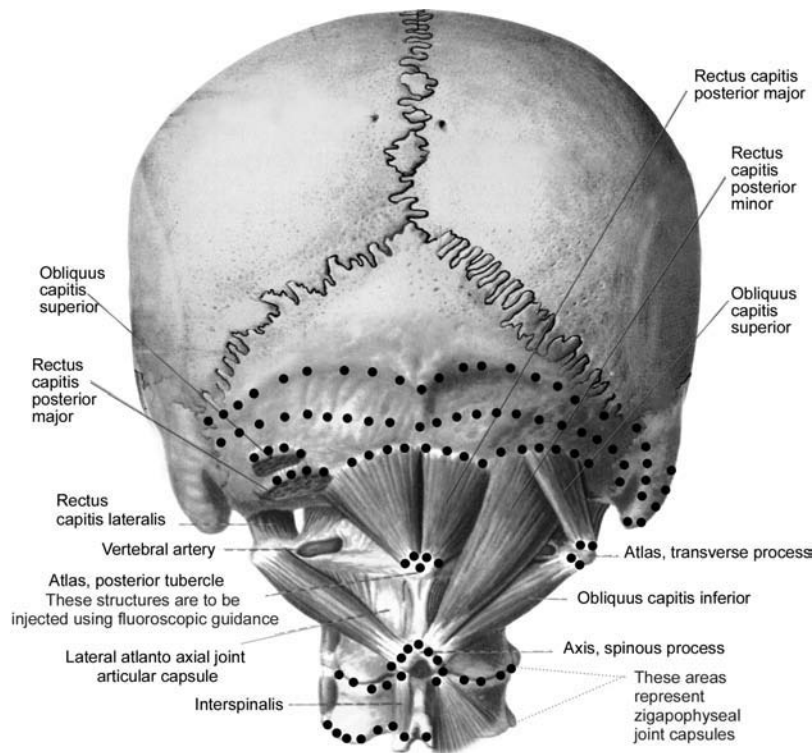
The first dorsal ramus, also called the sub-occipital nerve, supplies the muscles of the sub-occipital region, rectus capitis posterior minor and major, inferior and superior oblique, and semispinalis capitis. It has an ascending cutaneous branch that connects with the greater and lesser occipital nerves and may contribute to the occipital and sub-occipital headaches (Bannister, 1995; Bogduk, 1982, 1986, 1988). The second cervical dorsal ramus also sup-


FIGURE 62.8 Sites of tendon origins and insertions (enthesis) of the vertebral and paravertebral musculature in the upper cervical and occipital region. Clinically significant painful enthesopathies are common at locations defined by dots. Dots also represent most common locations of needle insertions and infiltration during RIT. (*Note:* Selected locations are treated at each visit.) From *Atlas of Anatomy* (Vol. 1)*,* by R. D. Sinelnikov, 1972, Moscow: Meditsina. Modified for publication by David M. Paul.

plies the inferior oblique, connects with the first one, and divides into LMBDR. Its medial branch, the greater occipital nerve, pierces the semispinalis capitis and trapezius at their insertion to the occipital bone on its ascending course. Thereafter, it connects with the branches from the third occipital nerve along the course of the occipital artery supplying the skin of the skull up to the vertex (Bannister et al., 1995; Bogduk, 1982, 1986, 1988).

Lateral branches supply the iliocostalis, longissimus cervices, and longissimus capitis. Similar anatomic relationships are observed in the thoracic region where medial branches of the upper six thoracic dorsal rami supply the zygapophyseal joints, semispinalis thoracis, multifidi, piercing trapezius, and rhomboid, and reach the skin most proximal and lateral to the spinous processes (Agur et al., 1991; Bannister et al., 1995; Bogduk, 1982).

Current trends in therapeutic and diagnostic blocks are based on the fact that the anatomy and course of the MBDRs is fairly constant, and that it arises from the intertransverse space and wraps around the waist of the respective articular pillars (Aprill et al., 1990; Bogduk, 1982, 1986, 1988). Recent clinical observations supported by ongoing research and microdissections of Willard (Figure 62.10) concur with the previous investigations (Bogduk, 1982). MBDR furnishes twigs to zygapophyseal joint capsules and continues along the lamina and spinous

process toward its apex, innervating structures inserting or originating at the lamina and the spinous process on its course often terminating in interspinalis muscles (Bogduk, 1982, 1988, 1996; Bogduk et al., 1996; Willard, 2003, see Figure 62.10 and Figure 62.11). For example, the fourth and fifth cervical MBDRs supply the semispinalis cervices and capitis, multifidi, interspinalis, splenius and trapezius, and supraspinous ligaments, and end in the skin. The lowest three MBDRs have a similar course (Figure 62.10).

However, variations in innervation occur, their incidence is unknown. Floating dorsal rami have been described in the cervical and thoracic regions, sometimes descending from the level of C5–6, C6–7, or C7–T1 to the level of T3–4, T4–5, T5–6. The latter "so-called" causes of thoracic pain of cervicogenic origin, which may complicate the differential diagnosis, explain failures after MBDR blocks or radiofrequency procedures, and *make tissue nociceptors specific targets for RIT* (Linetsky et al., 2004; Maigne, 1996; Willard, 2003; Figure 62.11).

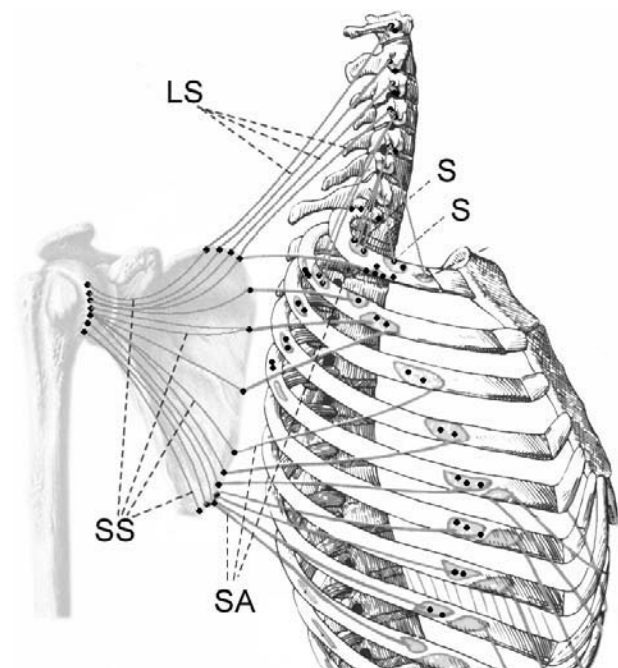
Three types of nerve endings in posterior ligamentous structures of the spine were confirmed microscopically. They are free nerve endings and Pacini and Ruffini corpuscles. The free nerve endings were found in superficial layers of all ligaments, including supraspinous and interspinous, with a sharp increase in their quantity at the spinous processes attachments (enthesis). Paciniform corpuscles are


FIGURE 62.9 Commonly overlooked painful enthesopathies of levator scapula (LS), subscapularis (SS), and serratus anterior (SA) especially superior fascicle often mimic upper trapezial pain. Contribution of rhomboid, scalenes (S), omohyoid (inferior belly), splenius services, posterior and anterior column structures including first costotransverse joint should be considered in differential diagnosis. (*Note:* Selected locations are treated at each visit.) From *Atlas of Anatomy* (Vol. 1)*,* by R. D. Sinelnikov, 1972, Moscow: Meditsina. Modified for publication by David M. Paul.

located in adipose tissue between supraspinous ligaments and lumbosacral fascia and in the deep layers of supraspinous and interspinous ligaments acting as nociceptors in all locations and as mechanoreceptors with a low threshold, and are stimulated by stretch of the ligaments and muscle actions. Ruffini receptors are located in the interspinous and flaval ligaments; they respond to stretch and control the reflex inhibitory mechanism (Yahia et al., 1989).

Variously shaped, synovium-covered menisci composed of adipose, fibroadipose, collagenous, and cartilaginous tissue extend into cervical synovial joint space and anchor at their periphery to the joint capsule where they receive their blood supply. Their shape and position changes with age and degeneration (Mercer & Bogduk, 1993; Yu et al., 1987). The nerve supply to the inferior synovial folds of lumbar z-joints has also been documented (Giles, 1988; Giles & Taylor, 1987).

CLINICAL ANATOMY OF CRANIOVERTEBRAL, CERVICAL, AND THORACIC REGIONS IN RELATION TO RIT

The subjective nature of pain and especially chronic pain, because of the suffering characteristics, is a major com-
FIGURE 62.10 Left dorsolateral view of the cervical medial branches of the dorsal rami (MBDRs). C–2 = apex of C2 spinous process, SC = semispinalis cervices, WAP = waist of articular pillar with the medial branch displaced anteriolaterally, 1 2 3 = MBDRs wrapping around the waists of articular pillars ramifying into multifidi. One of the two MBDRs that usually arise separately, innervating structures at the apex of C2. munication problem. Quite often a physician has not had a comparable experience and will have difficulty understanding what the patient is trying to communicate. Physicians, especially those involved in pain management, have to accept patients' "pain and tenderness" at face value without dismissal or allocation to a distant "proven" source. It is the knowledge of clinical anatomy, pain patterns, and pathology that should guide the clinical investigation, versus insurance policies and reimbursement especially in the current mismanaged care environment.

Hilton's law is clear that a nerve passing a joint is also supplying that joint, muscles are moving that joint, and the skin is covering insertions of these muscles (Hilton, 1891). This is in accord with anatomical, histological, experimental, and human studies that followed and are too numerous to count.

Scientifically verified are the following data. Cervical ZJ is responsible for 54% of chronic neck pain after "whiplash" injury. Intra-articular corticosteroid injections are ineffective in relieving chronic cervical ZJ pain (Barnsley et al., 1994, 1995). In cervicogenic headaches after whiplash, more than 50% stem from the C2–3 ZJ
FIGURE 62.11 Left dorsolateral view of cervical micro-dissection. Descending floating cervical MBDR with multiple branches reaching lateral aspects of the spinous processes at the enthesis of multifidi. Slide and micro-dissections are courtesy of Professor Frank Willard, Ph.D. Modified and prepared for publication by David M. Paul.

(Bogduk, 1986, 1996; Bogduk et al., 1996; Lord, 1996). Prevalence of cervical ZJ pain is as high as 67%; thoracic is 48% (Boswell et al., 2003; Lord, 1996; Manchikanti et al., 2002). The preceding statistical data were obtained by a painstaking adherence to precision protocols and strongly suggest a presence of nociceptors other than ZJ and IVD. Lack of statistical data on these "other, hidden, unproven pain generators" could not be misconstrued as their absence. Cervical and thoracic facet syndromes comprise the pathology of capsular ligaments, periarticular tendons with their enthesis, extrapment, and entrapment of menisci, and fractures of the articular pillars, which are not detected by current radiologic modalities. Also S-shaped intra- and periarticular degenerative changes of ZJ predispose intra-articular inclusions and subchondral bone to contusions during trauma (similar to an inadvertent bite on the buccal mucosa). The same changes make intra-articular needle placement from the inferior pole difficult even with fluoroscopic guidance.

Pain patterns resembling those of facet syndromes have been described from structures located distally on the course of MBDRs, lateral branches (LBs), and those receiving extrasegmental innervation. Further, patterns from AO and AA joints overlap with patterns from the lower z-joints (Aprill et al., 1990; Dreyfuss et al., 1994a),

as well as sub-occipital and posterior cervical soft tissues (Feinstein et al., 1954; Hackett 1958, 1960a; Hackett et al., 1962, 1991; Kellgren, 1939; Linetsky et al., 2004; Travell et al., 1983). AO and AA contribution to nociception requires confirmation with intra-articular blocks under fluoroscopic guidance by a practitioner with a significant amount of experience (Dreyfuss et al., 1994a). Usually it is a diagnostic procedures of exclusion and is employed after failure of mid-cervical and C2–3 ZJ interventions to provide a relief. (Bogduk, 1988; Dreyfuss et al., 1994a, 1994b). Conversely RIT injections are capsular ZJ injections that provide relief without fluoroscopic assistance in the cervicothoracic region as high as C2–3 ZJ capsule which is the highest palpable ZJ in the cervical spine, at a comparatively much lower cost (Blumenthal, 1974; Cyriax 1969, 1982, 1993; Hackett, 1958, 1962, 1991; Kayfetz, 1993a, b; Linetsky, 2002b, 2004; Maigne, 1996; Waldman, 1998). Current prevailing trends in diagnostic efforts are variable and are as follows. Cervical facetogenic pain is confirmed by MBDR block but AO, AA, CVJ, and sacroiliac joints are diagnosed by intra-articular blocks. Thoracic ZJ pain is diagnosed by both intra-articular and MBDR block, without consideration for chronic degenerative, painful changes in the tissue bed. Neuralgic spinal pain is diagnosed by translaminar or transforaminal block. Discogenic pain is addressed by needle placement and tissue distention with contrast or what is known as tissue bed block (Aprill et al., 1990; Bogduk, 1982; Linetsky & Willard, 1999; Linetsky et al., 2002a, 2004).

Consequently, therapy is directed toward neuromodulation or neuroablation with radiofrequency generators or corticosteroid injections for neuralgic pain. Surgical interventions and fusions are aimed to correct the mass effects in neurocompressive models or discogenic pain. The rest of pain generators are not included in differential diagnosis because of the spinal uncertainty principle. According to the principle even for a simple example of two motion segments, where disc, facets, and musculotendinous compartments, each considered as one putative nociceptive unit, the total number of clinically indistinguishable combinations rises to 63 possibilities. It is practically impossible to address such a magnitude of possibilities under fluoroscopic guidance (Dickey, 2001).

The tissue bed pathology and pain are the primary targets for RIT taking innervation into account. Therefore, RIT affords evaluation of many putative pain generators from the variety of pain presentations in the craniocervicothoracic region in addition to the posterior column. When correctly implemented, RIT offers an attractive, practical alternative that is accomplished at the same office visit.

The apices of the spinous processes (SP) and their entheses are well innervated and considered a "spinous rotator cuff" especially at C2 and C6–T12.

Standard MBDR blocks interrupt orthodromic and antidromic transmission at the proximal segment of MBDR. Other putative nociceptors located distally on MBDR course are excluded from the differential diagnosis without consideration to individual variation in the locations of terminal filaments of MBDR and LB. For RIT purpose, the blocks are performed beginning from the terminal filaments at SP enthesis, towards origins of innervation located proximally on the course of MBDR or LB (Hackett et al., 1991; Linetsky et al., 2002b, 2004; Steindler et al., 1938).

For example, at the cervicocranial junction, lateral aspects of the apex at the C2 spinous process (specifically enthesis of rectus capitus posterior major, obliquus capitus inferior, semispinalis services) are addressed initially. If pain persists, respective enthesis are addressed at the superior and inferior nuchal lines. If pain persists, the C2–3 posterior z-joint capsule is injected (Linetsky, 2002b, 2004; Figure 62.7, Figure 62.8, Figure 62.10, Figure 62.11). At the mid-cervical segments, central tenderness is rare while facet capsular tenderness is more prevalent, which is the reason the posterior ZJ capsules are blocked initially if this is the only presenting pain. Should this fail, subsequent intra-articular fluoroscopically guided injections are indicated. This approach may fail in the presence of paramedian pain and trapezial pain because it does not take into account extrasegmental innervation to some of the cervical and thoracic structures commonly involved in chronic pain syndromes that receive innervation from the cranial nerves or the ventral rami.

Multilevel C6–T9 midline pain with variable degree of tenderness in the projection of posterior syndesmotic joints and rhomboid-shaped trapezius (TR) aponeurosis is by far one of the most common presenting complaints encountered in pain practice (exact prevalence unknown) (Figure 62.3 through Figure 62.5). This is combined with variations of paramedian, lateral, middle and upper TR pain, and tenderness commonly ascribed to "trigger points" (TPs). Injections of these TPs often do not resolve the pain. What to do next? Search for all other tender sites in the region. This usually reveals exquisite tenderness at the superomedial angle of the scapula where levator scapulae (LS) share the insertion site, enthesis, with serratus anterior (SA) and subscapularis (SS). Innervation of these structures is as follows: TR — by the XIth pair, the accessory nerve; LS — by ventral rami (VR) from (C3–C4) and dorsal scapular nerve (C5); SA — by long thoracic nerve (C5–C7 VR); and SS — by superior and inferior subscapular nerves (C5–C6 VR). To base differential diagnosis and treatment of this condition on diagnostic blocks of all these nerves in one setting is impossible (Dickey, 2001).

Conversely, block of the common enthesis at the superomedial scapular angle addressing both dorsal and ventral surface may provide instant relief including disappearance of TPs. The following case will demonstrate

the necessity to consider all potential nociceptors in a given presentation (Figure 62.9).

For the purpose of RIT, when trapezial pain is accompanied by midline tenderness at C6–T6, those structures are injected initially. If TR pain persists and is accompanied by paramedian pain and tenderness, ZJ capsules are injected. If TR pain persists, the first CVJs are injected if tender. If not, scalene medius enthesis at the first rib is injected if tender. If pain persists, iliocostalicis services, thoraces, and serratus superior enthesis at the respective ribs are injected. If pain persists, LS and SA enthesis at superomedial angle of the scapula are blocked. This site may be blocked initially if it is the sole area of presenting complaint, pain, and tenderness. If pain persists, the above-described sequence may be initiated.

MECHANISM OF ACTION

The exact mechanism of action is unknown. The proposed and postulated RIT mechanisms of action are complex and multifaceted.

- Temporary neurolysis with chemoneuromodulation of peripheral nociceptors is achieved by chemical properties of the injectates and provides stabilization of antidromic, orthodromic, sympathetic and axon reflex transmissions.
- Temporary neurolysis is achieved via mechanical transsections of some small myelinated and unmyelinated C fibers by the needle or hydraulic pressure of the injected volume.
- Mechanical transsections of cells and extracellular matrix by the needle causes cellular damage, stimulates inflammatory cascade and release of growth factors.
- Compression of cells by relatively large extracellular volume as well as cell expansion or constriction due to osmotic properties of injectate stimulates the release of intracellular growth factors.
- Chemomodulation of collagen through inflammatory, proliferative, regenerative/reparative response is induced by the chemical properties of the injectates and mediated by cytokines and multiple growth factors.
- Modulation of local haemodynamics with changes in intra-osseous pressure leads to reduction of pain. Empirical observations suggest that dextrose/lidocaine action is much more prolonged than that of lidocaine alone.
- Temporary repetitive stabilization of the painful hypermobile joints, induced by inflammatory response to the injectates, provides a better environment for regeneration and repair of the affected ligaments and tendons.

- The large volume of injectate disrupts adhesions that were created by the original inflammatory attempts to heal the injury, akin to epidural or intra-abdominal lyses of adhesions.
- A relatively large volume of osmotically inert injectate assumes the role of a space occupying lesion in a tight and slowly equilibrating extracellular compartment of the connective tissue. It initiates inflammatory cascade and also irrigates catabolic interleukins

Putative Pain-Generating Structures Addressed by RIT/Prolotherapy

1. Ligaments: Intra-articular, periarticular, capsular
2. Tendons
3. Fascia
4. Enthesis: The zone of insertion of ligament, tendon, or articular capsule to bone (Anderson, 1988; Jozsa & Kannus, 1997; Klein & Eek, 1997) (also called fibro-osseous junctions of ligaments and tendons). In the orthopedic literature, this is referred to as OTJ (osseo/tendinous junction) (Jozsa & Kannus, 1997; Leadbetter, 1992, 1994, 1995; Linetsky et al., 2002a, b, c, 2004; Reeves, 2000). For the purpose of this chapter, enthesis and fibro-osseous junction are interchangeable.
5. Intervertebral discs

TISSUE PATHOLOGY TREATED WITH RIT/PROLOTHERAPY

1. *Sprain*: Ligamentous injury at the fibro-osseous junction or intersubstance disruption. A sudden or severe twisting of a joint with stretching or tearing of ligaments; also, a sprained condition (Leadbetter, 1994; Reeves, 1995; Simon et al., 1987).
2. *Strain*: Muscle/tendon injury at the fibromuscular or fibro-osseous interface. When concerned with the peripheral muscles and tendons sprains and strains are identified as separate injuries and in three-stage gradations: first-, second-, and third-degree sprain, and similarly for strain. With regard to vertebral and paravertebral ligaments and tendons, no consensus exists among authors and the definitions are quite vague (Anderson, 1985; Leadbetter, 1994).
3. *Enthesopathy*: A painful degenerative pathological process that results in the deposition of poorly organized tissue, degeneration and tendinosis at the fibro-osseous interface, and transition toward loss of function (Jozsa & Kannus, 1997; Klein & Eek, 1997; Leadbetter, 1994; Linetsky, 1999b; Reeves, 1995).

4. *Tendinosis/ligamentosis*: A focal area of degenerative changes due to a failure of cell matrix adaptation to excessive load and tissue hypoxia, with a strong tendency toward chronic recurrent pain and dysfunction (Best, 1994; Jozsa & Kannus, 1997; Klein & Eek, 1997; Leadbetter, 1994; Reeves, 1995; Roosth, 1991).
5. *Pathologic ligament laxity*: A post-traumatic or congenital condition leading to painful hypermobility of the axial and peripheral joints (Anderson, 1985; Dorman et al., 1991; Hackett, 1958; Reeves, 1995, 2000; Reeves et al., 2000; Simon et al., 1987).

INDICATIONS FOR RIT/PROLOTHERAPY

1. Chronic pain from ligaments or tendons secondary to sprains or strains
2. Pain from overuse or occupational conditions known as repetitive motion disorders (i.e., neck and wrist pain in typists and computer operators, "tennis" and "golfer's" elbows, chronic supraspinatus tendinosis)
3. Painful chronic postural neck and cervicodorsal junction problems
4. Painful recurrent somatic dysfunctions secondary to ligament laxity that improve temporarily with manipulation; hypermobility and subluxation at a given peripheral or spinal articulation or mobile segment(s), accompanied by a restricted range of motion at reciprocal segment(s)
5. Thoracic vertebral compression fractures with a wedge deformity that exerts additional stress on the posterior ligamento-tendinous complex
6. Recurrent painful subluxations of ribs at the costotransverse, costovertebral, and/or costosternal articulations
7. Spondylolisis and spondylolisthesis
8. Intolerance to NSAIDs, steroids, or opiates and failure of manipulative treatments or physical therapy
9. RIT is the treatment of choice when corticosteroid injections, RF, and surgery failed or are contraindicated

SYNDROMES AND DIAGNOSTIC ENTITIES CAUSED BY LIGAMENT AND TENDON PATHOLOGY THAT HAVE BEEN SUCCESSFULLY TREATED WITH RIT/PROLOTHERAPY

1. Cervicocranial syndrome (cervicogenic headaches, alar ligaments sprain, atlanto-axial and atlanto-occipital joint sprains)

2. Temporomandibular pain and dysfunction syndrome
3. Barre–Lieou syndrome
4. Spasmodic torticollis
5. Cervical segmental dysfunctions
6. Cervical and cervicothoracic spinal pain of "unknown" origin
7. Cervicobrachial syndrome (shoulder/neck pain)
8. Hyperextension/hyperflexion injury syndromes
9. Cervical, thoracic, and lumbar facet syndromes
10. Cervical, thoracic, and lumbar sprain/strain syndromes
11. Costotransverse joint pain
12. Costovertebral arthrosis/dysfunction
13. Slipping rib syndrome
14. Sternoclavicular arthrosis and repetitive sprain
15. Thoracic segmental dysfunction
16. Tietze's syndrome/costochondritis/chondrosis
17. Costosternal arthrosis
18. Intercostal arthrosis
19. Xiphoidalgia syndrome
20. Acromioclavicular sprain/arthrosis
21. Shoulder–hand syndrome
22. Recurrent shoulder dislocations
23. Scapulothoracic crepitus
24. Myofacial pain syndromes
25. Ehlers–Danlos syndrome
26. Marie–Strumpell disease
27. Failed back surgery syndrome

CONTRAINDICATIONS TO RIT/PROLOTHERAPY

1. Allergy to anesthetic or proliferant solutions or their ingredients, such as dextrose, sodium morrhuate, or phenol
2. Acute nonreduced subluxations or dislocations
3. Acute sprains or strains of axial and peripheral joints
4. Acute arthritis (septic or post-traumatic with hemarthrosis)
5. Acute bursitis or tendinitis
6. Capsular pattern shoulder and hip designating acute arthritis accompanied by tendinitis
7. Acute gout or rheumatoid arthritis
8. Recent onset of a progressive neurologic deficit, including but not limited to severe intractable cephalgia, unilaterally dilated pupil, bladder dysfunction, and bowel incontinence
9. Requests for a large quantity of sedation and/or narcotics before and after treatment
10. Paraspinal neoplastic lesions involving the musculature and osseous structures

11. Severe exacerbation of pain or lack of improvement after local anesthetic blocks
12. Relative contraindications: central spinal canal, lateral recess and neural foraminal stenosis

CLINICAL PRESENTATIONS

Patients may present with a variety of complaints ranging from one area of localized pain and tenderness to any combination of referred pain patterns known with cervical disc, cervicocranial, and cervicobrachial or cervical and thoracic facet syndromes. Headaches accompanied by cervical muscle spasms are a common complaint. Other complaints include (1) exacerbation of pain while standing or sitting in the same position for a given period of time, and increased pain after exertion or physical activity; (2) a feeling of weakness in the neck, back, or extremities and extreme fatigability; (3) pseudoradicular patterns of change in sensation, such as burning, numbness, and tingling; (4) difficulties in maintaining balance, ringing in the ears, and blurred vision; (5) feeling the need for repetitive self-manipulations, or chiropractic or osteopathic manipulations; (6) painful clicking, popping, or locking of axial or peripheral joints; (7) dropping of objects, weakness of the hands, and "heaviness of the head" (Dorman et al., 1991; Hackett et al., 1991; Kayfetz, 1963; Kayfetz et al., 1963; Reeves, 1995, 2000).

Physical Examination

Tenderness is the most common finding over the chronically strained or sprained ligaments or tendons. Provoked tenderness rarely reproduces radiating or referral pain; it is a local phenomenon. However, intensity of such tenderness may be changed or abolished completely after manipulation. Patients are able to point out such pain with their finger in the posterior cervicodorsal region.

Such local tenderness, as well as referred and radiating pain, can often be abolished by infiltration of nociceptors in the involved tissue with local anesthetic. Tenderness is an objective finding, especially when elicited at posterior structures (Borenstein et al., 1996; Broadhurst et al., 1996; Hackett, 1958; Hackett et al., 1991; Linetsky, 1999).

RADIOLOGIC EVALUATION PRIOR TO RIT/PROLOTHERAPY

1. Plain radiographs are of limited diagnostic value in painful pathology of the connective tissue; however, they may detect
   a. Structural or positional osseous abnormalities
   b. Anterior or posterior listhesis on lateral views (flexion, extension)
   c. Degenerative changes in general and deformity of zygapophyseal articulation

(Browner et al., 1998; Harris et al., 1981; Resnick, 1995; Watkins, 1996)

2. Videofluoroscopy has been popularized in the previous edition of this chapter; based on the experience of the last 3 years, our current opinion is that the findings of the interpreting practitioners do not correlate with the findings of clinical evaluation augmented by diagnostic blocks (Fielding, 1957)

3. MRI may detect intervertebral disc pathology, enthesopathy, ligamentous injury, interspinous bursitis, zygapophyseal joint disease and sacroiliac joint pathology, evaluation of the neural foraminal pathology, bone contusion, and neoplasia infection or fracture, as well as exclude or confirm spinal cord disease and pathology related to intradural, extramedullary, and epidural space (Resnick, 1995; Stark et al., 1999)

4. CT scan may detect small avulsion fractures of the facets, laminar fracture, fracture of vertebral bodies and pedicles, or degenerative changes (Resnick, 1995)

5. Bone scan is useful in the assessment of the entire skeleton, ruling out metabolically active disease processes (Resnick, 1995)

6. Ultrasound has been long practiced in Europe for diagnosis of "soft tissue" pathology (Jozsa & Kannus, 1997). It has been widely used in veterinary medicine in the United States (Herthel, 2003). Current radiologic publications also demonstrate the effectiveness of diagnostic ultrasound in soft tissue pathology (Zanetti et al., 2003; Jacobson et al., 2003). A case has recently been reported of trapezius rupture diagnosed by ultrasound and successfully treated with xylocaine/dextrose injections followed by ultrasound confirming the closure of the defect (Saberski, 2003).

TECHNICAL CONSIDERATIONS AND INJECTION SITES

Painful enthesopathies and arthropathies in the craniocervicothoracic region commonly affect the following sites: apices of spinous processes, occipital bone at inferior and superior nuchal lines, mastoid processes, anterior and posterior tubercles of transverse processes, tubercles, angles and tuberosities of the ribs, proximal and distal portions of the clavicle, superomedial and inferomedial margins and the spine of the scapula, sternum, and xyphoid, capsular ligaments of the cervical and thoracic synovial joints such as AA, AO, z-joints, costovertebral, costotransverse joints, and TMJs. (Figure 62.4 through Figure 62.9).

There is a significant overlap in published pain maps from the structures innervated by the DRs. which have been grouped for practical purposes into the dorsal ramus syndrome (DRS). Consequently, in the craniocervicodorsal area, only structures that receive innervation from DRs are considered potential pain generators. However, there are also many structures receiving extrasegmental innervation that do not fit into DRS. The question is, "How to navigate in this sea of unknown?" The physician continuously follows the main objective of RIT, specifically the painful tissue bed as the primary target of investigation, taking the nerve supply into account. For the purpose of RIT, the following step-by-step approach to differential diagnosis is implemented to investigate all potential nociceptors in the distribution of the medial and lateral branches extending it beyond z-joints.

Initially, pain generators are identified by reproducible tenderness and the areas are marked. Tenderness of the posterior structures is an objective finding, especially in the midline (Broadhurst et al., 1996; Hackett et al., 1991; Kayfetz et al., 1963; Linetsky et al., 2002b, 2002c, 2004; Maigne, 1996; Reeves, 2000; Wilkinson, 1992). Confirmation is obtained by needling and local anesthetic blocks of the tissue at the enthesis, taking the nerve supply into account (Figure 62.3 and Figure 62.4).

The C2 spinous process is the most prominent palpable structure of the upper cervical region, and because of bifurcation, it should be addressed from a lateral approach. C6–T2 are the most prominent structures at the cervicodorsal junction (Figure 62.7, Figure 62.8, and Figure 62.10).

In experienced hands, using palpable landmarks for guidance, the following posterior column elements innervated by the dorsal rami may be safely injected without fluoroscopic guidance: enthesis of ligaments and tendons at the spinous processes, from C2 caudad, lamina, posterior zygapophyseal joint capsule, posterior and anterior tubercles of the cervical transverse processes, and cervicodorsal fascia insertions when palpable. Transverse processes of C1 are rarely palpable and sometimes may be injected without fluoroscopy. It is easier to inject them under fluoroscopic guidance during upper cervical synovial joint injections. Fluoroscopy itself does not prevent intravascular or intraneural needle placement.

Lidocaine is usually used for diagnostic purposes. However, the dextrose/lidocaine solution is also an effective initial diagnostic and therapeutic option for pain arising from posterior column elements when used in increments of 0.2 to 1.0 ml injected at each bone contact, initially blocking the terminal filaments of the MBDRs with the sequence as follows:

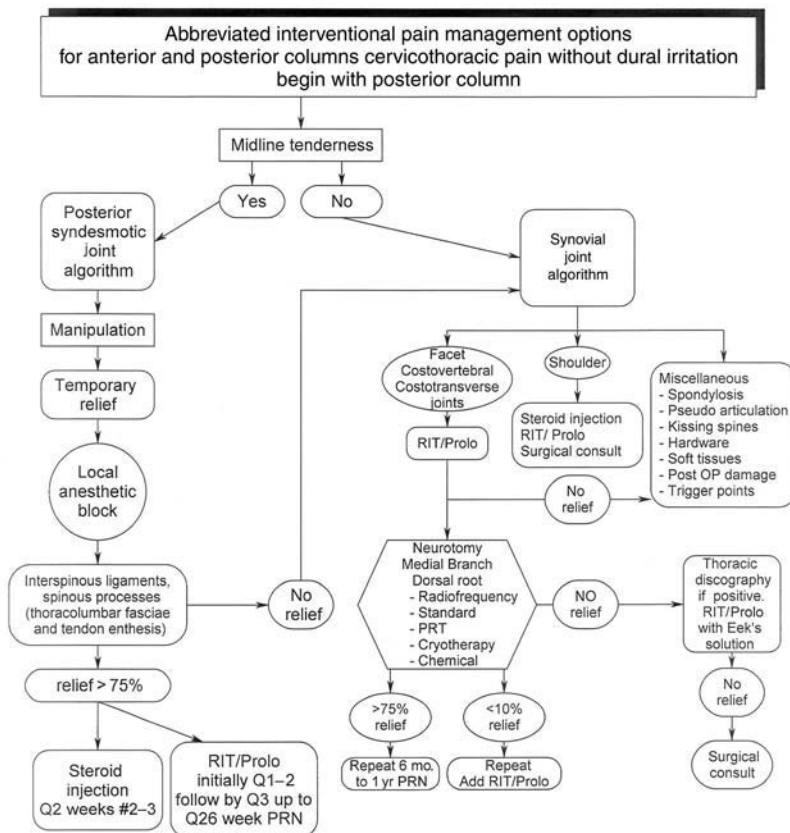
1. In the presence of midline pain and tenderness, the superior aspect of the SP is blocked initially in the midline at the enthesis. This is achieved with the caudal direction of the needle.


FIGURE 62.12 Modified excerpt from "Percutaneous Management Options for Cervical and Thoracic Spinal Pain" by Richard Derby, February 9–10, 2002, in *ISIS 9th Annual Scientific Meeting Syllabus, ISIS Presents: The Guidelines* (pp. 1476–1485), Orlando, FL.

2. If tenderness remains at the lateral aspects and the apices of the SP, then injections are carried out to the lateral aspects and the apices of the SPs, thus continuing on the course of MBDR. However, it should be noted that all cervical, and some thoracic, SPs are asymmetrically bifurcated at their apices. Therefore, the needle direction is from lateral to medial to prevent inadvertent intrathecal injections.

3. Persistence of paramedial pain dictates blocks of the facet joint capsules, costotransverse joints, or posterior tubercle of the transverse processes in the cervical region at their respective enthesis.

4. Perseverance of lateral tenderness dictates investigation of the structures innervated by the LBDR (i.e., iliocostalis tendon insertions to the ribs or structures receiving extrasegmental innervation such as serratus anterior and trapezius).

In this fashion, all of the potential nociceptors on the course of MBDR are investigated from its periphery to the origin. Using the previously described sequence, a differential diagnosis of pain developing from vertebral and paravertebral structures innervated by MBDRs and LBDR is made (Figure 62.3 through Figure 62.9). Modified percutaneous management options for cervical and thoracic spinal pain are a broad algorithm to follow while more specific algorithms are being developed.

Pain from the upper cervical synovial joints presents a diagnostic and therapeutic challenge. Because pain patterns overlap, it usually is a diagnosis of exclusion (Figure 62.12).

Intra-articular, atlanto-axial, and atlanto-occipital joint injections of 3 to 4% phenol in the final injectate have secured a long-lasting therapeutic effect in selected patients (Stanton-Hicks, 2003). Positive therapeutic effects with intra-articular injections of 25% dextrose to the same joints and mid-cervical synovial joints also were reported to relieve persistent pain after radiofrequency and capsular injection failure (O'Neill, 2003). All of the synovial intra-articular injections of the spine should be performed under fluoroscopic guidance.

To prevent complications, the following cardinal rules should be followed:

1. Injections should be made only after the needle contacts the bone and the pain is reproduced by the needle placement(s).

2. The needle should be slightly withdrawn to prevent subperiosteal placement of the injectate.

3. Should the needle fail to contact the bone at the expected depth, it must be withdrawn to the level of superficial fascia and redirected.

4. If blood or cerebrospinal fluid appears in the syringe, the injection should be aborted.

5. Should the needle contact the nerve (this may present itself with lancinating, lightening pain), the procedure should be aborted. If pain remains intolerable, the area should be infiltrated with corticosteroids and local anesthetic.

SOLUTIONS UTILIZED

The most common solution employed for RIT is dextrose 10%, 12.5%, 16.5%, 20%, and 25%. Dilutions are achieved with local anesthetic in 1:4, 1:3, 1:2, 2:5, and 1:1 proportions (i.e., 1 ml of 50% dextrose mixed with 3 ml of 1% lidocaine will produce a final 12.5% dextrose/lidocaine solution) (Hackett et al., 1991; Linetsky, 2002b, 2002c, 2004; Reeves, 1995, 2000).

For intra-articular knee injections, Hemwall recommended a 25% dextrose solution (Hackett et al., 1991). Reeves et al. (2000) have pointed out that a 10% dextrose solution may be equally effective. If this proves ineffective, gradual progression to sodium morrhuate full strength has been described (Dorman et al., 1991; Hackett et al., 1991).

Sodium morrhuate (5%) is a mixture of sodium salts of saturated and unsaturated fatty acids of cod liver oil and 2% benzyl alcohol, which acts as a local anesthetic and a preservative. Note that benzyl alcohol is chemically very similar to phenol.

Dextrose/phenol/glycerin solution, originally produced in England by Boots Company Ltd. of Nottingham, England, for treatment of varicose veins, was introduced to pain management by Ongley et al. (1988). The solution consists of 25% dextrose, 2.5% phenol, and 25% glycerin and is referred to as DPG (or P2G). Prior to injection it is diluted in concentrations of 1:2; 1:1, or 2:3 with a local anesthetic of the practitioner's choice. Some authors exclusively use this solution in 1:1 dilution (Dorman et al., 1991). Others modify it, reducing the percentage of glycerin to 12.5%.

The 6% phenol in glycerin solution was used by Poritt in 1931 and reintroduced in the late 1950s by Maher (1957) of England for intrathecal injections in the treatment of spasticity. Subsequently, after gaining sufficient experience with intrathecal use of this solution, Wilkinson (1992), a neurosurgeon trained at Massachusetts General Hospital, began injecting it at the donor harvest sites of the iliac crests for neurolytic and proliferative responses.

COMPLICATIONS

As with any interventional procedure, complications do occur with RIT, but statistically they are rare. The most recent statistical data are from a survey of 450 physicians performing prolotherapy. In the study, 120 respondents revealed that 495,000 patients received injections. Of the 29 pneumothoraces reported, two of them required chest tube placement; 24 non-life-threatening allergic reactions were also reported. Thus, the occurrence of pneumothoraces requiring chest tube is 1 per 247,500 patients, self-limited pneumothoraces is 1 per 18,333, and allergic reaction is 1 per 20,625. Assuming that each patient receives at least three visits and during each visit receives at least 10 injections, the numbers are relatively miniscule.

In the late 1950s and early 1960s, five cases of post-injectional arachnoiditis were reported (Keplinger et al., 1960). Two of them were fatal (Schneider, 1959; Hunt, 1961). One was a direct sequence of arachnoiditis; another was a sequence of incompetent shunt and persistent hydrocephalus with increased intracranial pressure (Schneider, 1959). Of the three other cases, the first, with mild paraparesis, recovered after a ventriculo-jugular shunt. The second recovered spontaneously with a mild neurological deficit (Hunt, 1961). The third case remained paraplegic (Keplinger et al., 1960). There have been a few recent cases of intrathecal injections not reported in the literature because of medicolegal issues. Two of them resulted in paraplegia. The first occurred after injection at the thoracic level, the second after lumbar injection. A third case was performed by a naturopath who injected solution containing zinc sulfate at the craniocervical level, which resulted in immediate onset of severe neurologic deficit, quadriplegia, and subsequent hydrocephalus.

One case of self-limiting sterile meningitis after lumbosacral sclerosing injections was reported 10 years ago (Grayson, 1994). A more recent report described a case of adjacent end plate fractures associated with intradiscal dextrose injections (Whitworth, 2002). Post-spinal puncture headaches are common, especially after lumbosacral injections (Yelland et al., 2003). Two such cases have occurred in Dr. Linetsky's practice during the past 14 years. Patients recovered after 1 week with bed rest and fluids without sequelae. Among the overall rare complications, pneumothoraces are the most common, occurring during injections of the costovertebral; costotransverse articulations; insertions of the tendons to the ribs such as iliacostalicis, serratus posterior, superior, and inferior, scalene insertions to the ribs, and levator and rhomboid insertions to the scapula especially in very muscular or significantly overweight patients. Anterior synovial joint injections, such as sternoclavicular, costosternal, and interchondral, may also result in pneumothorax in the same subset of patients.

CONCLUSIONS

As stated recently by Dr. Mooney, this treatment has advanced "from the fringe to the frontier of medical care" (Mooney, 2003).

1. RIT/prolotherapy is a valuable method of treatment for correctly diagnosed, chronic painful conditions of the locomotive systems.
2. Thorough familiarity of the physician with normal, pathologic, cross-sectional, and clinical anatomy, as well as anatomical variations and function is necessary.
3. Current literature supports manipulation under local joint anesthesia.
4. The use of RIT in an ambulatory setting is an acceptable standard of care in the community.
5. The current literature suggests that NSAIDs and steroid preparations have limited utility in chronic painful overuse conditions and in degenerative painful conditions of ligaments and tendons. Microinterventional regenerative techniques and proper rehabilitation up to 6 months or a year, supported with mild opioid analgesics, are more appropriate.

The future is such that, instead of indirect stimulation of growth factors through inflammatory cascade, specific growth factors will become available. The challenge will remain as to what specific growth factors to utilize. Most probably, a combination of several growth factors will be utilized, together with specific genes responsible for production of these growth factors. It appears that the delivery mode will be injections for deep structures; however, superficial structures will probably be addressed through transdermal delivery systems (Cook, 2000; DesRosiers et al., 1996; Kang et al., 1999; Lee et al., 1998; Marui et al., 1997; Nakamura et al., 1998; Reeves, 1995, 2000; Rudkin et al., 1996; Spindler et al., 1996).

Physicians versed in manipulation as well as diagnostic and therapeutic injection techniques as described in this chapter may find ample opportunity to use RIT in their pain management practice.

PRACTICAL SUGGESTIONS

Though Hackett's textbook is used by many as a primary source of information, even the 1991 edition is rudimentary and does not adequately explain the differential diagnosis. Standard anatomical texts are not current regarding innervation; therefore, it behooves physician to familiarize themselves with referral pain patterns and review clinical anatomy from primary sources referenced in this chapter. RIT/prolotherapy is not a panacea but another powerful tool in the armamentarium of many interventional procedures.

Readers interested in incorporating RIT/prolotherapy in their pain management practice may attend the courses and workshops conducted by The Florida Academy of Pain Medicine (http://fapm.med.new.net) and The American Association of Orthopedic Medicine (www.aaomed.org).

Cervical Facet Joint Interventions

Laxmaiah Manchikanti, MD, David M. Schultz, MD, and Vijay Singh, MD

INTRODUCTION

Among chronic pain complaints, pain arising in the cervical spine is one of the most common problems. The lifetime prevalence of spinal pain from the cervical spine has been reported as 65 to 80%.[1–14] Further, chronicity of neck pain has been demonstrated with chronic persistent pain resulting in 26 to 44% of the patients after an initial episode of neck pain or whiplash.[12–16] The prevalence of persistent neck pain due to the involvement of cervical facet joints has been described in controlled studies as varying from 54 to 67%.[17–21]

HISTORY

While Goldthwait[22] described lumbar facet joints as potential sources of back pain in 1911, it was not until 1977 that Pawl[23] reported the reproduction of pain in patients with neck pain and headache after injections of hypertonic saline into the cervical facet joints. However, cervical facet joints attracted relatively little attention as possible sources of neck pain and referred pain in the upper extremities in the late 1970s and early 1980s. Bogduk and Marsland[24] studied the role of cervical facet joints in causation of idiopathic neck pain by using diagnostic cervical medial branch blocks and facet joint injections. Dwyer et al.[25] mapped out specific locations of referred neck pain by performing facet joint injections in normal volunteers while Aprill et al.[26] confirmed the accuracy of the pain chart reported by them earlier following anesthesia of the medial branches of the dorsal rami above and below the symptomatic joint. Fukui et al.[27] also studied the referred pain distribution of cervical facet joints and cervical dorsal rami with similar results. Windsor et al.[28] investigated

electrical stimulation–induced cervical medial branch referral patterns. They concluded that electrical stimulation of the third occipital nerve, as well as the medial branch of the C3–C8 posterior primary rami, produced discrete reproducible referral patterns, which differ from those reported from other causes of neck pain.

PREVALENCE

Cervical facet joints have been shown to be capable of being a source of pain in the neck and referred pain in the head and upper extremities.[23–28] Based on responses to controlled diagnostic blocks of cervical facet joints in accordance with the criteria established by the International Association for the Study of Pain,[29] the prevalence of cervical facet joint pain has been shown to be 54 to 67% in patients with chronic neck pain.[17–21]

PATHOPHYSIOLOGY

As with any synovial joint, degeneration, inflammation, and injury of facet joints can lead to pain upon joint motion. Pain leads to restriction of motion, which eventually leads to overall physical deconditioning. Irritation of the facet joint innervation in itself also leads to secondary muscle spasm. It has been assumed that degeneration of the disc would lead to associated facet joint degeneration and subsequent spinal pain. These assumptions were based on the pathogenesis of a degenerative cascade in the context of a three-joint complex that involves the articulation between two vertebrae consisting of the intervertebral disc and adjacent facet joints, as changes within each member of this joint complex will result in changes

in others.[30–32] Many of the studies during the past 30 to 40 years have proposed that disc degeneration initiates degenerative changes in the facet joints by altering the mechanical function of the entire motion segment.[33] Further, facet joints have been implicated as responsible for chronic neck pain, headache, and upper extremity pain.

DIAGNOSTIC FACET JOINT BLOCKS

Blocks of a cervical facet or zygapophysial joint can be performed to test the hypothesis that the target joint is the source of the patient's pain.[34–36] Cervical facet joints can be anesthetized either with intra-articular injections of local anesthetic or by anesthetizing the medial branches of the dorsal rami that innervate the target joint. True-positive responses are secured by performing controlled blocks, in the form of either placebo injections of normal saline or comparative local anesthetic blocks, in which on two separate occasions, the same joint is anesthetized but using local anesthetics with different durations of action. However, an injected capsule may leak into the adjacent neural foramen and result in blockade of the dorsal root ganglion and segmental nerves, and produce a false-positive result.

The rationale for using facet joint blocks for diagnosis is based on the fact that cervical facet joints have been shown to be capable of being a source of neck pain and referred pain in the head and upper extremities. Consequently, facet joints are possible sources of pain in patients presenting with neck pain and referred pain. Historical and clinical features may be indicative, but not diagnostic of facet joint pain. However, there is no definitive valid indicator or clinical means to implicate cervical facet joints as the source of neck pain, headache, or upper extremity pain in a given patient. Numerous attempts by investigators to correlate neurophysiologic findings, radiologic findings, physical findings, and other signs and symptoms with the diagnosis of facet joint pain have been unsuccessful.[1] Thus, controlled diagnostic blocks with two separate local anesthetics or placebo-controlled blocks are the only means of confirming the diagnosis of facet joint pain in the neck.

Indications for diagnostic blocks are also based on the strong evidence demonstrating the reliability of cervical facet joint nerve blocks in the diagnosis of neck pain, upper extremity pain, and headaches.[1,34–36] The face validity of intra-articular injections and medial branch blocks is demonstrated under fluoroscopic visualization by determining the spread of contrast medium to confirm proper needle placement, then by injecting a small volume of local anesthetic.[37] Construct validity of facet joint blocks, which is an extremely important aspect to rule out placebo effect, also has been demonstrated.[38] Further, the theory that testing a patient first with lidocaine and subsequently with bupivacaine provided a means of identifying placebo

TABLE 63.1
Common Indications for Cervical Diagnostic Facet Joint Blocks

- Somatic or nonradicular neck and/or upper extremity pain
- Cervicogenic headache and/or upper back pain
- Lack of obvious evidence for discogenic pain
- Lack of disc herniation or evidence of radiculitis
- Duration of pain of at least of 3 months
- Failure to respond to more conservative management, including physical therapy modalities with exercises, chiropractic management, and nonsteroidal anti-inflammatory agents
- Average pain levels of greater than 5 on a scale of 1 to 10
- Intermittent or continuous pain causing functional disability
- No contraindications with understanding of consent, nature of the procedure, needle placement, or sedation
- No history of allergy to contrast administration, local anesthetic steroids, Sarapin, or other drugs potentially used
- Contraindications or inability to undergo physical therapy or chiropractic management or inability to tolerate nonsteroidal anti-inflammatory drugs

response has been tested and proved.[39–42] The reported false-positive rates of single facet joint blocks in the cervical spine have been demonstrated to be 27 to 63%.[19,20,43,44]

Indications for diagnostic facet joint blocks include neck pain, for which no cause is otherwise evident, and for which pain patterns resemble those evoked in normal volunteers upon stimulation of the facet joints. Table 63.1 illustrates indications for diagnostic cervical facet joint injections, whereas Table 63.2 indicates contraindications.

Contraindications are quite obvious and include bacterial infection, possible pregnancy, and bleeding diathesis. Relative contraindications include allergy to contrast media or local anesthetics and treatment with non-aspirin anti-platelet drugs, which may compromise coagulation. Raj et al.[45] provided a detailed description on the role of anticoagulants in interventional pain management.

TABLE 63.2
Common Contraindications for Cervical Facet Joint Blocks

- Infection
- Arnold Chiari malformation
- Inability of the patient to understand consent, nature of the procedure, needle placement, or sedation
- Allergies to contrast, local anesthetic, steroids, Sarapin, or other drugs
- Needle phobia
- Psychogenic pain
- Suspected discogenic pain or disc herniation
- Pregnancy
- Anticoagulant therapy
- Non-aspirin anti-platelet therapy
- Bleeding diathesis

THERAPEUTIC INTERVENTIONS

A significant role has been described for therapeutic facet joint injections, either intra-articular or by medial branch blocks in addition to medial branch neurotomy.[1] However, the evidence is poor for short-term, as well as long-term relief for intra-articular blocks of cervical spine based on one randomized controlled trial.[46] Manchikanti et al.[1] extensively reviewed the literature in preparing evidence-based guidelines for managing spinal pain. They concluded that except for the one negative randomized trial for intra-articular injections, there were no other non-observational trials qualifying to be included for evidence synthesis.

In addition to the intra-articular blocks, medial branch blocks have been used for therapeutic purposes in the cervical spine. One recent prospective, nonrandomized, observational study[47] showed significant effectiveness of medial branch blocks in managing chronic neck pain.

In addition to intra-articular cervical facet joint blocks and medial branch blocks, medial branch neurotomy has been described with well-controlled trials. The effectiveness of medial branch neurotomy has been described in case reports, observational studies, randomized trials, and systematic reviews, though yielding mixed results.[1,48–54]

ANATOMIC CONSIDERATIONS

The cervical facet joints are paired, diarthrodial, synovial joints located between the superior and inferior articular pillars in the posterior cervical column.[55] While cervical facet joints extend from C2/3 to C7/T1, the atlanto-occipital and atlanto-axial synovial joints are also present in the cervical spine. However, these are not considered facet joints. Cervical facet joints exhibit the features of typical synovial joints. The articular facets are covered by articular cartilage and a synovial membrane bridges the margins of the articular cartilage of the two facets in each joint.[56,57] Further, these joints, along with a meniscus, may contain a variety of intra-articular inclusions, with fibroadipose meniscoids the most common inclusions. The fibrous joint capsule is richly innervated with mechanoreceptors, as well as nociceptors.[58–60] The cervical facet joint surfaces are essentially planar and slope backward and downward. The articular surfaces of facet joints in the cervical spine are generally flat with only minimal concavity and convexity.[61] The obliquity of cervical facet joints averages about 45° but is flatter at C2/3 and steeper at C6/7.[62] The C2/3 joint is more oblique in its orientation than its adjacent counterpart. Thus, the inclination of lower joints is steeper.[63] The average joint volume is less than 1 mL.[25]

Cervical facet joints are well innervated by the medial branches of the dorsal rami.[35,37,64–67] The cervical facet joints below C2/3 are supplied by medial branches of the cervical dorsal rami above and below the joint, which also innervate the deep paramedian muscles. The C2/3 joint is supplied by the third occipital nerve.[37,68] However, innervation of the atlanto-occipital and atlanto-axial joints is derived from the C1 and C2 roots, respectively.[37,68,69] Each C3 to C7 dorsal ramus crosses the same segments transverse process and divides into lateral and medial branches. The medial branch curves around the waist of the articular pillar of the same numbered vertebra. The medial branch nerves are bound by fascia, held against the articular pillar, and covered by the tendinous slips of the origin of the semispinalis capitus.[65]

The vertebral artery ascends through the cervical transverse foramina of C1 to C6, which is located anteriorly. At C2 to C7, it is located anterior to the facet joints from both posterior and lateral injection approaches. However, the vertebral artery passes directly superior in the neck to the level of the transverse process of the axis, where it courses upward and laterally to the transverse foramina of the atlas.[70]

TECHNICAL CONSIDERATIONS

INTRA-ARTICULAR INJECTIONS

Even though they were described later than lumbar facet joint blocks, numerous techniques have been described for the cervical spine. In 1980 Sluijter and Koetsveld-Baart[71] described a technique for blocking the cervical dorsal rami near their origin and a percutaneous radiofrequency technique to coagulate these nerves. In 1988 Bogduk and Marsland[24] described cervical medial branch blocks distal to the target sites used by Sluijter and Koetsveld-Baart[71] in 1988. Okada[72] in 1981 introduced intra-articular cervical facet joint blocks using a lateral approach. Dory[73] described a posterior approach based on a pillar view of the cervical facet joints. Subsequently, others[74–77] have described intra-articular cervical facet joint blocks.

Cervical facet joint injections may be performed using posterior, lateral, or anterior approaches. The posterior approach is the most commonly used method, followed by the lateral approach. Hence, we describe both techniques.

Posterior Intra-Articular Blocks

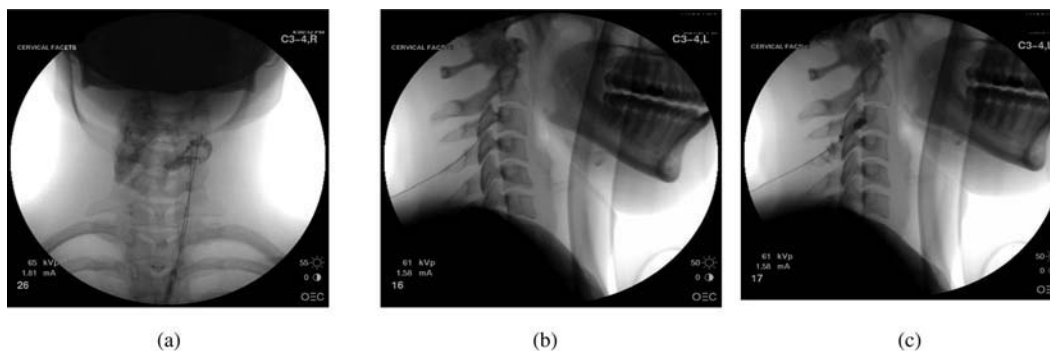
The posterior approach for cervical intra-articular blocks can be performed with the patient in a prone position, or if required, in a sitting position. It involves introducing a 22- or 25-gauge needle into the target joint from behind, along an oblique trajectory that coincides with the plane of the joint. Commonly, the patient is positioned in the prone position on an operating room table with a cushion under the chest and the neck rotated to the opposite side. Under aseptic conditions, the skin entry is carried out


FIGURE 63.1 Intra-articular needle placement with a posterior approach. (a) C3/4 anteroposterior view; (b) C3/4 needle placement lateral view; (c) C3/4 arthrogram lateral view.

approximately two or more segments below the target joint. The skin entry point may be determined either by directing an imaginary line to the skin along the plane of the joint (as determined by a lateral view) or by direct visualization of the joint via a pillar view and making a skin mark along the plane of the X-ray beam into the center of the joint lucency.[78]

The needle is passed with caution through the skin at approximately a 45° angle upward and ventrally through the posterior neck muscles until it makes the contact with the back of the target joint. At this point, the needle may be readjusted until it enters the joint cavity. One should be aware that directing the needle medially toward the interlaminar space or excessively laterally away from the joint will make the injection extremely difficult and dangerous. After satisfactory localization of the needle into the joint, contrast medium is injected to obtain an arthrogram and to verify accurate placement and then to inject local anesthetic and/or corticosteroid is injected. Figure 63.1 illustrates intra-articular needle placement with a posterior approach.

Overall, the posterior approach is considered safer because the needle penetrates only the skin and posterior neck muscles, with the deep cervical artery the only structure at risk of inadvertent puncture. Further, the posterior cervical artery poses minimal risk of morbidity, as it supplies no major structures. However, if the needle is inserted too deeply or too aggressively, it could penetrate the anterior joint capsule. Further, the risk is not only leakage of local anesthetic and steroid over to the dorsal root ganglion, but also the risk of puncture to the vertebral artery or ventral ramus of the spinal nerve lying in front of the joint. In addition, the needle may also enter the epidural space or spinal cord.

Lateral Intra-Articular Blocks

Proponents of the lateral approach argue that it is technically less demanding and may be performed with smaller-gauge needles.[25,72] In addition, it may be more comfortable for the patient because less soft tissue is traversed. Similar

to the posterior approach during insertion, the risk of morbidity is minimal because only the skin and postero-lateral neck muscles are penetrated with no other overlying structures at risk of puncture. However, an aggressive approach or overpenetration may lead the needle into the epidural space or spinal cord.

The lateral approach to the cervical facet joints is performed with the patient lying on his/her side. The target joint is identified on lateral screening of the neck and the needle is introduced through the skin over the midpoint of the joint. It is advanced deeply until it makes contact with the bone of either the superior or inferior articular process. Lateral fluoroscopic imaging identifies the left and right joints simultaneously. The object is to identify the image of the target joint, which lies uppermost in the patient. This may also be confirmed by insertion of the needle after it contacts the bone. Once the correct joint is clearly identified, the needle is advanced until the superior articular process is contacted just above the joint line. The needle is then directed and advanced through the joint capsule. The needle may be felt to pierce the capsule and to enter the joint space. Only minimal penetration is required and the operator may also notice loss of resistance as the needle pierces the capsule. The appropriate position into the joint may be confirmed either by injection of a small dose of contrast medium to obtain an arthrogram or by multiple x-ray views.

The C2/3 joint may be technically more difficult to visualize and more difficult to cannulate, due to anatomic features. The C2/3 joint is more angulated vertically and medially and is not clearly evident on lateral views. In such cases, the approach may be modified by rotating the patient's head to face the table. This will accentuate the cavity of the C2/3 joint into view as it rotates forward of the long axis of the vertebral column. Other modifications with the fluoroscopic unit may also be made. Figure 63.2 illustrates intra-articular placement with a lateral approach.

It is of paramount importance that low volumes be injected into the cervical facet joints. If volumes of

FIGURE 63.2 Intra-articular placement of C2/3 with a lateral approach.

more than 1 mL are injected, or injection is carried out rapidly or forcefully, the joint capsule may rupture and result in spread onto nearby structures. Extra-articular spread is extremely important, specifically when the diagnostic blocks are performed, as this will compromise the specificity.

MEDIAL BRANCH BLOCKS

The cervical facet joints can be anesthetized by blocking the nerves that supply them, namely, medial branches of the cervical dorsal rami. Table 63.3 illustrates the nerves to be blocked for each joint. The target points for these nerves, other than the third occipital nerve, are the crossing points of the waists of the articular pillars — a point proximal to the origin of the articular branches and a point where the nerves have a constant relationship to the bone.[34,78] These points may be reached by needles using a posterior, lateral, or anterior approach. Posterior and lateral approaches are the commonly used techniques.

Posterior Approach

The patient is placed in prone position with a pillow under the chest with the head turned opposite to the procedure site; turn head left for a right side procedure, and right for a left side procedure. Under sterile conditions and fluoroscopic visualization, a posteroanterior view is obtained to identify the posterior aspect of the waists of the articular pillars from C3 to C7. In some patients, the articular pillars of the superior cervical spine (C3 and C4) may be difficult to identify, specifically with the patient's head in neutral position. Turning the head to the opposite side will facilitate this. An additional maneuver may be to ask the patient to open the mouth to remove the mandible from the radiologic field. After identification of the waists of the articular pillars of the levels to be blocked, a 22- or 25-gauge, 2 or 2.5 inch spinal needle is inserted through the skin and posterior neck muscles aiming first for the dorsal aspect of the articular pillar medial to its lateral concavity. Once the needle has made the contact with the bone, it is readjusted laterally to the deepest of this concavity where C3 to C7 medial branches lie. Initially, directing the needle medially to bone ensures that the needle is not placed too deeply. The needle is then directed laterally until the tip reaches the lateral margin of the waist of the articular pillar. The needle should be felt to barely slip off the bone laterally in a ventral direc-

TABLE 63.3
Facet Joint Nerves Required to Be Blocked for Each Facet Joint in Cervical Region

Facet Joint	Facet Joint Nerves to be Blocked	Level of Transverse Process
C2/3	Third occipital nerve or C2 and C3 medial branches	At C2/3 joint
C3/4	C3 and C4 medial branches	At C3 and C4 articular pillars
C4/5	C4 and C5 medial branches	At C4 and C5 articular pillars
C5/6	C5 and C6 medial branches	At C5 and C6 articular pillars
C6/7	C6 and C7 medial branches	At C6 and C7 articular pillars
C7/T1	C7 and C8 medial branches	At C7 articular pillar, and at T1 transverse process for C8
FIGURE 63.3 Medial branch blocks with posterior approach. (a) Needle placement posteroanterior (PA) view; (b) needle placement lateral view.

tion at the deepest point of articular pillars concavity (Figure 63.3).[78]

Lateral Approach

For the lateral approach, the patient is positioned on his/her side and the needle is directed through the skin and posterolateral neck muscle toward the centroid of the articular pillar as seen on a true lateral radiograph.[78] If necessary, the uppermost articular pillar can be distinguished from the opposite side either by moving the fluoroscope or by rolling the patient. The needle will be seen to travel with the uppermost articular pillar as the two articular pillars separate on the fluoroscopic image. This approach is well suited for C3 to C6 medial branches.[78] However, the lateral approach for C7 medial branch is somewhat different.

To block the C7 medial branch by lateral approach, the needle is advanced so that it stays within the confines of the C7 superior articular process, which prevents excessive advancement into the C8 foramen and toward the vertebral artery.[78] Once the superior articular process is contacted, anteroposterior imaging should verify that the needle lies against the lateral aspect of the superior articular process. Figure 63.4 illustrates medial branch blocks with a lateral approach.

With posterior and lateral approaches, contrast in doses of 0.1 to 0.2 mL may be injected to confirm appropriate needle placement. However, it is not mandatory. After the confirmation of the needle position, local anesthetic in small doses with or without steroids is injected around the nerve.

Cervical medial branch blocks are extremely safe. Other than general risks associated with cervical injections, including fluoroscopic exposure, infection, needle trauma, etc., no specific complications are reported. The safety lies in the fact that these blocks are performed on the external surface of the vertebral column well away from any vital structures.

Local anesthetic injection for intra-articular injections, as well as medial branch blocks, should be limited

FIGURE 63.4 C3, C4 medial branch blocks with a lateral approach.

to 0.5 mL (0.3 to 0.6 mL) for a diagnostic block and approximately 1 mL for a therapeutic block. Authors[17,18,34] pioneering the concept of comparative local anesthetic blocks recommended potent local anesthetics such as 4% lidocaine and 0.75% bupivacaine to minimize the risk of false-negative medial branch blocks, which can occur at a 10% rate with 2% lidocaine in lumbar spine. Further, for diagnostic as well as therapeutic blocks, the literature has been limited to using local anesthetic agents of different durations of action, namely, lidocaine and bupivacaine. Manchikanti et al.[1,19–21] in multiple investigations used concentrations of lidocaine of 1% and bupivacaine of 0.25%, in contrast to 4% lidocaine and 0.75% bupivacaine as recommended by others, without compromising validity of diagnostic blocks and responsiveness to therapeutic blocks.

MEDIAL BRANCH NEUROTOMY

Radiofrequency lesioning is performed using either a heat lesion or pulsed mode radiofrequency. A thermal radio-

frequency neurotomy lesion for facet denervation is performed at 80 to 85°C. A radiofrequency lesion is performed when the temperature exceeds 45°C. Clinically, a higher temperature allows for a larger lesion to be made. The size of the lesion is influenced by the vascularity of the surrounding tissue. The greater the vascularity of the tissue, the smaller the lesion. Top mode equilibrium is achieved in about 60 seconds. The pulsed mode radiofrequency is an application of a strong electric field to the tissue that surrounds the electrode and the temperature of the tissue surrounding the tip of the electrode does not exceed 42°C. Essentially, the radiofrequency current is applied in a pulsed fashion and heat is dissipated during the silent period.[79]

Most commonly, radiofrequency thermoneurolysis of the cervical medial branches is performed in prone position, even though some clinicians use a supine or an oblique approach. Prone position is considered an optimal position providing maximal parallel needle placement to the target nerves with the least complication profile.

In the prone position, exposure to the medial branches is obtained as described earlier. The needles are placed directly down the beam into the target waist of the articular pillar that corresponds to the same numbered target nerve. Some have recommended that two to three lesions be made to account for superior to inferior nerve position variability. With this, the needle is placed at the middle of the articular pillar in a cephalad-to-caudad plane and then additional lesions can occur. One lesion is one radiofrequency needle diameter superior and the other is one radiofrequency needle diameter inferior. As many as six lesions have been performed.

SAFETY AND COMPLICATIONS

Complications from intra-articular injections or medial branch blocks in the cervical spine are exceedingly rare.[1,17–21,23–26,34,42–44,46,64,75–90] However, disastrous complications with cervical facet joint injections may occur. The complications include those related to the technique with placement of the needle and complications related to the administration of various drugs. Proximity to the vertebral artery and spinal cord, along with nerve root ganglion, make these injections highly vulnerable. Complications may include dural puncture, spinal cord trauma, subdural injection, neural trauma, injection into the intervertebral foramen and intervertebral formation; intravascular injection into the veins or, in a worst-case scenario, vertebral artery; infectious complications including epidural abscess and bacterial meningitis; and side effects related to the administration of steroids, local anesthetics, and other drugs. Vertebral artery and ventral ramus damage, along with a risk of embolus resulting in serious neurological sequelae with spinal cord damage and cerebral

infarction, is an exceedingly rare but potential complication with cervical facet joint injections.

Other, minor complications include lightheadedness, flushing, sweating, nausea, hypotension, syncope, pain at the injection site, and headaches. Side effects related to the administration of steroids are generally attributed to the steroid's chemistry or the pharmacology of the steroids.[80] These include separation of pituitary-adrenal access, hypocorticism, Cushing syndrome, osteoporosis, avascular necrosis of the bone, steroid myopathy, epidural lipomatosis, weight gain, fluid retention, and hypoglycemia.

Reported complications of radiofrequency thermoneurolysis include a worsening of the usual pain, burning or dysesthesias, decreased sensation and allodynia in the paravertebral skin or the facets denervated, transient leg pain, persistent leg weakness, and inadvertent lesioning of the spinal nerve or ventral ramus resulting in motor deficits, sensory loss, and possible deafferentation pain.[79] A spinal cord lesion can lead to paraplegia; loss of motor, proprioception, and sensory function; bowel and bladder dysfunction; Brown-Séquard syndrome; and spinal cord infarction.

CONCLUSION

Cervical facet joints are commonly identified as the cause of neck pain, upper extremity pain, and headaches. Cervical facet joint blocks can be performed to test the hypothesis that the target joint is the source of the patient's pain. The rationale for using facet joint blocks for diagnosis, as well as therapy, is based upon the facts that cervical facet joints have been shown to be capable of being a source of neck pain and referred pain in the head and upper extremities; cervical facet joint pain may not be diagnosed based on referral patterns, physical examination, history, neurophysiologic testing, or radiological evaluation; diagnostic cervical facet joint blocks have been shown to be highly valid and specific; degenerative process of the cervical spine and the origin of cervical spine is extremely complex; and the effectiveness of a large variety of therapeutic interventions in managing chronic pain arising from the cervical spine has not been demonstrated conclusively.

The validity of diagnostic facet joint blocks has been demonstrated conclusively. However, the value of therapeutic intra-articular joint injections is limited, the value of medial branch nerve blocks is moderate, and the value radiofrequency neurotomy is strong.

Thoracic Facet Joint Interventions

Laxmaiah Manchikanti, MD, David M. Schultz, MD, and Vijay Singh, MD

INTRODUCTION

Thoracic facet joints have been implicated as the source of chronic pain in 45 to 48% of patients with chronic thoracic pain.[1,2] These figures were based on responses to controlled diagnostic blocks of these joints, in accordance with the criteria established by the International Association for the Study of Pain.[3] The role of thoracic facet joints in chronic upper or mid back pain has received very little attention with only a few publications discussing these joints as the source of pain.[1,2,4–11] Even though thoracic spinal pain is less common, it can be as chronic and disabling as neck and low back pain. In the interventional pain management environment, the proportion of patients with thoracic disorders is relatively small, ranging from 3 to 22%.[12,13] Linton et al.[14] estimate the prevalence of all spinal pain in the general population as 66%, with 15% reporting thoracic pain, 44% reporting neck pain, and 56% reporting low back pain.

HISTORY

Diagnosis of thoracic facet joint pain is a relatively recent development. Involvement of lumbar facet joints in low back pain had been described by Goldthwait[15] as early as 1911. In 1927, the Italian surgeon Putti[16] published an article on articular facet degeneration as a cause of pain that supported the findings of Goldthwait. In 1963, Hirsch et al.[17] demonstrated that low back pain could be induced by injecting hypertonic saline in the region of facet joints. Pawl,[18] in 1977, reported the reproduction of neck pain and headache after injection of hypertonic saline into the cervical facet joints. However, thoracic facet syndrome was not described until 1987.[7] Subsequently, further men-

tions were made about thoracic facet joint pain in 1991.[6] In 1994, Dreyfuss et al.[4] described thoracic zygapophysial joint pain patterns in normal volunteers.

ANATOMY

The facet joints are paired diarthrodial articulations between the posterior elements of the adjacent vertebrae.[19,20] The facet joints are formed by the articulation of the inferior articular processes of one vertebra with the superior articular processes of the next vertebra. The joints exhibit the features of typical synovial joints. The articular facets are covered by articular cartilage, and a synovial membrane bridges the margins of the articular cartilage of the two facets in each joint.

In the thoracic region, the articular surface of the joints is inclined 60° from the horizontal to the frontal plane and rotated 20° from the frontal to the sagittal plane in a medial direction. Thus, the lateral aspect of the joint is placed anterior and the medial aspect of the joint posterior.[21,22] The superior articular facet from the inferior vertebrae is almost flat and faces posterior, superior, and slightly lateral. The inferior articular facet is oriented in a reciprocal manner. There is some variation in the inclination of the joints by region with the midthoracic level approximately 60° off the horizontal plane, while the upper segments achieve a more vertical orientation. The lower thoracic segments show some characteristics of the lumbar segments as their angle approaches the sagittal plane.[23]

A tough fibrous capsule composed of several layers of fibrous tissue and a synovial membrane, separated by a layer of loose alveolar tissue, is present on the posterolateral aspect of the facet joint. However, there is no

fibrous capsule on the ventral aspect of the joints. Instead, in its place the ligamentum flavum is in direct contact with the synovial membrane. Facet joints appear to be anatomically designed to restrain excessive mobility and distribute axial loading over a broad area.

Thoracic facet joints are innervated from branches of the thoracic dorsal rami arising from the spinal nerves. Chua and Bogduk[24] showed that the medial branches of the thoracic dorsal rami were found to assume a reasonably constant course except at mid-thoracic levels (T5–T8). They showed that the medial branches of the thoracic dorsal rami at mid-thoracic levels do not run on bone. Instead, they are suspended in the intertransverse space. They also reported that thoracic medial branches are not that close to the facet joint, as they swing laterally to circumvent the multifidus. Free nerve endings have been demonstrated in the capsules of the facet joints. In an analogy to the innervation of the cervical and lumbar facet joints, the thoracic facet joints receive a bisegmental innervation from the medial branches of the dorsal ramus of the upper segment and one or more cephalad levels.[24,25]

PATHOPHYSIOLOGY

Degeneration, inflammation, and injury of facet joints can lead to pain upon joint motion, leading to restriction of motion secondary to pain, which eventually leads to overall physical deconditioning and irritation of the facet joint innervation in itself, leading to secondary muscle spasm. It has been assumed that degeneration of the disc would lead to associated facet joint degeneration and subsequent spinal pain. These assumptions are based on the pathogenesis model of a degenerative cascade involving the three joint complex of a spinal motion segment consisting of the intravertebral disc and the two adjacent facet joints that make up the articulation between two vertebrae. Changes within one member of this joint complex will result in changes within the other members. This model should apply to cervical and thoracic as well as lumbar spinal segments.[26] However, this hypothesis was shown to be realistic in post-traumatic neck pain, and opposite conclusions were reached in low back pain.[27,28] Causes such as rheumatoid arthritis and ankylosing spondylitis, small fractures, capsular tears, splits in the articular cartilage, hemorrhage, osteoarthritis, meniscoid entrapment, synovial impingement, joint subluxation, chondromalacia, capsular and synovial inflammation, excessive mechanical injury to the joint capsule, and restriction to normal articular motion from various causes, synovial cysts, and infection have been described as sources of facet joint pain. However, radiographic changes of osteoarthritis have been shown to be equally common in patients with and without low back pain, and degenerative joints seen on computed tomography (CT) are not always painful, even though some studies report severely degenerated joints are more likely to be symptomatic.

Thoracic facet joint pain is considered relatively uncommon compared with pain from the lumbar and cervical spine. Van Kleef et al.[29] showed that thoracic pain was the presenting symptom in 12% of new patients attending a pain clinic in the Netherlands.

DIAGNOSIS

There is no evidence that thoracic facet joint pain can be diagnosed by clinical examination or by medical imaging.[30] The principles established for facet joint blocks utilizing controlled comparative local anesthetic blocks are the only means available to identify facet joint pain in the thoracic region. These joints can be blocked either by intra-articular injections or by anesthetizing the medial branches of the dorsal rami that innervate the target joint.

The rationale for using thoracic facet joint blocks for diagnosis is based on the fact that the thoracic facet joints have been shown to be capable of being a source of mid or upper back pain and referred pain into the chest wall in normal volunteers. Consequently, thoracic facet joints are possible sources of pain in patients presenting with mid back or upper back pain. There are no historical or clinical features that are pathognomonic for thoracic facet joint pain. Attempts by investigators to correlate demographic features, pain characteristics, physical findings, and other signs and symptoms with the diagnosis of facet joint pain in the cervical and lumbar spine have been proved to be unreliable. In addition, imaging technologies do not provide valid or reliable means of identifying symptomatic lesions. Thus, controlled diagnostic blocks with two separate local anesthetics (standard practice within the United States) or placebo-controlled blocks (standard practice in Australia and certain other countries) are the only means of confirming a diagnosis of facet joint pain. The diagnostic accuracy of controlled local anesthetic facet joint blocks has been reviewed and was determined to be high in the diagnosis of chronic low back pain and neck pain.[30,31]

The face validity of intra-articular injections for medial branch blocks has been established by injecting small volumes of local anesthetic into the joint or onto the target points of the nerve. Construct validity of facet joint blocks is determined by removing the placebo effect with controlled comparative local anesthetic blocks.[30,31] The indications and contraindications[32] for diagnostic facet joint blocks are described in Table 64.1 and Table 64.2.

Contraindications are quite obvious and include bacterial infection, possible pregnancy, and bleeding diathesis. Relative contraindications include allergy to contrast media or local anesthetics and treatment with non-aspirin antiplatelet therapy, which may compromise coagulation.[33,34] Patients on warfarin therapy should be checked

TABLE 64.1
Common Indications for Diagnostic Thoracic Facet Joint Blocks

- Somatic or nonradicular mid or upper back pain
- Lack of obvious evidence for discogenic pain
- Lack of disc herniation or evidence of radiculitis
- Duration of pain of at least of 3 months
- Failure to respond to more conservative management, including physical therapy modalities with exercise, chiropractic management, and nonsteroidal anti-inflammatory agents
- Average pain levels of greater than 5 on a scale of 1 to 10
- Intermittent or continuous pain causing functional disability
- No contraindications with understanding of consent, nature of the procedure, needle placement, or sedation
- No history of allergy to contrast administration, local anesthetic steroids, Sarapin, or other drugs potentially utilized
- Contraindications or inability to undergo physical therapy or chiropractic management or inability to tolerate nonsteroidal anti-inflammatory drugs

TABLE 64.2
Common Contraindications for Thoracic Facet Joint Blocks

- Infection
- Inability of the patient to understand consent, nature of the procedure, needle placement, or sedation
- Allergies to contrast, local anesthetic, steroids, Sarapin, or other drugs
- Needle phobia
- Psychogenic pain
- Suspected discogenic pain or disc herniation
- Pregnancy
- Anticoagulant therapy
- Non-aspirin antiplatelet therapy
- Bleeding diathesis

for prothrombin time (PT), and it should be at acceptable levels. In stopping anticoagulant therapy, one should take into consideration the risk/benefit ratio and also consult with the physician in charge of anticoagulant therapy. In our practice, we advise the patients to contact the physician in charge of anticoagulant therapy and let that physician make the decision of the date to stop, and for how long. Raj et al.[33] provide a detailed description of the role of anticoagulants in interventional pain management.

Stoppage of warfarin for 3 days should be sufficient. Longer intervals may only increase risk of thromboembolism. However, prior to facet joint injections, a PT must be performed. Various other drugs such as low-molecular-weight heparins — for example, enoxaparin (Lovenox®) or ardeparin ([Normiflo®) — or other antithrombotics such as danaparoid (Organaran®) should also be discontinued as

they increase the risk of bleeding. Similarly, antiplatelet agents such as ticlopidine (Ticlid®) and clopidogrel (Plavix®) are also relative contraindications.

Patients with diabetes mellitus should be informed about increases in blood sugar if steroids are used. They also should monitor their blood glucose after corticosteroid injection. Precautions should also be taken by patients with artificial heart valves, who may require the use of antibiotics before and after the procedure, as determined by the treating physician. However, use of pre-procedural antibiotics for patients with mitral valve prolapse is controversial.

THERAPEUTIC FACET JOINT INTERVENTIONS

Thoracic facet joint pain may be treated with intra-articular injections, medial branch blocks, or radiofrequency thermoneurolysis. However, there is a paucity of literature on the role of therapeutic interventions of thoracic facet joints.

INTRA-ARTICULAR BLOCKS

There are no descriptions in the literature concerning the role of thoracic intra-articular blocks in managing chronic pain.

MEDIAL BRANCH BLOCKS

There is no literature available describing the role of medial branch blocks as a therapeutic measure in managing chronic thoracic pain.

RADIOFREQUENCY NEUROTOMY

In a nonrandomized prospective trial, Stolker et al.[8] evaluated the effectiveness of percutaneous facet denervation in chronic thoracic spinal pain. They evaluated 40 patients with chronic thoracic spinal pain of greater than 12 months' duration, which failed to respond to conservative treatment. All patients were evaluated by specialists, mainly neurologists and orthopedic surgeons. The diagnosis of facet syndrome was made by clinical criteria and a transient positive response to a prognostic blockade of the medial branch of the dorsal ramus of the thoracic spinal nerve. The results showed that 40 patients underwent 51 percutaneous thoracic facet denervations. After 2 months, 19 patients (47.5%) were pain free and 14 patients (35%) had more than 50% pain relief, with a total of 82.5% of the patients reporting greater than 50% relief. With a long-term follow-up average of 31 months in 36 patients, 44% were pain free and 39% had more than 50% pain relief, with a total of 83% of the patients presenting greater than 50% relief.

TECHNICAL CONSIDERATIONS

Patients are placed in the prone position for thoracic intra-articular facet injections, medial branch blocks, and radiofrequency neurotomy. Posteroanterior (PA) view of the thoracic spine is essential for all interventions (Figure 64.1). Although thoracic facet joints are not quite evident in a PA view, their location can be estimated from the location of the thoracic pedicles (Figure 64.1).[30]

The joints slide behind the intervertebral foramina, and these foramina lie between the pedicles. The location of the target joint is determined by counting vertebrae and ribs from above.

INTRA-ARTICULAR INJECTIONS

The target joint will not be visible in the posteroanterior views but can be gauged to lie between the two pedicles bearing the same segmental number as the target joint.[30] Thoracic facet joints are difficult to enter directly from behind due to orientation in the coronal plane, and laterally they may carry the risk of pneumothorax.

Thus, the safest entry is from below, which requires an initial insertion of the needle approximately one to two segments below the target joint.

With intermittent fluoroscopic visualization, the needle is inserted through the skin cephalad pointing toward the superior articular process. The needle should remain on an imaginary vertical line connecting the midportion of the targeted facet joint and the one below. If the needle stays in this line without deviation, either medial or lateral, it will be safe. However, the risks with deviation of the needle include entering the epidural space and spinal cord, or pleural space and lung. After the insertion of the needle approximately 4 to 5 cm, or once the needle tip is seen to lie at the mid to inferior aspect of the pedicle, the fluoroscope is rotated away from the side being injected until the outline of the joint is clearly visible (almost a lateral position). Following this, the needle is advanced through the capsule into the inferior aspect of the joint (Figure 64.2).

FIGURE 64.2 Needle in thoracic facet.

After the needle is inserted into the inferior aspect of the joint, contrast is injected. After confirmation, local anesthetic and/or steroid may be injected.

The description provided is ideal for the joints below T6/7. However, for superior levels from T1/2–T5/6, a more perpendicular approach to the facet joints is needed. At these levels on PA imaging, skin entry is usually at the midportion of the vertebral body rather than its inferior aspect. Figure 64.2 illustrates intra-articular injection of a thoracic facet joint.

MEDIAL BRANCH BLOCKS

For thoracic medial branch blocks the target points are, in general, the superolateral corners of the thoracic transverse processes (Figure 64.3). The nerves to a particular joint are the ones that cross the transverse process above the joint and the transverse process below the joint. Numerically, if the joint to be blocked is the Tx/y joint, the transverse processes required are the Tx–1 and Tx transverse processes.[30] Respectively, these are crossed by the Tx–2 and Tx–1 medial branches. The numerical rela-
FIGURE 64.3 Thoracic medial branch blocks.

TABLE 64.3
Facet Joint Nerves Required to Be Blocked for Each Facet Joint in Thoracic Region

Facet Joint	Facet Joint Nerves (medial branches) to be Blocked	Level of Transverse Process
T1/2	C8 and T1 medial branches	At T1 transverse process for C8
		At T2 transverse process for T1
T2/3	T1 and T2 medial branches	At T2 transverse process for T1
		At T3 transverse process for T2
T3/4	T2 and T3 medial branches	At T3 transverse process for T2
		At T4 transverse process for T3
T4/5	T3 and T4 medial branches	At T4 transverse process for T3
		At T5 transverse process for T4
T5/6	T4 and T5 medial branches	At T5 transverse process for T4
		At T6 transverse process for T5
T6/7	T5 and T6 medial branches	At T6 transverse process for T5
		At T7 transverse process for T6
T7/8	T6 and T7 medial branches	At T7 transverse process for T6
		At T8 transverse process for T7
T8/9	T7 and T8 medial branches	At T8 transverse process for T7
		At T9 transverse process for T8
T9/10	T8 and T9 medial branches	At T9 transverse process for T8
		At T10 transverse process for T9
T10/11	T9 and T10 medial branches	At T10 transverse process for T9
		At T11 transverse process for T10
T11/12	T10 and T11 medial branches	At T11 transverse process for T10
		At T12 transverse process for T11
T12/L1	T11 and T12 medial branches	At T12 transverse process for T11
		At L1 transverse process for T12

tionships between nerves, transverse processes, and joints are, therefore, like those of the lumbar region. Caution should be taken to accurately interpret and report the level to be blocked, in terms of both the joint anesthetized and the nerves anesthetized.[30]

For medial branch blocks C8 to T10, the target transverse processes should be differentiated from the rib that lies in front and whose upper margin projects slightly above the transverse process.[30]

At the T12 level the medial branches of the thoracic dorsal rami assume a course that is similar to lumbar. The T12 medial branch assumes a course exactly analogous to that of typical lumbar medial branches, lying on the junction of the superior articular process and the transverse process.

Table 64.3 illustrates the nerve supply of thoracic facet joints.

Medial Branch Blocks T1 to T4 and T9 to T10

For the needle placement from T1 to T4 and T9 to T10, the needle is positioned directly overlying the target point of the nerve. The needle must be advanced until the contact is made with the target transverse process, with subsequent adjustment of the needle to rest on the back of the superolateral corner of the transverse process. Injectate may be instilled at this time.

Medial Branch Blocks at T5 to T8

At these levels, a single-needle or two-needle technique may be applied. The aim is to position the needle onto the nerve that is passing dorsally and caudally just above and slightly dorsal to the typical target joint on the superolateral corner of the transverse process. Consequently, the depth of the needle placement is the same as the depth of the transverse process.

With a two-needle technique, the first needle is introduced as for a typical thoracic medial branch block and left in place on the superolateral corner of the transverse process. Following this, a second needle is introduced parallel to the first but aiming at the back of the rib just above the corner of the transverse process. When the second needle touches the rib, it is a sign that it has been introduced more deeply than the first one. At this point, the second needle is withdrawn until its hub is at the same height from the skin as that of the first needle, indicating that its tip lies at the same depth as the back of the transverse process. At this point, local anesthetic injection may be carried out.

Medial Blocks of T11 and T12

Medial branch blocks of T11 and T12 are performed similarly to medial branch blocks of lumbar spine. The target location for the T11 and T12 medial branches is at the junction of the superior articular process and the transverse process that the nerve crosses, midway between the transverse process and the location of the mammillo-accessory notch. On AP imaging, the tip of the needle should be at least in line with the lateral margin of the silhouette of the superior articular process and, if possible, medial to this margin.

RADIOFREQUENCY THERMONEUROLYSIS

Radiofrequency lesioning is performed using either a heat lesion or pulsed mode radiofrequency. A radiofrequency neurotomy lesion for facet denervation is performed at 80 to 85°C. A radiofrequency lesion is performed when the temperature exceeds 45°C. Clinically, a higher temperature allows for a larger lesion to be made. The size of the lesion is influenced by the vascularity of the surrounding tissue. The greater the vascularity of the tissue, the smaller the lesion. Top mode equilibrium is achieved in about 60 seconds. The pulsed mode radiofrequency is an application of a strong electric field to the tissue that surrounds the electrode and the temperature of the tissue surrounding the tip of the electrode, does not exceed 42°C. Essentially, the radiofrequency current is applied in a pulsed fashion and heat is dissipated during the silent period.[35]

The approach and views for radiofrequency thermoneurolysis are the same as described for the medial branch blocks. Once satisfactory needle placement is confirmed via fluoroscopic imaging and contrast injection, the radiofrequency electrode is placed through the needle. Motor testing, injection of local anesthetic, and subsequent lesioning may be performed.

SIDE EFFECTS AND COMPLICATIONS

Complications from facet joint nerve blocks or intra-articular injections in the thoracic spine, though rare, may be serious.[36–50] The most common complications of this technique are twofold. These include complications related to the technique with placement of the needle and complications related to the administration of various drugs. The majority of the problems are short-lived and self-limiting to local swelling and pain at the site of the needle insertion, as well as pain in the upper or mid back. Complications may include pneumothorax, dural puncture, spinal cord trauma, subdural injection, neural trauma, injection into the intervertebral foramen and hematoma formation; infectious complications including epidural abscess and bacterial meningitis; and side effects related to the administration of steroids, local anesthetics, and other drugs.[36–47]

Other minor complications include lightheadedness, flushing, sweating, nausea, hypotension, syncope, pain at the injection site as described earlier, and nonpostural headaches. Side effects related to the administration of steroids are generally attributed to the steroid's chemistry or to the pharmacology of the steroids.[47] The major theoretical complications of corticosteroid administration include suppression of pituitary-adrenal axis, hypocorticism, Cushing syndrome, osteoporosis, avascular necrosis of bone, steroid myopathy, epidural lipomatosis, weight gain, fluid retention, and hypoglycemia. However, Manchikanti et al.[48] in evaluating the effect of neuraxial steroids on weight and bone mass density, showed no significant differences in patients undergoing various types of interventional techniques with or without steroids.

Reported complications of radiofrequency thermoneurolysis include a worsening of the usual pain, burning or dysesthesias, decreased sensation and allodynia in the paravertebral skin or the facets denervated, transient leg pain, persistent leg weakness, and inadvertent lesioning of the spinal nerve or ventral ramus resulting in motor deficits, sensory loss, and possible deafferentation pain.[8–11,35,49,56] A spinal cord lesion can lead to paraplegia, loss of motor, proprioception and sensory function, bowel and bladder dysfunction, Brown-Séquard syndrome, and spinal cord infarction.

CONCLUSION

Thoracic facet joints are identified as the cause of thoracic pain. Thoracic facet joint blocks can be performed in order to test the hypothesis that the target joint is the source of the patient's pain. The rationale for using facet joint blocks for diagnosis, as well as therapy, is based on the facts that thoracic facet joints have been shown to be capable of being a source of thoracic pain and referred pain in the chest; thoracic facet joint pain may not be diagnosed based on referral patterns, physical examination, history, neurophysiologic testing, or radiological evaluation; diagnostic facet joint blocks have been shown to be highly valid and specific; degenerative process of the thoracic spine and the origin of thoracic pain is extremely complex; and the effectiveness of a large variety of therapeutic interventions in managing pain arising from the thoracic spine has not been demonstrated conclusively. Literature evaluating therapeutic facet joint interventions is insufficient at the present time.

Lumbar Facet Joint Interventions

Laxmaiah Manchikanti, MD, David M. Schultz, MD, and Vijay Singh, MD

INTRODUCTION

The prevalence of persistent low back pain due to the involvement of lumbosacral facet joints has been described in controlled studies as varying from 15 to 45% based on types of population and settings studied.[1–17] Even though evidence is lacking for diagnosis of lumbar facet syndrome,[1–21] a preponderance of evidence supports the existence of lumbar facet joint pain.[1–50] However, the existence of facet joint pain has been questioned.[51-57]

As with the epidemiology and clinical significance of facet joint pain, significant controversy surrounds various treatments used in the management of chronic low back pain arising from lumbosacral facet joints. Long-term therapeutic benefit for facet joint pain has been reported with three types of interventions. These include intra-articular injections,[21,25–29,33,38–40] medial branch nerve blocks,[2,30,39–41] and neurolysis of medial branch nerves by means of radiofrequency, chemical neurolysis, or cryoneurolysis.[41–45,46–50] The long-term therapeutic benefit of intra-articular injections of facet joints is equivocal.[24–29,46] The evidence for long-term benefits of medial branch nerve blocks is preliminary,[2,30,39–41,46] and radiofrequency neurotomy is supported with moderate evidence.[42–49] However, all the treatments have been controversial.

HISTORY

As early as 1911, Goldthwait[58] recognized lumbar facet joints as potential sources of back pain and explained facet joints as a cause of many cases of lumbago, sciatica, and paraplegia. Some 20 years later in 1933, Ghormley[59] coined the term *facet syndrome* and defined it as lumbosacral pain with or without sciatic pain, particularly occurring suddenly after a twisting or rotatory strain of the lumbosacral region. Further, in 1941, Badgley[60] suggested that facet joints themselves would be a primary source of pain separate from the nerve compression component and made a plea for continuing focus on the facets to explain the large numbers of patients with low back pain whose symptoms were not due to a ruptured disc. Hirsch et al.[61] demonstrated that the low back pain distributed along the sacroiliac and gluteal areas with radiation to the greater trochanter could be induced by injecting hypertonic saline into the region of the facet joints. In subsequent studies, Mooney and Robertson[21] and McCall et al.,[18] using fluoroscopic visualization to confirm the location of intra-articular lumbar facet joint injections in asymptomatic volunteers, demonstrated causation of back and lower extremity pain after injection of hypertonic saline. Marks[22] and Fukui et al.[23] also described the distributions of pain patterns and confirmed the findings of previous researchers. Windsor et al.[62] also confirmed the ability of lumbar facet joints to be a source of pain in the low back. While Mooney and Robertson[21] and McCall et al.[18] showed that the stimulation of the facet joints with injections of hypertonic saline or contrast medium produces back pain and somatic referred pain identical to that commonly seen in patients, Kaplan et al.[36] and Dreyfuss et al.[37] showed that this pain can be relieved by anesthetizing the facet joints responsible for low back pain.

PATHOPHYSIOLOGY

Facet joints have been shown to produce low back pain in normal volunteers. Stimulation of facet joints with injections of hypertonic saline or contrast medium pro-

duces back pain and somatic referred pain identical to that commonly seen in patients.[16,18,21–23,62] In addition, this pain can be relieved by anesthetizing the facet joints deemed to be responsible for low back pain.[16,17,21,36,37] Pain originating from facet joints is predominantly present in the low back, buttocks, and thighs; however, it does not follow a reliable segmental pattern.[16–21] Even though radiation of referred pain below the knee as far as the foot has been described,[21] typically pain involves predominantly the proximal parts of the lower extremity. Mooney and Robertson[21] postulated that the distance of radiation of pain is proportional to the intensity of pain in the back.

Even though the prevalence of facet joint pain as a cause of low back pain has been extensively studied, its pathophysiology remains elusive. The lumbar facet joints can be affected by rheumatoid arthritis,[63–65] ankylosing spondylitis,[66] or inferior articular processes epiphyses that are not united.[66–69] It has been repeatedly documented by radiological surveys, as well as by postmortem studies, that the lumbar facet joints are frequently affected by osteoarthritis.[70–74] Further, intraoperative reports excising the facet joints have demonstrated changes similar to that of chondromalacia of the patella.[75] Even though it continues to be stressed that facet joint pain is due to osteoarthritis of facet joints, the evidence from controlled studies has been unable to establish this fact. It also has been shown on plain radiographs that facet joint arthritis appears as commonly in asymptomatic individuals as in patients with back pain.[66–69] Evaluation of facet joint arthritis with computed tomography (CT) scans also revealed the same results; even though CT scans were once hailed as indicative of facet joint pain,[76–78] controlled studies have shown that CT is of no diagnostic value for lumbar facet joint pain.[31] Thus, evidence to date shows that data from radiological evaluation preclude making the diagnosis of pain for facet joint arthropathy on the basis of either plain radiography or CT scanning, and also indicates either that osteoarthritis is not a cause of facet joint pain or that when it is, the pain is due to some factor other than the simple radiological presence of this condition. Further, assertions that facet joint arthritis is usually secondary to disc degeneration or spondylosis[72,79–83] may not be true, as in approximately 20% of the cases facet joint arthritis can be a totally independent disease;[70] correlation between discogenic pain and facet joint pain or a combination of discogenic and facet joint pain has not been established thus far.

Multiple injuries of facet joints have been described in the literature. These include capsular tears, capsular evulsions, subchondral fractures, intra-articular hemorrhage, and fractures of the intra-articular processes in both biomechanical studies and postmortem studies.[67,70,84–95] However, none of these abnormalities was observed on plain radiographs. Even though fractures are visible on CT scans, no such reports exist in the literature with

proven painful lumbar facet joint pain.[27] Lesions such as capsular tears cannot be detected by radiography, CT, or magnetic resonance imaging (MRI). Hence, the importance of these lesions, if they are present, is not known. Finally, the theoretical possibility of meniscus entrapment causing low back pain also appears to be only hypothetical, as it is difficult to visualize meniscoids radiologically. However, it may be one of the plausible explanations for some cases of acute low back pain, particularly in those responding to manipulative therapy.[96]

DIAGNOSTIC FACET JOINT BLOCKS

Lumbosacral facet joints can be anesthetized either with intra-articular injections of local anesthetic or by anesthetizing the medial branches of the dorsal rami that innervate the target joint.[16,17] The joint may be considered to be the source of pain if the pain is relieved. However, steps need to be taken to ensure that the observed response is not false-positive. True-positive responses are secured by performing controlled blocks, in the form of either placebo injections of normal saline or comparative local anesthetic blocks, in which the same joint is anesthetized on two separate occasions but using local anesthetics with different duration of action.

The rationale for using lumbosacral facet joint blocks for diagnosis is based on the fact that lumbar facet joints have been shown to be capable of being a source of low back pain and referred pain in the lower limb in normal volunteers. There are no historical or clinical features that are conclusively diagnostic of facet joint pain. There are no reliable clinical means of implicating zygapophysial or facet joints as the source of low back pain in a given patient. Referral patterns described for various joints are not only variable, but also restricted.[16,18,21–23] In addition, many of the other structures in the lumbosacral spine, such as the disc, in the same segment may produce the same pattern of pain. Attempts by multiple investigators to correlate demographic features, pain characteristics, physical findings, and other signs and symptoms with the diagnosis of facet joint pain have been proved to be unreliable.[1–6,16,17,20,31,35,97–99] In addition, imaging technologies provide neither valid nor reliable means of identifying symptomatic lesions.[31,99,100] Thus, in the United States, controlled diagnostic blocks with two separate local anesthetics or placebo-controlled blocks are the only means of confirming diagnosis of facet joint pain. The diagnostic accuracy of controlled local anesthetic facet joint blocks has been reviewed and was determined to be high in the diagnosis of chronic low back pain.[16,17,101]

The face validity of intra-articular injections or medial branch blocks is established by injecting small volumes of local anesthetic into the joint or onto the target points of the nerve.[37] Further, construct validity of facet joint blocks is also extremely important, as placebo effect is

the single greatest confounder of diagnostic blocks. The theory that testing a patient first with lidocaine and subsequently with bupivacaine provides a means of identifying placebo response has been tested and proven.[102–106] The specificity of controlled diagnostic blocks has been demonstrated in multiple controlled trials. Provocation response was shown to be unreliable.[98] The false-negative rate of diagnostic facet joint blocks was shown to be around 8% due to unrecognized intravascular injection of local anesthetic.[37] Confounding psychological factors also were shown to have lack of influence on the validity of comparative, controlled diagnostic local anesthetic blocks of facet joints in the lumbar spine.[11] False-positive rates as evaluated in multiple investigations were reported to be 22 to 47% in lumbar spine.[2–17,107]

The indications and contraindications for diagnostic facet joint blocks are listed in Tables 65.1 and 65.2.[108]

TABLE 65.1
Common Indications for Lumbar Diagnostic Facet Joint Blocks

- Somatic or nonradicular low back and/or lower extremity pain
- Lack of evidence, either for discogenic or sacroiliac joint pain
- Lack of disc herniation or evidence of radiculitis
- Duration of pain of at least 3 months
- Failure to respond to more conservative management, including physical therapy modalities with exercises, chiropractic management, and nonsteroidal anti-inflammatory agents
- Average pain levels of greater than 5 on a scale of 1 to 10
- Intermittent or continuous pain causing functional disability
- No contraindications with understanding of consent, nature of the procedure, needle placement, or sedation
- No history of allergy to contrast administration, local anesthetic steroids, Sarapin, or other drugs potentially utilized
- Negative provocative discography and sacroiliac joint blocks
- Contraindications or inability to undergo physical therapy, chiropractic management, or inability to tolerate nonsteroidal anti-inflammatory drugs

---

TABLE 65.2
Common Contraindications for Lumbosacral Facet Joint Blocks

- Infection
- Inability of the patient to understand consent, nature of the procedure, needle placement, or sedation
- Allergies to contrast, local anesthetic, steroids, Sarapin, or other drugs
- Needle phobia
- Psychogenic pain
- Suspected discogenic, sacroiliac joint, or myofascial pain
- Pregnancy
- Anticoagulant therapy
- Non-aspirin antiplatelet therapy
- Bleeding diathesis

Contraindications are quite obvious and include bacterial infection, possible pregnancy, and bleeding diathesis. Relative contraindications include allergy to contrast media or local anesthetics and treatment with non-aspirin antiplatelet drugs, which may compromise coagulation. Raj et al.[109] provides a detailed description on the role of anticoagulants in interventional pain management. Even then, there is no consensus as to the importance of discontinuation of aspirin before lumbar facet joint injection procedures. Patients on warfarin therapy should be checked for prothrombin time (PT), and it should be at acceptable levels.

THERAPEUTIC FACET JOINT INTERVENTIONS

There is a paucity of literature on the role of therapeutic facet joint blocks. However, facet joint pain may be managed by either intra-articular injections or medial branch blocks, in addition to neurolysis of medial branches.

Therapeutic benefit has been reported with the injection of corticosteroids, local anesthetics, or normal saline into the facet joints. The literature describing the effectiveness of these interventions is abundant. Manchikanti et al.,[46] in developing evidence-based practice guidelines for interventional techniques in managing chronic spinal pain, reviewed the available literature which included four randomized clinical trials[24,28,39,40] and multiple nonrandomized and observational reports.[26,27,29,32] Based on the definition of short-term relief as relief of less than 3 months and long-term relief as relief of 3 months or longer, the only randomized trial[24] meeting the inclusion criteria showed positive results at 6 months; however, authors of this study, Carette et al.,[24] described it as negative. Among the nonrandomized trials, positive results were noted for short-term relief in all the studies, whereas long-term relief was noted in only three of the five studies. Thus, Manchikanti et al.[46] conclude that the evidence of intra-articular injections of local anesthetics and steroids from randomized trials, complemented with that of nonrandomized trials (prospective and retrospective evaluations), provided moderate evidence of short-term relief and limited evidence of long-term relief of chronic low back pain.

Medial branch blocks have been extensively used for diagnostic and prognostic purposes with limited use for therapeutic purposes. The therapeutic role of medial branch blocks was evaluated in three randomized clinical trials,[30,39,40] and one nonrandomized clinical trial.[2] Based on the definition (short-term < 3 months and ≥ 3 months longterm) with one randomized trial and one nonrandomized evaluation, evidence for medial branch blocks appears to be strong for short-term relief and moderate for long-term relief of pain of lumbar facet joint origin. Indications and contraindications for therapeutic lumbar facet joint blocks are the same as for diagnostic blocks except that a negative

response to diagnostic facet joint blocks is a contraindication for therapeutic facet joint blocks.

Multiple investigators have studied the effectiveness of radiofrequency denervation of medial branches in the lumbar spine. Percutaneous radiofrequency neurotomy is a procedure that offers temporary relief of pain by denaturing the nerves that innervate the painful joint. However, pain may return when the axons regenerate. At this time, the procedure may need to be repeated to reinstate the relief. Radiofrequency neurolysis as a treatment of chronic intractable pain began in the early 1930s. Multiple systematic reviews have been performed recently[30,46–49] with controversial results. While Geurts et al.[47] and Niemistö et al.[49] showed that radiofrequency was not effective, Manchikanti et al.[48] in a systematic review showed that there may be strong evidence that radiofrequency denervation offers short-term relief and moderate evidence of long-term relief of chronic low back pain. These conclusions were based on the studies by Van Kleef et al.[43] and Dreyfuss et al.[42]

ANATOMIC CONSIDERATIONS

The lumbar facet joints are formed by the articulation of the inferior articular processes of one lumbar vertebra with the superior articular processes of the subjacent vertebra. The joints exhibit the features typical of synovial joints. The articular facets are covered by articular cartilage, and a synovial membrane bridges the margins of the articular cartilages of the two facets in each joint.[128] Surrounding the synovial membrane is a joint capsule that attaches to the articular processes a short distance beyond the margin of the articular cartilage.

Histological studies have shown that capsules of the lumbar facet joints are richly innervated with encapsulated, unencapsulated, and free nerve endings.[110–113]

The medial branches are of paramount clinical importance and relevance because of their distribution to the facet joints. The medial branches of the L1–L4 dorsal rami run across the top of their respective transverse processes and pierce the dorsal leaf of the intertransverse ligament at the base of the transverse process.[111] Subsequently, each nerve runs along bone at the junction of the root of the transverse process with the root of the superior articular process hooking medially around the base of the superior articular process, which is covered by the mamillo-accessory ligament. Finally, the nerve crosses the vertebral lamina, where it divides into multiple branches that supply the multifidus muscle, the interspinous muscle and ligament, and two facet joints. Thus, each medial branch supplies the facet joints above and below its course.[36,37,111,112,114,115] Two articular branches in an ascending and a descending branch arise from the nerve, the ascending branch arising from the nerve just beyond the mamillo-accessory ligament where the nerve starts to cross the lamina, in contrast to the descending articular branch, which arises slightly more distally and courses downward to the joint below. The medial branch of the L5 dorsal ramus has a different course and distribution than those of the L1–L4 dorsal rami in that instead of crossing a transverse process, it crosses the ala of the sacrum. Thus, the medial branch of the L5 dorsal ramus runs in the groove formed by the junction of the ala and the root of the superior articular process of the sacrum before hooking medially around the base of the lumbosacral facet joint.[111] The medial branch of the L5 dorsal ramus sends an articular branch to the facet joint before ramifying in multifidus.

TECHNIQUE

LUMBAR FACET JOINT INTRA-ARTICULAR INJECTIONS

The patient is placed in a prone position on the fluoroscopy table. A towel roll or pillow can be placed under the abdomen to distract the intended facet joint. This may allow for an easier entry into the joint. The target area is then prepped and draped in a sterile manner. The fluoroscopy beam is then rotated to gain an anterior-posterior view of the target facet joint. This view is most commonly used in the upper lumbar facet joints secondary to their sagittal plane alignment. An oblique view may be required for optimal visualization of the lower lumbar segments due to their more frontal plane orientation.[116] The target joint is then visualized under fluoroscopic guidance and the skin entry point is identified.

A skin wheal with 1 mL of 1% lidocaine is then raised at the site of entry. Care is taken not to infiltrate the deep subcutaneous area overlying the target site. Diffusion of this anesthetic could possibly cause a false-positive response to the zygapophysial joint injection. A 22- to 25-gauge, 3.5-in. spinal needle is then inserted through the anesthetized area. The needle is directed down toward the selected joint under direct fluoroscopic visualization. Contact is made with the inferior articular processes. This confirms the depth of the needle. The needle is then withdrawn slightly and redirected to enter the target facet joint. As the needle is felt to penetrate the joint, advancement is stopped to prevent any potential articular cartilage damage. If there is difficulty in obtaining capsular penetration, then one may try to access the articular recesses by redirection of the needle just off the margins of the inferior articular processes. Another method of gaining intracapsular entry is to redirect the needle slightly medially or laterally to the posterior joint line so the needle gains access via its medial placement to the insertion of the capsule on the articular process.[32] Once the needle is in an appropriate position, 0.2 to 0.5 mL of contrast is then injected into the joint to confirm proper placement. An arthrographic image should then be visualized.[117] During contrast injection, lack of vascular flow and no epidural

(A)

(B)
FIGURE 65.1 (A) 25-gauge spinal needle curving into L5–S1 facet joint. (B) L5–S1 arthrogram.

spread should be observed. After confirmation of placement with contrast, the joint is injected with anesthetic agent to complete a diagnostic block or in combination with a steroid agent for a therapeutic zygapophysial joint injection.[32,117] Figure 65.1 illustrates intra-articular placement of needles and injection of contrast.

MEDIAL BRANCH BLOCKS

To block the nerves supplying a lumbar facet joint, two medial branch blocks are necessary due to its dual innervation. Table 65.3 illustrates the nerves to be blocked for each facet joint in the lumbar region. It is extremely simple to remember to block a particular joint. The medial branch at the transverse process at the same level and the level below must be blocked. Thus, to block the L3/4 facet joint, two medial branches need to be blocked, which include the L2 medial branch at the transverse process of L3 and the L3 medial branch at the transverse process of L4. Similarly, to block the L5/S1 facet joint, the L4 medial branch at the L5 transverse process and the L5 dorsal

ramus at the sacral ala must be blocked. For the L5/S1 facet joint, it has been suggested that a communicating branch from the dorsal ramus of the S1 may provide additional supply, which may be blocked just above the exit from the S1 posterior foramina.[117] However, it has been suggested that blockade of the L4 medial branch and the L5 dorsal ramus alone adequately anesthetizes the L5/S1 facet joint from an experimental stimulus without the need for anesthetization of a potential ascending branch from S1.[36]

L1 to L4 Medial Branch Blocks

The nerves should be blocked proximal to the mamillo-accessory ligament and notch for L1–L4 medial branch blocks.[37] Dreyfuss et al.[37] described that the target location for the L1–L4 medial branch is at the junction of the superior articular process and the transverse process that the nerve crosses, midway between the superior border of the transverse process and the location of the mamillo-accessory notch. Dreyfuss et al.[37] believed that this point is not associated with an inadvertent spread of injectate into the intervertebral foramen or epidural space for L1–L4 medial branch blocks. They also described that on oblique views, the target point lies high on the "eye" of the "Scottie dog." Placement more superior at the most superior junction of the superior articular process and transverse process as previously recommended apparently leads to an unacceptable incidence of spread into the foramen. Dreyfuss et al.[37] validated a slight superior-to-inferior and lateral-to-medial needle approach to medial branch blocks. However, if an inferior-to-superior needle approach is used, the injected anesthetic theoretically may spread toward the spinal nerve root or the sinuvertebral nerve, thereby substantially decreasing the specificity of the block. For all medial branch blocks a 22- or 25-gauge spinal needle may be used.

The procedure is performed, generally, with the patient in the prone position. The C-arm must be adjusted either straight anteroposterior or oblique position from the skin entry point laterally using anteroposterior imaging, which is usually just above the tip of the target transverse process. The needle is advanced toward the back of the root of the transverse process to ensure safe needle depth away from the ventral ramus. However, it can also be achieved in an oblique view. Using an oblique view with a "Scottie dog," the needle is advanced "down the beam" toward the target using a slightly superior starting position to the final target. To maximally visualize the landmarks of the "Scottie dog," approximately a 25° to 30° angle is necessary based on the level of the injection from L1–L4 medial block(s). Thus, the needle will be directed anterior, medial, and caudad to reach the target location. However, if this is started in an oblique position, switching to an anteroposterior view is necessary to ensure that the needle

TABLE 65.3
Facet Joint Nerves Required to Be Blocked for Each Facet Joint in Lumbar Region

Facet joint	Facet Joint Nerves to be Blocked (medial branches or L5 dorsal ramus)	Level of Transverse Process or Sacral Ala
L1/2	T12 and L1 medial branches	At L1 transverse process for T12
		At L2 transverse process for L1
L2/3	L1 and L2 medial branches	At L2 transverse process for L1
		At L3 transverse process for L2
L3/4	L2 and L3 medial branches	At L3 transverse process for L2
		At L4 transverse process for L3
L4/5	L3 and L4 medial branches	At L4 transverse process for L3
		At L5 transverse process for L4
L5/S1	L4 medial branch L5 dorsal ramus	At L5 transverse process for L4 medial branch at sacral ala groove for L5 dorsal ramus

is placed medial enough despite contact on the oblique view, and an oblique view is necessary to ensure needle placement on the target if the needle is initially advanced on anteroposterior imaging.

L5 Dorsal Ramus Blocks

The target point for the L5 dorsal ramus is at the junction of the ala of the sacrum with the superior articular process of the sacrum. This target point is recognized as a notch between these two bones with a minor amount of ipsilateral obliquity. The target point lies opposite the middle of the base of the superior articular process and thus slightly below the silhouette at the top of the sacral ala. Higher placement is associated with spread into the L5/S1 epidural space and lower placement with spread to the S1 posterior sacral foramen.

For L5 dorsal ramus block, an approximately 10 to 15° oblique view can be helpful to optimally visualize the junction of the sacral ala and the superior articular process of S1. Further obliquity usually places the medial iliac crest in front of the trajectory to the target position. The needle is advanced directly down the beam to the target position on slight oblique imaging. Anteroposterior imaging is then obtained to verify that the needle is placed at or preferably medial to the lateral silhouette of the S1 superior articular process. After the needle is in the proper location, the bevel opening should be medial. This has been shown to reduce inadvertent spread to the S1 posterior foramen or the L5 vertebral foramen.[36,117] Figure 65.2 illustrates the technique of medial branch blocks under fluoroscopy.

Local anesthetic injection should be limited to 0.4 to 0.6 mL for a diagnostic block and approximately 1 mL for a therapeutic block. Dreyfuss et al.[37,117] recommend potent local anesthetics, e.g., 4% lidocaine and 0.75% bupivacaine, to minimize the risk of false-negative medial

branch blocks, which can occur at a 10% rate with 2% lidocaine. Kaplan et al.[36] describes that failure to obtain relief with lumbar medial branch blocks in a case in which venous uptake of contrast is observed, despite needle redirection with avoidance of subsequent venous uptake, carries a 50% risk for false-negative results.

For diagnostic, as well as therapeutic blocks, the literature has been limited to using local anesthetic agents of different durations of action, namely, lidocaine and bupivacaine. However, Manchikanti et al.[1] have shown the validity of diagnostic blocks is maintained with addition of adjuvant agents such as Sarapin and methylprednisolone, along with provision of a therapeutic benefit much longer than the local anesthetic alone. In addition, in multiple investigations, Manchikanti et al.[2,4–15] utilized concentrations of lidocaine of 1% and bupivacaine of 0.25% rather than 4% lidocaine and 0.75% bupivacaine, as recommended by others.

MEDIAL BRANCH NEUROTOMY

Radiofrequency lesioning is performed using either a heat lesion or pulsed mode radiofrequency. A thermal radiofrequency neurotomy lesion for facet denervation is performed at 80 to 85°C. A radiofrequency lesion is performed when the temperature exceeds 45°C. Clinically, a higher temperature allows for a larger lesion to be made. The size of the lesion is influenced by the vascularity of the surrounding tissue. The greater the vascularity of the tissue, the smaller the lesion. Top mode equilibrium is achieved in about 60 seconds. The pulsed mode radiofrequency is an application of a strong electric field to the tissue that surrounds the electrode and the temperature of the tissue surrounding the tip of the electrode does not exceed 42°C. Essentially, the radiofrequency current is applied in a pulsed fashion and heat is dissipated during the silent period.[118]

(D)

(E)

FIGURE 65.2 (A) Arrow points to L5 transverse process; white dot is on L4 medial branch. (B) Needles placed obliquely onto the medial branches of L2, L3, L4, and L5. (C) 0.5 mL of contrast injected, oblique view. (D) Needle placement for medial branch blocks in PA view. (E) 0.5 mL of contrast injected, PA view.

The patient is placed in a prone position. Appropriate preparation is performed. Following this, under fluoroscopic visualization in a posteroanterior (PA) view or oblique view, needles are positioned similarly to the descriptions of the medial branch blocks. For radiofrequency thermoneurolysis, the cannula is placed along the course of the medial branch or at the L5 level on the posterior primary ramus. A larger interruption of the nerve is made if the lesion is made parallel to the nerve, that is, along the course of the nerve, rather than placing the cannula more at a tangent to the nerve.[118] Theoretically, a larger lesion of the nerve allows for a prolonged and

improved pain relief. However, for pulsed radiofrequency, the needles may be positioned in a fashion similar to medial branch blocks.

SIDE EFFECTS AND COMPLICATIONS

Complications from facet joint nerve blocks or intra-articular injections in the lumbar spine are exceedingly rare.[42,43,117–127] However, the two most common complications of this technique include complications related to the technique with placement of the needle and complications related to the administration of various drugs. The majority of the problems are short-lived and self-limiting to local swelling and pain at the site of the needle insertion, as well as pain in the low back. Complications may include dural puncture, spinal cord trauma, subdural injection, neural trauma, injection into the intervertebral foramen and hematoma formation; infectious complications including epidural abscess and bacterial meningitis; and side effects related to the administration of steroids, local anesthetics, and other drugs.[119–127] Thompson et al.[126] reported instances of chemical meningism from penetration of the dural cuff leading to subarachnoid entry with two level facet joint injections and a one level medial branch block. However, large volumes of injectate were used and the descriptions of the needle placement and contrast flow under fluoroscopic imaging prior to injection were not discussed. Berrigan[125] also reported chemical meningism. With the use of fluoroscopy alone or fluoroscopy and contrast, damage to a spinal nerve root or needle placement into the epidural or subarachnoid spaces should be an exception. Spinal anesthesia following lumbar facet joint injections also has been reported.[120,121] Infection associated with facet joint injections has been reported.[119,123,125] Facet capsule rupture may occur, with large volumes of injectate, leading to diagnostic and therapeutic uncertainty.

Other minor complications include lightheadedness, flushing, sweating, nausea, hypotension, syncope, pain at the injection site as described earlier, and nonpostural headaches. Side effects related to the administration of steroids are generally attributed to the steroid's chemistry or to the pharmacology of the steroids.[127] The major theoretical complications of corticosteroid administration include suppression of pituitary-adrenal axis, hypocorticism, Cushing syndrome, osteoporosis, avascular necrosis of bone, steroid myopathy, epidural lipomatosis, weight gain, fluid retention, and hypoglycemia. However, Manchikanti et al.,[128] in evaluating the effect of neuraxial steroids on weight and bone mass density, showed no significant differences in patients undergoing various types of interventional techniques with or without steroids.

Reported complications of radiofrequency thermoneurolysis include a worsening of the usual pain, burning or dysesthesias, decreased sensation and allodynia in the paravertebral skin or the facets denervated, transient leg pain, persistent leg weakness, and inadvertent lesioning of the spinal nerve or ventral ramus resulting in motor deficits, sensory loss, and possible deafferentation pain.[42,43,118] A spinal cord lesion can lead to paraplegia, loss of motor, proprioception, and sensory function, bowel and bladder dysfunction, Brown-Séquard syndrome, and spinal cord infarction.

CONCLUSION

Lumbar facet joints are sources of local and referred pain in approximately 40% of patients with low back and lower extremity pain. The definitive diagnosis of facet joint pain relies on properly performed, controlled, diagnostic local anesthetic or placebo-controlled blocks. These techniques maintain an important diagnostic and potentially therapeutic role in the management of low back pain and should not be performed in isolation but rather in the context of other diagnostic and therapeutic methodology.

Cervical Discography

Vijay Singh, MD, and Laxmaiah Manchikanti, MD

INTRODUCTION

Neck pain is a common complaint among the general population in the United States.[1,2] Reports show that 35 to 40% of individuals will suffer from neck and arm pain and 30% may develop chronic pain symptoms. Of 100,000 people, there are 83.2 cases per year that demonstrate cervical radiculopathy,[3] and 38.4 cases per 100,000 who display definite radiculopathy proven to be due to disc prolapse.[4] In spite of attempts to use rational selection algorithms to choose the methods to diagnose the source of cervical pain, discussion in the literature continues concerning the selection and value of procedures because no one modality can provide the information required in every case. Complementary procedures are used to acquire the fullest picture of pathology. Techniques such as magnetic resonance imaging (MRI), computed tomography (CT) scanning, and myelography provide detailed resolution of abnormal anatomy. The images, however accurate, do not report a particular lesion as the cause or source of symptoms.[5] Correlation of reported symptoms with information obtained in imaging may not be sufficiently reliable to unequivocally determine the location or degree that symptoms and pathology coincide.[6–9]

This was the position taken by Roth[10] in 1976 when he defined a cervical discogenic (painful disc) syndrome to be uniquely diagnosed by analgesic discography. Over 2 years he found the technique of analgesic discography to be able precisely to locate and identify a pain-producing disc. His study marked the first time analgesic disc injection was advocated for diagnosis in the cervical discogenic pain syndrome. Provocative discography, the practice of reproducing a patient's pain with injection of contrast followed by local anesthetic injection to confirm the presence of a painful disc, has emerged as a useful technique in the evaluation of chronic cervical pain.

HISTORY

Although Lindblom[11] studied the effects of disc puncture in 1948 and coined the term *discography*, Schmorl[12] in 1921 first injected a disc for radiographic visualization. Hirsch[13] in 1948 followed Lindblom's work with the first clinical study of disc injection in 16 patients using saline and procaine to localize lumbar pain. Subsequent surgery showed an absence of signs of disc injury. Early data on intradiscal pressure were obtained by Erlacher[14] in 1952 who pressurized 200 discs removed at autopsy to 300 kPa without any instance of disc rupture. Also in the 1950s, Smith and Nichols,[15] and independently Cloward,[16] in work done to evaluate patients with chronic neck, shoulder, and headache pain, published procedures for the direct injection of cervical discs. Each group published nearly simultaneously, without the knowledge of the other's work. The techniques were similar, with similar indications and clinical findings reported in a series of papers. The authors reported that injection into an abnormal disc could produce pain and that the finding of painful disc correlated well with increasing age. Each considered the pain response upon injection more relevant than the radiographic appearance of the disc. Each also found that normal cervical discs accepted fairly small volumes (0.25 to 0.5 mL) and that injection of normal discs was not painful.

These surgeons developed their techniques for cervical disc excision and bony fusion using an anterior approach. To select the disc level for the surgical procedure, both groups used cervical disc injection as a diag-

nostic technique to support their choice. As a diagnostic technique, cervical discography in the 1960s was accepted by some and criticized by others. Still a relatively new procedure, basic clinical findings and their relevance were under study and evaluation.

Holt's 1964 study[17] of volunteer, asymptomatic prison subjects is noted for its negative conclusions, that discography was ineffective and useless. Simmons et al.[18] did a careful reexamination of Holt's study and conclusions in 1988 and exposed significant deficiencies and flaws in the study. The selection process of inmate subjects was questioned because bias was not controlled, the contrast agent used was an irritant itself, fluoroscopic guidance was not utilized, monitored anesthesia was not used, and the technique itself was suspect in the Simmons group's opinion. As an example, extravasation of contrast material was noted with every injection; it continued even with reduction in the amount injected. Its significance had not been investigated by Holt. Holt had rejected correlation of pain with any amount of material injected as without value. Control subjects had not been used. Any critical look at this study today is harsh in its appraisal. Briefly, Simmons et al.[18] concluded that the Holt paper should no longer be considered as either scientific or authoritative evidence in any discussion of discography.

Since that time, the basic knowledge of the physiology and pathology of the disc has expanded. The technique of cervical discography has undergone modification and significant advancement. Fluoroscopic guidance is routine, contrast dye media is far less toxic, and with greater numbers of discograms successfully done, experience has been gained so that the practice of cervical discography is safe and well established. Although cervical may be considered controversial by some, most discographers consider discography to be an essential part of a diagnostic evaluation of chronic cervicogenic pain.[19]

ANATOMY

Differences as well as similarities exist between cervical discs and others in the spinal column. Symptoms solely due to disc herniation are less common in the cervical region than in the lumbar region. Herniation posteriorly and laterally is prevented first by cervical facet joints, which form a bony barrier between the disc and the nerve root, and second, by the dense posterior longitudinal ligament that encloses the disc posteriorly. The nucleus also lies much more anteriorly in the cervical disc than in the lumbar disc, and its movement posteriorly is correspondingly much more difficult and unlikely. In adults, the cervical disc is composed of fibrocartilaginous material, which makes up the annulus fibrosus, with very little nucleus pulposus present. The cervical disc annulus does not consist of concentric laminae of collagen fibers as are found in lumbar discs. Rather, a crescent-shaped mass of

collagen fibers thicker anteriorly and tapered laterally toward the uncinate process characterizes the annulus fibrosus. It is more like a crescent-shaped anterior interosseous ligament than a ring of circular fibers surrounding a nucleus pulposus.[20,21] For the discographer, this has some practical meaning, as healthy cervical discs accept only small amounts of contrast media, usually on the order of 0.25 to 0.5 mL, due to the very small nucleus and small size of the disc. Injection of greater volumes usually means extravasation of contrast, with little resistance upon injection being appreciated by the discographer.

The volume of nucleus in the adult cervical intervertebral disc has been studied in cadavers in 1983 by Saternus and Bornscheuer.[22] They report that 75% of discs at C2–C3, C3–C4, and C7–T1 accepted less than 0.5 mL and 50% of discs at C4–C5, C5–C6, and C6–C7 accepted less than 0.5 mL. They also found that discs accepting more than 0.5 mL frequently demonstrated leakage from the posterolateral or uncovertebral portions of the annulus.

Kambin et al.[23] in 1980 made intradiscal volumetric determinations during discography at the time of cervical disc surgery and found that normal-appearing discs accepted 0.2 to 0.4 mL of contrast while maintaining sustained intradiscal pressures. Lower pressures were associated with higher volumes and posterior escape of solution. It can be concluded that a normal cervical nucleus will be filled by less than 0.5 mL of solution.

Anatomists usually make a distinction between the posterior or thinner part and the anterior or thicker portion of the cervical disc. A feature of cervical discs is the usual development in the first two decades of life of horizontal clefts or fissures in the annular tissue, thought to be a functional adaptation to maintain rotational ability as the elastic nature of the annulus decreases with age.[3] These are referred to as joints of Luschka by many authors.[20,21,24–26]

The uncovertebral articulations, or the joints of Luschka, warrant consideration. The lateral and posterolateral areas of the disc are relatively thinner than the anterior areas and this thinning of the annulus results in linear clefts that communicate with the nucleus. The clefts have not been reported in any patients except adults.[20,21] Clefts filling with contrast during discography also have been noted only in adults. They vary in size and configuration and may fill asymmetrically with contrast. Dispersal of contrast posterolaterally into clefts or joints of Luschka is not a result of degeneration of the disc but rather reflects maturation of the adult disc.[24] Degeneration in adulthood is common.

The cervical discs may dehydrate earlier than lumbar discs. Deterioration of the nucleus occurs early in the adult, and it may be absent after the age of 35 to 40. Characterization of the pathologic changes in adult intervertebral cervical discs was done by Gen[27] in 1990 in discs obtained at autopsy. He examined discs by plain roentgenography, discography, and CT discography, and histo-

logically with morphologic measurements. His data revealed that the anterior portion of discs became thinner with aging. The nucleus, initially located slightly anterior to the center of the disc, tended to migrate to the posterior with aging, and the anteroposterior diameter showed a gradual decrease with aging.

Cervical nerve roots branch off the spinal cord laterally through the intervertebral foramina. Radicular symptoms result if the posterior cervical disc herniates laterally and impinges on the nerve root. In 1993, Dubuisson et al.[28] reported on a retrospective series of 100 patients with soft cervical disc herniations. All were surgically treated and those with radiculopathy only as the presenting symptom had better outcomes than those with combined radicular and spinal cord involvement. Other than as presenting symptoms, the hernias were not further characterized.

Until the work of Yamazaki et al.,[29] no study had characterized the courses of herniated masses in cervical disc herniations. He found using CT discography that most herniated masses causing myelopathy have median penetration in the deep layer of the longitudinal ligament and oblique courses of herniation are common. He also noted that among herniated masses causing radiculopathy, most masses took an oblique course from the median penetration to the paramedian or lateral section.

Lateral disc herniation was found to be uncommon where the bony barrier of the uncovertebral junction exists on both sides of the disc. If the cervical disc herniates obliquely, it can impinge on the spinal cord, producing myelopathy that may cause upper and lower extremity neurologic signs.

PATHOPHYSIOLOGY

Innervation of the cervical intervertebral discs has been shown to be similar to that found in lumbar discs. Cervical sinuvertebral nerves have an upward course in the vertebral canal and supply the disc at their level of entry as well as the more cranial.[30–32] Both nerve fibers and proprioceptive receptors are found in the outer third of the annulus fibrosus, and these have been postulated by Bogduk to be the substrate for primary disc pain in disease and for the pain response of provocative cervical discography.[30]

Additionally, there have been advances in the past decade in understanding the biologic aspects of intervertebral disc cell function.[33] Disc cellular function produces the extracellular matrix components of the disc, which in turn shape the physiologic and biomechanical function of the disc. Ongoing research points to the cellular basis of disc degeneration and the very complex intradiscal metabolism involved in the interrelated phenomena of end-plate nutrient diffusion, the role of cytokines in modulating the inflammatory and pain responses of the disc, and how mechanical stimuli modify disc cell activity.

Injuries to the disc may evoke pain by the activation of sensory nociceptors. Injury of the annulus can lead to release of significant amounts of inflammatory chemicals that may in turn irritate or sensitize the annulus and adjacent structures in the spinal and intervertebral foramina. Inflammatory and immunological reaction to herniated disc material is well recognized as a pain-generating mechanism.[34] Determination of a particular disc as the pain-producing site is the goal of cervical discography.

An atypical case presentation of cervical disc herniation causing localized ipsilateral popliteal pain was described by Neo et al.,[35] using MRI as a diagnostic modality. An adult woman gave a 4-month history of increasing pain, eventually being unable to stand or walk. Physical examination and conventional radiography could not explain the pain. An MRI examination showed a large disc herniation on the right at C3/4 and narrowing of the spinal canal at C4/5. Following anterior decompression and fusion to prevent impending myelopathy, the popliteal pain resolved immediately and completely. The pain has not recurred in almost 3 years after surgery. This case exemplifies the infrequent but significant findings that cervical herniations can cause. The utility of discography in solving puzzling presentations of atypical pain resulting from cervical lesions was shown most recently in a patient with atypical cervicogenic headache, reported by Singh,[36] in which MRI did not disclose the pain-producing lesion. This particular patient had given a 6-year history of intractable pain and until the pain-producing lesion was identified by discography, no diagnostic modality or treatment had given any benefit.

Cervical discography has been used to establish a diagnosis of cervical angina or pseudoangina, which Wells[37] reported as chest pain resembling true cardiac pain coming from C7 nerve root compression. Guler et al.[38] defined cervical angina as chest pain that resembles true cardiac angina but originates from cervical discopathy with nerve root compression. Cervical discography can establish the diagnosis after coexisting coronary artery disease as been ruled out. Guler reported in his paper the first cases of cervical angina associated with acute electrocardiographic (ECG) changes brought on by neck motion. In a more extensive survey, Jacobs[39] reported his series of 164 patients with cervical angina giving similar presentations.

RATIONALE AND INDICATIONS

Discography is not a screening or initial examination in the investigation cervical pain. That role is met by patient history and physical examination, MRI examinations, CT scans, and myelography. Radiographic anatomy disclosed by these techniques is often precise and descriptive but it may not identify the origin of pain, and there can be discrepancies between the degree of pain and the apparent severity of changes observed in radiographic images.[40]

Parfenchuck and Janssen[41] in a 1994 study suggested that while several patterns seen with MRI correlate well with discography findings, others are equivocal. His opinion was that discography was required to diagnose the discogenic pain syndrome. A study by Schellhas et al.[42] in 1996 compared chronic head and neck pain sufferers undergoing MRI or cervical discography. He concluded that discographically normal discs were never painful, whereas painful discs exhibited annular tears that often escaped MRI detection and that MRI could not reliably discern the source of discogenic pain. Collins[43] noted the useful adjunct role played by cervical discography: it was particularly helpful in determining the level of fusion and the selection of patients with cervical discs that needed to be fused.

Cervical discography is indicated for the following situations:

1. Presence of persistent neck pain for which usual diagnostic modalities have failed to identify a cause
2. Findings using traditional modalities are equivocal for the cause of pain
3. Planning for surgical fusion requiring precise identification of painful levels
4. Persistent pain following fusion requiring levels above and below fusion to be examined as pain generators
5. Differentiation cannot be made of scar tissue from recurrent herniation by usual modalities

Guyer and Ohnmeiss[44] delineated indications for lumbar discography in the position statement of the North American Spine Society (NASS) in 1995. Points stressed in the NASS statement define the appropriate use of discography, with attention given that patients may recognize pain provoked in the procedure as similar or identical to their presenting complaint.

Disc injection has been used for well over two decades to select levels for surgical discectomy and fusion. Riley et al.[45] in 1969 used cervical disc injection at the time of surgery, with discometry and epidural leakage the primary diagnostic factors. Simmons and Segil[46] in 1975 used pain responses from saline injection distention of the disc to select disc levels for surgery. Both groups found high percentage rates of success determining the level for surgery. Different groups, such as Whitecloud and Seago,[47] Siebenrock and Aebi,[48] and Hubach,[49] report similarly high percentage success rates for discectomy and fusion of painful discs at levels diagnosed by discography. When discography *wa*s not employed preoperatively, success rates were reported only half as high.

Contraindications to cervical discography include known allergies to contrast dye, suspected or confirmed patient sepsis, infection at the site of injection, known coagulopathy, or patient refusal. Symptoms of cord compression or myelopathy are absolute contraindications.

TECHNICAL CONSIDERATIONS

Cervical discography is a technique in which proficiency and expertise are essential. The precise detailed knowledge of the anatomy of the cervical spine and the vital structures in the anterior cervical region is of utmost importance. The discographer must be skilled in airway management and cardiovascular resuscitation.

Pre-procedural preparations include usual preoperative considerations as well as a crucial aspect of cervical discography: the review of prior imaging studies of the cervical spine before beginning discography. The procedure should not be performed at any level where spinal cord compression exists, with or without myelopathy. Any cervical disc level revealing spinal cord deformity should be avoided or studied under extreme care, depending on the individual circumstances.

Prophylactic antibiotics are given within an hour before the procedure begins, usually Cefazolin or a similar antibiotic with known intradiscal diffusion characteristics and activity against staphylococcal and streptococcal skin inhabitants.

The procedure is performed with the patient in supine position and with support under the shoulders, the head and neck slightly hyperextended, and the head rotated away from the side used by the discographer. The disc cannot be entered posteriorly due to the spinal cord or anteriorly because of the trachea. Therefore, entry into the cervical disc is usually done from the right anterolateral approach. Complete aseptic technique is used throughout the procedure. The skin is prepped with Betadine or chlorhexidine solution and the solutions should remain on the skin for at least 2 minutes to kill any *Staphylococcus aureus* or *Streptococcus epidermidis* spp., which are the most common skin bacteria usually implicated in risk of deep tissue infections following skin puncture. An alcohol rinse of the site is done for maximal antibacterial effect.

A right paratracheal approach is used and the C-arm is placed in oblique position and the uncovertebral junction is identified. Unlike lumbar discography, where the disc is punctured on the side opposite the patient's symptoms, a right-sided approach is used by most discographers because of concern of accidental puncture of the esophagus with the left-side approach. The skin is anesthetized with 1% buffered, preservative-free lidocaine. Light intravenous sedation, usually with midazolam, may be used; however, the patient must always remain alert enough to respond to pain sensations and communicate them. The patient is monitored closely for vasovagal signs, which may be caused by compression of the carotid artery during manual displacement with needle entry. The C-arm

(A) AP view   (B) Lateral view
FIGURE 66.1 Illustration of cervical discography at C4/5, C5/6 and C6/7.

is placed in an oblique position with a slight cranial angulation to best visualize the disc space.

Skin puncture is made with an 18-gauge needle, medial to the anterior border of the sternocleidomastoid muscle, between the carotid sheath and trachea. A 22-gauge 3.5-inch styletted spinal needle is inserted through the puncture hole and slowly advanced to the target point just medial to the uncovertebral junction of the lower vertebral body. The carotid pulse is palpated and carotid sheath structures are displaced laterally by digital pressure. Additional local anesthetic is given along the needle tract. Slow, deliberate needle advancement is key to the successful procedure. The needle is advanced either into the disc or against the vertebra adjacent to the disc. The position is confirmed in the anteroposterior and lateral projections with the fluoroscope. Careful adjustment and redirection of the needle as necessary is made into the annulus of the disc.

Two levels, one superior and one inferior, to the level being examined should also be punctured to serve as necessary controls for the patient pain response.

From 0.25 to 0.5 mL of contrast solution is injected into the nucleus at each level and the pain response is noted. The discogram is positive when the patient reports concordant pain that closely resembles symptomatic pain in intensity and location. Injection of local anesthetic into a painful disc is used to further evaluate symptomatic relief and confirm a disc as a pain generator. Leakage of contrast out of the disc space is noted, as well as the overall disc appearance. Figure 66.1 illustrates cervical discography.

Intradiscal antibiotics may be injected at the discretion of the discographer, but with careful attention to leakage of antibiotic solution into the epidural space. Some discographers use antibiotic solution in combination with contrast. It is preferable and safer to not mix antibiotic with contrast and use antibiotic only when the pattern of

dye has been fully visualized and subarachnoid spread has been completely ruled out.

INTERPRETATION

Interpretation of the pain response is the *sine qua non* of the effective use of cervical discography. Pain is a subjective response that individuals report differently. Pain reporting cannot be objectively treated for bias-free analysis. Various methods have been used to rate the patient pain response; most incorporate self-reporting using a visual analogue scale, an independent observer rating pain appearance and behavior, and patient reporting the similarity of injection pain to chronic pain. The alleviation of pain following injection of local anesthetics is recorded to note the analgesic effect in an abnormal disc.

Cervical discography and the pain response are discussed by Klafta and Collis.[50] In their work a very low percentage of discs was judged to be normal, as pain occurred in the majority of injections, and this was taken as an indicator of disc abnormality but not diagnostic of disc protrusion. A subsequent paper addressed this finding; the authors did not consider pain from injection to be of significance and of concern only if a mass lesion in the disc itself was demonstrable.[51] This contrasts with current discographic practice, as exemplified by the report of Ohnmeiss et al.[40] Pain response and radiographic appearance of discs showed good agreement, with clinical pain provoked in 78% of discs appearing abnormal and in only 14% of normal discs.

Beginning with the report of Roth[10] in 1976, with discogenic pain accurately diagnosed prior to surgery by analgesic disc injection, many authors report that the most effective test for the identification and localization of a painful disc is cervical discography. Patients with cervicogenic pain are accurately and consistently diagnosed by

cervical discography reproducing their characteristic pain. Other modalities can identify pathology, but only discography can correlate abnormalities with pain.

The purpose of the procedure is to identify a source of pain. The information to be recorded for every procedure includes, but is not limited to, injection volumes; characteristics of all end points of injections reached; pain responses at each level examined on a 0 to 10 scale with 0 meaning no pain and 10 the worst pain possible; whether the pain felt is identical, similar, or not at all the same as the pain that led to the examination; location of pain from the examination; the morphology of the disc revealed by the examination (annular tears, end plate defects, anatomical abnormalities, fissures, or leakage of contrast media); correlation of these findings with MRI or CT imaging studies; and an opinion from the discographer concerning the apparent validity of the examination — patient pain response and cooperation.

Even though the pattern of contrast dispersal is the least important finding in cervical discography, some characteristic patterns of abnormal discs have been described. These include the following: escape of contrast beneath the longitudinal ligament or into the epidural space reveals rupture of the annulus; a deflated balloon appearance filling the disc space indicates degeneration of the nucleus; escape of contrast through the vertebral end plates shows interosseous herniation; leakage of contrast beneath an unfused ring epiphysis shows vertebral edge separation; escape of contrast into a communicating hemangioma related to end plate fracture.

COMPLICATIONS

Although very beneficial as a diagnostic tool, the procedure is not without risks.[52–60] Complications can occur due to incorrect needle placement in which the hypopharynx, esophagus, or even spinal cord could be punctured, with the attendant risks of infection or neurologic damage. Very deliberate and careful needle advancement and good fluoroscopic visualization prevent such occurrences and their sequelae.

Unusual complications are also possible. In one reported case, quadriplegia developed within seconds after injection into the intervertebral space. During the injection the patient reported having severe pain in her arm. Surgical evidence showed sequestered portions of a degenerate disc were pushed into the spinal canal during the examination. Slow recovery of neurologic deficits took place after the operation.[58] A recent study of a large group of patients undergoing cervical discography gave a 1.49% complication rate based on the number of discs injected.[54] There were two cases of discitis, one post-injection hematoma, and one patient developed headache.

The cord compression syndrome due to soft central disc herniation can be a potential complication with exacerbation of herniation causing myelopathy and even quadriplegia in extreme cases.

Another rare but significant potential complication, that of spinal epidural abscess mimicking disc herniation, was reported by Sawada et al.[59] His patient developed fever, sore throat, and nuchalgia with a sudden onset of quadriplegia following partial sigmoidectomy, and MRI showed characteristic findings of a cervical herniation. At discectomy, cervical discitis was discovered with an associated spinal epidural abscess. With antibiotic follow-up, he improved. A high index of suspicion must be accorded any MRI image and associated clinical signs of infection. Discitis, although rare, must remain in the differential diagnosis.

Discitis, one of the most dreaded complications of disc injection, is rarely reported and in reviews of the literature, rates of 0.1 to 0.2% are found. Guyer et al.[60] in their series report a rate of infection of 0.1 to 0.5%.

The author typically uses both intravenous and intradiscal antibiotics for prophylaxis. Although an intravenous bolus before the procedure can produce antibiotic penetration into the disc, timing of the bolus is critical. Studies have found that the minimum inhibitory concentration (MIC) for the most common agent responsible for discitis, *Staphylococcus epidermidis*, was not exceeded using cefazolin except in a well-defined time period of 15 to 80 minutes after an intravenous bolus.[61] Moreover, if the disc has undergone degeneration, it is likely that antibiotic concentrations intradiscally would be further reduced. Thus, intradiscal antibiotics are usually considered.[59–67] Studies support the use of appropriate broad-spectrum intradiscal antibiotics to minimize the risk of discitis; typical skin inhabitants *Staphylococcus aureus* and *Streptococcus epidermidis* are the organisms most likely to be contaminants. Cefazolin has been widely used because of its activity against these organisms and its documented inhibitory levels intradiscally.[61]

The argument has been made for the use of intradiscal antibiotics for prophylaxis of disc infection during discography and that with proper timing and choice of antibiotic, intradiscal placement of antibiotic should obviate the need for systemic administration to avoid the risk of generating antibiotic resistance.[63–66] Several antibiotics meet the requirement to be above the minimum inhibitory concentration of *Staphylococcus aureus* and *Streptococcus epidermidis* among them cefazolin, gentamycin, and clindamycin; ceftriaxone meets this requirement and also has been shown to persist at levels above the MIC for these organisms as long as 5 hours in the intervertebral disc space with administration systemically 1 hour prior to the procedure.[63,67]

There are, then, several classes of antibiotics shown to be efficacious. With proper selection and use, any allergic or sensitivity reaction should be avoided.

A recent case report by Boswell and Wolfe[68] details the first reported post-discography seizures associated with a cephalosporin, cephazolin. Caution would be advised mixing beta-lactam antibiotics or cephalosporins with contrast prior to disc injection. Accidental or inadvertent intrathecal injection with this class of antibiotic may provoke this reaction.

With the exercise of meticulous care at all times, discography can be done with few, if any, complications, when performed in sterile conditions and by those well experienced in the procedure. It is not a procedure to be attempted by the novice because it is very easy to pass a needle through the disc and into the spinal cord.

CONCLUSION

Cervical discography is a specialized procedure requiring the skill of a highly trained and competent interventionalist with expertise in the procedure. Diagnostic disc injection may be indicated in the evaluation of patients with symptomatology without a discernible etiology from other imaging studies. Discography is used to determine the presence of pathology and to reproduce pain felt by the patient, so-called concordant pain. It is not a screening procedure but rather a confirmatory one when cervical disc pathology is suspected and is best utilized with MRI and clinical examination.

There is a very low level of reported complications; patient selection, skilled operation, and maintenance of sterility are essential. Cervical discography has a unique position in the diagnosis and localization of the painful disc syndrome, correlating MRI findings with symptomatology and in determining the levels for successful surgical fusion of the cervical spine.

Thoracic Discography

Vijay Singh, MD, and Laxmaiah Manchikanti, MD

INTRODUCTION

Discography was first named by Lindblom[1] when he described diagnostic disc puncture. Hirsch[2] used the procedure to identify painful discs in patients with sciatica and lumbar pain. The foundation of the practice of discography was thus begun, and Lindblom did further work using the injection of contrast media to visualize radial tears in the annulus, thus expanding the diagnostic information from intervertebral discs. Pain provocation upon injection served to localize the painful disc, and radiographic appearance with contrast gave information about the internal morphology of the disc.

The clinical use of discography has expanded enormously in the ensuing years.[3–5] Lumbar discography and, to a somewhat lesser extent, cervical discography have been extensively documented and practiced over the past three decades. The technique of thoracic discography is very similar to that of lumbar discography.[6] Although thoracic disc herniation in association with spinal cord compression is documented as a source of back pain, cases of thoracic disc pathology with back pain and an absence of neurological deficits as the major findings are not as well documented in the literature. Imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI) showing an absence of disc herniation do not exclude the thoracic disc as the source of pain.[7,8] Here, as in lumbar and cervical studies, the well-known attribute of discography and its ability to identify exactly which disc is pain producing, makes it a valuable and unique procedure.

ANATOMY

Thoracic intervertebral discs have a well-defined nucleus pulposus surrounded by a denser fibroelastic aggregation of fibers comprising the outer portion of the disc, the annulus fibrosus. Like other discs, the annular layer is innervated by nociceptor fibers in the outer regions of the annulus, receiving them posteriorly from the sinuvertebral nerves. The anterior portion of the disc receives some fibers from the thoracic sympathetic chain. Dorsal and ventral rami branch from the spinal cord and exit via the intervertebral foramina laterally. Radicular symptoms can result if the disc herniates laterally and impinges on the thoracic nerve root as it leaves the foramen. Myelopathy causing lower extremity or bowel and bladder symptoms can result if the thoracic disc herniates posteromedially. More severe compression of the cord can result in paraparesis.

Neurological occurrences are a result of the spinal cord occupying a fuller extent of the canal. It is a more critical issue neurologically to identify precisely the disc level involved in a suspected disc herniation and the relationship of the herniation to the cord in the thoracic region. The corresponding case is the cauda equina occupying the larger diameter lumbar canal. With a larger diameter canal and a smaller diameter structure filling it, direct neurological insult is less likely.

PATIENT SELECTION AND INDICATIONS

Criteria for performing thoracic discography are not significantly different from those used in cervical or lumbar procedures. The desired result is the same in all three uses of discography — the identification and confirmation of a particular disc as a pain-generator. Thoracic discogenic pain without evidence of a true disc herniation is not a well-known or documented clinical entity. Application of the same principles guiding the use of discography pertain: discography is a useful procedure for patients who have

failed to benefit or are refractory to conventional therapies and have unremitting pain, as determination can be made whether a particular disc is a source of thoracic back pain.[9–14] These criteria apply to patients (1) having persistent thoracic radicular or spinal pain, for whom traditional diagnostic modalities have failed to identify the source of pain; (2) for whom traditional methods have identified abnormalities and to make the determination if they are responsible for the pain; (3) planning to undergo spinal fusion, where discography identifies the levels to be fused; (4) having post-fusion pain, to identify whether levels above or below those fused are pain producing; (5) for whom recurrent disc herniation cannot be differentiated from scar tissue using traditional imaging methods.

CONTRAINDICATIONS

These are similar to the contraindications for cervical or lumbar discography, with the added precautions due to the anatomical site and physiologic function: anatomy distorted by disease or deformity may preclude the procedure, and with the attendant risk of inadvertent lung puncture and pneumothorax, pulmonary function should be assessed. Thus, contraindications include thoracic deformity, inadequate pulmonary function, coagulopathy, infection at the puncture site, allergy or sensitivity to medications used, and patient refusal for the procedure.

TECHNICAL CONSIDERATIONS

The technique in thoracic discography is very much like that used for lumbar procedures. Prior imaging studies, ideally including an MRI, are reviewed. The discontinuation of aspirin or other anticoagulants is an important aspect, which needs to be discussed with the primary care provider. Prothrombin time/partial thrombin time (PT/PTT) with a platelet count is done if the medications are continued. Some patients will need anticoagulant therapy. In those patients undertaking an interventional procedure, it poses a high risk, but is not contraindicated.

The consent form is checked with the patient, with particular attention given to the risks and benefits of the procedure and of long-term administration of antibiotics should they be necessary. Specifically, the risk of pneumothorax is fully discussed. Post-procedural transportation is confirmed. ECG, blood pressure, and pulse oximetry monitoring is begun and done during and immediately after the completion of the procedure. Intravenous access is established and prophylactic antibiotics are given within 1 hour of the procedure. When the pre-procedural checklist is complete, the patient is taken to the procedural room.

The patient is positioned prone on the fluoroscopic table. The C-arm is positioned to visualize the pedicle, which projects beneath the superior articulating process

FIGURE 67.1 AP view. Thoracic discograms: T9/10 and T10/11.
FIGURE 67.2 Lateral view discography: T9/10, T10/11, T11/12.

of the vertebral body of the desired level. A steeper angle of needle insertion is required in the thoracic procedure than in the lumbar. By fluoroscopy, the superior articulating process can be positioned 30 to 40% of the distance across the ipsilateral ventral aspect of the vertebral body. It is important to keep the needle track along the lateral aspect of the superior articulating process and medial to the costotransverse junction to avoid pleural puncture. In lower thoracic levels some discographers have patients hold an expired breath to deflate the lung to reduce the chance of inadvertent pleural puncture, although at the time it is not necessary to make the patient more anxious and hence more motile. (See Figure 67.1 and Figure 67.2.)

Strict aseptic technique is maintained throughout the procedure. The skin at the site is prepped with betadine or chlorhexidine, which is left on the skin for at least 2 minutes followed by an alcohol wipe for maximal antiseptic effect. A fenestrated sterile drape is then applied. If it has

FIGURE 67.4 AP needle placement for discography at T10/11, T11/12, and T12/L1.

been decided to use conscious sedation, usually 1 to 2 mg of Versed and 50 to 100 mg of Fentanyl is sufficient to provide a mild degree of anxiolysis and analgesia. A skin wheal is raised with 0.25 mL 1% lidocaine; deeper tissues are anesthetized with 1% lidocaine or local anesthetic of choice. Before any injection of anesthetic, aspiration should be confirmed to be negative for blood or fluid to prevent accidental intravascular or subarachnoid injection.

Skin puncture may be done with a 22-gauge needle. A 25-gauge styletted needle is introduced through the puncture hole and the needle visualized in both antero-posterior and lateral projections to be in correct position similar to the lumbar procedure. One or two levels adjacent (one superior and one inferior) may be punctured to serve as controls as in the lumbar procedure. Injection of contrast follows with the removal of the needle stylet. Appearance of the contrast should be noted in two projection planes to be certain of injection location in the thoracic disc. For each level injected pain response and volume of injectate is noted. Pain responses are noted to be absent, concordant, or discordant. Intradiscal antibiotic is injected as needed. Needles are removed and skin puncture sites are dressed. (See Figure 67.3 and Figure 67.4.)

Patients are transferred to the recovery area and monitored until ready for discharge. Nonrenewable prescriptions appropriate for pain are given along with printed discharge instructions. Patients are advised that some pain or discomfort can be expected for up to 4 days later. If rare events such as fever, night sweats, chills, malaise, or worsening pain occur within a week, patients are instructed to call immediately as a disc infection could be developing. Patients are carefully monitored for signs of pneumothorax and advised to watch for breathing difficulties or pain. All patients are advised to rest for 24 hours after the procedure, with someone with them for that period in case breathing difficulty or another problem develops. Instruction is given to avoid immersion in water
for the 24 hours after the procedure to minimize the risk of infection. Transport is made to the CT facility as previously arranged. Attempts are made to contact all patients by phone within the next 24 hours to check their status.

As with other discography procedures, reporting of results completes the procedure:

1. Injection volumes and pressures reached, points of injection (end point, absence of end point, voluntary termination of injection) are recorded.
2. Pain response on a 0 to 10 Visual Analogue Scale (0 = none, 10 = worst possible) is recorded.
3. The amount of sedation and effect of sedation on the pain response should not be discounted.
4. Whether the pain was discordant or concordant is recorded for each level.
5. Locations of perceived pain and intensities are recorded.
6. Disc morphology as revealed by the spread of contrast should be recorded, especially annular tears, fissures, leakage of contrast media, and loss of disc height. The spread of contrast can provide very useful information. Annular spread of contrast will vary depending on the amount of degeneration and extent of annular disruption. Radial or concentric tears have different patterns. Although it is not easy for an untrained eye to decipher the pattern of an annular tear, the experienced discographer can certainly study the pattern of contrast spread. Anterior and lateral spread of contrast indicates annular incompetence in the anterior and lateral portion. These findings should be correlated with the MRI findings and the patient's symptoms.
7. Discometry records if pressure measurements were taken — opening pressure (first sign of

contrast media), pressure at which pain was first noted, maximum pressure reached during procedure.

COMPLICATIONS

Pneumothorax has been mentioned as a possible complication. By using meticulous technique and care this can be avoided. The same applies to damaging any retroperitoneal structure. Unintended puncture or damage can be minimized with strict attention to detail.

The most watched-for and serious complication in discography is discitis.[15] Prophylaxis with appropriate antibiotics given at proper times before any procedure can ensure that the disc achieves minimal inhibitory concentrations against the most common skin contaminants, *Staphylococcus aureus* and *Staphylococcus epidermidis*. Several antibiotics are suitable, including cefazolin, gentamycin, ceftriaxone, and clindamycin.[16] With several families of acceptable antibiotics, allergies and sensitivities should not be an issue. The use of intradiscal antibiotics is favored by some authorities, and all the previously mentioned agents have been used successfully.[17]

Note is made of a reported complication using cefazolin. Inadvertent or accidental introduction of cephalosporins to the intrathecal space may lead to the development of seizure activity, even if there is an absence of prior history.[18]

PAIN RESPONSE

As in lumbar and cervical discography, pain response is reason for the procedure. The result is called positive if the injection of contrast causes pain the patient recognizes as the same as pain leading to medical consultation. If the patient recognizes pain as same or very similar to the presenting pain, it is called concordant pain and grading on a sliding scale of 10 (worst) to 0 (none) is commonly done. The disc is considered to be the cause of the symptoms and noted. Although it is not fully elucidated what a finding of painful discordant disc means, it should not be regarded as normal. Some authors believe this finding is a discovery of a disc that is destined to become symptomatic although it may be asymptomatic at present. If the pain is unfamiliar, regardless of grade, it is called discordant and at that particular level is felt not to be implicated. Any equivocal response is usually an indication that the explanation for pain lies elsewhere and not in a thoracic disc, with further evaluation needed.

OUTCOMES

Thoracic discography does diverge from lumbar and cervical discography at the completion of the procedure.

Patients with thoracic disc herniations causing neurologic deficits are very likely to undergo immediate spinal fusion following discography for stabilization; other therapy is not considered.[3]

While lumbar and cervical patients have a range of interventional procedures as well as medical management available to them, thoracic patients usually have options of open discectomy and fusion for severe cases or traditional therapies involving medications and time. Disc herniations in the thoracic spine are reported in the literature as manyfold less likely to cause pain; there is a definite prevalence but apparently many are asymptomatic. Conservative therapy is appropriate.[8]

CONCLUSION

Discography, whether cervical, thoracic, or lumbar, has similar indications. The technique varies with the site of the anatomy. In conjunction with other imaging modalities, it can help provide a complete picture of disc pathology. There are common concerns over complications and risks; they can be accounted for with appropriate preparation and patient selection. The information produced by the procedure is quite similar, dependent on the patient's subjective reporting of concordant/discordant pain. Whether planning surgery, percutaneous procedures, medical management, or physical therapy and rehabilitation, it has proved to be invaluable as a tool to differentiate spinal pain.

Lumbar Discography

Vijay Singh, MD, and Laxmaiah Manchikanti, MD

INTRODUCTION

Provocative lumbar discography is an invasive diagnostic procedure in which contrast is injected into the intervertebral disc. It is a procedure that has been practiced for over 50 years and is accepted by many as a valid investigative tool. In the evaluation of spinal pain, it is of critical importance to diagnose accurately precise origins of pain or structural derangement.[1] It is also important to evaluate findings of pathological significance from imaging studies and correlate them with patient symptoms.[2] When a disc problem is suspected by history or physical examination, imaging studies such as magnetic resonance imaging (MRI) can determine disc pathology in many cases, but they do not always identify a particular abnormal finding as coincident with painful symptoms.

Lumbar provocative discography is a complementary examination to confirm if an abnormal disc determined by radiologic imaging and patient complaint is the pain-generating entity.[3] Discography has been shown by formal investigation, when performed by experienced and knowledgeable interventionalists, to improve both surgical and nonsurgical outcomes.[4] Clinical questions such as the following may be answered using discography:

- Is disc pathology observed by imaging studies of clinical significance?
- What therapeutic intervention is indicated?
- Is a satisfactory surgical outcome likely?
- Which spinal segments should be treated?
- What prognosis is likely?

HISTORY

The study of lumbar disc puncture to obtain clinically relevant information was begun by Lindblom in 1948.[5] In the same year Hirsch injected discs with saline and procaine.[6] His hypothesis that pressurization of an injured or degenerative disc would reproduce pain was confirmed. Procaine injection alleviated the pain response following pressurization. The importance of this work was that it showed disc puncture could be used to make a clinical diagnosis of the cause of a patient's back pain.

In the 1950s, Cloward[7] developed techniques for lumbar disc injection and its indications. Erlacher[8] documented the dispersal pattern of dye in cadaveric discs and established radiographic correlation between dispersal patterns and radiographic images. The suggestions that mechanisms other than simple nerve root compression could cause pain were made first by Fernstrom.[9] Discography was relevant for its role in the development of this concept, as painful discs were diagnosed without a nerve compression being present.

Holt's[10,11] papers critical of discography have been challenged and are not considered today other than for their historical significance in the development of techniques for successful discography. His papers have been thoroughly reviewed and several issues raised to question their relevance to current discographic practice, including patient selection, contrast dyes used, techniques employed, and interpretation made of observed findings.

Important developments over the last three decades include the use of water-soluble and less irritating contrast

media, fluoroscopic guidance for accurate needle placement, styleted needles to minimize infection, stricter criteria for patient selection, and the use of axial computed tomography (CT) scanning after discography to enable viewing the discs in three planes. Derby et al.[4] developed the practice of manometric measurement of injection pressures during the assessment, adding further information useful to the interpretation of the status of the disc.

Advancements and technological development have made lumbar discography the standard by which painful discs are diagnosed. It is a useful test in the evaluation of candidates for surgery, and for patients undergoing minimally invasive procedures for low back pain.

There is now recognition of the metabolic complexity of the intervertebral disc and the manner in which it responds to injury. The early theory of disc rupture and nerve root compression from the work of Mixter and Barr[12] has been extensively developed and work continues today. Crock[13] put forth the idea of symptomatic disc lesions, from internal disruption to prolapse and protrusion, with different mechanisms causing each particular pathology. The exact mechanism of pain production by an injured or damaged disc is unknown, but active research implicates inflammatory and immunological mediators as well as the interaction of metabolic mechanisms and enzyme activation.[14] Lumbar discography is required to differentiate symptomatic from asymptomatic discs and establish the diagnosis of internal disc disruption.

ANATOMY

The lumbar intervertebral disc is made up of an external layer of concentric rings of fibrocartilage composed of collagen and fibroblastic cells, the annulus fibrosus surrounding the nucleus of the disc, and the nucleus pulposus. The collagenous end plates consist of collagen fibers and chondrocytes, and through this layer all nutrients vital to the maintenance of the disc diffuse. These end plates cover the superior and inferior aspects of the disc, and collagen fibers from the most superficial aspects of the annulus join the end plate fiber and inset directly into the bone of the vertebral body.

The lamellae or layers in the annulus are not continuous; many are found to extend 40 to 50% or less of the circumference of the disc. They are thicker in the center of the disc and in the anterolateral portion, becoming thinner posteriorly.[15] The nucleus is a three-dimensional intricate network of glycoproteins, collagen fibers, and aminoglycans. The water content may be as high as 70%, decreasing with age. This water–glycoprotein–aminoglycan gelatinous combination gives the disc its shock-absorbing capacity and its multiaxial weight-bearing properties during flexion and extension of the spine. Innervation of the disc has been shown histologically with the outer third of the annulus being innervated with fibers

from the sinuvertebral nerve. Both nerve fibers and mechanico-receptors are found in the outer third of the annulus fibrosus. These have been characterized by Bogduk et al.[16] and postulated as the substrate for primary disc pain in disease and for the pain response of provocative lumbar discography.

Activities of daily living, trauma, and age cause changes in the disc found clinically as degeneration. With disc degeneration not only is the internal structure of the disc jeopardized as well as its function, but pain results from a variety of mechanisms.[17] The release of potent mediators of inflammation, direct stimulus of intradiscal nerve fibers, the action of proteolytic enzymes from the nucleus itself, and activation of potent cell cytokines all are documented to be involved in the production of pain from injured lumbar discs.[18–23]

INDICATIONS

Indications for discography follow the position statement per the North American Spinal Society (1995):[24]

1. A primary indication for lumbar discography is the identification of a particular disc as a pain source or the correlation of pain with a disc with a known abnormality.
2. Patients with persistent low back pain in whom an equivocal MRI has not confirmed a disc as a source of pain.
3. Further assessment of patients who have had surgery who continue to have persistent pain. A painful disc in a fused segment or possible recurrent disc herniation can be determined by provocative lumbar discography.
4. Disc assessment prior to surgery to determine if discs in the proposed fusion segment are painful and to find if discs adjacent to this disc are normal and nonpainful.
5. Assessment of patients prior to undergoing minimally invasive procedures to confirm a painful contained disc herniation or to identify the distribution pattern of dye in disc to fully discern disc degeneration.

CONTRAINDICATIONS

Absolute contraindications to the procedure include discitis, local skin infection, cord compression, known coagulopathies, and allergies to contrast media. Relative contraindications are allergies to other medications used, pregnancy, and known disc herniations. Patients with abnormal profiles on psychological screening examinations require careful evaluation and may give variable, difficult-to-interpret pain responses.

TECHNIQUE

Discographers must be experienced in the technique and knowledgeable in anatomy, as well as skilled in the interpretation of results. The techniques specific to the performance of lumbar provocative discography are presented in several texts; it is not a procedure for amateurs. Consultation and close communication with the primary care physician is maintained, especially in matters of discontinuing aspirin or anticoagulants. Consent is checked with the patient with attention given to the risks involved and the potential risk of long-term antibiotic therapy should it be necessary.

PREMEDICATION

For purposes of premedication or intravenous sedation, it is preferable to use only anxiolytics if sedation is deemed necessary. Analgesics such as Fentanyl should be avoided but in rare cases they may become necessary for those patients who have needle phobia or a very low pain threshold. A broad-spectrum antibiotic should be given intravenously 30 minutes before the start of a procedure, as a prophylactic measure to prevent discitis. Cefazolin is commonly used; if there is sensitivity to cephalosporins or penicillins, clindamycin or gentamycin may be substituted.

Needle placement is accomplished under fluoroscopic guidance in the operating room or special diagnostic procedure suite. Meticulous attention to asepsis is of paramount importance.

INJECTION OF CONTRAST

A normal disc can accept 1 to 2 mL of contrast agent without eliciting pain. Injection without resistance or injection exceeding 2 mL of contrast should alert the interventionalist to the likelihood of extravasation of contrast and should be discontinued immediately. Resistance to injection should be noted as well as any pain response. The location and character of any pain are part of the evaluation. Concordant pain is pain produced upon disc injection, which matches the chief complaint pain as perceived by the patient. Pain that is elicited but of a different character intensity or location as perceived by the patient is termed discordant. This may signify an injured or damaged disc but is not considered the disc producing the patient's pain. A disc level that, upon injection, does not elicit pain is termed a control level. The recording of clinical information for later interpretation is detailed below.

Following disc injection, it may be deemed appropriate to inject antibiotic intradiscally. A range of 0.5 to 2.0 mg antibiotic is typically used. (The range of intradiscal antibiotic use varies. Some use much higher doses.) The

needles are removed and the puncture site is dressed with antibiotic ointment and a sterile dressing.

INTERPRETATIONS OF DISCOGRAMS

Patterns of dye dispersal consistently show one of five sets of features that can be correlated with distinct stages of disc degeneration. The discogram pattern is created by the distribution of contrast intradiscally. The descriptions of the contrast pattern seen on radiographs and the subsequent correlation of their relationship to actual disc degeneration is derived from the work of Adams et al.[25] in his cadaveric study.

ADAMS CLASSIFICATION OF RADIOGRAPHIC APPEARANCE

1. Cottonball discogram: The contrast medium appears to be contained within the nucleus and is of uniform density. The shape tends to be round or central. Discs giving this pattern of contrast do not show signs of degeneration. No fissures into the annulus are seen. The injection pressure into the nucleus is low; if the needle is moved into the annulus the injection, pressures rise significantly, as the intact annulus does not easily deform to accept fluid.

2. Lobular: The contrast appears to be contained within the nucleus and has more of a lobulated appearance, with greater density toward the end plates and lesser or absent density in the center. A shape suggesting a hamburger is perceived by many observers. These patterns are shown by mature discs with the nucleus beginning to coalesce into fibrous lumps separated by clefts or lines of fracture. The annulus is intact, without obvious fissures extending from the nucleus. Contrast injected may not appear to move freely from one part of the intradiscal space to another. As in the previous case, injection into the annulus was difficult.

3. Irregular: The contrast pattern first begins to show disc degeneration. There is poor differentiation between the nucleus and annulus, with a fibrous-appearing nucleus and multiple small clefts and fissures between the nucleus and inner annulus. Injection pressures are usually low except in the outer margins of the annulus, which appears relatively intact.

4. Fissured: The discogram shows contrast extending to the outer edge of the annulus, even beyond the edge of the vertebral body in some cases. No contrast is observed to escape from the annulus of the disc. One or more radial fissures are seen in the annulus and these extend to the posterior or posterolateral margin of the

FIGURE 68.1 Lateral view. L3/4: Cotton ball appearance (normal/control disc); L4/5: Degenerated disc with posterior leakage of contrast material into the epidural space; L5/S1: Posterior bulging and degeneration.

annulus. The posterior annulus often bulges and extends well beyond the edge of the vertebral body. Injectate tends to form pools in the nucleus and annulus, filling the fissures but not escaping from the disc itself. Injection is relatively easy into any region.

5. Ruptured: Contrast material is observed extending to the outer margin of the annulus and escaping from the disc. A large quantity of contrast might be seen in the disc; there is no limit on the volume of contrast that can be injected. Almost always a complete fissure is identified, usually in the posterior annulus. The escaping contrast can be readily identified, even if hindered by the posterior longitudinal ligament. (See Figure 68.1 and Figure 68.2.)
FIGURE 68.2 AP view L3/4, L4/5, L5/S1.

MODIFIED DALLAS DISCOGRAM DESCRIPTION

Sachs et al.[26] developed the Dallas Discogram Description classification system, modified by Schellhas et al.,[27] using five grades (0 to 4) to delineate the appearances of annular tears found in discograms:

Grade 0: Normal discs with an intact annulus
Grade 1: Fissure/tear involving inner one third of annulus
Grade 2: Fissure/tear involving inner two thirds of annulus
Grade 3: Tear extending from the nuclear space either into or through the outer one third of the disc annulus, involving up to 30° of the disc circumference
Grade 4: Tear extending from the nuclear space either into or through the outer one third of the disc annulus, involving greater than 30° of the disc circumference

This modified system of Grade 0 to Grade 4 is straightforward and is commonly used to describe the appearance of tears seen in lumbar discography.

INTERPRETATION OF PAIN RESPONSES

The provocation of pain from injection of an abnormal disc is the *sine qua non* of contemporary discography, along with the confirmation of relief with injection of analgesics. Pain provocation with disc injection is not fully understood. Different hypotheses have been advanced, including pain provocation by raised intradiscal pressure, causing nerve fibers in the annulus to be stretched, pain from biochemical or neurochemical stimulation, or disc injection increases pressure at the vertebral end plates resulting in pain or, similarly, intraosseous pressure increase in the vertebral body itself from pressure transfer across the end plates, resulting in pain.

The topic of pain responses in lumbar discography has generated a voluminous literature. By its subjective and changeable nature, pain itself is difficult to report and record, making statistically valid conclusions or even inferring results for comparison subject to issues of bias, placebo effect, and psychological interpretation. Several authors have made and expounded on this point, and it still enters the literature as a viable topic, when the natural history of lumbar pain is discussed or treatment modalities are compared.[28–30] It will continue to be one point of potential controversy until an objective, quantifiable means of measuring the pain response is found. Close attention should be paid to the interpretation of the pain response during the injection of the disc, that is, reports of whether the pain and the intensity of the pain are similar to or exactly like that for which the patient seeks relief.

Pressure-controlled discography is one measure for the determination of the level of pain response. A disc is determined to be symptomatic or asymptomatic based on the provocation of pain and the pressure at which that pain is produced. The opening pressure at which the patient reports pain, which may be similar or dissimilar to the usual pain experienced by the patient, is used to produce a manometric classification of the intervertebral disc. This classification is based on the work of Derby et al.,[4] which classifies discs as chemically sensitive, mechanically sensitive, or indeterminate according to the pressure giving the onset of pain. In a chemically sensitive disc, pain appears at pressure less than 15 psi greater than opening pressure, mechanically sensitive discs replicate pain with pressures between 15 and 50 psi, and indeterminate discs are those giving a painful response at greater than 50 psi; these findings usually warrant further investigation of a pain source other than the disc. The clinical correlation suggested by Derby is that chemically sensitive discs may be candidates for an IDET (intradiscal electrothermal therapy) procedure (annular pathology), mechanically sensitive discs may be candidates for laser or other discectomy, and indeterminate discs should be reevaluated as the source of pain.

Along with a lack of definitive evidence of the source or mechanism of pain from disc injection, other factors make the assessment of pain difficult — psychological factors are reported to have a profound influence on the accuracy of pain reporting, and a perplexing situation exists whereby some patients report pain upon injection of otherwise normal, nonpathogenic discs. There may exist subtle disc changes with respect to prolapsed annular fibers not contiguous with the disc, or this may be a manifestation of a psychological factor. Nonetheless, patients report pain with radiographically normal-appearing discs. The salient point is that recognition of psychological factors must not be ignored and information given that is pertinent to a patient's prognosis may contribute to the patient's sense of well-being apart from any immediate treatment decision.[29,30]

COMPLICATIONS

The risk of disc infection, discitis, is one of the most respected potential complications. Prophylactic antibiotic use and adherence to strict sterile technique has reduced this risk to very low levels.[31–34] Other complications, which are rare, include meningitis, spinal headache, subdural and epidural abscess, intrathecal hemorrhage, severe reaction to accidental intrathecal injection, disc herniation, retroperitoneal hemorrhage, nausea, convulsions, and increased pain.[35] Poor needle placement may cause damage to the vertebral end plate, leading to vertebral end plate necrosis. Infrequent reports also include the cauda equina syndrome, febrile reactions, and myalgias.[35]

CONCLUSION

Lumbar provocative discography provides information about the structure and pain sensitivity of the disc that cannot be obtained by any other method. Its role is to identify a particular disc as a pain generator and aid in the correlation of abnormal radiographic imaging with that pain. It should be performed by those who are well experienced in the procedure, under strict sterile conditions and with fluoroscopic guidance. There is ample evidence for the use of antibiotics, either intradiscally or intravenously, for prophylaxis against discitis. Correspondingly, maintenance of strict and meticulous sterile technique may accomplish the same end. Information from the procedure should include the volume injected into the disc, the pressure eliciting pain, the patient's pain response with emphasis on the location and similarity to the patient's symptomatic pain, and the observed pattern of contrast distribution. The interpretation and correlation of the pain response is the reason for the examination; increased knowledge of the disc morphology may lead to better treatment planning.

Intradiscal Therapies

Vijay Singh, MD, and Laxmaiah Manchikanti, MD

INTRODUCTION

"Intradiscal therapies" is a term commonly used for the minimally invasive, percutaneous techniques applied to the treatment of symptomatic contained disc herniation and discogenic pain due to internal disc disruption or annular fissures.

Historically, intradiscal therapies were directed to the disc nucleus pulposus to remove portions of nuclear material and decompress the disc and reduce pain. Later, methods were introduced to treat fissures or tears in the annulus fibrosus of the disc. The development of intradiscal therapies began with the introduction of chymopapain use in the 1950s. Percutaneous injection of chymopapain was done by Lyman Smith in 1964.[1] This led to a gradual evolution of intradiscal therapies.

Open laminectomies and discectomies have been widely performed and have been established as treatment for disc herniations for many years. Small, contained disc herniations investigated by Carragee and Kim[2] were found less amenable to laminectomy than large herniations. In these subsets of patients with small, contained herniations, percutaneous disc decompressions have been found to be effective with reported success rates of 50 to 70%. Since the introduction of chymopapain injection by Smith, others have done clinical evaluations and patient studies using various techniques of percutaneous disc decompression. Choy[3] produced data for laser discectomy, Onik et al.[4,5] published work done with an automatic technique, automated percutaneous lumbar discectomy (APLD), and more recently several others[6–10] have published data and patient studies with coblation technology, which was introduced in 2000. All of these methods targeted the nucleus pulposus. Derby[11–13] published a review and early clinical

data of the technique termed IDET (intradiscal electrothermal therapy), a minimally invasive method targeting the disc annulus for annuloplasty based on the observations that the fibers of the annulus shortened when heat was applied. Saal and Saal[14–16] also published clinical studies of this intradiscal technique in the same year.

The indications for the use of these annuloplasty techniques are similar to those for other intradiscal therapies. Understanding the pathomechanisms of discogenic pain whether from internal disc disruption or from a small contained disc herniation with or without internal disc disruption is vital to a successful outcome.

DISCOGENIC PAIN

Intervertebral discs are innervated by fibers from a branch of the sinuvertebral nerve, but only in the outer third of the annulus in healthy discs. In pathological discs, the nerve endings have been found to extend into the inner portion of the annulus. Mechanical stimulation of these annular fibers results in some cases of discogenic pain, but this is not the only mechanism capable of causing pain. Pain from a degenerated or otherwise damaged disc is now also thought to derive from complex interaction of chemicals released by the disc itself and the interaction of these proinflammatory chemicals with the mediators of the inflammatory cascade beginning with phospholipase A_2 released from damaged cell membranes.[17–19]

Damaged lumbar discs may also herniate portions of nucleus material posterolaterally and increase mechanical pressure on nerve roots, causing radicular pain. Herniation of nuclear material itself may induce the above-mentioned painful inflammatory cascade. Minor trauma, including

that resulting from normal activities of daily living and aging, may result in tears or fissures developing in the annulus of the intervertebral disc and, by either direct irritation on nerve endings or activation of the inflammatory cascade, cause pain. Fissures or tears in the annulus may be extensive enough to allow extrusion of disc tissue into the spinal canal and this may also be a pain-producing event. In summary then, the intervertebral disc may undergo insult sufficient to lead to the development of pain, so-called discogenic pain. Regardless of the cause, treating discogenic pain has been a challenge to the medical community for many years and only in the past three decades has real progress been achieved in creating therapies specifically directed to this problem.

There is discussion and ongoing research concerning the exact mechanisms of discogenic pain and the relative importance of each in clinical situations. It is commonly accepted that stretching (mechanical) irritation of the disc by whatever means is not the only method of pain generation. Chemical mediators, enzymes from the disc itself, inflammatory moieties, and proinflammatory intermediates, along with immunological factors and members of the cytokine cascade increase the sensitivity of nociceptors and play a role in the production of discogenic pain.

INTRADISCAL THERAPIES

Open surgical procedures and techniques, which began in the 1930s to relieve radicular pain from a mechanical standpoint, continue to be performed; however, it is increasingly recognized that they may not offer the optimal therapy for some patients with discogenic low back pain. Open surgical intervention to treat spinal pain is indicated for diagnoses of nerve root compression or spinal stenosis with an abnormal neurological examination. Omitting the obvious need for surgery in cases of trauma or mechanical instability, spinal surgery to relieve pain without a confirmed lesion may not be successful if only because of the complex nature of the etiology of spinal pain.

According to the discussion of O'Brien,[20] the diagnosis and treatment of painful degenerative disc disease is one of the more controversial topics in the spine literature today. The points of contention concern the reliability of the diagnosis of the painful site and the reported inadequacies of surgical outcomes combined with the risks and costs of surgery.

Advocates of the surgical approach usually follow guidelines that include failure of previous conservative therapies and confirmation of an involved disc as the source of pain. Even with strict criteria for patient selection many sources report 10 to 30% failure rates in efforts to control pain with open surgery or to achieve the preoperative goals of pain relief and return to normal func-

tioning. This remains an area of controversy and discussion in the literature.[21]

The impetus behind the development of intradiscal therapies was to offer an option to those who were not candidates for surgery. The development of intradiscal therapies has been directed at relieving pain, focusing on either the nucleus or the annulus of the disc and using minimally invasive percutaneous methods. In the last few decades many authors have proposed methods to effect disc decompression by percutaneous routes to relieve pain. One, chymopapain, is no longer available in the United States. Others include manual or automated percutaneous nucleotomy, using a nucleotome, percutaneous laser disc decompression, and percutaneous disc decompression using coblation; another technique (IDET) uses a resistive coil in an attempt to enhance the integrity of the annulus of the disc and control discogenic pain.

CHEMONUCLEOLYSIS

Chemonucleolysis or the injection of enzymes or chemically active agents into the nucleus was introduced in the mid-1960s and developed the concept of removing nuclear material, sparing other intradiscal tissues, which would lead to a reduction in external pressure on an affected nerve root. The enzymes were numerous; including chymopapain, Chymodiactin, and collagenase, among others, and the chemicals included denaturants such as ethanol and others with proteolytic function such as aprotinin. This was the initial attempt to decompress a disc that targeted the disc itself. A wide array of enzymes and enzymatically active chemicals were used to dissolve nuclear material to cause a volumetric decrease in nuclear material and thus a reduction in intradiscal pressure. The difficulty in this method was the control of the chemical activity in the disc and the real potential for spread outside the disc where inflammation and tissue damage could occur and not be monitored or known to the interventionalist. The possibility this could lead to irreversible nerve root damage and rare occurrences of anaphylactic reactions put a damper on its use in the United States. Eventually the manufacturer decided to stop producing chymopapain for the U.S. market, and the method is now available only outside the United States. Research in its use continues in Europe.

Indications: Discogenic pain, contained herniated disc with intact annular margin, failure of other therapy.

Contraindications: Allergy or hypersensitivity to chemical, fissured annulus with communication to the subarachnoid space.

Outcomes: Due to variety of enzymes and chemicals used, and that the amounts and exposure

times were different, it is difficult to make valid comparisons.

Complications: Concerns arose because it was found difficult to control where enzymes/chemicals would go and because they could cause anaphylactic reaction outside the discal environs and scar adjacent tissues and nerves irreversibly.

PERCUTANEOUS INTRADISCAL NUCLEOTOMIES

The concept of a minimally invasive approach to treat discs responsible for radicular pain by the volumetric removal of intradiscal tissue to cause a reduction in internal pressure, introduced by chemonucleolysis, was further developed and refined in techniques designed to perform percutaneous discectomies. These were introduced in the 1970s and have been modified in several ways, utilizing endoscopic visualization and an automatic disc shaver technique with aspiration of nuclear material. Reports of efficacy varied with different patient populations and methods used to evaluate outcomes. Nevertheless, most reported series showed reasonably favorable outcomes.

Kambin[22] developed a procedure using an arthroscope for direct visualization in microdiscectomy. He was able to evacuate herniated disc material through a posterolateral approach as well as perform elimination of central disc nuclear mass and effect a decompressive nucleotomy. The method was further enhanced with direct video and fluid management through a single portal approach.

Onik[4,5] introduced an automatic suction shaver to perform an APLD. By drawing and cutting with a reciprocating blade under fluid suction, a percutaneous microdiscectomy could be done. Percutaneous endoscopic lumbar discectomy (PELD) using a rigid endoscope for visualization was described by Mayer and Brock[23] in 1987.

There have been extensive reviews involving many patients. These methods are more technically demanding and patient acceptance is complicated by occasional occurrences of muscles spasm and a sense of post-procedural instability. Reported infection rates in some series have approached 1%, which is higher than that found with other intradiscal methods.

Indications: Discogenic pain, contained herniated disc, failure of other therapies.
Contraindications: Local infection, cord compression, coagulopathies.
Outcomes: Usually reported as successful in 60 to 70%.
Complications: Higher risk of infection often reported; somewhat longer recovery times due to the nature and time of the procedure.

LASER-ASSISTED PERCUTANEOUS DISC DECOMPRESSION

Laser procedures for disc decompression were introduced about 10 years after the emergence of the manual methods. Percutaneous laser disc decompression treated herniated intervertebral discs by using laser energy to vaporize small amounts of intradiscal tissue. The small amount of tissue removed caused a fall in intradiscal pressure with subsequent migration of the herniated portion of the disc away from the affected nerve root.[3] An ongoing concern with this method is the need to control unintentional or inadvertent thermal damage to surrounding tissue. Pulsed lasers gave more of an opportunity to achieve this over the use of continuous lasers, with some types and wavelengths being far more efficacious than others. Success rates were reported in the 70 to 80% range in most series of patients, with relatively few discernible complications. Thermal damage to the vertebral body end plate was reported in several series, and infection rates and other complications remained in the <1% range. Although seemingly an improvement in procedural time and complication rates was found over those of manual methods, the method has some drawbacks.

Indications: Failure of conservative therapy, contained herniated disc with discogenic pain, positive provocative discogram.
Contraindications: Large herniations, local infection, coagulopathies.
Outcomes: Generally reported as favorable in 70% range.
Complications: Inadvertent thermal damage to tissues due to difficulty controlling laser; difficult to control amount of tissue vaporized, thermal damage to vertebral end plates a risk.

PERCUTANEOUS DISC DECOMPRESSION USING COBLATION

Coblation technology uses radiofrequency (RF) energy to effect dissolution of nuclear material and denaturation of intradiscal proteoglycans. By reducing intradiscal volume, intradiscal pressure is reduced, and this is thought to be a factor in the reduction of pain.

Effects on the intradiscal environment may also decrease the inflammatory-cascade mediated stimulus for pain. Animal studies have shown that the application of RF energy results in minimal damage to the surrounding tissue. A lower temperature than other methods is used and results in the absence of necrotic tissue intradiscally. Significant reductions in intradiscal pressure have been reported in human cadaveric specimens, and measurement of intradiscal temperature variations showed an absence of temperature increase 5 mm from the RF source.

Prospective trials have given similarly favorable results. Reduction of pain, reduction in use of medications for pain, and decreases in numeric pain scores all have been significant in patients followed for 6 to 12 months.[8,9] Patient acceptance has been equally high and, with lessened tissue damage, its use for discogenic low back pain provides another option with short recovery times.

Indications: Failure of conservative regimens, discogenic pain, including that from small contained disc herniations, inadequate pain control with medication, positive provocative discogram.

Contraindications: Local infection, sepsis, coagulopathies.

Outcomes: Generally in the 70+% range, excellent patient acceptance.

Complications: None reported to date.

INTRADISCAL ELECTROTHERMAL THERAPY

This method is a minimally invasive one in which the annulus and not the nucleus is the targeted entity. Unlike the other methods, it is not indicated for radicular pain. IDET is a therapy directed toward tears in the annulus; by resistive heating these tears are thought to be coagulated and stabilized, and annular nerve fibers are rendered nonviable.[24] A normal neurological examination without deficits is required, with 6 months of persistent symptoms. Imaging studies are performed to confirm the absence of disc herniation. The procedure uses a resistive coil, inserted percutaneously and positioned to assume a circular configuration within the annulus. This coil is heated to a temperature and for a time sufficient to coagulate annular collagen and destroy annular neural elements. The actual mechanism of action, however, remains unverified. Neither collagen denaturation nor nerve ablation has been confirmed in patients. However, successful outcome percentages have been reported with the method that are comparable to those reported with the nuclear procedures. In a large, randomized, controlled prospective study Pauza et al.[25] examined 64 patients who met eligibility requirements including 6 months discogenic pain, positive discography, and an absence of comorbidity. Improvement in pain scores and disability scales was seen only in the IDET group, but 50% of those treated experienced no benefit. This report supports strict inclusion criteria to provide relief for a small proportion of patients undergoing the IDET procedure.

Restricted activities and back bracing are usually advised for 6 to 8 weeks; many patients wear a brace for 12 months or longer.[26] In many instances pain relief is not apparent until 6 months.

Indications: Failure of aggressive conservative therapy, discogenic pain with confirmed annular lesions, positive provocative discogram.

Contraindications: Presence of herniated disc tissue, stenosis, evidence of neural compression on magnetic resonance imaging (MRI), previous lumbar surgery, presence of significant psychological issues.

Outcomes: Generally favorable over 2-year period in uncontrolled reports; one controlled study found success rates varying from 23 to 60% depending on the criteria used. The percentage of patients on disability is reported as unchanged. Somewhat longer recovery times; bracing and restricted activities for up to 1 year post-procedure.

Complications: Poorer results when patient is obese, presence of pain continuing after the procedure with half of patients reporting dissatisfaction in one retrospective analysis.

CONCLUSION

Intradiscal therapies have emerged as an option for patients who have failed conservative therapies and are not candidates for open surgery. For many, they are an option for treatment of pain and can reduce or eliminate the need for long-term medication, with its well-known costs and risks. There is ample evidence that long-term use of nonsteroidal anti-inflammatory drugs (NSAIDs) is not without risks, even life-threatening risks in some cases due to renal effects of NSAIDs, as well as more well-known gastrointestinal bleeding problems. The long-term use of opioids for pain carries another set of medical and social costs. Frequent monitoring for compliance, risks of tolerance, and potential addiction are common concerns for patients and providers alike.

The impetus for these intradiscal treatments has come out of a need to provide an option to the number of people who would prefer not to take medications long term and who are not considered able to benefit from open surgical intervention. Ideally, treatments would reduce pain and the need for medication, and not impede a return to desired function. Among the most important criteria for the use of these methods is patient selection. Accurate diagnosis and fundamentally sound correlation of symptoms with findings are essential to the success of any of these therapies.

Percutaneous Lysis of Lumbar Epidural Adhesions and Hypertonic Saline Neurolysis

Laxmaiah Manchikanti, MD, and Vijay Singh, MD

INTRODUCTION

Treatment of chronic back pain, specifically for postsurgical patients and patients with epidural fibrosis, continues to be a challenge. The effectiveness of epidural steroid injections in patients with epidural fibrosis has not been studied. Further surgery for peridural scarring has resulted in disappointing results, with success rates as low as 12%.[1–3] One of the techniques described to effectively manage chronic low back pain secondary to epidural fibrosis is adhesiolysis of epidural scar tissue.[4–18] The purposes of percutaneous epidural lysis of adhesions are to eliminate deleterious effects of a scar, which can physically prevent direct application of drugs to nerves or other tissues, and to assure delivery of high concentrations of injected drugs to the target areas. In a 2002 review describing the role of decompressive surgery in managing chronic pain of spinal origin after lumbar surgery, Phillips and Cunningham[19] reported that no form of surgical treatment or adhesion lysis procedure for this diagnosis has proved to be safe and effective.

HISTORY

Epidural injection for chronic low back pain was performed by Sicard[20] in 1901. Eight years later, reports on cures of sciatica with epidural anesthesia were made by Caussade and Queste.[21] The initial epidurography was performed in 1921 by Sicard and Forestier.[22] Hitchcock[23] administered cold hypertonic saline in 1967 for the treatment of chronic pain intrathecally. Ventrafridda and

Spreafico[24] reported the use of intrathecal saline to relieve pain in patients with cancer. Hitchock[25] also reported that the determining factor in the therapeutic effect of this solution was its hypertonicity rather than the temperature.

Racz and Holubec[6] reported the first use of epidural hypertonic saline to facilitate lysis of adhesions. In 1989, Racz et al.[26] evaluated dural permeability in dogs, demonstrating slow transdural equilibration of hypertonic saline. Payne and Rupp[27] used hyaluronidase in an attempt to alter the rapidity of onset and extent, intensity, and duration of caudal anesthesia. Moore[28] also described the addition of hyaluronidase to caudal epidural injections to enhance the spread of local anesthetic.

Cyriax's[29] extensive experience with 20,000 patients showing significant improvement with large volumes of caudal epidural anesthetic was reported by Ombregt and Ter Veer.[29] Brown[30] also injected large volumes ranging from 40 to 100 mL of normal saline, which was followed by the injection of 80 mg of methylprednisolone in an attempt to mechanically disrupt and prevent preformation of presumably fibrotic lesions in patients with sciatica. Hyaluronidase was introduced as an alternative agent by Stolker et al.[31] Over the years, multiple investigators[6–18, 26] have studied the effectiveness of adhesiolysis and hypertonic saline neurolysis with or without hyaluronidase.

PURPOSE

Adhesiolysis of epidural scar tissue, followed by the injection of hypertonic saline, described by Racz et al.,[6,7–11,26]

involved epidurography, adhesiolysis, and injection of hyaluronidase, bupivacaine, triamcinolone diacetate, and 10% sodium chloride solution on day 1, followed by injections of bupivacaine and hypertonic sodium chloride solution on days 2 and 3. Manchikanti et al.[10,12–17] described and studied a modification of the Racz protocol from a 3-day procedure to a 1-day procedure.

The purpose of percutaneous epidural lysis of adhesions is to eliminate deleterious effects of scar formation, which can physically prevent direct application of drugs to nerves or other tissues to treat chronic back pain with or without radiculopathy. The goal of percutaneous lysis of epidural adhesions is to assure delivery of high concentrations of injected drugs to the target areas.

PATHOPHYSIOLOGY

Kuslich et al.[32] identified intervertebral discs, nerve root dura, facet joints, ligaments, fascia, and muscles as tissues capable of transmitting pain in the low back and lower extremity. The pathophysiology of spinal radicular pain continues to be a subject of ongoing research and controversy. Proposed etiologies include neural compression with dysfunction, vascular compromise, inflammation, and biochemical influences.[33] Multiple causes described for chronic low back and lower extremity pain include not only disc herniation with neural compression and dysfunction, but also vascular compromise, inflammation, biochemical influences, postlumbar laminectomy syndrome, and spinal stenosis. Postlumbar laminectomy syndrome or pain following operative procedures of the lumbar spine is estimated in approximately 5 to 40% of patients after surgical intervention.[11,13,34–37] Although there are multiple etiologies responsible for postlumbar laminectomy pain, descriptions of causes of continued pain after surgical intervention have included epidural fibrosis, facet joint arthritis, spinal stenosis, and other causes.

Among patients with postlumbar laminectomy syndrome, epidural fibrosis is seen as a common phenomenon, which contributes to approximately 60% of the patients with recurring symptoms in conjunction with instability.[37] McCarron[38] reported an inflammatory reaction in the spinal cord sections taken from dogs sacrificed after the initial injection of homogenized nucleus pulposus. Cooper et al.[39] reported periradicular fibrosis and vascular abnormalities occurring with herniated intervertebral disc. Hoyland et al.,[40] in a cadaveric study, found significant pathological changes within and around the nerve root complex, including peri- and intraneural fibrosis, edema of nerve roots, and focal demyelination, proposing that venous obstruction may be an important pathogenic mechanism in the development of perineural and intraneural fibrosis. Epidural adhesions were also demonstrated in cadavers with lumbar disc herniation, with 40% of cadavers showing adhesions at L4/5 level, 36% at L5/S1

level, and 16% at L3/4 level.[41] Further, it was shown that perineural fibrosis, which interferes with cerebrospinal fluid–mediated nutrition, can render nerve roots hyperesthetic and hypersensitive to compression forces.[42,43] Songer et al.[44] showed that postoperative scar tissue renders the nerve susceptible to injury. Even though epidural fibrosis is commonly seen in patients with recurring symptoms in conjunction with instability in postlumbar surgery syndrome,[19,34,35,37,45–50] its role as a causative factor of chronic spinal pain or as a pain generator continues to be questioned.[13,19,35,45,48,49] In a study of the relationship between peridural scar evaluated by magnetic resonance imaging (MRI) and radicular pain after lumbar discectomy, Ross et al.[50] showed that subjects with extensive peridural scarring were three times more likely to experience recurrent radicular pain.

Multiple investigators have stated that epidural adhesions are difficult to diagnose by conventional studies such as myelography, computerized tomography (CT), and MRI, even though modern technology has made significant improvements in this area.[4–18,51,52] Thus, it is believed that epidural adhesions are best diagnosed by performing an epidurogram, which is most commonly performed via the caudal route, followed by the other routes, including the lumbar interlaminar route.[4–18,51–57] Epidural filling defects have been reported in a significant number of patients after surgical intervention, but also in patients with no history of prior surgery.[51]

It is accepted that while peridural scarring in itself is not painful, it can produce pain by "trapping" spinal nerves so that movement places tension on the nerves, thus eliciting pain in an inflamed nerve.[8,9,32,44] Kuslich et al.[32] reported that back pain was produced by stimulation of several lumbar tissues, even though the outer layer of the annulus fibrosis and posterior longitudinal ligament innervated by sinuvertebral nerves was the most common source of pain.

RATIONALE

The rationale for adhesiolysis and hypertonic saline neurolysis in the management of spinal pain stems from the concept that epidural adhesions are a common source of chronic low back pain. The epidural space restricted by adhesions is safely accessible using a special catheter. Removal or correction of structural abnormalities of the lumbar spine may fail to cure and may even worsen painful conditions; degenerative processes of the lumbar spine and the origin of spinal pain are complex; the effectiveness of a large variety of therapeutic interventions in managing low back pain has not been demonstrated conclusively; and the reasonable effectiveness of adhesiolysis and hypertonic saline neurolysis has been demonstrated.[4,6–19]

It was rationalized by Racz et al.[7–9,53] that in patients requiring adhesiolysis, the following may be present:

TABLE 70.1
Results of Published Reports of Percutaneous Adhesiolysis and Hypertonic Saline Neurolysis for One to Three Procedures

Ref.	Study Characteristics	No. of Patients	No. of Days of Procedure	3 Months	6 Months	12 Months
Manchikanti et al.[17]	P, C, RA, DB	Group I = 25*	1	0%	0%	0%
		Group II = 25**		60%	60%	60%
		Group III = 25***		72%	72%	72%
Heavner et al.[9]	P, C, RA, DB	59	3	49%	43%	49%
Manchikanti et al.[16]	P, RA, C	45	1	97%	93%	47%
Racz and Holubec[6]	R, RA	72	3	43%	13%	N/A
Manchikanti et al.[14]	R, RA	103	2	70%	28%	15%
Manchikanti et al.[14]	R, RA	129	1	68%	36%	13%
Manchikanti et al.[12]	R	18	1	89%	61%	17%

inflammation, edema, fibrosis, and venous congestion; mechanical pressure on posterior longitudinal ligaments, annulus fibrosus, and spinal nerve; reduced or absent nutrient delivery to the spinal nerve or nerve root; and central sensitization. Hence, it was postulated that it is reasonable to treat back pain with or without radiculopathy with local application of anti-inflammatory medication (e.g., corticosteroids), agents aimed at reducing edema (e.g., hypertonic sodium chloride solution), corticosteroids, local anesthetics, and hyaluronidase to promote lysis. Thus, percutaneous lysis of adhesions is indicated in patients with appropriate diagnostic evaluation and after failure or ineffectiveness of conservative modalities of treatment has been proved.

While most commonly used methods involve entry into the epidural space through the sacral hiatus, medication placed in the posterior or posterolateral epidural space may not reach pathology in an intravertebral foramen or in the anterior epidural space.[4,5,18,58–71] The rationale for transforaminal approach is based on lesion-specific adhesiolysis and delivery of medication to fulfill the aim of reaching the primary site of pathology, thus improving the ultimate outcome. In fact, present evidence evaluating the effectiveness of transforaminal steroids is encouraging compared with that for interlaminar and caudal epidural steroid injections.

CLINICAL EFFECTIVENESS

Clinical effectiveness of percutaneous adhesiolysis was evaluated in three randomized, controlled trials[9,16,17] and five retrospective evaluations,[6,12,14,15] and is summarized in Table 70.1.

Manchikanti et al.[17] in a randomized, double-blind trial evaluated the effectiveness of 1-day lumbar epidural adhesiolysis and hypertonic saline neurolysis in the treatment of chronic low back pain. In this study, they evaluated the effectiveness of not only adhesiolysis, but also hypertonic saline neurolysis. The results showed significant improvement in patients undergoing adhesiolysis with hypertonic saline neurolysis and in patients with adhesiolysis and hypertonic saline neurolysis at 3 months, 6 months, and 12 months, compared with baseline measurements, as well as compared with control group without adhesiolysis, for numerous parameters measured. In the study, 72% of patients with adhesiolysis and hypertonic saline neurolysis (Group III), 60% of patients with adhesiolysis only without hypertonic saline neurolysis (Group II), compared with 0% in control group (Group I), showed significant improvement at 12-month follow-up. Figure 70.1 through Figure 70.3 and Table 70.2 illustrate improvement in multiple outcome parameters.

Heavner et al.[9] studied percutaneous epidural adhesiolysis, with a prospective evaluation of 0.9% sodium chloride solution versus 10% sodium chloride solution with steroids, with prospective 1-year follow-up. They concluded that percutaneous epidural neuroplasty, as part of an overall pain management strategy, reduces pain in 25% or more of patients with radiculopathy plus low back pain refractory to conventional therapies. They also noted that the use of hypertonic saline and hyaluronidase may reduce the number of patients that require additional treatments. However, adhesiolysis was effective, even in the patients receiving normal saline. They also showed that the percent of patients requiring additional treatments during 1-year follow-up was approximately 70%, at, on average, around

70 days. This figure was approximately 60% in patients receiving hypertonic saline, and 80% in patients receiving normal saline. Finally, Heavner et al.[9] concluded that the most significant finding of the study was that at 1-year follow-up, 49% of the patients had pain relief in the body area targeted for the lesion-specific therapy.

Manchikanti et al.[6] evaluated the role of 1-day epidural adhesiolysis in the management of chronic low back pain in a randomized clinical trial involving 45 patients. In the study, 15 patients were randomly assigned to the

control group and treated with conservative modalities including medication, physical therapy, and an exercise program; and 30 patients in group II were treated with percutaneous epidural adhesiolysis and hypertonic saline neurolysis. The patients were evaluated over a period of 1.5 to 3 years. The study showed that overall health status improved significantly in the treatment group in all parameters, including average pain, physical health, mental health, functional status, psychological status, and narcotic intake.

The effectiveness of percutaneous adhesiolysis with hypertonic saline neurolysis was also evaluated in refractory spinal stenosis. Manchikanti et al.[12] studied patients failing to respond to multiple modalities of treatment, including fluoroscopically directed epidural steroid injections with spinal stenosis. This retrospective evaluation included 18 patients derived from a total sample of 239 patients undergoing adhesiolysis and hypertonic saline neurolysis over a period of 3 years. The results showed significant improvement with reduction in pain and improvement of physical health, mental health, and functional status. They also reported improvements in psychological status and decrease in narcotic intake. The results showed that with one to three injections, cumulative relief with greater than 50% relief was seen in 89% of the patients at 1 month and 3 months, declining to 61% of the patients at 6 months. They also evaluated cumulative relief (greater than 50%) with 1 to 10 injections and reported 89% of patients achieving greater than 50% relief at 3 months, 72% at 6 months, 17% at 1 year, and 11% at 2 years.

In contrast to the above reports, Devulder et al.[57] concluded that epidurography might confirm epidural filling defects, but a better contrast spread, assuming scar lysis does not guarantee sustained pain relief, as filling defects were confirmed in 88% of the patients with epidurography; but significant pain relief was seen in only 33% of the patients at 1 month, 13% at 3 months, and 0% at 12 months. However, the problem with this study was that lysis of adhesions was not lesion specific. Consequently, the delivery of drugs was also nonspecific.

The quality of evidence presented in clinical effectiveness studies reviewed for this report includes two randomized clinical trials[9,17] that are of high quality, one randomized trial[16] of moderate quality, followed by five retrospective reports, two of which were randomized. The type and strength of efficacy evidence are strong for short-term and long-term relief.

INDICATIONS

Percutaneous epidural adhesiolysis and hypertonic saline neurolysis are indicated in patients with chronic low back pain who have failed to respond to conservative modalities of treatments, including epidural injections administered

under fluoroscopic guidance and other well-documented therapeutic modalities. Racz et al.[6–9,11] described various conditions in which epidural lysis of adhesions is indicated, including postlaminectomy syndrome, epidural adhesions, disc disruption, traumatic or pathologic vertebral body compression fracture, spinal stenosis, and resistant multilevel degenerative arthritis (Table 70.3).

COMPLICATIONS

The most common and worrisome complications of adhesiolysis in the lumbar spine are related to dural puncture, spinal cord compression, catheter shearing, infection, steroids, hypertonic saline, and hyaluronidase.[4,5,29,72–94] Unintended subarachnoid or subdural puncture with injection of local anesthetic or hypertonic saline is one of the major complications of the procedure. Hypertonic saline injected into the subarachnoid space has been reported to cause cardiac arrhythmias, myelopathy, paralysis, and loss of sphincter control.[76] In fact, Aldrete et al.[74] attributed incidences of arachnoiditis following epidural adhesiolysis with hypertonic saline to subarachnoid leakage of hypertonic saline. A case of myelopathy has been reported after intrathecal administration of hypertonic saline of 15%, 10 mL, diluted with cerebrospinal fluid to a volume of 12 mL, preceded by an injection of 1 mL of an aqueous solution of morphine sulfate without preservative, 10 mg/mL, diluted with cerebrospinal fluid to a volume of 10 mL, and 1 mL of which was slowly administered intrathecally.[76] Autopsy findings of this patient, who died 16 months after intrathecal administration of hypertonic saline, showed peripheral accentuated loss of myelinated fibers within the spinal cord from T12 downward, as well as dense collagenous thickening of the dorsal leptomeninges from T9 to T11. This case report was a devastating complication.[76] However, in a large study of 108 patients suffering from intractable pain and treated with intrathecal hypertonic saline, it was reported that sphincter disorders occurred in 8% of the patients, with 2.7% experiencing cauda equina syndromes with paraplegia.[76] They also reported rapid recovery in one patient, but quite slow and incomplete recovery in the others, attributing the cauda equina syndromes to preexisting arachnoiditis in one patient and two arteriovascular diseases in the others. In a survey of 648 neurosurgeons, it was reported that 31.2% had used intrathecal hypertonic saline to treat pain in 1,943 patients with adverse reactions in 11.2% of the patients compared with 7.6% of those treated with normal or diluted saline injections.[78]

Further, 22 patients, or 1%, suffered significant morbidity with paraplegia or tetraplegia in 16, or 0.76% of the patients, and monoparesis in 1 patient (0.05%).[78] Other reports of spinal cord lesions by subdural injection of neurolytic agents and local anesthetics included descriptions of exuberant pachymeningitis reaction in dogs.[80] However, the other postmortem examinations in humans after saline injections were more sobering.[78]

The second specific complication of percutaneous epidural adhesiolysis is related to catheter shearing and its retention in the epidural space. Even though the RK™ needle (Epimed International, Inc.) and Racz™ catheter (Epimed International, Inc.) have been specifically designed for this procedure, catheter shearing has been reported. This problem was reported as occurring in five such cases by Racz and others.[10] Manchikanti and Bakhit[75] also reported a torn Racz catheter in the lumbar epidural space, which was successfully removed.

Spinal cord compression following rapid injections into the epidural space, which may cause large increases in intraspinal pressure with a risk of cerebral hemorrhage, visual disturbance, headache, and compromise of spinal cord blood flow, has been mentioned. However, the only complication reported following epidural injection has been vision loss, but no such complications have been reported following adhesiolysis and hypertonic saline neurolysis.

Epidural infection following this procedure is a distinct possibility due to the procedure itself, as well as potential immunosuppression secondary to steroid injection. Racz et al.[6–9,11] have reported no instances of epidural abscess in their patient population. Manchikanti et al.[12-17] reported serious infection in one patient with the development of an abscess; however, no involvement of the spinal canal was noted. They also reported a suspicion of infection in 2% of the cases. In a 1-year study of the incidence of spinal epidural abscess, nine cases of epidural abscess formation from a total of 17,372 epidural catheters were noted.[88] Others described epidural abscess formation as an uncommon but devastating complication that has been associated with continuous epidural analgesia, as well as single-shot epidural injections.[90] They also noted that epidural abscess most often arises in association with systemic infection, but it rarely occurs following epidural analgesia.[90]

Direct trauma to the spinal cord following lumbar epidural injections has been rarely reported, but it can result in disastrous complications.[89] None of the case reports has involved percutaneous lysis of epidural adhesions. The potential for spinal cord trauma is more likely with percutaneous adhesiolysis with hypertonic saline injection than with other epidural procedures, as the injection of adjuvant agents with preservatives may be unforgiving. Additional issues with transforaminal epidural adhesiolysis include intravascular penetration and neural trauma that may be higher than with the caudal or intralaminar approaches. The incidence of vascular epidural injections documented by contrast-enhanced fluoroscopic imaging and negative blood aspiration has varied from 5 to 11%.[95,96]

Neural trauma is a potential complication, even though there are no such case reports with either caudal or transforaminal epidural adhesiolysis.[97,98] Once again, this emphasizes the risks associated with all types of neural blockade, specifically epidural adhesiolysis, with either the caudal or transforaminal routes, even when performed with precautions; following the protocol and diligence are extremely crucial. Thus, no injection should be performed without confirming the location of the needle under fluoroscopic visualization with contrast injection.

Occasional sensitivity (3%) to hyaluronidase has been reported in a series of 1,520 epidural administrations of hyaluronidase.[28] However, Racz et al.[6–9] reported no such incidences of hyaluronidase sensitivity and postulated that the steroid leaves the space more slowly than hyaluronidase, which may help protect against allergic reaction, as the steroid is placed exactly at the site where the hyaluronidase is also deposited.

Other side effects are related to the administration of steroids and are generally attributed to the chemistry or pharmacology of the steroids. The safety of steroids and preservatives at epidural therapeutic doses has been demonstrated in both clinical and experimental studies.[99–109] The major theoretical complications of corticosteroid administration include arachnoiditis, suppression of the pituitary-adrenal axis, hypocorticism, Cushing syndrome, osteoporosis, avascular necrosis of bone, steroid myopathy, weight gain, fluid retention, and hyperglycemia.[107–117] Other potential complications include hypertension, hypokalemia, epidural lipomatosis, retinal hemorrhage, increased intraocular pressure, subcapsular cataract formation, insomnia, mood swings, psychosis, facial flushing, headache, gastrointestinal disturbances, and menstrual disturbances. Although the use of corticosteroids repeatedly for days or even a few weeks does not lead to adrenal insufficiency upon cessation of treatment, prolonged therapy with corticosteroids occasionally may result in the suppression of pituitary–adrenal function that can be slow in returning to normal. Rare hypothalamic–pituitary–adrenal suppression during corticosteroid administration with epidural injections and after its withdrawal has been reported. However, no such reports have implicated percutaneous adhesiolysis and hypertonic saline neurolysis. Table 70.4 illustrates the comparative pharmacology of commonly used steroids in neural blockade in general and adhesiolysis and hypertonic saline neurolysis in particular.

TABLE 70.4
Pharmacologic Profile of Commonly Used Steroids

Name of Drug	Equivalent Dose	Epidural Dose	Anti-Inflammatory Potency	Sodium Retention Capacity	Duration of Adrenal Suppression		
					IM	Single Epidural	Three Epidurals
Triamcinolone acetonide (Kenalog®)	4 mg	40–80 mg	5	0	2–6 weeks	N/A	2–3 months
Betamethasone (Celestone Soluspan®)	0.6 mg	6–12 mg	25	0	1–2 weeks	N/A	N/A
Triamcinolone diacetate (Aristocort®)	4 mg	40–80 mg	5	0	1–2 weeks	1–5 weeks	N/A
Methylprednisolone acetate (Depo-Medrol®)	4 mg	40–80 mg	5	0.5	1–6 weeks	1–3 weeks	N/A

Note: IM = Intramuscular. Adapted from Manchikanti et al.[5]

TECHNICAL CONSIDERATIONS

The technique of adhesiolysis involves accessing the lumbar epidural space by utilizing a caudal, an interlaminar, or a transforaminal approach. Entry is performed with a 16-gauge RK needle (Epimed), followed by advancement of a Racz catheter into the epidural space, with appropriate lysis of adhesions under radiographic control using nonionic contrast medium. Subsequently, a combination of local anesthetic and steroid is injected into the epidural space through the catheter, following which hypertonic saline neurolysis is carried out by slow and intermittent injection of hypertonic saline, either by infusion or in incremental doses. In the classic Racz technique, the procedure is repeated without steroids on day 2 and day 3; whereas, with other modifications, the catheter is removed after the initial procedure is performed. Racz and his followers also recommend hyaluronidase with these injections.

RACZ TECHNIQUE

The technique employed by Racz and colleagues[6–9,11] is described as percutaneous epidural neuroplasty and outlined in Table 70.5.

General Principles

- The consent form should include all possible complications related to the procedure.
- Intravenous access is recommended. It may be necessary to sedate the patient with midazolam and fentanyl. Injection of solutions into the epidural space of a patient with adhesions is usually quite painful because of distention of affected nerve roots. The patient typically experiences pain in the dermatomal distribution of the nerve roots being stretched. Although sedation is given, it is important that the patient be awake and responsive during the procedure to

TABLE 70.5
Percutaneous Epidural Neuroplasty Technique as per Racz and Colleagues

In the operating room:
  Place epidural needle.
  Inject iohexol (Omnipaque-240) and visualize spread of contrast medium (epidurogram).
  If filling defect corresponding to area of pain is present, thread Racz Tun-L-Kath® (Epimed) catheter into filling defect (scar), while injected normal saline through the catheter; observe fluoroscopically to visualize washout of contrast and opening of scar.
  Inject additional iohexol to ascertain opening of scar and spread of injectate within the epidural space.
  Inject preservative-free saline with or without hyaluronidase (Wydase).
  Inject 0.25% bupivacaine and triamcinolone.
  Tape catheter in place.
In the postoperative care unit:
  Inject 10% saline 30 minutes after steroid/local anesthetic injection.
In clinic area:
  Once on each of the following 2 days, inject 0.25% bupivacaine; 30 minutes later, inject 10% saline.
  After the last treatment, remove the epidural catheter

Note: Adapted from Heavner et al.[9]

ensure that the spinal cord is not compressed during the injection.
- Fluoroscopy is mandatory for lysis of adhesions.
- A water-soluble, nonionic contrast medium is used because of the possibility of unintended subarachnoid injection. Even in the most careful of hands, scar tissue may dissect during injection of contrast and enter the subarachnoid space. Nonwater-soluble ionic contrast medium in the subarachnoid space can cause spinal cord irritation, spinal cord injury, seizures or clonus, arachnoiditis, and paralysis.
- The steroid that is currently used for this procedure by Racz et al.[6–9] is triamcinolone acetate.

Methylprednisolone is discouraged due to clumping when mixed with local anesthetics or normal saline.

- Hypertonic saline is used to prolong pain relief because of its local anesthetic effect.

The Caudal Approach

- The patient is placed prone with a pillow under the abdomen to straighten the lumbar spine. Monitors are applied, including electrocardiography sensors, a pulse oximeter, and a blood pressure cuff. The sacral area is then prepared with sterile technique and draped from the top of the iliac crest to the bottom of the buttocks. Abduction of the legs and inversion of the feet ("pigeon toe") facilitate entry into the sacral hiatus.

- The sacral cornua and the sacral hiatus are palpated with the index finger of the operator's nondominant hand. The entry point through the skin, approximately 1 to 2 cm lateral and 2 cm inferior to the sacral hiatus, is in the gluteal fold opposite the affected side. This allows the needle and the catheter to be directed toward the affected side. Lateral needle placement also tends to avoid penetration of the dural sac or subdural area with either the needle or the catheter. The entry point is infiltrated with a local anesthetic such as lidocaine. A 16-gauge epidural needle (preferably an RK needle) is passed through the described entry point and into the sacral hiatus, using the sacral cornua as landmarks to locate the hiatus. The needle is advanced to a point below the S3 foramen to prevent S3 nerve root damage. To verify that the needle is within the bony canal, placement is confirmed by a lateral fluoroscopic view before any injections. This is important because anatomic variations of the sacrum could lead to incorrect needle placement that nevertheless "feels" correct. Next, an anteroposterior view should verify that the needle tip points toward the affected side.

- After aspiration is negative for blood and cerebrospinal fluid, 10 mL of iohexol (Omnipaque®-240) or metrizamide (Amipaque®) is injected under fluoroscopy. As the medium is injected into the epidural space, a Christmas-tree shape develops as the dye spreads into the perineural structures inside the bony canal and along the nerves as they exit the vertebral column. Epidural adhesions prevent dye spread so dye does not outline the involved nerve roots. A lateral view likewise shows no dye outlining

the scarred nerve roots. If cerebrospinal fluid is aspirated, it is best to abort the procedure and repeat it another day. If blood is aspirated, the needle is first retracted caudad in the sacral canal until no blood can be aspirated. If this is unsuccessful, an attempt can be made to proceed with catheter placement into the proper site. Aspiration through this catheter should be negative for blood, and lack of venous runoff should be confirmed with injection of contrast medium.

- The ideal epidural catheter is a stainless steel, fluoropolymer-coated, spiral-tipped Racz Tun-L-Kath-XL (Epimed International, Inc.). The bevel of the needle should face the ventrolateral aspect of the caudal canal on the affected side. This facilitates passage of the catheter to the desired side and decreases the chance of shearing the catheter. Because scar formation is usually uneven, multiple passes may be necessary to place the catheter into the scarred area. For this reason, it is best to use a 16-gauge RK epidural needle, which has been specially designed to allow multiple passes of the catheter. To facilitate steering of the catheter into the desired location, a 15° bend is placed at its distal end. After final placement of the catheter and negative aspiration, another 5 to 10 mL of contrast medium is injected through the catheter. This additional dye should spread into the area of previous filling defect and outline the targeted nerve root. Then 1,500 units of hyaluronidase (Wydase®) in 10 mL of preservative-free saline is injected rapidly. Afterward and after negative aspiration, 10 mL of 0.2% ropivacaine and 40 mg of triamcinolone are injected through the catheter in divided doses. This additional volume promotes further lysis of adhesions, because the catheter tip is in the scar tissue. The area of scarring and subsequent scar dissection should be noted and recorded. Because steroids cannot be injected through the 0.2-m bacteriostatic filter, the steroid must be injected before the in-line filter is installed.

- When the procedure is completed, the catheter should be secured to the skin with 2-0 nylon on a cutting needle. The puncture site where the catheter exits is covered by a large clump of a triple-antibiotic ointment such as polymyxin, and two 2×2-inch split venous gauze dressings are used to cover the antibiotic ointment and prevent its spread outside the area of the gauze. The surrounding skin is sprayed or covered with tincture of benzoin, and with a single curve of the catheter toward the midline, all of the above are covered with a 4×6-inch Tegaderm

(OpSite®) dressing. The catheter is connected to an adapter and the bacteriostatic filter, which is not removed until three daily injections have been completed. The filter is capped, and the catheter is taped to the flank of the patient. During the hospitalization, the patient is given intravenous antibiotics in the form of cephalosporin (Rocephin®), 1 g/day, to prevent bacterial colonization that is especially hazardous because of the epidurally administered steroid.

- Once the patient is taken to the recovery room and vital signs are checked, 9 mL of 10% hypertonic saline is infused over 20 to 30 minutes. Occasionally, the patient may complain of severe, burning pain during the infusion. The cause is usually the introduction of hypertonic saline into unanesthetized epidural tissue. Should this occur, the infusion must be stopped; and another 3- to 5-mL bolus of local anesthetic is given. After 5 minutes, the hypertonic saline infusion can be restarted without incident. After completion of the hypertonic saline infusion, 1.5 mL of preservative-free normal saline is used to flush the catheter. Once this task is completed, the cap is replaced on the filter.

- The catheter is left in place for 3 days. On the second and third days, it is injected once a day with 10 mL of 0.2% ropivacaine after negative aspiration from the catheter. Then, 15 minutes later, 10 mL of 10% saline is infused over 20 minutes for patient comfort. As in any hypertonic saline infusion series, the catheter must be flushed with 1.5 mL of preservative-free normal saline. On the third day, the catheter is removed 10 minutes after the last injection. A triple antibiotic ointment is placed on the wound, which is covered with a bandage or another appropriate dressing.

Interlaminar Lumbar Approach

The technique for lysis of epidural adhesions in these areas of the spinal cord must be modified to ensure that initially the needle is positioned in the epidural space and that spinal cord compression by subsequent injections is avoided.

- The patient is placed in the left lateral position on the fluoroscopy table. With the fluoroscopy C-arm in the vertical position, which actually provides a lateral view of the spine, the bases of the spinous processes are visualized. Sterile preparation and draping are carried out.

- A 16-gauge epidural needle (preferably an RK needle) is advanced with the stylet in place to the ligamentum flavum. Skin entry should be 1.5 to 2 levels below the desired epidural entry to facilitate catheter placement. After local anesthetic is used on the skin, an 18-gauge needle is inserted through the same puncture site to form an entry wound. Through the puncture site, a 16-gauge epidural needle is first advanced under fluoroscopic guidance (anteroposterior view) to determine the *direction* of the needle. Next, in the lateral view, the needle is advanced to the point just before the "straight line" formed by the fluoroscopic image of the anterior border of the spinous process in the lateral view (the insertion site of the ligamentum flavum). The lateral view under fluoroscopy demonstrates the *depth* of needle placement. Last, an anteroposterior view is checked again to confirm the *direction* of the needle. When the direction is satisfactory, the loss-of-resistance technique with a Pulsator (Concord Labs) syringe filled halfway with normal (0.9%) saline and halfway with air is used to advance the needle into the epidural space.

- A Racz Tun-L-Kath or Racz Tun-L-Kath-XL epidural catheter is passed in an anterocephalad direction toward the filling defect outlined by the dye, until the catheter tip enters the scarred area. The catheter adapter is attached to the external end of the catheter for injection. After negative aspiration, 1 to 3 mL of nonionic dye is injected while observing the fluoroscope screen for spread within the adhesions. Once an outflow or runoff tract is seen, i.e., either opening of the neuroforamina or caudal spread, 3 to 5 mL of 0.9% preservative-free saline with 1,500 units of hyaluronidase is injected. Last, 0.2% ropivacaine (4 mL) and 40 mg (1 mL) triamcinolone diacetate are injected after negative aspiration, while attention is directed to watch for displacement of the contrast. For safety purposes, the local anesthetic is given in divided doses to first rule out intrathecal subdural (1 to 2 mL) or intravascular injection. After 5 minutes, the remaining volume of the local anesthetic and steroid is injected.

- The procedure may also be performed in the prone position similar to the caudal approach, but with interlaminar entry.

- The volume of ropivacaine injected depends on the level where the tip of the catheter lies, with 10 mL injected in the lumbar and caudal area. The catheter is then secured as described for the caudal approach. After 30 minutes, 10% saline is injected after negative aspiration, in small increments or by slow infusion over 20

TABLE 70.6

Percutaneous Epidural Neuroplasty Technique, as per Manchikanti et al.

In the operating room:

 Place epidural needle.

 Inject Omnipaque 240 and visualize spread of contrast medium with caudal or lumbar epidurogram.

 After identification of the filling defect corresponding to the area of the pain, thread a Racz catheter into filling defect.

 Inject additional Omnipaque 240 to ascertain opening of the scar and spread of injectate within the epidural space and nerve roots.

 Inject preservative-free saline 10 to 20 mL.

 Inject 2% Xylocaine 5 mL.

 Tape the catheter in place in a sterile fashion.

In the recovery room:

 After ascertaining for motor blockade, inject 6 mL of 10% saline in two divided doses of 3 mL each, 15 to 30 minutes after injection of local anesthetic.

 Inject 6 to 12 mg of Celestone Soluspan, or 40 to 80 mg of alcohol-free Depo Medrol, or 40 to 80 mg of triamcinolone.

 Inject 0.5 to 1 mL of normal saline and remove the catheter.

Note: Adapted from Manchekanti et al.[16]

minutes. Again, the volume used is dependent on the location of the tip of the catheter, with 9 mL used in the lumbar area.

MODIFIED TECHNIQUE

Multiple modifications have been applied to the above-described technique. Some modifications were developed by Racz et al.[6–9,11] themselves; others were introduced by others. The technique utilized by Manchikanti et al.[16] as outlined in Table 70.6, is as follows.

Procedure Environment

The procedure is performed in a sterile operating room under appropriate sterile precautions using fluoroscopy and a specially designed RK needle, as well as a spring-wire Racz catheter (Epimed International).

Preparation

After the initial evaluation, the patient is transferred to the holding area, where appropriate preparation is carried out, including preoperative evaluation, with intravenous access, and administration of antibiotic, based on protocol and patient condition.

Consent

An appropriate detailed consent is obtained from the patient.

Operating Room

Following this, the patient is taken to the operating room or a sterile procedure room where preparation is carried out with iodophor solution skin preparation. Draping is carried out to cover the patient, extending into the midthoracic or cervical region, even if the procedure is performed in the lumbosacral region. Appropriate monitoring is carried out, with monitoring of blood pressure and pulse and pulse oximetry. Sedation is slowly administered.

The fluoroscope is adjusted over the lumbosacral region for anteroposterior and lateral views. A physician, scrubbed and in sterile gown and gloves, infiltrates the area for needle insertion with local anesthetic. Following this, an RK needle is introduced into the epidural space under fluoroscopic guidance. Once the needle placement is confirmed to be in the epidural space, a lumbar epidurogram is carried out using approximately 2 to 5 mL of contrast. Finding the filling defects by examining the contrast flow into the nerve roots is the purpose of the epidurogram. Intravascular or subarachnoid placement of the needle or contrast is avoided; if such malpositioning occurs, the needle is repositioned.

After appropriate determination of epidurography, a Racz catheter, which is a spring-guided, reinforced catheter, is slowly passed through the RK needle to the area of the filling defect or the site of pathology determined by MRI, CT, or patient symptoms. Following the positioning of the catheter into the appropriate area by mechanical means, adhesiolysis is carried out.

After completion of the adhesiolysis, a repeat epidurogram is carried out by additional injection of contrast. If appropriate adhesiolysis is completed, nerve root filling as well as epidural filling will be noted. Figure 70.4 through Figure 70.8 illustrate examples of the procedure.

At this time, variable doses of local anesthetic are injected. Commonly injected are 5 to 10 mL of 2% lidocaine hydrochloride or 5 to 10 mL of 0.25% bupivacaine.

Following completion of the injection, the catheter is taped using bio-occlusive dressing; the patient is turned to the supine position and transferred to the recovery room.

Recovery Room

The patient is very closely monitored for any potential complications or side effects. If no complications are observed and the patient reports good pain relief without any motor weakness, hypertonic saline neurolysis is carried out at this time by injection of variable doses of 10% sodium chloride solution. This may be carried out by an infusion pump or repeat injections in doses of 2 to 3 mL, ranging from 6 to 10 mL total, followed by injection of steroid (Celestone 6 to 12 mg or Depo-Medrol 40 to 80 mg).

The catheter is flushed with normal saline and removed and checked for intactness. The wound is also checked at this time. The patient is ambulated if all parameters are satisfactory, intravenous access is removed, and the patient is discharged home with appropriate instructions.

TRANSFORAMINAL ADHESIOLYSIS

Transforaminal adhesiolysis is described by Hammer et al.[18]

Procedure

To reach the anterior portion of the nerve, a needle is placed obliquely through the intervertebral foramen. Double rotation, fluoroscopic images are required. After squaring off the vertebral endplates, the fluoroscope is directed in a 35° to 40° oblique angle to visualize the opening of the intervertebral foramen. A 17-guage Tuohy or blunt trocar is advanced using tunnel vision under the pedicle. Once bone contact has been confirmed, the fluoroscopic beam is

(e) Lateral view

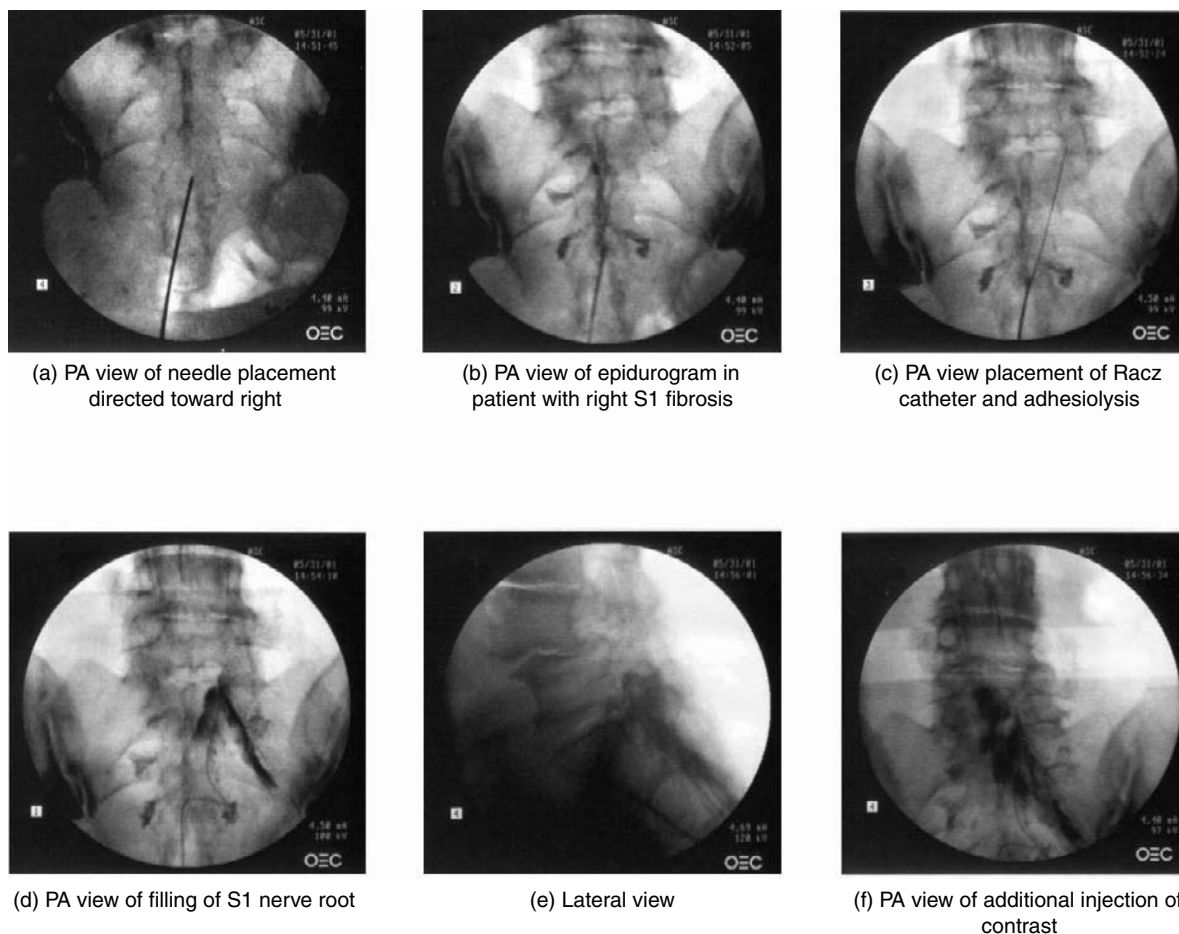
(f) PA view of additional injection of
contrast


FIGURE 70.5 Illustration of the technique of adhesiolysis involving right S1 nerve root. From L. Manchikanti, C. W. Slipman, & B. Fellows, Eds., *Interventional Pain Management: Low Back Pain — Diagnosis and Treatment* (p. 374), Paducah, KY: ASIPP Publishing. Reproduced with permission of the authors *Pain Physician,* and the American Society of Interventional Pain Physicians.

directed posteroanteriorly to demonstrate proximity of the needle trocar tip to the lateral foraminal zone. The fluoroscope is then redirected to a cross-table (lateral) view to prepare for final positioning. The needle/trocar is then slowly advanced from the posterior (dorsal) border of the neuroforamina to the retrovertebral space parallel to and "hugging" the inferior border of the pedicle. Paresthesia should not be elicited, or very minimally so, while advancing to the posterior vertebral body. After contact, a posteroanterior image should reveal the tip to be in the mid foraminal or subarticular zone. With the needle bevel facing posteriorly a BreviKath (Epimed International, Inc.) catheter is gently advanced under the exiting nerve root and into the ventral epidural space. The bevel may be rotated cephalad to steer the catheter appropriately if needed.

Having achieved a confirmation of ventrolateral epiradicular contrast spread, initial injection of 3.5 cc of 0.5% bupivacaine with or without 100 mg of fentanyl followed by hyaluronidase 1,500 units (1 mL) and slow infusion of 10% sodium chloride (hypertonic saline) and injection of triamcinolone acetate 40 mg (1 to 3 mL) are carried out.

CAUTION

Whatever the technique and whatever the route applied, it is of paramount importance that a physician pay attention to subarachnoid spread of the contrast and local anesthetic blockade following the injection. Injection of local anesthetic prior to lysis of adhesions, although practiced widely in the past, is no longer recommended. In addition, hypertonic saline should never be injected directly into the epidural space through the needle; rather it should be injected through the catheter in incremental doses after waiting at least 15 minutes following short-acting local anesthetics and 30 minutes following long-acting local anesthetics. Deviation from these descriptions may include:

- Injection of steroid at the end after the injection of hypertonic saline; however, the deviation should never occur with regard to injection of local anesthetic, specifically a long-acting local anesthetic, prior to the lysis and confirmation

of the position of the catheter and lack of sub-arachnoid spread

- Injection of hypertonic saline through the needle
- Injection of hypertonic saline, without appropriate waiting time, through the catheter

The injection procedures with such deviations as described above may result in disastrous complications, including arachnoiditis, which may be attributed to the injection, even though there is no substantial proof at the present time to indicate that 10% sodium chloride solution in fact causes arachnoiditis.

CONCLUSION

Chronic low back pain is a major health care and social problem. Much of the confusion surrounding epidural adhesiolysis in managing refractory low back pain results

FIGURE 70.9 Illustration of transforaminal adhesiolysis. From L. Manchikanti, C. W. Slipman, & B. Fellows, Eds., *Interventional Pain Management: Low Back Pain — Diagnosis and Treatment* (p. 377), Paducah, KY: ASIPP Publishing. Reproduced with permission of the authors *Pain Physician,* and the American Society of Interventional Pain Physicians.

from overemphasis on biopsychosocial problems and inappropriate selection of patients for this treatment modality. Considering the cumulative evidence available in the literature on epidural adhesiolysis, the efficacy of this procedure is similar, if not superior, to various other modalities of treatment available in managing chronic low back pain, including surgical intervention.

While this is a very effective technique in managing chronic low back pain, caution must be exercised, as there are significant risks of complications. While a pain practitioner needs to individualize the choice of treatment to each patient and personal experience, we recommend epidural adhesiolysis. This has proved to be a valuable, safe, and cost-effective technique for relieving chronic intractable pain in a patient nonresponsive to other conservative treatment modalities. Epidural adhesiolysis can also be performed in an out-patient setting, with reasonable and customary charges for the facility and physician services.

Endoscopic Lysis of Lumbar Epidural Adhesions

Laxmaiah Manchikanti, MD, and Vijay Singh, MD

INTRODUCTION

Spinal endoscopic lysis of epidural adhesions is an interventional pain management technique that emerged during the 1990s.[1–11] It is an invasive, but important, treatment modality in managing chronic refractory low back pain that is resistant to fluoroscopically directed epidural steroid injections and percutaneous adhesiolysis. Endoscopic adhesiolysis is based on the premise that the three-dimensional visualization of the contents of the epidural space provides the operator with the ability to steer the catheter toward structures of interest, allowing the examination of a specific nerve root and its pathology, lysis of adhesions, and target-specific injection of a drug(s).

HISTORICAL CONSIDERATIONS

Epidural injections for chronic low back pain were performed independently by Sicard,[12] Cathelin,[13] and Pasquier and Leri[14] to treat low back pain, sciatica, relief of pain due to inoperable carcinoma of the rectum, and to provide anesthesia for surgical procedures. The initial epidurography was performed by Sicard and Forestier.[15] Over the years, various authors[1–11,16–20] have studied the effectiveness of epidural steroid injections and percutaneous adhesiolysis facilitated by a spring-guided catheter. Development of endoscopic adhesiolysis added a third dimension to epidural delivery of drugs.

Medical literature has described various types of endoscopes for 60 years.[21] Integration of fiber-optic technology with computer-enhanced imaging provided a new medium for viewing the central nervous system.[21] Burman[22] first described the possibility of direct visualization of the spinal canal and its contents in 1931. However, direct visualization of spinal contents could not be achieved until the advent of flexible fiber-optic light sources and optics.[23] Burman[22] concluded that myeloscopy was limited by the available technology, but with higher quality instrumentation, he felt that the ability to visualize the contents of the spinal canal might be especially important in establishing a diagnosis of tumor or inflammation. Stern,[24] in 1936, described a spinascope, which was specifically designed for the *in vivo* examination of the spinal canal contents during spinal anesthesia.

Pool[25] in 1937, attempted to improve the preoperative diagnostic assessment of lumbar-sciatic syndrome by examining an anesthetized patient. However, only a fleeting glimpse of the lumbosacral nerve roots was possible due to hemorrhage, which obscured the field of vision. In subsequent evaluations[26,27] of the cauda equina and blood vessels in seven volunteers, blood flow through epidural vessels was visualized. Pool[26,27] subsequently summarized his experience with 400 patients with endoscopic evaluation.

In the late 1960s and 1970s, Ooi et al.[28–31] developed a miniature endoscope for intradural and extradural examinations. Ooi et al.[32,33] and Satoh et al.[34] performed 208 myeloscopies using various types of equipment from 1967 to 1977. With publication of their technique of myeloscopy and cauda equina blood flow changes during Lasègue's test in 1981, Ooi et al.[35] also reported that abdominal straining, coughing, and sneezing did not alter the blood flow and caused only mild movements of the cauda equina in the lateral position.

Blomberg[36] studied the anatomical variations of the epidural space and the appropriate delivery of epidural anesthetics, under epiduroscopy or spinaloscopy. Blomberg[36] reported that epidural adhesions between the dura mater and the ligamentum flavum restricted the opening of the epidural space. Blomberg and Olsson[37] reported experience with 10 epiduroscopies of patients scheduled for partial laminectomies for herniated lumbar discs. Following the experience of endoscopy in live patients, Blomberg[38] concluded that the opinions drawn from previous autopsy work were not applicable to the clinical setting. He also confirmed the presence of a dorsomedian connective tissue band that divided the epidural space into compartments.[38]

Modern era evaluations of several fiber-optic systems for use in clinical epiduroscopy in 1991 were started by Saberski and Brull.[21] Heavner et al.[39,40] in the early 1990s reported endoscopic evaluation of the epidural and subarachnoid spaces in rabbits, dogs, and human cadavers, with the aid of a flexible endoscope. Since then, multiple publications[5–11,41–45] have described various aspects of spinal endoscopy, including clinical basis, safety, and cost effectiveness.

PURPOSE AND GOALS

Since the introduction of epidural corticosteroids, it has always been the objective of pain specialists to deliver them close to the site of pathology, presumably onto an inflamed nerve root. For many reasons, this objective has been hindered in caudal as well as interlaminar delivery of epidural corticosteroids. Consequently, the reports of effectiveness of epidural corticosteroids have shown a wide disparity, ranging from 18 to 90%.[3]

The purpose of spinal or epidural endoscopy is to directly visualize the contents of the epidural space, lyse the adhesions, and directly apply drugs, thus assuring delivery of high concentrations of injected drugs to the target areas. Thus, spinal endoscopy with lysis of adhesions incorporates multiple therapeutic goals into one treatment, similar to percutaneous lysis of adhesions with a spring-guided catheter, with added advantages of direct visualization of the epidural space and its contents, a three-dimensional view, and increased steerability of endoscopic equipment with a fiber-optic catheter. Nomenclature used to describe this procedure includes spinal canal endoscopy, spinal epiduroscopy, myeloscopy, spinal or lumbar epiduroscopy, and endoscopic adhesiolysis.

PATHOPHYSIOLOGY

Epidural fibrosis is described as an inflammatory reaction of the arachnoid, a fine nonvascular and elastic tissue enveloping the CNS. Anular tear, hematoma, infection,

surgical trauma, and injection of intrathecal contrast media are considered potential etiologies of epidural fibrosis. The invasion of fibrous connective tissue into the postoperative hematoma resulting in epidural fibrosis was demonstrated by LaRocca and MacNab.[46] The irritative effect of material from the nucleus pulposus upon the dural sac, adjacent nerve roots, and nerve root sleeves independent of the influence of direct compression upon these structures was investigated by McCarron et al.[47,48] They also further reported an inflammatory reaction in the spinal cord sections taken from dogs after an initial injection of homogenized nucleus pulposus, while the spinal cord remained grossly normal after an injection of normal saline.

Epidural fibrosis, recurrent disc herniation, new disc herniation at a different level, local arachnoiditis, facet joint arthritis, spinal stenosis, instability, and spondylitis or spondylodiscitis are common causes of continued or recurrent low back and/or lower extremity pain following surgical interventions. Epidural fibrosis is considered a major cause of continued or recurrent pain following surgical intervention, if not surgical failure, in almost 60% of cases in conjunction with instability in postlumbar surgery syndrome. The role of epidural fibrosis as a causative factor of chronic pain or a pain generator, however, has been questioned.[48–53] In spite of the debate on whether epidural fibrosis causes pain, it is widely accepted that postoperative scar tissue renders the nerve susceptible to injury.[54]

Ross et al.[55] showed that subjects with extensive peridural scarring were 3.2 times more likely to experience recurrent radicular pain. Parke and Watanabe[56] in cadavers with lumbar disc herniation showed significant evidence of adhesions in 40% at L4/5 levels, in 36% at L5/S1 levels, and in 16% at L3/4 levels. Berger and Davis[57] diagnosed epidural fibrosis preoperatively in 0.67% and postoperatively in 11%. Further, in a study of 400 patients with multiple operations, they confirmed that, at the time of the second operation, the incidence of periradicular fibrosis had risen to 47%. Epidural adhesions have also been seen without surgery. Leakage of the irritants of the nucleus pulposus into the epidural space has been documented to cause an inflammatory response, resulting in an increase in fibrocytic deposition, resulting in epidural fibrosis.[16–20,47,48,56–60]

Mooney[61] postulated that persistent low back pain without segmental instability or another structural cause may result form poor healing of annular injuries due to inadequate blood supply. Wheeler and Murrey[62] described pathophysiology of chronic lumbar spine and radicular pain. In experimental studies, trauma to canine discs resulted in elevated concentrations of multiple neuropeptides, including substance P, calcitonin gene-related peptide, and vasoactive intestinal peptide in the dorsal root ganglion.[63,64] The noxious inflammatory and neurochemical influences on spinal tissues may explain induction of

lumbar and radicular pain. Proposed etiologies of radicular pain include neural compression with dysfunction, inflammation, vascular compromise, and biochemical influences. Perineural fibrosis can render nerve roots hyperesthetic with heightened sensitivity to compressive forces.[61,62,65,66] It was also shown that compensatory nutrition from cerebrospinal fluid (CSF) diffusion during low-pressure radicular compression in the face of epidural inflammation or fibrosis is probably inadequate.[55,56] Thus, present evidence suggests that the etiology of radiculitis is multifactorial beyond neural dysfunction due to impingement. Numerous authors[62–66] have identified the likely role of chemical irritation of the nerve root by the nucleus pulposus. Soon after Mixter and Barr's[67] landmark description of mechanical compression in 1934, it was noticed that the removal of the disc did not always result in pain relief.[68] Barr[69] reported that a patient may have persistent low back pain, sciatica, or both, in spite of surgical intervention. Mixter and Ayers,[70] soon after their own discovery of neurocompressive lesion, reported that low back and leg pain may occur without disc herniation and with normal appearance of a disc. It has been long recognized that mechanical factors are not the only causative factors of radicular pain. Histological injury may occur without compression, resulting in persistence of radicular symptoms. Nerve roots may be exposed to chemical irritant substances from degenerated intervertebral discs or facet joints, which can generate pain.[17] Structures in the ventral epidural space may become highly sensitized by chemical irritation, resulting in axial pain. These structures include ventral dura, posterior longitudinal ligament, vertebral periosteum, dural attachments, and epiradicular components.[71]

Innervation to the ventral epidural space is extensive and, thus, may become highly sensitized, resulting in chronic low back pain. Histopathological studies have demonstrated sinuvertebral nerve and sympathetic innervation pain.[17] Thus, evolved the concept of noncompressive lesion and irritation of the nerve root, as well as the definition of failed back surgery syndrome or postlumbar laminectomy syndrome with persistent or recurring low back pain, with or without radiculitis following one or more lumbar operations, which followed the theories of neurocompressive lesion and its decompression.

Prior to 1935, the condition of chronic adhesional arachnoiditis was generally described as chronic spinal meningitis.[49] Thus, epidural fibrosis or arachnoiditis was a relatively rare entity prior to the introduction of lumbar spine surgery for degenerative conditions. The speculation of the association of recurrent symptomatology with perineural scarring originated from multiple authors reporting epidural fibrosis at repeat surgery.[49,72] The prevalence of recurrent disc herniation and facet joint pain in postlumbar laminectomy syndrome was shown to be 5 to 11%[73] and 32%.[74] The prevalence of epidural

scarring, arachnoiditis, and mechanical instability is not accurately known.

Kuslich et al.[75] postulated that the presence of scar tissue compounded pain associated with the nerve root by fixing it in one position and thus increasing the susceptibility of the nerve root to tension or compression. They also concluded that sciatica can only be reproduced by direct pressure or stretch on the inflammatory, stretched, or compressive nerve root. Further, compromised delivery of nutrition has also been described.[61,66]

Epidural fibrosis is found in the three compartments of the epidural space: dorsal, ventral, and lateral. Dorsal epidural scar tissue is formed by resorption of surgical hematoma and may be involved in pain generation.[76] Ventral epidural scar tissue, often dense, is formed by ventral defects in the disc, which may persist despite surgical treatment and continue to produce either chronic low back or lower extremity pain after the surgical healing phase.[47] The lateral epidural space includes epiradicular structures out of the root canals or sleeves, containing the exiting nerve root and dorsal root ganglia, susceptible to lateral disc defects, facet overgrowth, neuroforaminal stenosis, etc.[77] Thus, it is postulated that various changes producing low back pain and lower extremity pain include inflammation, edema, fibrosis, venous congestion, mechanical pressure on the posterior longitudinal ligament, reduced or absent nutrient delivery to the spinal nerve or nerve root, and central sensitization.

Epidural fibrosis with or without symptoms of back pain is not readily diagnosed by conventional studies such as myelography, computerized tomography (CT), and magnetic resonance imaging (MRI), in spite of modern technology and its significant improvements. Epidural fibrosis is best diagnosed by performing an epidurogram. The presence of epidural filling defects has been demonstrated in a significant number of patients with no history of prior surgery.[60]

RATIONALE

Although Phillips and Cunningham[78] reported that surgical decompression or surgical lysis of adhesions was not effective for postlumbar laminectomy syndrome, the rationale for spinal endoscopy and adhesiolysis in the management of chronic, resistant spinal pain stems from the concept that epidural adhesions are a common source of chronic low back pain. Indeed, the effectiveness of percutaneous adhesiolysis with a spring-guided catheter has been demonstrated.[3]

The epidural space that is restricted by adhesions is safely accessible to a fiber-optic endoscope, and spinal endoscopy and therapeutic application of drugs in selected cases have been shown to be clinically effective and safe.[1] Additional aspects of the rationale include the mechanical and hydrostatic effect of the procedure with high-volume

TABLE 71.1
Results of Published Reports of Spinal Endoscopy

Ref.	Study Characteristic(s)	No. of Patients	Relief		
			3 Months	6 Months	1 Year
Manchikanti et al.[11]	P, RA, DB	C = 33	0%	0%	0%
		T = 50	80%	56%	48%
Geurts et al.[8]	P	20	40%	35%	35%
Richardson et al.[7]	P	34	Sig	Sig	Sig
Manchikanti et al.[5]	R	60	75%	40%	22%
Manchikanti[6]	R	85	77%	52%	21%

Note: P = prospective; RA = randomized; DB = double-blind; R = retrospective, Sig = significant number of patients; C = control; T = treatment.

fluid administration and direct access to the target site, removing or diluting the chemical irritants.

CLINICAL EFFECTIVENESS

Clinical effectiveness of endoscopic adhesiolysis with direct visualization was evaluated in one randomized, double-blind trial,[11] two prospective case series,[7,8] four retrospective trials,[5,6,9,44] and some case reports.[41,43] The results of those trials eligible are summarized in Table 71.1.

In a prospective, randomized, double-blind trial with a 1-year follow-up of spinal endoscopic adhesiolysis in patients with chronic low back pain, refractory to multiple other modalities of treatments, including percutaneous adhesiolysis, Manchikanti et al.[11] showed that significant improvement was seen without any adverse events in 80% of the patients at 3 months, 56% at 6 months, and 48% at 12 months. They considered that short-term relief was noted in 80% and long-term relief was noted in 56% based on the definition of short-term improvement as less than 6 months and long-term improvement as greater than 6 months.

Geurts et al.[8] in a prospective case series reported results of spinal endoscopic adhesiolysis in 20 patients with greater than 50% reduction in pain in 40% of the patients at 3 months, 35% at 6, 9, and 12 months.

Richardson et al.[7] evaluated the role of spinal endoscopy in a prospective case series of 34 patients suffering with chronic, severe low back pain, with 50% of the patients having failed back surgery syndrome. They reported the presence of epidural adhesions in 100% of the patients, with 41% having dense adhesions. A follow-up over a 1-year period showed significant reductions in pain scores and disability.

Manchikanti et al.[5] in a study evaluating the effectiveness of endoscopic adhesiolysis in postlumbar laminectomy syndrome in 60 patients, showed that 100% of the patients reported significant pain relief at 1 month, whereas 75% reported significant relief at 3 months, 40%

reported significant relief at 6 months, and 22% reported significant relief at 12 months.

Manchikanti et al.[6] in a retrospective evaluation of 85 consecutive patients undergoing 112 epidural endoscopic procedures reported significant pain relief in 100% of the patients initially. However, this relief decreased to 94% at 1 to 2 months, to 77% at 2 to 3 months, to 52% at 3 to 6 months, to 21% at 6 to 12 months, and to 7% after 12 months.

Krasuski et al.[9] reviewed 22 cases. They reported initial improvement in 64% of the patients. The relief declined to 50% of the patients after 1 month and 32% after 3 months. Medication decrease was noted in 32% of the patients.

INDICATIONS

Endoscopic epidural adhesiolysis is indicated in patients with chronic low back pain who have failed to respond to conservative modalities of treatment, including epidural injections administered under fluoroscopic guidance, percutaneous lysis of adhesions with a spring-guided catheter, and other well-documented therapeutic modalities. Various conditions in which spinal endoscopy is indicated include postlumbar laminectomy syndrome, epidural adhesions, and disc disruption resulting in chronic, intractable pain nonresponsive to other modalities of treatment. Probable indications include low back pain nonresponsive to other modalities of treatments and chemical irritation.

COMPLICATIONS

The most common and worrisome complications of spinal endoscopy with lysis of adhesions are related to instrumentation and administration of high volumes of fluids, resulting in excessive epidural hydrostatic pressures, which may cause spinal cord compression, excessive intraspinal and intracranial pressures, epidural hematoma, bleeding, infection, increased intraocular pressures with

resultant visual deficiencies, and even blindness and dural puncture.[79–125] Even though dural puncture was noted in 8 of 112 procedures[6] and 7 of 77 procedures,[5] subarachnoid blockade was seen in only 30 to 40% of patients, without any other complications. However, excessive pressure development has the potential to affect both local and distant perfusion, possibly resulting in visual changes and even blindness. Even though the incidence is rare, it appears that it would be much higher with spinal endoscopic procedures with a combination of high volumes of fluid and generation of high hydrostatic pressures.[79] This also has been reported with routine epidural injections, presumably resulting from transmission of spinal canal pressures cephalad into the brain by the CSF, affecting retinal perfusion or causing macular hemorrhage.

Kushner and Olson[80] evaluated patients who complained of visual-field defects or blurred vision after receiving epidural steroid injections and conclude that retinal hemorrhage is uncommon but significant and a previously unemphasized complication of epidural steroid injections in general. Retinal hemorrhages mainly have been attributed to rapid epidural injections of high volumes, causing a sudden increase in intracranial pressure, resulting in the increase of retinal venous pressure.[80–86] Hence, there may be a causal relationship between these complications and spinal endoscopy and adhesiolysis with administration of high volumes of saline, and other agents, specifically with rapid injections.

Epidural infection following this procedure is a distinct possibility due to the procedure itself, as well as potential immunosuppression secondary to steroid injection.[80–114] Manchikanti et al.[6] reported a serious infection in one patient requiring prolonged antibiotic therapy and skin grafting. In this report, infection occurred following 2 of 112 procedures, was suspected in 6 others, which were managed by prophylactic antibiotics.[6] Manchikanti et al.[5] in another study also report suspicion of infection following 8 of 77 procedures, with no major complications. Sampath and Rigamonti,[87] in a review of epidemiology, diagnosis, and treatment of spinal epidural abscess, note that spinal nerve block was responsible for 7% of the patients, whereas a multitude of other predisposing factors included intravenous (IV) drug use, diabetes neuritis, multiple medical illnesses, trauma, prior spinal surgery, morbid obesity, HIV disease, and end-stage renal disease in a descending order of frequency. Wang et al.,[88] in a 1-year study of the incidence of spinal epidural abscess after epidural analgesia, report nine cases of epidural abscess formation from a total of 17,372 epidural catheters.

Direct trauma to the spinal cord following spinal endoscopy in the lumbar spine is only a theoretical possibility. Neural trauma is a potential complication, even though there are no such case reports. Subdural injection, neural trauma, injury to the spinal cord, and hematoma formation have been described with epidural injections,

even though there are no specific descriptions relating to spinal endoscopy.[115–120] Spinal cord trauma or spinal cord or epidural hematoma formation is a catastrophic complication possible with spinal endoscopic adhesiolysis, although there are no case reports in the literature.

Potential complications include increased or continued pain, transient dysesthesias, paresis, paralysis, local surgical site bleeding, allergic reactions, and side effects related to the administration of steroids. While paresis, paralysis, and intractable pain may be related to needle trauma, epidural hematoma, elevated hydrostatic pressures, ischemia, or nerve injury, severe headache, dysesthesia, and intractable acute back pain may indicate epidural hematoma, cord ischemia, and elevated hydrostatic pressure. However, the safety of steroids and preservatives at epidural therapeutic doses has been demonstrated in both clinical and experimental studies.[121–131] The major theoretical complications of corticosteroid administration include arachnoiditis, suppression of the pituitary-adrenal axis, hypocorticism, Cushing syndrome, osteoporosis, avascular necrosis of bone, steroid myopathy, weight gain, fluid retention, and hyperglycemia.[130,131]

Additional complications include hypertension, hypokalemia, epidural lipomatosis, retinal hemorrhage, subcapsular cataract formation, insomnia, mood swings, psychosis, facial flushing, headache, gastrointestinal disturbances, and menstrual disturbances. The use of corticosteroids repeatedly for days or even a few weeks does not lead to adrenal insufficiency upon cessation of treatment, but prolonged therapy with corticosteroids occasionally may result in the suppression of pituitary-adrenal function that can be slow in returning to normal. Rare hypothalamic-pituitary-adrenal suppression during corticosteroid administration with epidural injections and after its withdrawal has been reported.[130,131] However, no such reports have implicated spinal endoscopy and administration of steroids. Manchikanti et al.[132] evaluated the effect of neuraxial steroids on weight and bone mass density (BMD) prospectively. The results of serial determination of weight and BMD showed no significant change at any interval or at the end of 1 year in any of 123 patients with or without steroid administration.

Houten and Errico[123] report three cases of paraplegia after lumbosacral nerve root block in post laminectomy patients. They report that in each case, performed at three different facilities, in the hands of two different physicians, the needle placement was verified with injection of contrast in conjunction with CT or biplanar fluoroscopy. In each patient, paraplegia was reported suddenly after injection of steroid solution, and in each instance, post-procedure MRI revealed spinal cord edema in the low thoracic region. The authors postulate that in these patients the spinal needle penetrated or caused injury to an abnormally low dominant radiculomedullary artery, a recognized anatomical variant. This vessel, also known as the

artery of Adamkiewicz, in 85% of individuals arises between T9 and L2, usually from the left, but in a minority of people, it may arise from the lower lumbar spine and rarely even from as low as S1.[123] This artery travels with the nerve root through the neural foramen, supplying the anterior spinal artery. Injury of the artery or injection of particulate steroid may result in infarction of the lower thoracic spinal cord.

Cousins[124] also reports similar complication as above.[123] He reports a potential complication of particulate depo-corticosteroids related to inadvertent intravascular administration, producing occlusion of small end arteries, which resulted in visual defects in one case and hearing loss in another case, involving suboccipital nerve block. It is felt that prednisolone acetate tends to form aggregates of the steroid material when mixed with local anesthetic and may pose more of a risk for this problem than other depo-steroids.

TECHNICAL ASPECTS

Spinal endoscopy is best performed by a caudal approach based on anatomy, equipment, and experience with epidural adhesiolysis with spring-guided catheter. The straight entry into the epidural space through the caudal approach is much easier and more practical than entry into the lumbar epidural space through a paramedian approach, even with a steep angle. This facilitates not only the easy passage of the fiber-optic endoscope but also reduces damage to the device.

ANATOMY

The spinal canal extends from the foramen magnum to the sacrum, which is bounded posteriorly by the ligamentum flavum and periosteum and anteriorly by the posterior longitudinal ligament that lies over the dorsal aspects of the vertebral bodies and discs. The spinal cord ends at L1, and the dural sac continues to the level of S2.

The dural sac rests on the floor of the vertebral canal.[133] The anterior relations of the dural sac, therefore, are the backs of the vertebral bodies and the intervertebral discs, and covering these structures is the posterior longitudinal ligament.[133] Thus, anterior spinal arteries and sinuvertebral nerves run across the floor of the vertebral canal and are located anterior to the dural sac. The dural sac posteriorly is related to the roof of the vertebral canal, the laminae, and ligamentum flava.

The epidural space is a potential space intervening between the dural sac and the osseo-ligamentous boundaries of the vertebral canal. The epidural membrane is a thin layer of areolar connective tissue, which varies from diaphanous to pseudomembranous in structure.[134,135] The membrane surrounds the dural sac and lines the deep surface of the laminae and pedicles.[133] Ventrally, opposite the vertebral bodies, the membrane lines the back of the vertebral body and then passes medially deep to the posterior longitudinal ligament, where it detaches from the anterior surface of the deep portion of the ligament.[134] However, the membrane does not cover the back of the anulus fibrosus and is prevented from doing so by the posterior longitudinal ligament as it expands laterally over the back of the disc. The size of the posterior epidural space averages 4 to 6 mm at the lumbar level.

TECHNIQUE

Prior to undergoing spinal endoscopy, all the patients must be assessed with a comprehensive physical and psychological evaluation. All less invasive and conservative modalities of treatment, including fluoroscopically directed epidural steroid injections and spring-guided catheter lysis of adhesions, should be exhausted. In addition, appropriate laboratory studies should be considered to rule out bleeding disorders. Nonsteroidal anti-inflammatory drugs, aspirin, and anticoagulants should be discontinued prior to spinal canal endoscopy to avoid unusual bleeding.

An antibacterial scrub with a shower the night before should be considered. In addition, the patient should have an empty stomach. No general anesthesia should be contemplated. The patient should understand all the implications of the procedure and sign an informed consent.

After the initial evaluation, the patient is transferred to the holding area, where appropriate preparation is carried out with preoperative evaluation, checking of vital signs, and establishment of IV access, as well as antibiotic administration.

Following this, the patient is taken to the operating room or a sterile procedure room where preparation is carried out with iodophor solution. Draping is carried out to cover the entire patient, extending into the cervical region. At this time, under appropriate monitoring with blood pressure and pulse oximetry, sedation is administered and continuous monitoring is performed.

The procedure is performed in a sterile operating room under appropriate sterile precautions using fluoroscopy. The fluoroscope is adjusted over the lumbosacral region to perform the procedure in the lumbosacral region for a lumbar or caudal procedure, both anteroposterior and lateral views.

After appropriate positioning of fluoroscopy, a physician scrubbed and with sterile gown and gloves infiltrates the area for needle insertion with local anesthetic. Following this, an epidural needle is introduced into the epidural space using fluoroscopic visualization. Once the needle placement is confirmed to be in the epidural space, a lumbar epidurogram is carried out using approximately 2 to 5 ml of non-ionic contrast. Finding the filling defects

by examining the contrast flow into the nerve roots is the purpose of the epidurogram. Intravascular or subarachnoid placement of the needle or contrast is avoided; if such malpositioning occurs, the needle is repositioned.

A 0.9-mm guide wire is inserted through the needle, which is advanced under fluoroscopic guidance to the level of suspected pathology, followed by advancement of a 2-mm × 17.8-cm dilator with catheter (sheath) over the guide wire. Once the catheter is advanced to the tip of the guide wire, the wire is removed. At this time, a 0.8-mm fiber-optic spinal endoscopy is introduced into the catheter through the valve and is advanced until the tip is positioned at the distal end of the catheter, as determined by video and fluoroscopic images. In conjunction with gentle irrigation using normal saline, the catheter and fiber-optic myeloscope are manipulated and rotated in multiple directions, with visualization of the nerve roots at various levels. Gentle irrigation may also be carried out by slow, controlled infusion. Adhesiolysis and decompression are carried out by distension of the epidural space with normal saline and by mechanical means using the fiber-optic endoscope. Figure 71.1 through Figure 71.3 illustrate the procedural considerations.

Confirmation is accomplished with injection of non-ionic contrast material. An epidurogram is performed on at least two occasions. Following completion of the procedure, generally, lidocaine 1%, preservative free, mixed with 6 to 12 mg of betamethasone acetate and phosphate mixture or methylprednisolone or triamcinolone is injected in each case after assuring that there is no evidence of subarachnoid leakage of contrast. If there is a question of subarachnoid leakage of the contrast, a Racz catheter may be passed into the epidural space, and a mixture of local anesthetic injected very slowly in incremental doses, followed by injection of the steroid.

Following completion of the procedure, if necessary, self-absorbed sutures are applied, followed by sterile Bio-clusive dressing. Subsequently, the patient is turned to the supine position and transferred to the recovery room. In the recovery room, the patient is very closely monitored for any potential complications or side effects. If a patient has a catheter and no complications are observed and good pain relief is reported without any motor weakness, steroid is injected.

CONCLUSION

Chronic low back pain is a major health care and social problem. Much of the confusion surrounding spinal endoscopy and adhesiolysis in managing refractory low back pain results from overemphasis on biopsychosocial problems and inappropriate selection of patients for this treatment modality. Considering the cumulative evidence available, the efficacy of this procedure is similar, if not superior, to multiple other modalities of treatments available in managing chronic low back pain, including surgical intervention.

Cryoneurolysis: Principles and Practice

Andrea M. Trescot, MD

DEFINITION

Cryoanalgesia, cryoneuroablation, or cryoneurolysis is a specialized technique for providing long-term pain relief when pain has been shown to be caused by sensory nerves.

HISTORY

Humans have known about the use of cold for analgesia for thousands of years. Hippocrates (460–377 B.C.) left us the first written records of the use of ice for pain relief, describing how snow was brought down from the mountains in ancient Greece and applied to wounds for pain relief.[1] The ancient Egyptians documented the use of low temperature for analgesia.[2] Avicenna of Persia (A.D. 982–1070), an early physician, described the use of cold for preoperative analgesia.[3] Baron Dominique Jean Larre, Napoleon's Surgeon General, noted in 1812 that half-frozen soldiers in the Moscow battle were able to tolerate limb amputation with little or no pain.[4] In addition, Hunter noted in 1777 that when rooster comb tissues were killed by cold, the base of the comb healed without scarring.[5] In 1851, Arnott[6] avidly promoted the application of cold to relive certain types of cancer and nerve pain, using mixtures of ice and salt at –20°C. He also noted the hemostatic and anesthetic effects of cold. Richardson[7] introduced ether spray in 1866 for topical anesthesia, which was followed by ethyl chloride spray in 1891; thus "to freeze" became synonymous with "to numb." Trendelenberg[8] demonstrated that freezing tissues caused severe nerve damage and loss of function, but noted that the nerves regenerated without neuroma formation.

Modern cryoanalgesia traces its roots to Cooper et al.[9] who developed in 1961 a device that used liquid nitrogen in a hollow tube that was insulated at the tip and achieved a temperature of –190°C. Amoils,[10] an ophthalmic surgeon, developed a simpler handheld device in 1967, which used carbon dioxide or nitrous oxide and could achieve temperatures of –70°C. Lloyd and his co-workers[11] coined the term *cryoanalgesia* for its use in pain management. They proposed that this technique was superior to other methods of peripheral nerve destruction, e.g., alcohol, phenol, or surgical lesions, because it is not followed by neuritis or neuralgia.[12]

Current probes range in size from 1.4 to 2 mm in size and have as well a built-in nerve stimulator for localization of the nerve and a thermistor to identify temperature at the tip. Barnard and Lloyd,[13] Evans,[5] and Glynn and Carrie[14] popularized cryoneuroablation in the early 1980s, but relatively little has been written on the technique since then. This chapter is an attempt to describe the contemporary role of cryoneuroablation.

PHYSICS AND EQUIPMENT

The cryoprobe consists of a hollow tube with a smaller inner tube. Pressurized gas (usually N_2O or CO_2) at 600 to 800 psi travels down the inner tube and is released into the larger outer tube, which is at a low pressure of 10 to 15 psi through a very fine aperture (0.002 mm), allowing the gas to rapidly expand (Figure 72.1) into the distal tip. This extracts heat from the tip of the probe, dropping the temperature to as cold as –89°C at the tip itself (Joule-Thompson effect). This forms an ice ball, creating temperatures in the range of –70°C.[15] The gas is then vented back to the machine itself through the outer tube, and is scavenged through a ventilated outlet. The "closed system" construc-
FIGURE 72.1 Probe.

tion of the probe and machine assures that no gas escapes into the patient's tissues. The 2.0-mm probe forms a 5.5-mm ice ball while the 1.4-mm probe forms a 3.5-mm ice ball. Precise gas flows are necessary for safe and effective cryoneuroablation; inadequate gas flows will not produce an ice ball while excessive flows can cause freezing proximally up the probe, which may increase the risk of skin burns. The probe also includes a nerve stimulator, with sensory and motor capabilities, which allow precise localization of the target nerve.

The application of cold to tissues creates a conduction block, similar to the effect of local anesthetics. At 10°C, larger myelinated fibers stop conducting, but all nerve fibers stop conducting at –20°C. The extent and duration of the analgesic effect, therefore, is a function of the degree of cold obtained and the length of exposure.[16] Long-term pain relief from nerve freezing occurs because ice crystals create vascular damage to the vasa nervorum, which produces severe endoneural edema. Endoneural fluid pressure increases about 20 mm within 90 minutes of the cryolesioning. Changes in the elastic properties of the perineurium cause a decrease in extracellular fluid pressure within 24 hours, which increases again and then reaches a plateau about 6 days post-lesion, disrupting the nerve structure and creating Wallerian degeneration but leaving the myelin sheath and endoneurium intact.[17] The Schwann cell basal lamina is spared and ultimately provides the structure for regeneration. Although demyelination and degeneration of the axon occurs, Sunderland[18] demonstrated that when the endoneurium remains intact, neuroma formation does not occur, and the nerve is typically able to regenerate at a rate of 1 to 1.5 mm/week. He described five categories of nerve injury based on histology and prognosis:

- First degree (neurapraxia) — An injury with minimal histologic changes with neurons failing to conduct impulses for several days to months.
- Second degree (axonotmesis) — An injury with loss of axonal continuity without breaching the endoneurium. This is the goal of cryoneuroablation, and occurs when a short section of a peripheral nerve is frozen to –20°C.

- Third, fourth, and fifth degree (neurotmesis) are associated with neural and stromal destruction.

Autoimmune phenomena are also implicated in the long-term effects of cryoneuroablation, with a release of sequestered proteins that may trigger an autoimmune response to the targeted lesioned tissues, which might explain the prolonged analgesic effect.[19–21]

The extent of the freezing (and subsequent nerve damage) is a function of the following:

1. The proximity of the probe to the nerve
2. The size of the cryoprobe
3. The size of the ice ball formed
4. The completeness of the freezing (rate and duration)
5. The temperature of the tissues in proximity to the probe, which is affected by local heat sinks (such as cerebrospinal fluid/blood flow)

The intensity and duration of analgesia is dependent on the degree of nerve damage from the ice ball.[22] For example, exposure of the fingers or toes to winter cold can lead to numbness (which is reversible) up to frostbite (which may result in permanent changes). The use of the nerve stimulator, meticulous localization of the nerve, the use of the largest probe appropriate, and the use of appropriate freeze and defrost cycles will increase the degree of nerve disruption and therefore the success rate. Repeat cycles decrease the temperature at sites farther from the probe, increasing the size of the ice ball formed and increasing the length of nerve incorporated into the ice ball. The use of saline with epinephrine injected in proximity to the target structure may decrease the "heat sink" of the nearby warm blood flow and at the same time potentially decrease bruising from the placement of the probe, which would be expected to decrease post-procedure soreness. The cryoprobe should typically be withdrawn only after the ice ball has thawed, as trying to withdraw the probe with the ice ball present could tear the attached tissues and avulse a nerve segment.

Current probes range from 1.4 to 2 mm in size. Most have a built-in nerve stimulator for localization of the nerve and a thermistor to identify temperature at the tip. The nerve stimulator allows a frequency choice for sensory (100 Hz) or motor (2 Hz) responses. Use of an introducer is recommended because the introducer can be used to infiltrate local anesthetic, isolate the electrical current stimulation to the tip of the probe (should the Teflon coating fail over time), and afford skin protection from the ice ball during treatment of superficial structures. The most commonly used introducer is a large-gauge intravenous (IV) catheter. The sharp tip pierces the tissues more easily than the probe itself, and the stylet can be removed to allow introduction of the probe. A 12-gauge catheter is

used for the 2.0-mm probe and a 14- or 16-gauge catheter is used for the 1.4-mm probe.

CLINICAL ASPECTS

"You cannot treat what you cannot diagnose," is the tenet of the effective interventional pain management specialist. The cryoneurolysis technique is only as good as the diagnostic technique that precedes it. It is critical that a precise diagnosis be made prior to an attempt to freeze any nerve. In fact, the first step is to confirm that pathology is primarily isolated to sensory nerves. Performing a meticulous diagnostic block, using small volumes of local anesthetic no greater than the volume of the freeze that would be created (0.2 to 0.8 cc), does this. Use of a nerve stimulator as well as fluoroscopic guidance, direct exposure, or absolute anatomic location of the structure is critical. Because the nerve is *expected* to regrow, it is critical that the period of pain relief after the cryoneuroablation be used to restore as normal environment as possible so that, as the nerve regenerates, the original pathology (entrapment) does not recur. Cryoneuroablation may address the issue of "wind up" (the continued stimulation of a nerve causes increased sympathetic outflow and thus more stimulation), resulting in a period of reduced sympathetic stimulation that may allow aggressive rehabilitation. There is no evidence of permanent neurologic damage as a result of multiple cryoneuroablation procedures.[23] Success of cryoanalgesia is directly related to patient selection, accurate probe placement, and the post-procedure rehabilitation process.

PATIENT PREPARATION

Informed consent is as important for this technique as it is for any other interventional procedure. Risk, potential complications, and specific contraindications should be discussed and that discussion documented. The machine and gas supply should be checked, and the cryoprobe purged of the room air gases. The patient is placed in the appropriate position, and the nerve location confirmed by palpation and, when appropriate, by fluoroscopic localization. Minimal, if any, sedation should be used, as it is critical that the patient be awake enough to respond to the stimulation.

TECHNIQUE

The technique requires precise localization of the target nerve. Depending on the anatomy and ease of locating landmarks, cryoneuroablation can be done with or without fluoroscopy. After a sterile prep and drape, a small amount of local anesthetic is infiltrated subcutaneously. A 27-gauge, 1.5-inch needle is then advanced into the subcutaneous tissues, and 1 cc of saline with freshly added epinephrine 1:200,000 is then infiltrated for hemostasis. A small incision is made in the skin, and an IV introducer is then advanced to the target area. Small doses of additional local anesthetic can be injected through the introducer, as it is advanced, taking care not to anesthetize the actual target area.

When the introducer comes in contact with the target area, the stylet is removed and the cryoprobe is then advanced through the catheter and the tip of the probe is then exposed by withdrawing the catheter into the subcutaneous tissues. (Most of the techniques described it this chapter use bone as the "backstop," allowing the nerve to be "pinned" against the bone to facilitate maximal nerve contact with the probe.) Not all catheters are created equally. It is important, especially when changing brands, to confirm that the probe will fit through the catheter prior to introducing the catheter through the skin. There is little worse than getting the catheter placed perfectly, only to be unable to advance the probe through the catheter.

Accurate and meticulous sensory stimulation is critical for success. As the probe moves across the periosteum, sensory stimulation (100 Hz), first at 2 volts and then as low as 0.5 volts, is used to identify the nerve. Particular care must be used in the movement of the probe, because the movement itself may cause a paresthesia that is not an actual sensory stimulation but rather a "piezoelectric" or traction effect. As soon as the patient perceives stimulation in, or paresthesia to, the target nerve, the stimulation should be immediately turned to zero to avoid overstimulation of the nerve. Turning the stimulator back on its previous setting should again provide stimulation without movement of the probe, confirming the actual electrical and not mechanical stimulation of the nerve. The procedure is repeated with progressively decreasing voltages, until stimulation can be reliably obtained at 0.5 volts. At this time motor stimulation (2 Hz) is used at its highest voltage to confirm that the probe is not too close to nearby motor nerves. Gas flows are then turned up to 10 to 12 liters/minute (for the 2.0-mm probe) or 8 to 10 liters per minute (for the 1.4-mm probe) and a series of 2- to 3-minute freezes with 30 seconds defrosting between each cycle is performed. There is usually a burning pain on initiation of the first freeze cycle, which often replicates the pain and should resolved within approximately 30 seconds. The rest of the procedure should be completely painless.

Freeze cycles of 2 to 3 minutes result in optimal density of the ice ball. It is clear that freeze cycles longer than 3 minutes do not result in any additional benefit because the ice acts as its own insulation. Adequate thawing (more than 20 seconds but less than 40 seconds) allows subsequent freezes to increase the size of the freeze zone. After the last defrost cycle, the probe is withdrawn from the catheter and 1 cc of 0.5% bupivacaine is used to infiltrate the tissues as the catheter is withdrawn. This provides post-procedure analgesia.

It is critical that minimal sedation be used for the procedure, allowing the patient to interact fully with the determination of sensory stimulation. Done with a gentle technique, this should not be a painful procedure, and it is commonly done with no sedation at all. Small doses of a short acting opioid (50 to 100 μg of fentanyl) should be more than adequate for analgesia.

ALTERNATIVES

There are few options other than cryoneuroablation for the ablation of large sensory nerves. Surgical resection has been used, but is all too often associated with postoperative neuroma formation. One of the clinical uses for cryoneuroablation is the treatment of those postoperative neuromas. Alcohol and phenol will destroy the nerve but are also associated with neuroma formation. Opioids do not treat nerve pain, rather they only "mask" the pain. Anticonvulsants should be used before attempting cryoablation. Pulse radiofrequency lesioning has recently been used. The theoretic advantage would be the use of smaller (22-gauge) probes; however, long-term results are not available, and the mechanism is not yet well elucidated.

CONTRAINDICATIONS

General contraindications to percutaneous cryoneurolysis are quite basic: bleeding diathesis, infection (local or systemic), and an uninformed patient. The bleeding contraindication is relative and is important primarily in those situations where bleeding could go unnoticed, such as an intercostal cryoneurolysis with bleeding into the thorax or an obturator nerve cryoneurolysis where there could be hidden bleeding into the pelvis. Placing the probe through infected tissue could seed the infection into deeper tissues. Patients must be warned of the risks of depigmentation or hyperpigmentation at the cryolesion site. In addition, a diagnostic block should be used to let the patient "preview" the effect, stressing that the lesion creates numbness and not just pain relief. Some patients have actually felt distressed by the numbing effect, for instance, complaining about numbness when brushing their hair after an occipital cryolesion. Alopecia may also occur at the cryo site, especially at the eyebrow when performing a supraorbital cryolesion. There is only one reported case of neuritis after cryoneuroablation.[24] With a well-informed patient, outcomes will be improved and patients' expectations are more likely to be met.

CLINICAL USES

CRANIOFACIAL PAIN

Supraorbital Nerve

The supraorbital nerve is the termination of the first division of the trigeminal nerve. Irritation of the nerve occurs primarily at the supraorbital notch. A small ligament completes the inferior border of a foramen through which the nerve passes prior to passage through the orbicularis oculi. Commonly confused with migraine headaches and frontal sinusitis, the pain of supraorbital neuralgia most typically manifests as frontal headache, often associated with blurred vision, nausea, and photophobia. Vulnerable to blunt trauma, this nerve can be injured by trauma caused by being hit on the forehead by an automobile windshield or an abuser's fist. This neuralgia tends to worsen with time following the trauma as the injured tissue slowly develops a cicatrix, which eventually envelopes the nerve. Contraction of the orbicularis oculi (such as frowning or squinting) exacerbates the entrapment. This etiology is supported by the efficacy of botulism toxin in the forehead region in the treatment of "migraines." However, the relief from botulism is expected to last only 2 to 3 months, whereas cryoneuroablation relief can be for up to a year. Less commonly, the nerve can be injured as the result of acute herpetic infection (e.g., shingles), Paget's disease, and neoplasm. Patients will often experience an increase in headache intensity and frequency with menstruation (associated with fluid retention), salt intake, stress, and bright light (which causes squinting).

Technique: Cryoneuroablation of the supraorbital nerve can be accomplished via an "open" operative technique involving dissection under local anesthesia. The nerve can then be frozen under direct vision. The "closed" technique involves using the 1.4-mm probe, passed via a 14-gauge intravenous catheter introducer. Two or three 2-minute cycles are usually sufficient. The supratrochlear nerve, located at the medial aspect of the orbit, may also be involved and is lesioned in a similar manner. In this cosmetically important area, particular care must be used to avoid thermal damage to the sensitive skin around the eye. Entry of the catheter and probe should be below or above the eyebrow line. This avoids damage to the brow follicles, which could cause subsequent alopecia. Changes in skin color can be expected, but generally resolve in a matter of months; however, the patient must be counseled appropriately.

Infraorbital Nerve

The infraorbital nerve is the termination of the second division of the trigeminal nerve. Irritative peripheral neuropathy occurs principally at the infraorbital foramen. Also vulnerable to blunt trauma, this nerve is often injured by pugilistic blows. This neuralgia tends to worsen with time following the trauma as the injured tissues slowly develop a cicatrix, which entraps the nerve. This nerve can also be injured as the result of fracture of the zygoma, with entrapment of the nerve from the formation of bony callus. Commonly confused with maxillary sinusitis, the pain of infraorbital neuralgia typically presents as maxil-

lary pain worsened by smiling and laughter (which put tension on the zygomaticus musculatures). Because of referred pain to the teeth, patients often undergo futile dental procedures prior to presentation. As with the aforementioned entrapments, these patients will often experience an increase in headache intensity and frequency with menstruation, salt intake, stress, and bright light.

Technique: Cryoneuroablation of the infraorbital nerve can be accomplished via an open operative technique involving dissection under local anesthesia, and the nerve can be thereby frozen under direct vision. This is usually performed submucosally. The closed technique involves using the 1.4-mm probe, passed via a 14-gauge introducer, as close as possible to the foremen. This can be accomplished by a direct percutaneous approach, but this area is also cosmetically important; so to minimize cosmetic damage, the intraoral approach can be employed. The same or a larger introducer and probe are inserted through the superior buccal-labial fold. The probe is then advanced until it lies over the infraorbital foramen. Two or three 2-minute cycles seem to be sufficient.

Mandibular Nerve

The mandibular nerve derives from the third division of the trigeminal nerve. This nerve can be injured or irritated at many locations along its path. It is most commonly injured as the result of muscular hypertrophy of the pterygoids, which in turn results from chronic bruxism. It may also be injured as the result of loss of vertical dimension of the oral cavity, i.e., loss of posterior dentition resulting in dysfunctional dental occlusion and subsequent pressure on the mandibular nerve as it passes through the pterygoid fossa.

Technique: Cryoneuroablation of the mandibular nerve can be accomplished using an open or closed technique. In the closed extraoral approach, the patient is placed in the semirecumbent position and the jaw is opened 3 to 5 mm, allowing the coronoid process of the mandible to rotate rostrally. An inverted equilateral triangle can be imagined with the base of this triangle being formed by the zygoma, one segment of the triangle being formed by the neck of the mandible, and the last segment of the triangle being formed by the coronoid process of the mandible. After injecting a small amount of local anesthetic into the skin and subcutaneous tissues, a 27-gauge needle is passed to the center of this triangle until a second "pop" is felt as the needle enters the fascial plane between the temporalis and the lateral pterygoid muscles. Saline containing epinephrine 1:200,000 is injected in the area to minimize bruising. Notation is made as to the depth of the needle, and the needle is withdrawn. A 14-gauge intravenous catheter is then placed to this depth, and a 1.4-mm cryoprobe is advanced using a peripheral nerve stimulator. After location of the nerve, two or three 2-

minute freeze cycles are generally sufficient. Patients need to be warned about potential tongue anesthesia because this technique would affect the lingular branch of the mandibular nerve. A similar approach to the maxillary nerve can be used, angling the probe anteriorly and using the sensory nerve stimulator. Because of cosmetic considerations, an intraoral approach to the mandibular nerve can be used, locating the inferior alveolar branch of the mandibular nerve at the medial superior border of the lingular mandible. Because the lingular branch takes off prior to this, tongue sensation is usually preserved.

Mental Nerve

The mental nerve is the termination of the third division of the trigeminal nerve. Irritative peripheral neuropathy occurs principally at the mental foramen. Less vulnerable to blunt trauma, this nerve is most often injured as the result of bony impingement following changes in mandibular bone architecture. Occurring chiefly in elderly edentulous patients, the pain of mental neuralgia most typically manifests as pain in the chin, lower lip, and gum line; however, trauma from tooth extractions or telephone receivers can also irritate this nerve.

Technique: The closed cryoneuroablative technique for the mental nerve involves using the 1.4-mm probe, passed via a 14-gauge introducer, percutaneously or intraorally. Two or three 2-minute cycles seem to be sufficient. Insofar as this area is also cosmetically important, the considerations mentioned above should be entertained for this area as well.

Auriculotemporal Nerve

The auriculotemporal nerve derives from the third division of the trigeminal nerve. Irritative peripheral neuropathy occurs principally at two sites along the course of this nerve. The most common site of entrapment is immediately proximal to the parietal ridge at the attachment of the temporalis musculature. Less commonly, the nerve can be injured posterior to the ramus of the mandible. This is often triggered by clenching or bruxism. Clinical presentation of the auriculotemporal pathology consists of temporal pain associated with retroorbital pain. Referred pain to the teeth is often seen. The patient often awakens at night or in the early morning with temporal headache (especially at 3 or 4 A.M.). The pain is described as throbbing, aching, and pounding, and the pain can be unilateral or bilateral. Because it is associated with blurry vision, nausea, and emesis, this headache is mistaken for vascular "migraine." Most commonly associated with cross bite, bruxism, and functional abnormality of the temporomandibular joint, this syndrome is also associated with malformation or dysmorphia of the mandible or maxilla, as well as trauma (including dental work). Patients will often

experience an increase in headache intensity and frequency with menstruation, salt intake, or stress.

Technique: To locate the auriculotemporal nerve distally, the base of an equilateral triangle is imagined between the corner of the eye and the anterior tragus. The apex of the triangle locates the parietal attachment of the temporalis musculature and the distal site of entrapment of the auriculotemporal nerve. A 12-gauge intravenous catheter is used as the introducer for the 2.0-mm cryoprobe. Three 2-minute cycles are used. The proximal entrapment occurs just in front of the temporomandibular joint as the nerve curves in front of the joint. Particular care must be taken to avoid the facial nerve, which exits at this level. The smaller 14-gauge catheter is used with the 1.4-mm probe to limit possible trauma to the facial nerve.

It is not usually necessary to destroy the trigeminal nerve itself because pathology is mostly confined to individual branches; however, occasionally, the entire nerve needs neuroablation. Tic douloureux pain that does not have a distal trigger zone may respond to lesioning of the nerve, as it leaves the cranium.

Technique: Using fluoroscopy with the patient supine and neck extended, the foramen ovale is identified, and a 27-gauge needle is used to infiltrate the region with saline containing epinephrine 1:200,000 to minimize bruising. The 1.4-mm probe is advanced through a 14-gauge intravenous catheter, which has been positioned under fluoroscopy, and using sensory stimulation, the area of maximal stimulation identified. With care, the ophthalmic portion of the trigeminal nerve can sometimes be avoided, but clearly the patient needs to be warned regarding the risks of hypoesthesia of the eye with this technique, which obviously limits this approach.

Posterior Auricular Neuralgia

Posterior auricular neuralgia is often seen weeks to years after blunt injury to the mastoid area. Seen commonly in physically abused women, the left side is most often involved, due to the preponderance of right-handed spouse abusers. The clinical presentation consists of pain in the ear, along with a feeling of "fullness" and tenderness. This syndrome is often misdiagnosed as a chronic ear infection, and again is often worse with menstruation and salt intake. The nerve may also be entrapped by the sternocleidomastoid (SCM) muscle. Klein et al.[25] described the diagnosis and treatment of "cryptogenic earache" with posterior auricular nerve blocks. Trigger point treatment of the SCM may be adequate for most patients; but, some will need more aggressive treatment such as cryoablation.

Technique: The posterior auricular nerve runs along the posterior border of the sternocleidomastoid musculature, superficially and immediately posterior to the mastoid. A 12-gauge intravenous catheter is used as the introducer for the 2.0-mm cryoprobe, employing three 2-minute cryocycles. The skin is quite thin here, and special care must be taken to avoid freezing the skin. Approaching the nerve from inferiorly, as far down on the cranium as possible, gives one more skin depth with which to work.

Glossopharyngeal Neuralgia

The glossopharyngeal nerve exits the skull, with the vagus and spinal accessory nerves, through the jugular foramen. It descends anteriorly to the carotid artery and passes deep to the styloid. Then it turns to the tongue, where it passes through the tonsillar fossa. Both a motor and sensory nerve, it provides sensation to the middle ear, the posterior third of the tongue, the palatine tonsils, and the pharynx. There is a paroxysmal glossopharyngeal neuralgia that presents with lacinating pain similar to trigeminal neuralgia; but, it is with pain in the throat instead of the face. Although the glossopharyngeal nerve block is primarily used as an anesthesia block for intubations, cryoneuroablation may be appropriate for postoperative pain relief for tonsillectomies as well as for cancer-related throat and neck pain or to break the reflex cycle of intractable hiccups.

Technique: Cryoneuroablation at the styloid process is not recommended, as the carotid artery is directly behind the target, and a 12-gauge hole in the carotid artery from the introducer would be difficult to manage. In addition, the vagus and spinal accessory nerve also pass through this area, and it would be difficult to avoid lysis of these nerves as well. As a result, the usual site for cryoneuroablation is at the tonsillar fossa. The patient is placed supine and the tongue retracted medially. The nerve is located at the inferior portion of the tonsillar pillar. The mucosa is anesthetized with a topical spray or pledget, and 1 cc of saline with epinephrine 1:200,000 is infiltrated for homeostasis. Intravascular epinephrine from an unrecognized blood vessel injection may cause a rapid increase in heart rate, and should caution the practitioner regarding needle placement. The 12-gauge introducer is then advanced subcutaneously, and the 2-mm probe advanced through the catheter. Sensory stimulation should refer to the ear and throat, and there may be a throat motor stimulation. Care must be used to avoid the palatine artery. This may be done most easily at surgical tonsillectomy when the nerve is exposed.

Clinical Effectiveness

Intractable face pain from a variety of causes may be treatable with cryoneuroablation. Bernard et al.[26] reported on 21 patients with intractable face pain, unresponsive to medical and surgical management. They diagnosed pain secondary to entrapments of several nerves, including supraorbital, infraorbital, mental, and lingular. All the nerves were treated with open (or exposed) cryoneuroablation. Barnard et al.[27] reported on 54 patients with chronic

facial pain. Patients were selected for cryoneuroablation after they had a temporary response to local anesthetic injections. The mean duration of sensory loss was 60 (5 to 117) days. The success of the blockade appeared to be an "all or nothing" effect; i.e., the patients with only 5-day duration of pain relief reflected the failure to adequately freeze the nerve. They emphasized the difference between nerve "killing" and simple nerve "cooling." Diagnoses included nonherpetic neuralgia, tic douloureux, postsurgical neuralgia, atypical facial neuralgia, and postherpetic neuralgia (PHN). Of the patients other than the those with PHN, 30 to 40% had relief for more than 6 months. No patients with PHN had relief for greater than 1 year; however, the other groups had more than a year's relief in 17 to 20% of the cases.

Trigeminal neuralgia or tic douloureux has caused debilitating pain in a group of very unfortunate patients. The advances in anticonvulsant therapy have helped, but the lancinating pain that may occur spontaneously or with the lightest touch of a "trigger zone" can be extremely debilitating. Nally and Zakrzewski[28] looked at 112 patients with paroxysmal trigeminal neuralgia. Intraoral or periorbital dissections of the peripheral branches of the trigeminal were performed. These included the supraorbital, supratrochlear, infraorbital, mental, posterior and middle superior dental, greater palatine, lingular, and long buccal nerves. An average of 2.2 procedures per patient over a 5-year period was reported. As an example, 68% of the 78 mental nerves treated remained pain free over 52 months. Similar results were seen with the other nerves, and patients noted that if and when the pain returned, it was at a lower level. Several patients noted that when the pain returned it was to a different site, but freezing the new site also provided relief. Nally[29] looked at 211 patients over a 22-year period and concluded that cryotherapy offered significant long-term relief.

In 1988, Zakrzewska and Nally[30] initially reported a 6-year experience with cryoanalgesia in the treatment of paroxysmal trigeminal neuralgia. Then in 1991, Zakrzewska[30a] further reviewed 475 patients with trigeminal neuralgia followed over a 10-year period. Of those patients, 145 underwent cryotherapy, 265 underwent radiofrequency thermocoagulation, and 65 underwent microvascular decompression. Mean follow-up was 45 months in each group. Morbidity after cryotherapy was low, whereas radiofrequency thermocoagulation resulted in more prolonged sensory loss (88%), anesthesia dolorosa (8%), and eye problems (15%). Microvascular decompression was associated with eighth cranial nerve problems in 11% of the patients and a 1% mortality rate. None of the cryoneuroablation patients developed anesthesia dolorosa. Of the patients treated with radiofrequency, 75% continued to have sensory loss. In the cryoablation patients, the area of sensory loss was small but in the radiofrequency patients it sometimes extended across all three divisions of the trigeminal nerve, and 62% of these patients felt the sensory loss affected their lives.

One of the most commonly preformed surgical procedures is a tonsillectomy, and pain management has been a significant problem. Postoperative tonsillectomy pain is thought to be due to a combination of nerve irritation, inflammation, and pharyngeal muscle spasms. In a prospective, randomized, double-blinded study of 59 patients, Robinson and Purdie[31] reported that bilateral tonsillectomies were performed and the patients randomized to cryoneuroablation of the glossopharyngeal nerve or a control group. The cryoprobe was inserted superficially into the tonsillar fossa at surgery. Treatment resulted in a reduction of pain for 10 days and a faster return to work or school compared with controls.

Occipital Nerve

The occipital nerve is one of the most discussed nerves for cryoneuroablation. When diagnostic injections have given excellent but only temporary relief, cryoneuroablation may be an excellent option.

Clinical Presentation: Occipital neuralgia is a frequent cause of occipital and retro-orbital headaches. The greater occipital nerve is made up of the dorsal rami of C2 and C3 and causes occipital pain. However, because the ganglion of this nerve interconnects with the trigeminal nerve ganglion in the brainstem, pain may be referred to any branch of the trigeminal nerve. The occipital nerve pierces the nuchal fascia at the base of the skull and is prone to trauma from flexion/extension injuries and well as entrapment by spasm of the trapezius muscle. The lesser occipital nerve comes from the cervical plexus and is located slightly more laterally. The third occipital nerve consists of the posterior ramus of C3. Standard anesthesia texts describe occipital nerve blocks as injections of large volumes (10 cc) at the nuchal ridge in a "fan" fashion; however, this type of injection is not diagnostic and will not predict a response to cryoneuroablation. The technique recommended by Trescot et al.[32] identify the injection site (in this case describing the right side) by placing the thumb of the right hand at the foramen magnum (which identifies midline and avoids the cisternal injection); the index finger is placed at the conjoined tendon attachment, and the second finger identifies the injection site at the base of the skull. Small volumes (less than 2 cc) of local and steroid are thereby injected underneath the tendon where the nerve pierces the tendon. Cryoneuroablation is done at the same site.

Technique: The technique requires precise localization of the target nerve. With the patient positioned prone or seated with head flexed and resting on the patient's hands, the tenderness at the base of the skull is identified by palpation. After local anesthetic infiltration subcutaneously, 1 cc of saline with epinephrine 1:200,000 is infil-

FIGURE 72.2 Occipital.

trated to the periosteum, using the 27-gauge needle as a "seeker needle" to find the periosteum. The 12-gauge IV catheter is then advanced to the periosteum. When the introducer comes in contact with the target bone, the stylet is removed and the 2.0-mm probe is then advanced through the catheter and the tip of the probe exposed by withdrawing the catheter into the subcutaneous tissues (Figure 72.2). The "gritty" feeling of the periosteum should be appreciated; if not, replace the stylet and advance the catheter farther. Accurate and meticulous sensory stimulation is critical for success. As the probe moves across the periosteum in a medial to lateral direction, sensory stimulation (100 Hz), first at 2 volts, and then as low as 0.5 volts, is used to identify the median branch nerve. Particular care must be used in the movement of the probe, as the movement itself may cause a parasthesia that is not an actual sensory stimulation but rather a "piezoelectric" or traction effect. The procedure is repeated with progressively decreasing voltage, until stimulation can be reliably obtained at 0.5 volts. Three 2-minute freeze cycles are usually adequate.

Clinical Effectiveness: Kappes[33] described cryoablation of the occipital nerve in 72 patients with intractable headaches: 62% of the total patients had 75% or greater improvement in symptoms, 90% enjoyed a reduction of 50% or more, 47% were symptom free for 6 weeks to 1 year.

UPPER EXTREMITY PAIN

Suprascapular Nerve

The suprascapular nerve arises from the upper trunk of the brachial plexus and travels downward and laterally to pass through the suprascapular notch to provide innervation to the supraspinatus, infraspinatus, and shoulder joint. Clinically, the patient complains of a poorly localized upper shoulder pain, usually triggered by a lifting injury

with the arm internally rotated. Tenderness is elicited by palpation of the suprascapular notch (the "Vulcan death grip"). Diagnostic blocks should be performed using a peripheral nerve stimulator. The classic approach to the suprascapular notch is to advance the needle perpendicular to the scapular spine from above, and then "walk it off" anteriorly until the needle drops into the suprascapular notch. This technique, however, has a high risk of pneumothorax. I recommend instead that the needle (with a peripheral nerve stimulator) be directed perpendicular to the scapula itself, using the scapular wall as a "backstop," and then directed medially or laterally to find the nerve. This technique works for both the diagnostic nerve block and the cryoneuroablation.

Technique: The patient is positioned prone with the chest supported on pillows, letting the arm hang anteriorly. Alternatively, the patient can be positioned seated with the affected arm hanging by the patient's side. The 12-gauge catheter is advanced into the supraspinatus notch parallel to the direction of the nerve. Consider using fluoroscopic guidance to locate the superior border of the scapula if the scapula is not easily palpated. The 2.0-mm probe is then advanced through the catheter and the suprascapular nerve is identified using sensory or motor stimulation; this is one of the few mostly motor nerves amenable to cryoneuroablation. Three 2-minute freeze cycles are usually sufficient.

Superficial Radial Nerve

The superficial radial nerve runs under cover of the brachioradialis into the forearm and onto the posterior surface of the wrist to supply the skin along the radial portion of the wrist and fingers including portions of the dorsum of the hand. This is the nerve injured when the hand is bumped on a table, the classic "trivial injury" resulting in sympathetic overstimulation and CRPS (chronic regional pain syndrome). This nerve is also injured after chronic wrist movements and Colles fractures. Cryoanalgesia may address the "wind up" phenomenon seen with these injuries.

Technique: The area of maximal tenderness is identified, usually between the brachioradialis and extensor carpi radialis muscles. If possible, the 12-gauge intravenous catheter is used, advanced distally parallel to the nerve (similar to starting an IV). The 2.0-mm probe is then placed through the catheter. Sometimes the tissues in this area are too tight to accept the larger probe, and the 14-gauge catheter and 1.4-mm probe must be used. The skin may be quite thin in this region, and extra caution regarding skin burns must be observed.

Palmar Branch of the Median Nerve

The palmar median branch of the median nerve travels over the carpal ligament at the wrist and thus bypasses

possible median nerve entrapment from carpal tunnel syndrome (CTS). Unfortunately, it is therefore vulnerable to trauma to the palmar structures, such as seen with falls onto an outstretched hand, or the chronic repetitive trauma of pounding a stapler with the palm. It may be misdiagnosed as CTS, and neuromas of this nerve may also occur as a result of CTS surgery. Diagnosis is made by small local anesthetic injections proximal to the carpal crease, and cryoneuroablation is done via the smallest probe available.

Clinical Effectiveness

Wang[34] performed percutaneous cryoneurolysis on various peripheral nerves (ulnar, median, sural, occipital, palmar branch of the median, and digital) in 12 patients with 6 patients reporting relief of 1 to 12 months' duration.

CHEST WALL PAIN

Intercostal Nerve

Of all the postoperative indications for cryoneurolysis, lesioning of the intercostal nerve intraoperatively has been the most extensively studied. The nerve is very easily identified at thoracotomy, and intraoperative cryoneuroablation can provide significant and long-lasting postoperative analgesia. It has been somewhat more difficult to address post-thoracotomy neuromas, persistent pain after rib fractures, or thoracic post herpetic neuralgia, but a percutaneous technique can provide excellent analgesia.

Technique: In the open technique, after the thoracotomy is complete, the cryoprobe is placed directly on the nerve at the posterior rib angle. The nerve is easily visualized beneath the parietal pleura. Meticulous use of diagnostic nerve blocks is critical for accurate nerve localization. Because each rib has an innervation contribution from the rib below and the rib above, it is advisable to lesion the intercostal nerves above and below the incision line as well. Because the nerves are exposed, one or two 1-minute freeze cycles should be adequate.

With the percutaneous approach, the technique has to take into consideration the underlying lung and the intercostal artery, which acts as a heat sink. Physicians are traditionally taught to perform intercostal nerve blocks by advancing the needle perpendicular to the inferior edge of rib and then "walking it off the edge of the bone," dropping to just before the parietal pleura. However, the nerve is actually up under the curve of the rib. In addition, the intercostal artery acts as a huge "heat sink," limiting the size of the ice ball and therefore the effectiveness of the cryolesion. By introducing the probe perpendicular to the nerve, the area of freezing is limited, which also limits the effectiveness of the cryolesion. In addition, the temptation is to use a smaller probe because of the concern regarding advancing a 12-gauge needle into the pleural

FIGURE 72.3 Rib picture.

space, causing a pneumothorax. The technique I recommend somewhat different. I recommend approaching the rib edge tangentially from posterior to anterior (medial to lateral), then pushing the tip up under the edge of the rib (Figure 72.3). This accomplishes several things. It dramatically reduces the risk of pneumothorax, and it increases the length of contact of the probe on the nerve, which increases the effectiveness of the cryolesion. It is important to use the largest probe possible to overcome the arterial heat sink.

Clinical Effectiveness

Nelson et al.[35] first described intraoperative intercostal cryoneurolysis. The technique is most effective in relieving incisional pain and provides relatively little relief of visceral pleuritic pain or the pain of ligamentous or muscle pains. It provides no relief for chest tube pain. The multiple pain generators involved in post-thoracotomy pain make cryoneuroablation difficult to use as a sole treatment. Despite these limitations, studies have shown that patients have less postoperative pain and less opioid requirement, both in the immediate postoperative period and in the weeks following the procedure. Orr et al.[36] studied 45 patients randomized into three groups: a control group that received intramuscular morphine postoperatively, a cryoanalgesia group, and a morphine infusion group. All patients underwent a general anesthetic, and while the chest was open, the control and infusion groups had rib blocks performed with 0.5% bupivacaine while the cryoanalgesia group underwent a sharp dissection of the nerves followed by a 45-second freeze cycle under direct vision. The number of requests for analgesics was less for the cryoanalgesia group than for the controls, and the morphine infusion and control groups used the same total dose of morphine. The authors noted that the cryoneuroablation added about 10 minutes to the procedure but gave better postoperative pain relief. This same group did a further study comparing the original patients with an addi-

tional group of patients that included 23 patients who received the cryoneuroablation as well as a continuous infusion of morphine.[37] Pain relief was best in the cryoplus-infusion group, and at 8 days postoperatively the cryoanalgesia patients had the best pain relief at rest (although there was no significant difference in pain with movement). Although a morphine infusion gave good relief and required very little special equipment or expertise, the authors felt that cryoneuroablation of the intercostals nerves at the time of surgery gave enough extra relief to be worth the extra 10 minutes of surgical time.

It must be noted that cryoanalgesia of the third and fourth intercostals can cause ipsilateral nipple anesthesia. Riopelle et al.[38] suggested using a lower incision and not freezing nerves above the fifth intercostal nerve. Denervation of the intercostal nerves appear to have no consequence, but loss of tone from the external and internal oblique muscles can cause a subtle but definite subcostal bulge that resolves with the return of sensation.[39] There has been one case report of a neuroma formation after the use of cryoneuroablation for post-thoracotomy pain,[24] and several patients have noted sensory deficits for up to 6 months. Comparative studies suggest superior relief with epidural analgesia,[40] and the time necessary to perform lesions at multiple levels limits the usefulness of the technique. However, with the elimination of reimbursement for preoperative epidurals, the need for continuous monitoring during the epidural infusion, and the weeks of postoperative relief available with cryoneuroablation, thoracic surgeons may be interested in resurrecting the technique.

It is the experience with post-thoracotomy pain and cryoneuroablation that leads to its use in other chronic chest wall pains. The postoperative neuroma, costochondritis, postherpetic neuralgia, and rib fractures have all been treated with cryoneuroablation. Two large series suggest improved pain relief and few complications. Green et al.[41] studied the effectiveness of cryoanalgesia on 43 patients with postherpetic neuralgia or intercostal neuralgia: 50% of the patients noted significant relief of 3 month's duration, no patients developed neuritis, and the pain relief outlasted the return of sensory function. Another study of 70 patients with chest wall pain of a variety of etiologies resulted in pain relief from 1 week to 12 months, with the patients with postherpetic neuralgia uniformly noting a poorer response.[42]

ABDOMINAL AND PELVIC PAIN

Ilioinguinal, Iliohypogastric, Genitofemoral, Subcostal Neuralgia

Arising from the anterior primary ramus of the first lumbar nerve root via the lumbar plexus, the ilioinguinal nerve pierces the internal oblique muscle mediocaudally to the anterior superior iliac spine and then passes through the inguinal canal and accompanies the spermatic cord through the superficial inguinal ring to supply the thigh and scrotum or labia. This nerve is often injured at the lateral border of the rectus sheath, approximately 5 cm from midline and 10 cm inferior to the umbilicus, where it perforates the superior crus of the superficial inguinal ring. The ilioinguinal nerve may be injured during inguinal herniorrhaphy, and as the result of compression from the bladder retractor during abdominal surgery, particularly when the Pfannenstiel incision is employed. Even midline incisions may be associated with entrapment of the nerves, often months or years later as the scar cicatrix contracts. Occasionally, this nerve is injured by tight-fitting garments, e.g., belts and weapon holsters. The iliohypogastric nerve pathology will present in a similar manner but this nerve entrapment occurs about two fingerbreadths higher. There may be a communication between these two nerves, and their sizes are often inversely related. Both can be traumatized by the expanding abdomen of late pregnancy or ascites. Both can mimic appendicitis (on the right) or diverticulitis (on the left). The fluid retention associated with the perimenstrual timeframe can also result in entrapment of the nerves and subsequent "endometriosis" pain.

The genitofemoral nerve (GFN) rises from the first and second lumbar nerves. The genital branch of the nerve passes under the inguinal ligament and over the symphysis pubis immediately lateral to the pubic tubercle. This sensory nerve then travels to the labia or scrotum. Vulnerable to trauma as it passes over the ramus of the pubis, the genitofemoral nerve can be injured as the result of blunt surgical trauma, and the pain tends to worsen with time. Pfannenstiel incisions for hysterectomy or cesarean section, and inguinal herniorrhaphy (especially with mesh because of the "bite" taken on Poupart's ligament) can result in chronic, intractable pain. A slowly developing cicatrix can entrap this nerve, and the pain generally develops months to years following the surgery. Less commonly, this nerve can be injured as the result of compression of the nerve during late pregnancy. A similar syndrome results from entrapment of the subcostal nerve, which arises from the T10 to T12 nerve roots and passes around the ribs anteriorly to the rectus sheath. This neuropathy results in an upper quadrant pain that may mimic cholecystitis or pancreatitis or may be caused by the surgical treatment of upper abdominal pathology.

Clinical presentation of genitofemoral, ilioinguinal, or iliohypogastric pathology consists of dull, aching pain in the lower lateral abdomen. This pain is worse with Valsalva's maneuver, cough, bowel movement, and lifting. Patients will often experience increase in pain intensity and frequency with menstruation, salt intake, and sexual intercourse. Irritation of either nerve can result in referred pain to the testicle or vulva, interior thigh, or upper lumbar region. A localized tenderness and pain with digital pressure worsened during Valsalva's maneuver is observed.

Occasionally the ilioinguinal nerve is trapped more laterally at the attachment of the external oblique onto the iliac crest. A "double crush" situation may result from pathology at both places, requiring the more proximal treatment for complete relief. The genitofemoral nerve entrapment is usually found at the pubic tubercle. Unfortunately, in the case of surgical scar entrapment, it may be difficult to address the pathology more proximally, as the nerve becomes intra-abdominal at that point.

Technique: After superficial infiltration with local anesthetic and deep infiltration with saline containing epinephrine 1:200,000, a 12-gauge intravenous catheter is used as the introducer for the 2.0-mm cryoprobe. After precise confirmation of probe placement employing the peripheral nerve stimulator, three 2-minute cryocycles seem to be sufficient. Fluoroscopic localization may be useful for the identification of the nerves at the pubic tubercle or iliac crest in the obese patient. Occasionally, especially in the face of surgical scarring from multiple surgeries, the abdominal and pelvic nerves must be addressed more proximally. Paravertebral nerve blocks under fluoroscopy, with a peripheral nerve stimulator at T12 or L1 (depending on the nerve target) will predict response to cryoneuroablation. If the diagnostic injections give temporary relief, cryoablation of the nerve root can give good relief distally into the groin or lower abdomen. The transverse process of the target nerve root is identified by fluoroscopy. After local anesthetic subcutaneous injection and saline with epinephrine infiltration, the 12-gauge catheter is advanced tangentially to the foramen, taking care not to advance into the foramen itself. The 2.0-mm probe is then advanced through the catheter, and using the sensory stimulation mode, stimulation into the groin is obtained. Special care must be taken not to have motor stimulation down the leg, although motor stimulator into the groin is acceptable. Proximal treatment of the GFN nerve is more problematic. The GFN runs most of its course along the surface of the psoas muscle. At laparotomy, the nerve can be easily visualized, and lesioned under direct vision. Recent descriptions of pelvic pain mapping under sedation and minimal insufflation laparoscopy have confirmed the GFN as a common cause of chronic pelvic pain, and it may be amenable to transabdominal lesioning under laparoscopic visualization.[43]

Sacral Neuralgia

Perineal pain and coccydynia can be due to pathology of the sacral nerve roots. If the patient has failed nonsteroidal anti-inflammatory drugs (NSAIDs) and caudal epidurals, then coccygeal nerve blocks done bilaterally as the S5 nerve roots leave the sacral foramen may be an option. The diagnostic blocks assist in confirming the lack of rectal dysfunction and predict the success. The nerve is identified under fluoroscopy at the medial border of the sacral cornu, and sensory stimulation at 50 Hz aids in localization of the nerve. In the same way, cryoneuroablation of the dorsal S4 nerve roots can provide pain relief of the scrotum, vagina, perineum, and anus without affecting bowel or bladder function. The probe is either placed through the sacral hiatus up to the level of the fourth sacral foramen or passed through each foramen laterally to medially. Diagnostic transforaminal nerve blocks (I use a peripheral nerve stimulator and contrast to confirm location) will give a temporary block, which allows the patient to "preview" the pain relief.

Clinical Effectiveness: Intraoperative lesioning of the ilioinguinal nerve at the time of inguinal hernia surgery adds only a minute to the procedure but can provide significant pain relief. After repair of the inguinal ring and the posterior wall, the ilioinguinal nerve is isolated and elevated onto a retractor. The cryoprobe is placed directly on the nerve and the freeze cycle initiated. A visible ice ball forms, and a 1-minute freeze (with perhaps a second freeze cycle, taking care not to pull on the ice ball which can tear the nerve) should be adequate. Wood et al.[44] first described cryoanalgesia after herniorrhaphy in 1979. Open cryoneurolysis of the ilioinguinal nerve decreased the analgesic requirements postoperatively. The follow-up study[45] looked at three groups of patients after hernia repair: those who received cryoneurolysis, paravertebral nerve blocks, or as needed oral narcotics. Not only did the cryoneurolysis patients have less postoperative pain, but they used fewer narcotics, ate a regular diet earlier, and returned to work sooner. In contrast, Khiroya et al.[46] found no significant difference in pain scores, pulmonary function, or analgesic use in a randomized, double-blinded study of 36 patients. Callesen et al.[47] studied cryoneuroablation of the ilioinguinal and iliohypogastric nerves compared with sham cryoneuroablation and found no statistical difference. The authors postulated that the post-herniorrhaphy pain might originate from deep muscle layers innervated by nerves other than the ilioinguinal and iliohypogastric nerves (such as the subcostal and genitofemoral nerves). Abdominal pain relief, when diagnostic blocks have given excellent but only temporary relief, may be provided by cryoneuroablation. In one study, 15 patients with chronic abdominal pain underwent cryoneuroablation of the ilioinguinal and iliohypogastric nerves. Of the 15, 7 (47%) noted good to excellent relief; 3 of the 7 had permanent relief, while the other 4 had relief lasting between 4 and 30 months.[48] Raj[23] describes the use of cryoneuroablation of the ilioinguinal nerve to treat the abdominal pain of late pregnancy, which results in severe traction on the ilioinguinal nerve, especially if the nerve is tethered by scar tissue from prior surgery. Glynn and Carrie[14] reported on the use of cryoanalgesia to treat pelvic pain at the symphysis pubis during pregnancy (most likely treating the genitofemoral nerve at that level).

Evans and colleagues[49] performed cryoneurolysis of the lower three sacral nerve roots in 40 patients with intractable perineal pain; 78% of the patients received at least 30 days of relief. At the Hospital of the University of Pennsylvania, Loev et al.[50] described a novel cryolesion approach to the ganglion impar in a patient with rectal pain, which provided more than 6 months of relief. Jain et al.[51] described a case report of a 38-year-old multiparous woman complaining of severe sacrococcygeal pain of 6 years' duration. The pain began after the birth of her second child and was not relieved by oxycodone. Diagnostic blocks with 1% lidocaine on several occasions gave temporary relief. A cryoprobe was inserted into the sacral extradural canal under fluoroscopy, two 60-second freeze cycles were performed, and the patient was noted to be pain free at follow-up 1.5 years later.

Pudendal Neuralgia

The pudendal nerve can be a cause of intractable perineal, vaginal, penile, scrotal, and rectal pain. Providing almost sole enervation of the perineum, the pudendal nerve arises from the second, third, and fourth sacral nerves in the pelvis, passes through the sciatic notch medial and inferior to the sciatic nerve, and then crosses the ischial spine to enter the perineal region. Familiar to obstetricians, the pudendal nerve is often traumatized during vaginal deliveries. However, it can be a cause of pain in both males and females and may be triggered by trauma from bicycle seats, surgery, radiation, or perirectal infections. The pain is often hard for the patient to localize, and a meticulous physical exam, including rectal and pelvic exam, may be necessary to identify the nerve entrapment.

Technique: The nerve can be approached vaginally or percutaneously. The vaginal approach is a simple modification of the obstetrician's pudendal nerve block done during delivery to anesthetize the perineum. Using a modified Iowa trumpet with the patient in the lithotomy position, first the 12-gauge introducer and then the 2.0-mm probe are advanced through the trumpet to the ischial spine. Cryoneurolysis at this site will lead to profound hypoesthesia, including the possibility of loss of clitoral sensation. The percutaneous approach can be much more selective in the isolation of specific branches of the pudendal nerve. If the pain is primarily vaginal or penile, I will place the patient in a modified lithotomy position with the feet on the table instead of in stirrups. The 12-gauge catheter is directed toward the sacrospinous ligament instead of the ischial spine itself, and the 2.0-mm probe sensory stimulation is used to select the stimulation field needed. In the same way, if the pain is primarily rectal, I position the patient prone in a jackknife position, placing the 12-gauge catheter and then the 2.0-mm probe more inferiorly, using stimulation to direct the probe toward the rectal branches.

SPINAL PAIN

Facet Joint Pain

The most common use for cryoanalgesia for low back pain is the long-term treatment of lumbar facet pathology. When diagnostic lumbar facet blocks (either intra-articular or median branch blocks) have given good but only temporary relief, one option for further treatment is cryoneuroablation of the median dorsal rami.

Clinical Presentation: The clinical presentation, anatomy, and innervation of the lumbar facet disease and pain syndrome have been described in many texts. Facet pain is often considered a "biomechanical "pain, typically made worse on movement, particularly with hyperextension. There may be significant myofascial spasms in the paravertebral region as the muscles try to "splint" the injured joint. Patients will often fail a physical therapy program because therapy will aggravate the pain. There are usually no neurologic signs despite the referred pain down the leg ("pseudosciatica"). Cervical pain as well as thoracic or abdominal pain can also be due to facet pathology. Radiographs may or may not show facet sclerosis, and there may be a history of trauma such as "whiplash" in the cervical region or twisting injuries in the lumbar region. Pain is transmitted to the spinal cord via the articular facet nerves, the nerves of Luschka, the dorsal median nerve, the meningeal nerves, the anterior communicating ramus, and other branches of the posterior ramus. Palpation reveals exquisite tenderness along the paravertebral muscles. Other biomechanical problems are also often seen, including leg discrepancy (functional vs. anatomy), sacroiliac (SI) joint dysfunction, and scoliosis. Median branch blocks may give a better predictive indication of potential success from cryoneuroablation than do intra-articular injections. In the neck or thorax, facet pathology can refer down the arm, between the shoulders, or around to the anterior chest. These are commonly seen after "whiplash" injuries, because of the mobility of the neck and upper thorax. Because the pain relief is expected to be temporary, it is critical to use the pain-free period to facilitate a rehabilitation program. The success of the cryolesion is a direct function of the patient selection, accurate probe placement, and the rehabilitation.

Technique: The technique requires precise localization of the target nerve. The inferior border of the transverse process at the level of the inferior articular process is identified by fluoroscopy. When the introducer comes in contact with the target bone, the stylet is removed, the 2.0-mm probe is advanced through the catheter, and the tip of the probe exposed by withdrawing the catheter into the subcutaneous tissues. Accurate and meticulous sensory stimulation is critical for success. As the probe moves across the periosteum in a medial to lateral direction, sensory stimulation (100 Hz), first at 2 volts, and then as

FIGURE 72.4 Lumbar facet.

FIGURE 72.5 Cervical facet.

low as 0.5 volts, is used to identify the median branch nerve. Particular care must be used in the movement of the probe, as the movement itself may cause a paresthesia that is not an actual sensory stimulation but rather a "piezoelectric" or traction effect. The procedure is repeated with progressively decreasing voltage, until stimulation can be reliably obtained at 0.5 volts. This position is usually at the "neck of the Scottie dog," consistent with the position of a "collar" or at the junction of the transverse process and pedicle — the Scottie dog's eye (Figure 72.4). Similar techniques are used for the neck and thorax (Figure 72.5). At this time motor stimulation (2 Hz) is used at its highest voltage to confirm that the probe is not too close to the spinal nerve root. Three 2-minute freeze cycles are usually adequate.

Clinical Effectiveness: Brechner[52] studied the effects of percutaneous cryoneuroablation of the lumbar facet in patients with neck and low back pain. There was 70% pain relief after 1 hour and relief lasted 1 week. Pain relief decreased to 50% at 3 weeks and, by 3 months, had

returned to baseline. Schuster[53] studied 52 patients followed for a 13-month period: 47 patients had significant relief of low back pain after cryoneuroablation, and only 1 patient had a repeat cryoneuroablation when the pain recurred after a 9-month pain-free period. Ross[54] described 23 patients with complete but only short-term relief from lumbar facet blocks, who were treated with cryoneurolysis of the dorsal median nerve: 21 had complete relief for a follow up of 6 months to 2 years; 2 patients had return of pain 6 to 8 months later and underwent subsequent cryoneurolysis with complete relief. These studies are limited by a lack of certainty that the facet was the sole pain generator. Prognostic blocks, if performed, did not utilize currently recommended techniques.

Prognostic blocks should be performed one level at a time, one side at a time, and repeated to assure validity. All too often, pain generators are assumed based on a single trial of anesthetic (remember the placebo effect) with multiple levels injected and volumes of anesthetic far in excess of that needed to anesthetize the median dorsal ramus, a nerve a fraction of a millimeter in diameter. Small volumes, less than 0.2 cc, are more than sufficient for adequate precision prognostic blocks. Volumes larger than that only serve to spread throughout the area and to confuse the issue.

As described above, it is well known that there is dual innervation of the facet joint. Median branch block diagnostic injections are commonly done both above and below the level of pathology. However, complete denervation of the joint does not appear to be necessary for adequate pain relief. There are theoretic advantages to avoidance of a Charcot joint. In at least one case, an experienced pain physician treated another pain physician with a neurolytic facet block, resulting in a Charcot joint situation with resultant paraparesis when a listhesis developed at the treated segment.[55] Fortunately, recovery ensued, but the concern about multiple neurolytic facet blocks is very real.

In addition, in "virgin backs" the goal is to provide a period of "analgesia" to allow appropriate rehabilitation; this does not necessarily require complete "anesthesia." My practice is usually to freeze only the most symptomatic level, with a goal of "good" rather than "complete" analgesia. Sensation to the joint is expected to return in 2 to 6 months as the nerve regenerates, but this timeframe usually provides ample rehabilitation time, and most patients who have not undergone prior surgery will note long-term relief. In patients with operated backs, however, the formation of postoperative neuromas from the surgery itself, coupled with the surgical destabilizing of the posterior muscle and ligamentous structures, sets the stage for continued instability and pathology. Although these patients will also get relief with a cryoneuroablation, the effect is shorter-lived due to the multiple pain generators. However, the procedure

can be repeated, and it has not been uncommon in my practice to have post-laminectomy patients returning every 6 to 8 months to have the facet nerves refrozen, noting significant relief in the interim.

Pseudosciatica

Since Mixter and Barr[56] described herniations of the nucleus pulposus as a cause of pain going down the leg, the term *sciatica* has become synonymous with herniated discs. The definition of *sciatica* from *Taber's Cyclopedic Medical Dictionary* is "compression or trauma of the sciatic nerve or its roots, especially that resulting from ruptured intervertebral disc."[57] However, both physicians and patients use the term to describe pain going down the leg, despite the fact that there are several clinical entities that will cause similar or identical pain going down the leg, which are not related to disc disease. These I have termed "pseudosciaticas," and several are quite amenable to treatment with cryoneuroablation. While facet pathology could also be considered a pseudosciatica, this section discusses interspinous ligament pathology, superior gluteal neuralgia, sacroiliac joint, and cluneal neuralgia.

Intraspinous Ligament

The intraspinous segment of the dorsal ramus (ISDR) is the termination of the medial branch of the dorsal ramus of the spinal nerve. Injury to the soft tissues of the axial skeleton occur as the result of hyperextension or hyperflexion of the spine with injury to the ligamentous structures between the spinous processes, segmental muscle spasm, and bursitis. The ISDR is responsible, in large part, for sensory innervation of these structures. Irritation of this nerve will refer pain down the leg (one or both sides) in a dermatomal pattern consistent with the level involved.[58,59] This pathology is seen commonly after spinal surgery, and patients will present with well-localized midline tenderness with localized swelling over the intervertebral space and may benefit from injection of small volumes of local anesthetic and steroid solutions. When this provides only temporary relief, cryoneuroablation may be indicated.

Technique: With the patient in the prone position, a large pillow is placed under the abdomen, and the patient is thereby flexed forward. Local anesthetic is infiltrated 2 cm lateral to the targeted interspace. Infiltration with local anesthetic containing epinephrine 1:200,000 is performed deeply until contact is made with the lamina. The 2.0-mm probe is passed via a 12-gauge introducer aimed at the junction of the lamina and the spinous process. A nerve stimulator is used to ensure that the probe is away from the spinal nerve itself. Three 2-minute cycles seem to be sufficient. This procedure is performed bilaterally at each desired level, and

can be performed with fluoroscopic guidance, or can be done using bony landmarks.

Clinical Effectiveness: Klein and Trescot[60] reported in a poster presentation on the clinical effectiveness of the cryoneurolysis technique, describing 10 patients with low back pain treated effectively with dorsal median nerve cryoneuroablation.

Superior Gluteal Neuralgia

Superior gluteal nerve (SGN) entrapment may also be a source of pseudosciatica. The superior gluteal nerve, formed from the posterior branches of L4, L5, and S1, passes from the pelvis above the piriformis muscle. Deep to the gluteus maximus and medius muscles, the nerve accompanies the superior gluteal artery and vein over the surface of the gluteus minimus muscle. It supplies the gluteus medius and gluteus minimus muscles and innervates the tensor fascia lata muscle by a branch, which accompanies the lower branch of the deep division of the superior gluteal artery.

Clinical Presentation: Neuralgia due to irritation of the SGN is commonly seen after a lifting injury involving the lower back and hip. After exiting the sciatic notch, the SGN passes caudal to the inferior border of the gluteus minimus and penetrates the gluteus medius. Vulnerable as it passes in the fascial plane between the gluteus medius and gluteus minimus musculature, the SGN is injured as a result of shearing between the gluteal musculature with forced external rotation of the leg, and with extension of the hip under mechanical load. Occasionally, this nerve is injured with forced extension of the hip, as might occur in a head-on automobile collision where the foot is pressed against the automobile floorboards with the knee in extension, as the patient anticipates impact. The clinical presentation consists of sharp pain in the lower back, dull pain in the buttock, and vague pain to the popliteal fossa and occasionally down to the foot. Patients generally experience pain with prolonged sitting, leaning forward, or twisting to the contralateral side. Often, patients will describe a "giving away" of the leg. Patients will sit with the weight on the contralateral buttock or cross their legs in such a manner as to minimize pressure on the involved side.[61] Clinically, the presentation can be similar to SI pathology, but examination will show the SI tenderness medial to the posterior iliac crest while the SGN is lateral. Diagnostic blocks under fluoroscopy, with nerve stimulation, are critical for accurate diagnosis, as it is easy to confuse this nerve with a piriformis entrapment syndrome or the myofascial pain of the gluteus medius muscle itself.

Technique: With the patient in the prone position, the medial border of the ilium is palpated. The nerve is located about 5 cm lateral and inferior to the attachment of the gluteus medius (Figure 72.6). Infiltration with local anesthetic is followed by a saline solution with epinephrine 1:200,000. A 12-gauge intravenous catheter is again used

FIGURE 72.6 Superior gluteal nerve (marker and cryo).

as the introducer for the 2.0-mm cryoprobe. The nerve is approached from superior-laterally and the probe is directed inferior-medially. The nerve stimulator is employed to ensure the avoidance of motor nerves (e.g., sciatic nerve). Three 2-minute freeze cycles seem sufficient.

Prospective data regarding clinical and/or cost-effectiveness have not yet been reported.

Sacroiliac Joint

Prior to 1934, the SI joint was considered the most common cause of idiopathic low back pain;[62] however, that was the year Mixter and Barr described the herniated nucleus pulposus. The sacroiliac joint then was ignored for many years. The difficulty of imaging this joint also contributed to its obscurity. New appreciation of the SI joint as a cause of lumbosacral and leg pain has been triggered by new diagnostic physical exam techniques, injection approaches, and treatment options. It is estimated that 22% of low back pain (and 33% of low back

FIGURE 72.7 SI joint injection.

pain in elementary and high school students) is from SI pathology.[63]

Clinical Presentation: The SI joint is not fused, as is often taught, but rather is a joint with a fibrous lateral surface and a cartilaginous medial surface. The joint is designed to lock while in stance position and unlock as part of the stride. It is therefore vulnerable to "dislocation" and "jamming." Slamming on brakes during motor vehicle collisions or falling on the buttocks or a sudden twisting injury can cause pain in the buttocks radiating down the leg. Physical exam shows tenderness at the medial aspect of the posterior iliac crest — the "Fortin finger test"[64] — and diagnosis is confirmed by fluoroscopic injection of local anesthetic and contrast into the joint with subsequent resolution of pain (Figure 72.7). The innervation of the sacroiliac joint is primarily by way of the dorsal rami of S1 through S3.[62] Because these nerves enter the spinal column at the level of the leg nerves, pathology of the sacroiliac joint will refer pain down the leg in a radicular pattern. The most common major innervation in my experience is usually S2. The exiting dorsal ramus leaves the foramen usually at the 4 o'clock position on the right and the 8 o'clock position on the left. A diagnostic block using a peripheral nerve stimulator can aid in the determination of the most significant level of nerve innervation, and a small dose of contrast will outline the nerve root, giving a good "roadmap" for the subsequent cryoneuroablation procedure (Figure 72.8). The subcutaneous structures overlying the joint are innervated by branches of the L5–S1 facet nerves and medial cluneal.

Technique: For the cryoneuroablation procedure, the patient is positioned prone and the target sacral foramina identified by fluoroscopy. After prep, a small dose of local anesthetic is infiltrated subcutaneously, and deeper infiltration is performed with the saline/epinephrine solution, again about 1 cc. After a small skin nick is made, the 12-gauge introducer is advanced to the inferior border of the foramen laterally (as described above, at 4 o'clock on the right and 8 o'clock on the left). The stylus is then removed

FIGURE 72.8 S2 nerve root.

FIGURE 72.9 Cluneal injection.

FIGURE 72.10 Cluneal cryo.

and the 2.0-mm probe advanced through the catheter. Using the stimulation pattern described for facets, the area of maximal stimulation is identified. Care must be taken to avoid actually cannulating the foramen, as this could potentially affect the nerves to the bowel and bladder.

Clinical Effectiveness: Lloyd et al.[11] and Evans et al.[5] used cryoanalgesia to treat the sacral nerve roots in patients with intractable "sciatica" and perineal pain. Prospective data regarding clinical and/or cost-effectiveness have not yet been reported.

Cluneal Neuralgia

The superior cluneal nerves are an under recognized source of hip, back, and leg pain. These nerves are the lateral cutaneus branches of the dorsal rami of the upper three lumbar nerves. They pierce the quadratus lumborum fascia at the lateral border of the erector spinae muscle, cross the iliac crest a short distance in advance of the posterior iliac spine, and distribute to the skin of the gluteal region as far as the greater trochanter. Pain can refer to the posterior thigh, calf, and foot.

Clinical Presentation: Two recognized nerve pathologies will cause pain in this region. One pathology is of the cluneal nerve itself, either after surgical iliac crest graft harvesting or, much more commonly, secondary to entrapment of the nerve as it pierces the quadratus lumborum fascia. Thus, the muscle spasm of a "pulled muscle" would entrap the cluneal nerve, causing a referred pain down the leg, potentially all the way to the foot. This "pseudosciatica" would clinically mimic a radiculopathy. Diagnosis is made by physical exam because palpation of the iliac crest will be markedly tender and will usually replicate the leg pain. At fluoroscopy, the maximal tenderness is usually seen at the medial iliac crest (Figure 72.9), and a traction spur of the attachment of the quadratus lumborum is often seen just medial to the area of maximal tenderness. Injection of 1 cc of local anesthetic using a peripheral
nerve stimulator is diagnostic and depo-steroids at this spot are often very effective in completely relieving the pain. If the relief is complete but only temporary, placement of the cryoprobe (Figure 72.10) at that same spot (confirmed by sensory stimulation and lack of motor stimulation), using the technique previously discussed, can give dramatic and long-term relief. Maigne's syndrome is a T12–L1 facet pathology referring pain to the iliac crest via the cluneal nerves. There is tenderness of the skin over the iliac crest, and the diagnosis is made by the use of a thoracolumbar (T12–L1) facet block. Treatment would then include cryoneuroablation of the median branch at that level, identical to that described above for lumbar facets.

Technique: The initial steps are as described above, and as noted, accurate and meticulous sensory stimulation is critical for success. As the probe moves across the periosteum, sensory stimulation at first at 2 volts, then 1 volt, and then 0.5 volts is used to identify the cluneal nerve. Small movements of the probe are used as described above. The position of the probe is where the

quadratus lumborum attaches to the periosteum. At this time motor stimulation is used at its highest voltage to confirm that the probe is not too close to the L5 nerve root. Gas flows are then turned up to 10 to 12 liters per minute and a series of three 2-minute freezes with 30 seconds defrosting between each cycle is performed as for the facet cryoneuroablation. There is usually a burning pain on initiation of the first freeze cycle, which often replicates the pain and should resolve within approximately 30 seconds.

Clinical Effectiveness: Saberski et al.[65] described a syndrome of "painful iliac crest donor site" in a patient who had undergone iliac crest bone harvesting for a lumbar fusion. This patient experienced 1 year of complete relief after cryoneuroablation of the region of the iliac crest. Although this was not identified as the cluneal nerve, the clinical description appears to be consistent with a cluneal nerve pathology. Long-term (in excess of 5 years) relief has been obtained with open cryoneurolysis of cluneal nerves injures during bone graft harvesting. Noback[66] presented a technique of exposure of the graft site by reopening the surgical incision with dissection to the iliac crest. Cluneal neuromata are often found where the chiseled nerve has retracted to the upper anterior (abdominal) portion of the graft site. After exposure and stimulation during the procedure performed with local anesthetic, the severed nerve is cryoablated just proximal to its severed end with the 2 mm probe according to previously described techniques.

LOWER EXTREMITY PAIN

Obturator Nerve

The obturator nerve is rarely a pain problem except in cases of spasticity. It has, however, also been observed after surgical manipulation and in association with retroperitoneal hemorrhage. The obturator nerve has both sensory and motor components, and provides sensation to the medial distal thigh and knee. Diagnostic blocks may be useful in the evaluation of hip pain, as the articular branch of the obturator nerve is involved with sensation to the hip. The obturator is formed from branches of the second and third sacral nerve roots and passes anteriorly into the pelvis and then out onto the thigh via the obturator canal.

Technique: The patient is placed supine, with the affected limb abducted slightly. Fluoroscopy may be useful in the obese or severely spastic patient. The pubic tubercle is the palpated, and local anesthetic is infiltrated subcutaneously approximately one fingerbreadth laterally and inferiorly to the tubercle. After saline with epinephrine infiltration, the 12-gauge catheter is carefully and gently advanced to the inferior border of the ramus. If done blindly, hitting the edge of the ramus will confirm depth. If done under fluoroscopy, the catheter can be directed to

just below the inferior border of the ramus. To treat spasticity, this is one of the few times that motor stimulation for localization is appropriate. Adduction of the thigh at low voltages (0.5 to 1 mV) will confirm position. Spastic muscles should relax quickly, usually during the first freeze cycle. For pain, on the other hand, localization with the sensory mode is more effective, and an effort is made to avoid strong motor simulation, repositioning the probe if needed.

Clinical Effectiveness: Kim and Ferrante[67] reported cryoneuroablation of the obturator nerve for the treatment of adductor spasticity and obturator neuropathy. However, with the increased use of botulium toxin, this technique may be less useful.

Infrapatellar Saphenous Nerve

Neuralgia due to irritation of the infrapatellar branch of the saphenous nerve is seen weeks to years after blunt injury to the tibial plateau, or following knee replacement. The nerve is vulnerable as it passes superficially to tibial collateral ligament, piercing the sartorius tendon and fascia lata, inferior to the medial tibial condyle. The clinical presentation consists of dull pain in the knee joint, and achiness below the knee. Patients have trouble localizing the pain and tend to ambulate in such a manner as to minimize flexion of the knee joint. Physical exam shows tenderness to palpation just inferior to the medial tibial plateau. Pain with digital pressure is diagnostic, and most patients respond extremely well to a small volume local anesthetic and depo-steroid injection. Cryoneuroablation can be very useful for those patients in whom the injection gives only temporary relief.

Technique: A 12-gauge intravenous catheter is used as the introducer for the 2.0-mm cryoprobe, employing three 2-minute cryocycles. Special care must be taken to prevent frostbite injury to the skin. Approaching the nerve from a caudad to cephalad direction and keeping the probe positioned at an acute angle will help keep the ice ball below skin level and thereby decrease the frostbite risk.

Superficial Peroneal and Saphenous Nerves

Neuralgia due to irritation of the superficial peroneal and saphenous nerves can be seen weeks to years after injury to the foot and ankle. These superficial sensory nerves pass through strong ligamentous structures and are vulnerable to stretch injury with inversion of the ankle, compression injury due to edema, and sharp trauma due to bone fragmentation.

The superficial peroneal nerve runs superficial and medial to the lateral malleolus and continues superficial to the inferior extensor retinaculum, terminating in the fourth and fifth toes. Particularly vulnerable to injury following sprains of the lateral ankle, the clinical presenta-

tion consists of dull ankle pain, worse with passive inversion of the ankle. Signs and symptoms consistent with reflex sympathetic dystrophy or CRPS (a disproportionate swelling, vasomotor instability, and allodynia) are remarkably common. Patients tend to ambulate in such a manner as to minimize weight bearing on the lateral aspect of the foot. Pain with digital pressure in the area between the lateral malleolus and extensor retinaculum is diagnostic. Sometimes the patients are so diffusely tender that it is hard to determine where the worst tenderness is. The history can be very helpful here because the mechanism of injury is consistent enough that almost all of these injuries result in superficial peroneal neuralgia. Small-volume diagnostic injections with local anesthetic and depo-steroid can give rapid and dramatic relief, sometimes decreasing the swelling "right before your eyes." The saphenous nerve at the ankle passes anterior to the medial malleolus, and is injured by eversion ankle trauma. The pain, swelling, and hyperesthesia from this entrapment can result in a chronic regional pain syndrome (CRPS). Pain will radiate up the medial shin and down to the great toe, but the patient may have difficult identifying the exact location. It is important, therefore, to explore the mechanism of injury to predict the likely pathology.

Technique: A 12-gauge intravenous catheter is used as the introducer for the 2.0-mm cryoprobe, employing three 2-minute cryocycles. Special care must be taken to prevent frostbite injury to the skin. Approaching the nerve from a caudad to cephalad direction and keeping the probe positioned at an acute angle will help keep the ice ball below skin level and thereby decrease the frostbite risk.

Deep Peroneal Neuralgia

The deep peroneal nerve runs beneath the tendon of the extensor hallucis brevis, superficial to the dorsal interosseous muscle, between the first and second metatarsal heads, terminating in the first and second toes. Individuals with diabetes and women seem to be most vulnerable to this compression injury, which results from tightly fitting shoes. Seen less commonly following blunt injury to the dorsum of the foot, the clinical presentation consists of dull pain in the great toe, often worse after prolonged standing. There may also be pain at ball of the foot, poorly localized and occasionally burning in nature. Patients tend to ambulate in such a manner as to minimize weight bearing on the anterior foot. Pain with digital pressure in the area between first and second metatarsal heads (especially with concomitant pressure on the metatarsal heads) is diagnostic. Morton's neuromas (digital neuromas, intermetatarsal space neuromas) will present similarly but are located between the second and third metatarsal space or between the third and fourth (Figure 72.11). Neuromas that have not been surgically treated

FIGURE 72.11 Digital neuroma.

are easier to treat because there is room for the large (2.0-mm) probe, which increases the success rate. Unfortunately, many patients are sent for evaluation only after the surgical treatment has failed. The cryoprobe must be placed proximal to the surgical trauma to be effective, and there is not much room in the proximal portion of the metatarsal triangle apex, necessitating the use of the smaller (1.4-mm) probe.

Technique: The appropriate introducer (12 gauge for "virgin" nerves and the 1.4 gauge for postoperative neuromas) is introduced through the skin perpendicular to the nerve and directed toward the apex of the metatarsal bones. Care must be used with the saline and epinephrine because of the risk of digital ischemia. Placing the non-introducing hand at the plantar surface will detect if the probe is too close to the skin of the sole of the foot. Stimulation should replicate the patient's usual pattern of pain. Nonsurgically treated neuromas and the deep peroneal nerve can use the 12-gauge catheter and the 2.0-mm probe.

Clinical Effectiveness: Cryoneurolysis of an intermetatarsal space neuroma has been reported to provide at least 6 months of relief.[68] Wang[34] performed percutaneous cryoneurolysis on various peripheral nerves (ulnar, median, sural, occipital, palmar branch of the median, and digital) in 12 patients with 6 patients reporting relief of 1 to 12 months' duration.

Medial and Lateral Calcaneal Nerves

Heel pain, especially on the plantar surface, is often diagnosed as plantar fascitis. However, occasionally the heel pain is caused, instead, by entrapment of the medial and less commonly the lateral calcaneal nerves. The medial calcaneal nerve is a terminal branch of the posterior tibial nerve and passes under the flexor retinaculum at the bony attachment of the abductor hallucis. The small overhang

of bone is the site of entrapment and the target for the cryolesion. A similar anatomy exists laterally, although the bony outcropping is less distinct and therefore a harder landmark to find.

Technique: A 14-gauge intravenous catheter is used as the introducer for the 1.4-mm cryoprobe, employing three 2-minute cryocycles. Care must be used to avoid frostbite, and the technique seems to work best when the probe is directed cephalad to caudad along the groove in the bone.

Peripheral Neuropathy

Patients who have been diagnosed as having peripheral neuropathies may actually have distal nerve entrapments. The digital, superficial peroneal, and saphenous nerves described above have been implicated in all or a vast majority of the foot pain attributed to peripheral neuropathy. The patient is questioned regarding the area of initial pain onset, and a diagnostic block in that area is performed. If this results in good but only temporary relief, cryoneuroablation of that nerve is attempted.

Clinical Effectiveness: Milleret[69] described the use of cryoanalgesia in elderly patients with distal arteritis. Dellon[70] described surgical decompression of peripheral nerves for the symptoms of diabetic peripheral neuropathy. However, he noted up to 1 year for wound healing. Cryoneuroablation, which is much less invasive and results in minimal tissue trauma, would be expected to be at least as effective.

PHANTOM LIMB PAIN

Brief Review of Phantom Limb Pain

Phantom-limb pain is a common sequela of amputation, occurring in up to 80% of people who undergo the procedure.[71] It must be differentiated from nonpainful phantom phenomena, residual-limb pain, and nonpainful residual-limb phenomena. The term *phantom-limb pain* was coined for this sensation by Mitchell.[72] Phantom-limb pain is commonly classified as neuropathic, and it is assumed to be related to damage of central neurons. However, it was Ambroise Paré in 1552 who postulated that peripheral factors as well as a central pain memory might be causing phantom-limb pain, and he was actually the first to describe the phenomenon.[73] Searching for peripheral triggers for phantom pain symptoms can be guided by the nerve pattern of the phantom pain, tracing the known path of the nerve proximally, and examining for proximal tender regions. Diagnostic injections will confirm the site, and cryoanalgesia can give long-term relief.

CONCLUSION

In conclusion, cryoneuroablation is an effective interventional pain management technique, providing significant analgesia in an outpatient or office setting. The effect is routinely reversible, relatively painless, and not associated with neuroma formation. An accurate diagnosis with specific diagnostic injections of small volumes of local anesthetic and meticulous localization of the nerve is critical for successful outcome. Remember, "*You cannot treat what you cannot diagnose.*"

Endoscopic Surgery and Minimally Invasive Techniques

Anthony T. Yeung, MD, and Christopher Alan Yeung, MD

INTRODUCTION

EVOLUTION OF ENDOSCOPIC SPINE SURGERY

Spinal endoscopy is poised to parallel the development and evolution of knee, shoulder, and ankle arthroscopy.[1] Without endoscopy, spine surgeons must depend heavily on imaging systems that while extremely sensitive in identifying pathologic conditions, do not always correlate that condition with the patient's pain. Endoscopic disc surgery is evolving rapidly due to the introduction of improvements in endoscope design and instrumentation (Figure 73.1).[2] The introduction of various cannula configurations combined with excellent optics gives the endoscopic spine surgeon the ability to probe spinal anatomy in a conscious patient while protecting sensitive spinal nerves, allowing the surgeon to evaluate the pathologic process causing the patient's pain. When spinal endoscopy can be performed, conditions previously not even considered for surgery may be evaluated and managed.[3]

ENDOSCOPIC SURGERY COMPLEMENTING INTERVENTIONAL PAIN MANAGEMENT

Patients who find temporary relief with interventional pain management injections directed toward a pain generator may find more lasting and definitive relief with surgical correction or modification of the pathoanatomy. Our understanding of discogenic back pain is enhanced by diagnostic and surgical endoscopy of the lumbar spine, as endoscopic visualization of pathologic lesions not previously seen with traditional techniques is increasing our understanding of the pain generators in the lumbar spine.

The pain pattern does not always match the anatomic dermatome, which confuses many surgeons dependent on identifying a mechanical condition compressing sensitive spinal nerves and on correcting the spinal condition. With endoscopy, aided by discography, epidurography, and therapeutic injections, it is possible to evaluate, diagnose, and treat spinal conditions not usually considered for the more invasive open surgical techniques.[4] The technique first depends on directing a needle to the pain generator, desensitizing or anesthetizing it, dilating a path that will allow a tubular retractor to be inserted, followed by an operating endoscope. With this capability, we will gain a better understanding of the biology of back pain and sciatica, and also will be able to study the pathoanatomy and pathophysiology of pain in specific individuals. It is also well known that although a spinal structure is capable of pain, spinal pathology on imaging studies does not always correlate with the debilitating pain. What may be very painful in one person may be well tolerated or painless in another. Evocative discography™ is helpful in identifying the disc as a pain generator in axial back pain and sciatica.[5] Spinal endoscopy and probing in a sedated, awake patient can identify painful and nonpainful structures and help correlate the patient's pain to imaging studies. This increased knowledge of back pain can eventually lead to more targeted and alternative treatment options.
FIGURE 73.1 The YESS discoscope and partial instrument set. The spinal endoscope is designed with multichannel irrigation and a cannula system that allows access to targeted areas while protecting sensitive nerves.

INDICATIONS

Any pathologic lesion accessible, visible, treatable, or requiring endoscopic confirmation through the foramen may ultimately become an indication for diagnostic and therapeutic endoscopy.[6] Patient selection for pain and radiculopathy from disc herniation is similar to selection criteria for traditional spine procedures, but endoscopic surgical indications may be dictated by the limitations of the endoscopic procedure itself with respect to the patient's anatomy or the surgeon's skill and experience with endoscopic spinal surgery.[7] At L5–S1, anatomic restrictions may cause the surgeon to opt for the posterior transcanal approach (Figure 73.2a). For herniations from T-10 to L5, the foraminal approach provides excellent access to the disc and epidural space (Figure 73.2b). As the surgeon's experience increases, previous contraindications become relative, dependent partly on the surgeon's ability to endoscopically visualize, probe, and access the pathologic lesion. Restrictions are dictated only by anatomic considerations in accessing the patient's spinal pathology and the rationale of the endoscopic procedure itself.[8] Anatomic structures within reach of the spine endoscope transforaminally are illustrated in Figure 73.3.

INCLUSION CRITERIA

Discogenic pain as determined by evocative discography may implicate the disc as a pain generator. Symptomatic disc herniation is the obvious indication, with surgical

decompression limited only by the accessibility of endoscopic instruments to the herniated fragment.[9,10] Because of the posterolateral foraminal approach, the ideal lesion for endoscopic discectomy is a far lateral, extraforaminal disc herniation. Traditional approaches to far-lateral, extraforaminal disc herniations are more difficult, requiring a paramedian incision through the vascular intertransverse ligament. This surgical area is often called the "hidden zone" for traditional surgeons. Although a traditional spinal surgeon can access the lateral zone of the disc with a paramedian incision, it is easier to access the extraforaminal zone endoscopically via the posterolateral portal. A typical foraminal view of nucleus pulposus extruded past the posterior annulus is shown in Figure 73.4. With this approach to the disc, relatively easy access is possible from T-10 to L5 (Figure 73.2b). This is also the preferred approach for disc herniations in the upper lumbar and lower thoracic spine because the transcanal approach will require more extensive laminectomy that may destabilize the spinal segment if the herniation is above L3–L4.

Recurrent herniations after posterior discectomies are another good indication. The posterior scar usually limits any migration of the herniated disc, and the postero-lateral endoscopic approach avoids going through the scar tissue. Endoscopic excisional biopsy and disc space debridement are ideal for surgically treating infectious discitis (Figure 73.5).[11] Currently treated with immobilization and parenteral antibiotics, discitis is much more effectively treated when augmented by endoscopic debridement. Unlike the open posterior approach, no dead space is

(a)

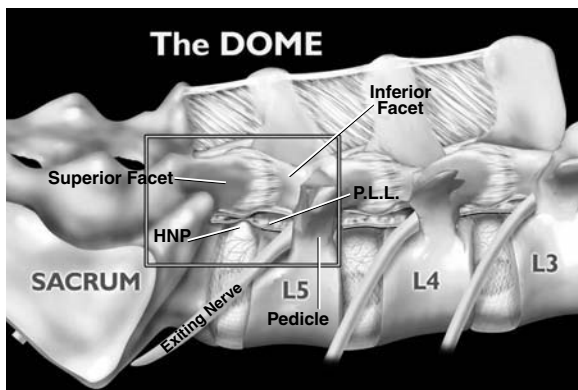
(b)
FIGURE 73.2 (a) The anatomy of the posterior portal provides easier access to the posterior disc and spinal canal at L5–S1, but with planning, most contained disc herniations can be removed posterolaterally. (b) Anatomy of the posterolateral foraminal portal from L2 to S1. Only at the L5–S1 disc space is access to the spinal canal restricted due to the pelvis and the relatively wide facet. High lumbar disc herniations from L1 to L3 are easier to reach endoscopically through the posterolateral foraminal portal. L4–5 provides ample room for either approach. Note the furcal nerve branches entering the psoas muscle.


FIGURE 73.3 The dome. Spinal structures in the foramen accessible to visualization and surgical intervention and probing via the posterolateral approach.
FIGURE 73.4 Foraminal view of an extruded disc herniation through the posterior annulus. The vital dye stains the disc for easier identification and extraction. Here, the herniation has clearly extruded through the posterior annulus.
FIGURE 73.5 Intradiscal view of discitis post-debridement. Usual findings of inflammatory disc material and loose end plate cartilage are readily removed from the disc space. Pain relief is immediate, and abundant tissue is available for laboratory analysis. The micropituitary forceps is visualized through a biportal fenestration of the disc.

created. Thus, the surgeon will not have to worry about spreading the infection. The clinical results are dramatic, and tissue biopsy is more accurate than needle aspiration in identifying the cause of discitis. Even sterile discitis will benefit from intradiscal debridement and irrigation.

Endoscopic foraminoplasty by endoscopic techniques is also possible for experienced endoscopic surgeons.[3,7,12] Although trephines, rasps, and burrs can be used, the Ho:Yag laser has enhanced the procedure technically as the laser is a very precise cutting tool for visually controlled soft tissue and bone ablation. Endoscopic laser foraminoplasty is further validated by research studies by Osman and Panjabi[13] demonstrating that decompression through the foramen can be as effective as posterior decompression, but will not produce further instability (Figure 73.6). The foramen can be enlarged up to 45.5% versus the 34.2% attainable with the standard posterior

facet (SAD)

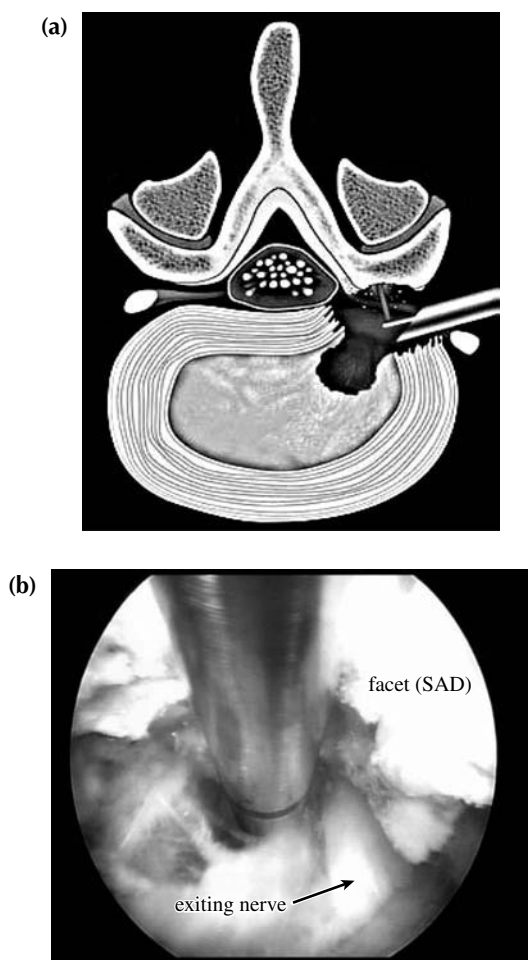
exiting nerve


FIGURE 73.6 (a) The technique of endoscopic foraminal decompression. The annulus can be decompressed and even resected, while the capsule, ligamentum flavum, and inferior facet surface can be ablated with a side-firing laser to enlarge the foramen and free the traversing as well as the exiting nerve. (b) Side firing laser ablating bone under the superior articular process. Intraoperative view of foraminoplasty at L5–S1. Note exiting nerve at 5 o'clock.

technique of removing only the medial third of the facet. Posterior decompression of the lamina with removal of the medial third of the facet will produce increased extension and axial rotation postoperatively.[13] Endoscopic foraminal plasty has not been shown to cause increased instability even in spondylolisthesis.[3] The technique is most useful for lateral recess stenosis, a condition that is responsible for atypical leg pain rather than true intermittent claudication of central spinal stenosis. In central spinal stenosis, when there is concomitant posterior disc protrusion, decompression of the spinal canal can be effectively accomplished by resecting the bulging annulus in a collapsed disc, thus lowering the floor of the foramen. In isthmic and degenerative spondylolisthesis, when there is more leg than back pain, this is usually due to impingement on the exiting nerve by the pars pseudoarthrosis

defect or the undersurface of the superior articular facet. The goal is then to decompress the compromised exiting nerve by elevating the dome formed by the superior facet and lamina without further destabilizing the spinal column segment.

EXCLUSION CRITERIA

Except perhaps for pregnancy, there are no absolute exclusion criteria but only relative contraindications dependent on the surgeon's skills and experience. Spinal endoscopy and spinal probing can be used for diagnostic purposes in a very difficult or confusing clinical problem. Therefore, if endoscopy is helpful for diagnostic purposes, exclusion criteria may depend mainly on the accessibility of the spinal pathology and the endoscopic skills of the surgeon. A high narrow pelvis may make it difficult to access the posterior aspect of the L5–S1 disc and extract the herniation. If the herniation is sequestered and a free fragment, then a posterior microdiscectomy may be a better option for herniation removal. The risks and benefits of the procedure must be weighed against the need to use this fluoroscopically guided procedure under local anesthesia or sedation.

FUTURE CONSIDERATIONS

It is not inconceivable that the spine scope will eventually be used for all conditions where visual inspection is desired. The senior author (A.T.Y.) has utilized spinal endoscopy to inspect a spinal nerve suspected to be irritated by orthopedic hardware adjacent to the pedicle, to remove suspected recurrent or residual disc herniations that do not show up on imaging studies, to decompress the lateral recess by foraminoplasty, to remove osteophytes and facet cysts that cause unrelenting sciatica, and to locate painful lateral annular tears or small disc herniations not evident on physical examination or on magnetic resonance imaging (MRI). Some of these correctable lesions are responsible for failed back surgery syndrome. The lateral "hidden" zone is rarely visualized by surgeons. It has been reported that most tears that do not heal are too extensive or are caused by interpositional disc material keeping the tear open. Simply removing the interpositional disc tissue will then allow the tear to heal, and the pain to resolve. It has been demonstrated that with endoscopy, it is possible to perform isolated disc and annulus surgery using a visualized thermal modulation procedure (Figure 73.7), challenging the old concept that disc surgery is merely nerve decompressive surgery. For example, discogenic pain from annular tears is currently being evaluated and correlated with the pathoanatomic conditions visualized.[14–25] Some minimally invasive spinal surgeons use an endoscope, but only through the traditional transcanal approach. Because most surgeons are more com-
FIGURE 73.7 (a) Annular tears. Grade V annular tears open into the epidural space or psoas muscle, allowing the ingrowth of nerves and capillaries that create an inflammatory response that, if next to a spinal nerve or the dorsal root ganglion, can cause pain out of proportion to what may be anticipated from traditional imaging studies. If patients with annular tears get relief from foraminal epidural blocks, more lasting relief of 1 or 2 years is possible with selective endoscopic discectomy (SED™) and thermal annuloplasty. (b) Far-lateral annular tear. This far-lateral annular tear is thermally modulated by a side-firing Ho:Yag laser ablating the interpositional disc tissue that kept the tear open and prevented healing. The laser probe was inserted on the side opposite the tear. (c) Illustration of the Ellman bipolar trigger-flex probe treating a grade IV annular tear. Interpositional disc material embedded in the annular layers is the usual cause of annular tears not healing. Nucleus pulposus should be removed from the annular layers to treat the annular tear effectively. (d) Intraoperative evocative chromo-discography identifies a large grade V annular tear. (e) Nucleus pulposus found in annulus, demonstrating a small herniated foraminal disc fragment unrecognized on MRI. (f) Annular tear exposed after removal of herniation. Vascularization of the tear is demonstrated. (g) Thermomodulation of the annular tear with a bipolar radiofrequency probe helps close the defect.

fortable with the anatomy encountered in a traditional approach, this is a good way to begin the transition to other endoscopic techniques. Once they feel comfortable with the endoscope, however, it is not difficult to transition to the posterolateral portal. Those who take the time to learn other approaches, including the posterolateral approach, will be in the best position to do what is best for their patients.

NON-OPERATIVE TREATMENT

With endoscopy, conservative treatment should be labeled non-operative treatment. Physicians specializing in spinal medicine, rehabilitation, and pain management are becoming more sophisticated in their ability to identify the tissue source of back pain. Once the source is identified, physical therapy and diagnostic and therapeutic injection methods are used for pain relief. These techniques, such as foraminal epidural blocks and selective nerve blocks, may be labeled "conservative," but are therapeutically beneficial. They may also be limited in their ability to ultimately correct the painful condition. Endoscopic spine surgeons are still needed to address correctable lesions, but their effectiveness is enhanced by incorporating the help of a multidisciplinary team. The senior author has devised a new technique for performing foraminal epidurography and therapeutic injections that is done with a far-lateral trajectory into the foramen, mimicking the surgical approach.[4] Familiarity with foraminal injections will enhance the endoscopic surgeon's surgical skills and provide the surgeon with a "trial run" if endoscopic surgery is ultimately required.

The world literature on conservative treatment has presented strong evidence that a multidisciplinary approach to back pain, coupled with behavioral modification and exercise therapy, gives the best results. With spinal endoscopy, a new concept for treatment should be non-operative versus operative treatment, as the ability to more specifically diagnose a painful condition in the lumbar spine with endoscopy makes early surgical intervention the more "conservative" approach.

PLANNING

Patients with chronic back pain and atypical sciatica are the most difficult to treat. Traditional methods of nonsurgical treatment are often not effective or relief is very transient, and the patient is often labeled drug seeking or psychologically unstable. In this situation it is extremely helpful to utilize a multidisciplinary team approach. Psychologic profiling, behavioral modification, active exercise, and manual therapy help the patients overcome their pain and focus on becoming functional. The team approach with psychologists, physiatrists, addictionologists, and pain management specialists who are working with each other and agree on the overall treatment plan has helped rescue many chronic pain sufferers from total disability and reliance on salvage procedures. Around the disc, foraminal epiduroscopy and foraminal epidural blocks will help determine the ease of reaching the disc and epidural space. A temporary response to the foraminal epidural injection is a good indicator for a foraminal approach to the pathologic lesion to be addressed surgically.

CURRENT IMAGING METHODS

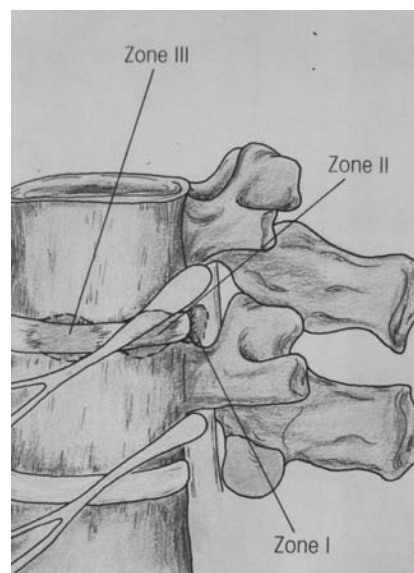
In the senior author's experience, imaging studies are only about 70% accurate and specific for predicting pain.[3,6,26–29] Conditions such as lateral annular tears, rim tears, small subligamentous disc herniations, end plate separations, anomalous nerves in the foramen, and miscellaneous discogenic conditions are cumulatively missed about 30% of the time. These conditions are diagnosable and often treatable with spinal endoscopy. Tears that are in the lateral and ventral aspect of the disc are routinely missed by MRI studies (Figure 73.8). Very small disc herniations that protrude past the outer fibers of the annulus are also missed because the fragment may be flattened against the posterior longitudinal ligament or nerve, appearing on the MRI as a thickened or bulged annulus, but really containing a subligamentous herniation. When the nerve root is "swollen" or enlarged, the MRI is not always capable of distinguishing a swollen nerve from a conjoined nerve or a nerve with an adherent fragment of disc. When the disc tissue is in direct contact with the nerve, the nerve can be irritated and a


FIGURE 73.8 The three zones of disc herniation and annular tears. Zone III is usually missed on routine imaging studies, often produces nondermatomal symptoms, and is often only identified by evocative discography. Zone III annular tears can cause groin pain at L5–S1, and small extraforaminal disc herniations are difficult to diagnose by physical examination.

painful inflammatory membrane forms. Even an epidural venous plexus that is inflamed can contribute to back pain and sciatica. Anomalous nerve branches known as furcal nerves are never seen on MRI but can be visualized with spinal endoscopy of the foramen.[22,30]

When an inflammatory membrane is present, the patient's pain pattern can be confusing. Diagnostic spinal endoscopy has confirmed "nondermatomal" pain in scores of patients with proximal thigh, buttock, and groin pain at levels distal to the root origin of the anatomic area. Removal of the source of irritation will resolve or improve the patient's pain.

EVOCATIVE DISCOGRAMS

The senior author uses evocative chromo-discography™ as an integral part of spinal endoscopy.[5] The literature on discography is currently considered controversial because of the high interobserver variability by discographers in reporting the patient's subjective pain as well as the ailing patient's ability to give a clear response, especially if the pain response is altered by the use of analgesics or sedation during the procedure. Surgeons who are accomplished in endoscopic spine surgery prefer to do the discography themselves to decrease the interobserver variability interpreting the patient's response. When the surgeon compares his own assessment of the patient's pain response with another discographer's report, there can be some variability in diagnosis and interpretation. This variability may result in unpredictable treatment outcomes. False-positive discography, however, can be significantly decreased in an experienced endoscopic surgeon's hands. The surgeon learns to correlate the patient's response to the discogram pattern of the painful disc the surgeon is treating. There is good correlation of discograms with different types of annular tears and disc herniations. The surgical result can then be predicted on the basis of the visualized condition. For example, the discogram can be used to predict the presence of a collagenized disc fragment versus a soft herniation, the extrusion of a disc fragment as a noncontained herniation, or the presence of the type, grade, and location of a painful versus nonpainful annular tear.

TECHNIQUE

ENDOSCOPIC SPINE SURGERY: THE POSTEROLATERAL APPROACH

The current technique used by the senior author has evolved over a 13-year period beginning in 1991 after learning arthroscopic discectomy from Parviz Kambin. Previously the author had experience in the use of chymopapain, automated percutaneous discectomy, laser discectomy, and discography. The current technique combines the best features of each endoscopic procedure into a visu-

alized method that is described as selective endoscopic discectomy (SED™) and thermal discoplasty and annuloplasty. It continues by incorporating endoscopic foraminoplasty techniques for degenerative conditions of the lumbar spine. The foraminal approach is refined further by a standardized surgical protocol that helps decrease the learning curve. A prospective, Institutional Review Board–approved study of 56 patients undergoing SED and thermal discoplasty by the senior author for conditions ranging from discogenic pain to spondylolisthesis, targeting the pain generator, revealed a satisfactory outcome of 89% by modified MacNab criteria and 91% by patient questionnaire.[8] Surgical results continue to improve, consistent with the refinement of indications and techniques for specific conditions treatable by this endsocopic method.

Accessing the foramen is simplified and standardized by drawing coordinates on the patient's skin to determine the optimal skin window and annular window for positioning the surgical instruments to the center of the disc (Figure 73.9). Reference points are the anatomic center of the disc, the superior facet of the inferior vertebra, and the skin window. The needle trajectory must also be in a line of inclination between the end plates of the adjacent vertebrae. Adjustments in the trajectory will be made to accommodate individual anatomic considerations and the pathology to be accessed. Once the optimal trajectory is established, the cannulas are inserted to allow for endoscopic surgery under direct visualization.

The spinal structures accessible with this technique are the facet joints, the pedicles of the superior and inferior vertebra, the traversing and exiting nerve roots, and the disc annulus. The epidural space is accessible with flexible instruments and special cannulas (Figure 73.3). The posterolateral approach can avoid the spinal canal if desired and does not require the stripping of muscle or ligament to access the disc. A third-generation system, the Yeung Endoscopic Spine System (YESS), features a cannula set with configured openings that allow instruments to exit the cannula for surgical work, while a protruding tongue protects and retracts adjacent structures. The beveled cannula allows visualization of the disc and epidural space at the same time, facilitating the removal of subligamentous, extruded, and sequestered disc fragments. Its configuration also allows for dilation of the disc space for intradiscal surgery. The foramen can be enlarged by foraminoplasty to decompress foramenal and lateral recess stenosis. Adjuvant tools and therapies such as radiofrequency, chymopapain, steroids, intradiscal injections, and laser can be employed for tissue modulation or ablation when the visualized spinal pathology dictates its use.

POSTOPERATIVE CARE

Postoperative management may differ from the typical postoperative program used for disc herniations with

L4-5 DISC

MIDLINE

TRANSVERSE PLANE
L5-S1 DISC

P-A fluoroscopic exposure enables topographic location of spinal column midline & transverse planes of target discs. Intersections of drawn lines mark P-A disc centers.

Lateral fluoroscopic exposure enables topographic location of the lateral disc center and allows visualization of the plane of inclination for each disc

The inclination plane of each target disc is drawn on the skin from the lateral disc center to the posterior skin surface.

The distance between lateral disc center & posterior skin surface plane is measured along each disc inclination line.

The distance is then measured from the midline along the respective transverse plane line for each disc. At the end of this measure a line parallel to midline is drawn to intersect each disc inclination line. This intersection marks the skin entry point or "skin window" for each target disc. Needle insertion at this point toward the target disc at an angle 30 – 25 degrees to the surface skin plane will determine the path of all subsequent instrumentation.

FIGURE 73.9 Determination of optimal instrument path.

radiculopathy. Endoscopic treatment for discogenic back pain often involves multiple levels, and disc segments with extensive circumferential annular tears that involve the entire 360° circumference. This differs from a disc herniation that involves only one quadrant of the annulus that after disc extraction, has a better chance of healing when the disc extrusion no longer acts as a barrier to healing. With an extensive annular delamination and tear, the annulus of the spinal segment must be protected while the collagen of the annulus heals, and only light non-axial loading movement is allowed. After 6 to 8 weeks, gauged by the patient's response to decompression and thermal modulation, a therapeutic exercise program is initiated consisting of lumbar stabilization exercises and MacKenzie extension maneuvers. Ultimately, the goal of mobilization and aerobic conditioning is functional recovery.

PROBLEMS AND COMPLICATIONS

As with arthroscopic knee surgery, the risks of serious complications or nerve injury are low — about 1 to 3% in the senior author's experience.[31] The usual risks of infection, nerve injury, dural tears, bleeding, and scar tissue formation are always present as with any spine surgery. Fenestration past the anterior annulus is a potential hazard creating a bowel or vascular injury. Although this is a rare complication because the thickness of the anterior annulus will usually prevent fenestration, it must be recognized as a potential risk if the annulus is weakened or fenestrated by an anterior disc herniation. This risk is also present with the posterior approach. One limitation of the endoscopic technique is the need to use some instruments in a "blind" fashion. That is, shavers, pituitary rongeurs, and basket forceps are too large to fit in the working channel of the endoscope, and must be monitored with fluoroscopy. The surgeon must be cognizant of the depth of the instruments and develop a feel for the working instruments while in the disc. The cannulas are designed to protect vital structures by utilizing windows as surgical portals. Spinal nerves may be adherent to the disc and annulus, and can be extracted along with the disc or annulus by shavers or cutting instruments. In addition, the author has identified anomalous autonomic and peripheral nerves in the foramen (furcal nerves), buried in the annular fat, that connect with the sacral plexus or the traversing nerve. These nerves are described in the medical literature and can be symptomatic (Figure 73.10a). The inflammatory membrane may contain tiny nerves and blood vessels that contribute to severe discogenic pain (Figure 73.10b).

Dysesthesia, the most common postoperative complaint, occurs about 5 to 15% of the time but is almost always transient. Its cause is still incompletely understood

(a)

(b)
FIGURE 73.10 Anomalous nerves. (a) Anomalous nerve identified in the annular fat in the foramen. When found in the foramen, it is considered an anomalous branch, but furcal nerves are common branches from the exiting nerve entering the psoas muscle. These communicating branches are described as furcal nerves in the anatomy and literature. Small sympathetic nerves are occasionally seen. (b) Neo-angiogenesis and neo-neurogenesis are commonly present in the inflammatory membrane adjacent to annular tears in patients who have severe discogenic pain and sciatica, but a rather benign MRI.

and may be related to nerve recovery, as it can occur days or weeks after surgery, or it may be due to irritation of the dorsal root ganglion. This condition cannot be completely avoided, as neuromonitoring with dermatomal somatosensory evoked potentials (SEP) and continuous electromyography, the most sensitive means of monitoring, has not identified the cause of dysesthesia.[32] The symptoms can be similar to complex regional pain syndrome (CRPS), but less severe, and usually without the skin changes that accompany CRPS. Stimulation of the doral root ganglion of the exiting spinal nerve can also result in dysesthesia when foraminoplasty is performed, even with the exiting nerve clearly identified and protected.

Endoscopic spine surgery has a high learning curve, but is within the grasp of every endoscopic surgeon with proper training. As with any new procedure, the complication rate is higher during the learning curve and may vary with each surgeon's skills and experience. The endoscopic technique, because of its approach, may incur additional risk for iatrogenic injury, but it is possibly safer than traditional surgery for the patient as the patient is awake and able to provide immediate input to the surgeon when pain is generated. The surgeon's ability to perform the surgery without causing the patient undue pain will self-select for surgeons who can master the technique to the extent that the surgeon prefers endsocopic to traditional surgery for the same condition. For most disc herniations and discogenic pain, experienced endoscopic spine surgeons will opt for the endoscopic approach as the treatment of choice for their patients. New neuromonitoring techniques and equipment help warn the surgeon of nerve irritation even when there is no direct contact of surgical instruments with the nerve proper. About 66% of the time, there is EMG activity recorded that warns the surgeon that there is nerve irritation. Neuromonitoring may make the procedure safer, but it has not been demonstrated to be safer than the use of dilute local anesthetic. It is imperative for the surgeon to insist that the anesthesiologist not use general or spinal anesthesia. The senior author requires anesthesiologists to not use propofol or any anesthetic that has the potential for the patient not to feel pain, as the patient's ability to feel pain becomes the surgeon's main safety net. The author also uses only a dilute solution of local anesthetic such as 0.5% lidocaine or its equivalent. The patient's ability to report pain during the procedure will also help the surgeon recognize the pain generators in the spine when the surgeon correlates the production of pain with the anatomy the surgeon is probing.

Frequently observed improvement in nerve conduction latencies and abnormal preoperative EMGs immediately postoperation may help predict the surgical efficacy of each procedure.[32]

ALTERNATIVES TO FUSION FOR THE TREATMENT OF BACK PAIN

Fusion has traditionally been reserved for spinal instability and deformity. More recently, the utilization of spinal instrumentation and intervertebral fusion cages has extended the indications to discogenic pain from internal disc disruption and degenerative disc disease, but, overall, the results remain disappointing; adjacent-level disease remains a problem. Discogenic pain has been discovered to arise primarily from the annulus, but can also involve the end plates (intranuclear herniations), the inflammatory membrane surrounding the annulus, and sensitized tissue surrounding the annulus. Patients with debilitating back pain are currently offered surgical fusion as a treatment option to stabilize the motion segment. However, patients with recurrent, relatively annoying or debilitating pain from annular tears in the lumbar disc may be also be helped by electrothermal treatment. Type III and IV pain nociceptors in the annulus are deformed by heat at 42 to 45°C. When the heat is increased to 65°C, the annulus contracts and thickens. This novel approach, touted in the literature as intradiscal electrothermal therapy (IDET), is limited because of the lack of endoscopic

visualization. Patient selection is critical, but even if initially successful in the immediate postoperative period, follow-up studies have reported significant deterioration of results months to years later. A visualized endoscopic variation of the technique, SED and thermal annuloplasty, overcomes some of the pitfalls of the blind technique. The tear is detected by evocative discography. Indigo carmine dye, mixed with a non-ionic contrast material, Isovue 300, stains the degenerative disc and annular tear a light blue. The degenerative disc is removed from the posterior disc quadrant, exposing the annular tear for thermal annuloplasty. When imaging studies identify these lesions as a high intensity zone, there is a high incidence of concordant pain by evocative discography and endoscopic confirmation of a focus of ingrown granulation tissue. This tissue can then be ablated under direct visualization. The senior author's endoscopic version of IDET has converted 80% of IDET failures to satisfactory results.[33] Spinal endoscopy has enabled surgeons to identify interpositional disc tissue as the single most common finding preventing annular tears from healing. Other novel approaches are currently being studied to help the tears heal, as annular modulation may incorporate injection of therapeutic solutions utilizing hypertonic dextrose, glucosamine sulfate, and chondroitin sulfate. These novel approaches deserve study and may provide a viable alternative to fusion as a first line of surgical treatment for debilitating discogenic back pain from annular tears and internal disc disruption. Ultimately, techniques to enhance disc healing, regeneration, or arthroplasty may replace fusion as treatments of choice.

OUTCOMES

The results of percutaneous spine surgery in the literature focus on blind techniques such as laser disc decompression and automated percutaneous lumbar discectomy. The visualized technique, however, as described by Kambin, ranges from 85 to 93% good/excellent in studies with a minimum 2-year follow-up. In a prospective manner, Kambin has also validated the visualized technique as a valuable tool in the armamentarium of a spinal surgeon. When performed in an experienced endoscopic surgeon's hands, Kambin found results equal to a traditional microdisectomy, but with less morbidity and an earlier return to work.[35–37] The high learning curve has curtailed its universal acceptance at this time, but those surgeons willing to invest the time in learning this technique will soon earn the loyalty and acceptance of their patients and referring physicians.

The evolution of endoscopic surgery is enhanced when physicians document their findings by video-imaging and then study the tapes postoperatively. By studying the video of their surgeries in the early part of the learning curve, surgeons will soon learn to associate visualized conditions with their ability to affect those conditions.

This will help surgeons evolve their diagnostic and surgical skills faster.

THE AUTHOR'S EXPERIENCE WITH ENDOSCOPIC SPINE SURGERY

Since 1991, the senior author has used a rod–lens system for endoscopic disc excision through a posterolateral approach as described by Parviz Kambin. Kambin coined the term *arthroscopic microdiscectomy* to describe his method of disc removal from the dorsal half of the intervertebral disc using uniportal and biportal techniques. In 1997, a newly designed spinal endoscope (YESS) featured a working channel and multiple inflow and outflow ports. This allowed consistent clear visualization through fluid volume and pressure control, to provide consistent hemostasis. The ability of the surgeon to visualize structures clearly and the concomitant development of flexible instruments to be used with slotted cannulas opened the door for true endoscopic spine surgery and spinal probing in a sedated, but awake patient. From 1991 to 2004, the senior author treated more than 2,400 patients with discogenic pain, degenerative conditions of the lumbar spine, and the whole spectrum of disc herniations including extruded and sequestered fragments. The success rate in the first 500 patients was 432/500 (86%) good/excellent using modified MacNab criteria.[26] A subsequent retrospective study of 219 consecutive patients with radiculopathy secondary to large intracanal noncontained lumbar disc herniations revealed a satisfactory outcome in 204 (93.1%) by modified MacNab criteria, but even higher (94.8%) when patients were asked to respond to a study patient-based outcome questionnaire.[9] The evolving methodology in the treatment of discogenic back pain by SED is reviewed in a prospective study that validates SED as an alternative for a variety of spinal conditions treated by traditional methods (Yeung & Gore, 2001). *The Practice of Minimally Invasive Spinal Technique* is a recent book edited by Martin Savitz, John Chiu, and Anthony Yeung. A journal by the same name has been endorsed by multiple spine specialty societies to bring endoscopic spine surgery into the next millennium.

NEW HORIZONS — THE FUTURE OF ENDOSCOPIC SPINE SURGERY

The learning curve in endoscopic spine surgery is steep compared with knee surgery because surgical misadventures are unforgiving in the spine. Intensive surgical instruction with preceptorship programs has produced small numbers of spinal endoscopists worldwide. It is strongly recommended, however, for further advancement of endoscopic spinal surgery, that a preceptorship be completed before attempting endoscopic spine surgery. Even-

tually, for further advancement, endoscopic spine surgery may have to be a subspecialization for most surgeons. If young surgeons could obtain their training in their fellowship or post-fellowship program, endoscopic spine surgery would advance faster. For now, the small number of surgeons should hone their endoscopic skills by limiting their indications to contained small, soft disc herniations. With the development of artificial nucleus disc replacements, interest in posterolateral spinal endoscopy is expected to surge, as this represents the best surgical approach for nucleus replacements.

CONCLUSION

The future of endoscopic spine surgery is extremely bright. There will soon be an explosion of new imaging systems, endoscopes, and endoscopic instruments. Refined techniques and image-guided systems may help shorten the learning curve. Coupled with advancements in tissue regeneration and enhancement of tissue healing, and the trend toward tissue healing instead of removal, regeneration over healing, and arthroplasty instead of fusion, the spinal surgeon may no longer have to consider spine surgery as paradoxical. As a treatment modality, it will no longer be considered a last resort in a desperate patient. There will be a paradigm shift in the way we view and approach patients with back pain, especially when endoscopic spinal surgery is further validated with outcome studies and becomes routinely available.

KEY POINTS

1. The endoscopic foraminal posterolateral surgical approach to the lumbar disc offers the least trauma to normal anatomy.
2. Spinal endoscopy offers expanded diagnostic as well as therapeutic benefits not possible with traditional surgery.
3. Spinal endoscopy is a complement to interventional pain management, and techniques are beginning to merge.
4. New terminology and concepts, evocative discography, evocative chromo-discography, selective endoscopic discectomy, and thermal annuloplasty, are introduced and explained in the text.
5. The learning curve is steep, but once mastered, this approach will revolutionize surgical treatment of the lumbar disc, and provide the delivery system for emerging technology in tissue repair and regeneration.

Spinal Cord Stimulation

Milan P. Stojanovic, MD, and Salahadin Abdi, MD, PhD

INTRODUCTION

Spinal cord stimulation (SCS), also known as "dorsal column stimulation," is a common mode of neuromodulation technique used for the treatment of a variety of pain syndromes — e.g., failed back surgery syndrome (FBSS), complex regional pain syndrome, postherpetic neuralgia, peripheral vascular disease, and diabetic neuropathy. The SCS implantation involves placement of the stimulating electrodes in the epidural space. The SCS lead is connected to the subcutaneously internalized pulse generator (IPG) and the internal or external power source. Generally, an SCS screening trial is performed before permanent SCS implantation.

SCS has recently gained in popularity for treatment of chronic low back pain. SCS is minimally invasive and is reversible as opposed to nerve ablation. The recent improvements in hardware design have made implantation techniques simpler and prolonged equipment longevity. Stimulation trials become less invasive, allowing patients to test its effects before final implantation. The scientific evidence has shown better outcomes of SCS in comparison with other modalities for treatment of some forms of low back pain.

Up until 10 years ago, the SCS was considered as the last treatment option, "only when everything else failed." However, the current practice of many clinicians is to utilize this mode of treatment earlier in the course of the above-mentioned pain syndromes. In fact, SCS can arguably be the best treatment option in some forms of chronic low back pain, such as FBSS, considering the relative low cost of the trials, low risk/benefit ratio, and positive outcome studies.

One can argue that the SCS trial and possible permanent implant may have better long-term risk/benefit ratio than the trial of chronic opioid therapy. Although many studies support opioid therapy for nonmalignant pain, no long-term studies on iatrogenic addiction rate with chronic opioid treatments have been published.

HISTORY

Humans opened an era of SCS, by utilizing the electrical power of torpedo fish, in 600 B.C. The first attempts of brain electrical stimulation were reported in 1874. However, the first implantation of brain electrodes was performed in 1948 for treatment of psychiatric disorder. Many attempts to use electrical central nervous system (CNS) stimulation for treatment of pain emerged in 1950s and 1960s. Based on the gate theory of pain proposed by Melzack and Wall,[1] Shealy et al.[2] introduced SCS in 1967. Initial SCS procedures involved open intrathecal implantation of electrodes via laminotomy. The lack of adequate hardware and the paucity of clinical outcome studies significantly slowed the development of neurostimulation in the 1970s.

Recently, the hardware technology has substantially improved. The development of minimally invasive percutaneous stimulation trials enabled a variety of patients with low back pain to test SCS. Electrodes have become smaller and easier to navigate through the epidural space. Internal pulse generators have new programming capabilities and longer battery lifespan.

ANATOMY AND HARDWARE

For chronic low back pain treatment, the SCS electrode leads are placed in thoracic epidural space, with a lead tip location at the T8–T10 level. An electrical field from

the SCS lead acts on the dorsal columns of the spinal cord and modulates its pain transmission. The anatomical position of the SCS lead can influence the pain relief and SCS "coverage." Holsheimer et al.[3] measured the thickness of cerebrospinal fluid (CSF) layers in thoracic areas corresponding to SCS electrodes placement and correlated results with paresthesia perception from SCS coverage. They concluded that the thickness of the dorsal CSF layer is the main factor determining the perception threshold and paresthesia coverage in spinal cord stimulation: an increasing CSF layer thickness raises the threshold and reduces the coverage, and vice versa. In the same study, the effects of an asymmetrical electrode position with respect to the spinal cord midline were also analyzed by computer modeling. It is concluded that a lateral asymmetry of less than 1 mm gives a significant reduction of perception threshold and may result in unilateral SCS coverage.

The same group of investigators using magnetic resonance imaging (MRI) found that spinal cord midline and vertebral midline are apart by at least 1 to 2 mm in all levels investigated in 40% of patients. Adequate symmetrical SCS coverage of low back and lower extremity is in many cases difficult to achieve. Barolat et al.[4] found that only 27% of paresthesia was felt symmetrically when the stimulating contacts were perfectly located at the radiological midline.

The permanent SCS hardware consists of SCS lead, an extension cable, a power source, and a pulse generator. Many leads contain a removable stylet, which eases lead steering during implantation. The lead design varies in the number of electrodes from four (Medtronic and Advanced Neuromodulation Systems, ANS) to eight (ANS). The distance between the electrodes and the length of the leads also can differ. It is not clear if an increased number of electrodes provides better coverage, but it might be beneficial in case of lead migration. The leads with minimal space between electrodes (such as Medtronic Quad compact lead) might be better suited for isolated axial low back pain without radiating component to the lower extremity.

There are two types of pulse generators: (1) the completely implantable pulse generator (IPG) containing a battery and (2) IPG supplied by external power through a radiofrequency antenna applied to the skin. The implanted pulse generator is more convenient to use and can be easily adjusted by the patient using a small telemetry device. Patients can turn the stimulator on and off and control the stimulation amplitude, frequency, and pulse width. A separate external programmer allows for more complex IPG reprogramming by the physician. In case of inadequate stimulation, the physician can change polarity and number of functioning electrodes in order to provide better stimulation coverage. The batteries have to be changed every 3 to 6 years, which requires a brief visit to the operating room. The battery life depends on how many hours a day the system is used and the intensity of the stimulation. The externally powered IPG has an advantage over the implanted one in patients requiring higher amplitudes of stimulation, which would deplete the implanted batteries in a short period of time.

The permanent SCS implant can be achieved by placing the percutaneous lead via epidural needle or "paddle" lead via open laminotomy. The configuration of SCS electrodes varies in these two techniques. Percutaneous electrodes are the same configuration as the ones used for stimulation trial. Paddle electrodes are larger, and can be anchored directly to the dura, potentially minimizing migration.

PATHOPHYSIOLOGY AND MECHANISM OF ACTION

The basic foundation for initial SCS trials was Melzak and Wall's gate control theory.[1] Their theory proposed that stimulation of Aβ-fibers modulates the dorsal horn "gate" and thus reduces the nociceptive input from periphery. Indeed, several studies demonstrated that dorsal horn neuronal activity caused by peripheral noxious stimuli could be inhibited by concomitant stimulation of the dorsal columns.[5] However, it seems that other mechanisms may play a more significant role in the mechanisms of action of SCS.[6,7]

Many animal studies have shown a suppressive effect of SCS on tactile allodynia, which is mediated via Aβ-fibers[8] and represents a state of central hyperexcitability.[9] Allodynic animals have lower extracellular levels of γ-aminobutyric acid (GABA), and that GABA antagonists abolish the allodynia suppressive effect of SCS indicates that one of the proposed mechanisms of actions of SCS is augmenting the dorsal horn inhibitory action of the GABAergic system.[9–11] Furthermore, intrathecal administration of $GABA_B$ agonist, baclofen, enhances the antinociceptive action of SCS in an animal model of neuropathic pain.[12] In humans, the intrathecal baclofen infusion produces significant augmentation of SCS effects.[13] Future studies must clarify if concomitant use of SCS and intrathecal $GABA_B$ agonists may have a synergistic effect in treating certain forms of neuropathic pain.

Apart from that, several other putative mechanisms may be responsible for the pain relief induced by SCS. Recent animal and human studies revealed a potential role of adenosine in mechanisms of action of SCS. Intrathecal administration of adenosine$_A$ receptor agonist was found to have potentiating effect with SCS and also synergistic effect with baclofen.[6] The disinhibition of descending analgesia pathways originating in periaqueductal gray and the release of serotonin and substance P can be other explanations for the mechanism of actions of SCS.[14,15]

SCS may abolish peripheral ischemic pain by rebalancing the oxygen demand and supply and preventing

ischemia.[7] At low levels of stimulation, SCS may act by suppressing the sympathetic activity via α-adrenoreceptors. However, at increased levels of stimulation, the nitric oxide–dependent release of calcitonin gene-related peptide (CGRP) may be more responsible for the vasodilatation effect.[16] Better survival of skin flaps during SCS seems to be due to the CGRP-mediated mechanism.[17] However, recent studies utilizing Doppler imaging did not reveal any changes in peripheral blood flow despite good SCS effects.[18]

Patients with end-stage myocardial ischemia respond well to SCS. Many possible explanations exist for SCS mechanism of action in myocardial ischemia. The most likely mechanism for pain relief consists of redistribution of the coronary blood flow from regions with normal perfusion in favor of regions with impaired myocardial perfusion.[19] The anti-ischemic effect of SCS was shown by coronary blood flow measurements and positron emission tomography. Other lines of evidence show that modulation of the intrinsic cardiac nervous system might contribute to the therapeutic effects of SCS in patients with angina pectoris.[20] In this proposed mechanism, SCS may suppress the excitatory effects of myocardial ischemia on intrinsic cardiac neurons.

The effects of SCS on human brain activity were studied using functional magnetic resonance imaging. The SCS produced increased activity in human somatosensory cortex (SI and SII areas), contralateral to the side of pain and cingulate gyri. The somatosensory cortex activation becomes more pronounced with increased SCS activity.[21] These brain areas activated by SCS correspond to CNS pain pathways involved in processing of somatosensory (SI, SII) and affective components (cingulate gyri) of pain. Further research may better define the role of higher CNS structures during SCS.

RATIONALE

SCS is not a neurodestructive procedure, as opposed to neuroablation. Thus, its effects are easily reversible. The relative low invasiveness of SCS trial (similar invasiveness as an epidural catheter placement) makes SCS the treatment of choice for certain forms of low back pain. In the long term, this treatment modality can be more cost-effective than conservative treatment options. Many studies have confirmed good outcomes of SCS for low back pain and highlighted its advantages over repeat back surgery.

INDICATIONS

Failed Back Surgery Syndrome

FBSS is the most common indication for SCS placement in the United States.[22] It is defined as persistent pain after

attempted surgical treatment for low back pain. FBSS occurs in 20 to 40% of more than 200,000 American patients who undergo lumbar spine surgery each year.[23] In patients who have failed medical management, physical therapy, and nerve blocks, SCS may be the best treatment choice. Many studies support the role of SCS in these patients, emphasizing its advantages over reoperation.[24]

Low Back Pain and Lumbar Radiculopathy

Surgically naive patients who are poor candidates for surgery may respond well to SCS. The chronic radicular pain in these patients is often of neuropathic origin. However, it is important to rule out other sources of pathology (e.g., facet disease, internal disc disruption, piriformis syndrome, myofascial pain) before choosing SCS.

Axial Versus Radicular Pain

Traditionally, patients with a radiating pattern of pain to the leg seem to respond better to SCS than patients with isolated axial low back pain.[23,25,26] Further, axial low back pain in combination with bilateral leg pain responds well to SCS.[27–29]

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS), previously known as reflex sympathetic dystrophy and causalgia, was first described by Mitchell in 1864.[30] CRPS I and II respond well to SCS with reported effectiveness ranging from 50 to 91%.[31–33] Typically, patients with upper or lower extremity pain are the best candidates. In a randomized trial by Kemler et al.[33] patients with CRPS who received SCS treatment and physical therapy had better improvement (56% success rate) than patients who received physical therapy alone. A 2-year follow-up in the same study confirmed the long-term benefits.[34]

It seems that a subgroup of patients with neuropathic pain (sympathetically dependent/maintained pain) respond better to SCS than patients with sympathetically independent pain. Recent study by Hord et al.[35] reports that patients with good response to sympathetic block before SCS are more likely to have a positive response during their SCS trial and long-term pain relief after placement of a permanent SCS device.[35] Therefore, the SCS is an excellent treatment option in carefully selected patients with CRPS. However, SCS should be combined with other treatment modalities in a multidisciplinary setting.

Diabetic Neuropathy

SCS is effective treatment for certain cases of diabetic neuropathy. It can provide pain relief and possibly help in salvaging the affected limb. Because of a higher infection risk, special precautions in patients with diabetic neurop-

athy should be used when SCS implantation is anticipated.[36] The patients with an increase in transcutaneous oxygen tension (TcpO$_2$) during SCS trial seem to respond better to SCS.[37]

POSTHERPETIC NEURALGIA

Although the scientific evidence on the efficacy of SCS for postherpetic neuralgia is scarce, a recent European study shows excellent outcomes with this modality.[38] To date, SCS treatment of postherpetic neuralgia is considered investigational in United States. Further randomized studies are needed to better establish a role for SCS in postherpetic neuralgia.

OTHER NEUROPATHIC PAIN STATES

Other neuropathic pain pathologies such as deafferentation pain (e.g., phantom-limb pain) and spinal cord injury do not seem to respond well to SCS, most likely due to a cortical reorganization in these painful conditions.

PERIPHERAL VASCULAR DISEASE

Peripheral vascular disease in nonsurgical candidates is currently one of the most common indications for SCS implantation in Europe. Several studies reported excellent pain relief with SCS in these patients, ranging from 60 to 100%. Besides providing pain relief, SCS may increase the peripheral blood flow, promote ulcer healing, and potentially contribute to limb salvage. Studies have shown that an increase in TcpO$_2$ during the first 2 weeks post-implantation predicts future limb salvage. Additionally, ischemic ulcers of less than 3 cm^2 are likely to heal with SCS treatment.[39–42]

CORONARY ARTERY DISEASE

Coronary artery disease with anginal pain responds well to SCS.[43] The best indication for SCS trial is angina refractory to pharmacologic and surgical treatments. Patients with ischemic heart disease treated with SCS demonstrated an increase in exercise capacity, reduction in anginal complaints, decreased use of short-acting nitrates, and improved quality of life. In 60% of the patients, SCS was effective 5 years after implantation and more than 80% patients benefited from SCS for at least 1 year.[44]

In a randomized trial setting, SCS proved advantageous to coronary artery bypass surgery in certain patients with severe angina pectoris.[45] More studies are needed to support this treatment modality for the use in anginal pain in United States.

The fear of potentially masking myocardial ischemia does not seem to be justified, as SCS does not completely abolish anginal pain, but only raises the anginal threshold. It is also important to point out that it does not seem to affect left ventricular ejection fraction or cardiac arrhythmias.[46]

CONTRAINDICATIONS

Severe psychiatric diseases present major contraindications for SCS implantation. Before SCS implantation, a psychological evaluation of the patient is recommended. One should use caution in SCS placement in patients with cervical and thoracic spinal canal stenosis. This applies in particular to dual-lead systems. Infection, drug abuse, and coagulopathies are also contraindications for SCS placement.

TECHNIQUE

STIMULATION TRIAL

A stimulation trial is warranted before proceeding with permanent SCS implantation. The percutaneous SCS trial is a minimally invasive procedure and can positively predict a long-term outcome in 50 to 70% of cases. The trial allows patients to evaluate the SCS analgesic activity in their everyday surroundings. The criteria for a successful trial include at least a 50% reduction in pain intensity, a decrease in analgesic intake, and significant functional improvement.

There is no consensus on technical approach and the length of an SCS trial. Minimal trial time should be 24 hours, although many centers perform 3- to 5-day trials. The initial inpatient trial allows for proper SCS adjustment after which the patient is discharged home for several days of "home" trial. In cases of equivocal results, the trial time can be extended.

There are two technical approaches for SCS trials. In the first approach, the SCS lead is placed percutaneously. Once the trial is completed, the lead is removed. At a later date, a new lead and internal pulse generator (IPG) are placed. The other approach is to tunnel and anchor the trial lead via surgical incision and to later internalize it for permanent SCS placement. This approach simplifies the final procedure and assures that stimulation coverage remains the same during both the trial period and permanent implantation. Its major disadvantage is the need for a second visit to the operating room for lead removal, in case of an unsuccessful trial. The advantage of a percutaneous trial is its minimal invasiveness, with similar low risk of complications as in routine epidural catheter placement.

The percutaneous trial followed by lead placement via laminectomy is another, less frequently used approach for SCS. In this case a lead with wider electrodes is placed via laminotomy during permanent implantation. Wider electrodes might provide better coverage in certain

FIGURE 74.1 Anteroposterior fluoroscopic view of the position of percutaneously placed SCS lead. The lead electrodes are positioned at T12–L1 level.

patients and are less prone to migration in comparison with standard SCS leads.[47]

IMPLANTATION TECHNIQUES

The patient is placed in prone position, with a pillow under the abdomen, to facilitate approach to the epidural space. Both trial and permanent implantation are performed under local anesthesia with light intravenous sedation. The most common entry sites for the lumbar area are the T12–L1 or L1–L2 spinal interspaces.

For the cervical area, the entry sites at T1–T2 or spinal levels in close proximity are recommended. Alternatively, the entry site can be in lumbar (T12–L1) area and a long SCS lead can be treaded up to the cervical levels.

True anteroposterior (AP) fluoroscopic images are obtained, making sure that the spinous processes are placed midline to the pedicles. The needle entry site is just lateral to the spinous process. The epidural space is identified by loss of resistance technique. It is recommended that the lateral fluoroscopic views be checked during needle insertion, in order to assess the needle depth. The SCS lead is inserted into the epidural space under continuous fluoroscopic guidance. The curved lead tip can facilitate desired lead positioning and treading (Figure 74.1). The goal is to position the lead midline to the spinous process or to its lateral margin if unilateral coverage is intended. This is verified with fluoroscopic image

in the AP view. A too-lateral position of SCS lead can cause SCS lead dislodgement to the lateral or even anterior epidural space and, consequently, inadequate coverage. It is noteworthy to mention that some cases of lumbar radiculopathy may require SCS lead placement directly through the neural foramina (retrograde lead placement).[48]

Once adequate lead position is obtained (Table 74.1), the trial stimulation is performed. It is important that stimulation paresthesias provide at least 70 to 80% overlap with the patient's pain location. At the end of the procedure, it is recommended that the lateral views be saved to assure epidural placement (Figure 74.2 and Figure 74.3).

The permanent stimulator placement technique is similar to the trial. While the trial is usually done in the pain clinic setting, permanent SCS placement is reserved for the operating room. Under local anesthesia and intravenous sedation, skin incision is made along the lumbar insertion site where the stimulator lead is placed and anchored to the skin. A separate subcutaneous pocket is made for a pulse generator in the gluteal or abdominal area. The SCS lead is then connected with the IPG through an extension cable tunneled through the skin. The skin and subcutaneous tissues are closed in layers.

Patients should avoid any extreme activity for the first 6 to 8 weeks following permanent SCS implantation to prevent lead migration and to allow for epidural scar tissue formation.

During trial and permanent lead implantation, care should be taken to obtain the best possible pain coverage ("sweet spot placement"). The SCS topographic coverage depends on the spinal level where the SCS lead tip is positioned. For low back pain and lower extremity pain the T8–10 levels are recommended; however, there is a high intersubject variation in these guidelines.

CLINICAL EFFECTIVENESS

There is substantial scientific evidence on the efficacy of SCS for treatment of low back and lower extremity pain of neuropathic nature. Clinical studies have revealed from 50 to 70% success rates with certain methods of SCS.[23,49–51] Those studies have shown decreased pain intensity scores, functional improvement, and decreased medication use with SCS treatment. The main drawback

TABLE 74.1
Recommended Anatomical SCS Lead Placement

Pain Location	Upper Extremity	Lower Extremity	Foot	Low Back	Chest	Pelvic Pain
Recommended SCS lead tip placement	C2–C5	T9–T10	T11–L1	T8–T10	T1–T3	S2–S4
FIGURE 74.2 Lateral fluoroscopic view of properly positioned SCS lead in thoracic area.

FIGURE 74.3 Cervical SCS lead in lateral fluoroscopic view.

of neurostimulation is a decrease in its effectiveness over time, as seen in 20 to 40% of patients. It seems that this "tolerance" to treatment is due to reorganization of CNS (CNS plasticity) that takes place in neuropathic pain states. Anecdotal evidence suggests that not using the SCS continuously (e.g., shutting it off overnight) may decrease the development of tolerance.

North et al.[24] reported that patients with FBSS respond better to SCS than to reoperation. According to the literature, the success rate of treating FBSS using SCS varies from 12 to 88%, with higher efficacy reported in recent studies.[27,52,53] A systematic review of literature by Turner et al.[54] revealed that an average of 59% of patients with FBSS treated with SCS had ≥50% pain relief. The average complication rate in the same study was 42% and was related to mainly minor complications. Besides pain relief, the SCS improves functional status in a significant number of patients, with a 25% return-to-work rate[27] and up to 61% improvement in activities of daily living.[55] Moreover, the reduced consumption of analgesics with SCS treatment varies from 40 to 84% in published reports.[50,56] It is critical to utilize an appropriate psychological screening test to appropriately select patients who might benefit from the procedure. Certain psychological tests have been shown to correlate with outcomes to SCS.[57]

Although SCS is an excellent treatment choice for patients with FBSS,[28,58] more studies are needed to further narrow the patient selection criteria and improve long-term success rates.

COST-EFFECTIVENESS AND OUTCOMES

If compared with the more conservative treatments, such as medical regimens and physical therapy, SCS may appear costly. However, the overall cost of SCS can actually be lower than conservative management costs, provided a good outcome is achieved. If taken together, the cost of medications, emergency room visits, multiple physician visits, radiological workups, and absence from work can easily surpass the cost of an SCS implant. Bell et al.[59] have shown that for those patients for whom SCS is clinically efficacious, the SCS pays for itself within 2.1 years.

COMPLICATIONS AND TROUBLESHOOTING

SCS complications can be divided into surgical complications and hardware complication. The most common surgical complication is infection. Wound hematoma and seroma are the other commonly encountered surgical complications. Turner et al.[54] performed a meta-analysis of SCS for FBSS publications and found the incidence of infection and other surgical complications to be 5 and 9%, respectively. The authors further report that hardware complications — lead migration, lead failure, and pulse generator failure — to be 7, 2, and 24%, respectively. As Turner et al.'s study analyzed publications that used old hardware systems, we speculate this incidence to be much lower with the current hardware system. Nevertheless, we see much lower complication rates with SCS in our institution.

Surgical Complications

Bleeding at the IPG site (subcutaneous hematoma) is usually self-limiting and gradually reabsorbs in a few weeks. Frequent observation of the hematoma is important because hematoma can lead to infection.

Antibiotic prophylaxis regimens for SCS vary. The minimal prophylaxis should consist of preoperative antibiotic coverage (Cefazolin 1 g intravenously). However, at many institutions prophylactic antibiotics are given up to 10 days post-implantation. Obtaining a complete blood count with differential and sedimentation rate is important to rule out infection. Although not proven advantageous, some centers obtain a urine specimen for culture 3 to 10 days before anticipated implantation.

Other clinical signs of infection are increased temperature and tenderness at incision site. Redness, swelling,

and discharge at insertion site can also occur. If infection occurs at the IPG insertion site, one should make sure to first aspirate the site for cultures before initiating antibiotic coverage and removing the hardware.

INADEQUATE COVERAGE OR SCS MALFUNCTION

In case of SCS malfunction, one should obtain AP and lateral fluoroscopic images of the SCS lead tip, IPG, and all connections to rule out lead migration, breakage, or disconnection. If the cause is not found by fluoroscopy, one should analyze the IPG using the programmer. The battery status and impedance of each electrode in relation to the IPG should be checked. Exactly the same impedance of two electrodes raises a possibility of a short circuit between the two electrodes, most commonly located at the connector or IPG site. Some mechanical failures might require surgical revision and replacement of affected SCS components.

DECREASE IN STIMULATION AMPLITUDE

The decreased stimulation threshold can be caused by intrathecal migration of the SCS lead. If migration stays unnoticed, it can lead to serious complications such as spinal cord injury. This complication seems to be most common in patients with significant spinal canal stenosis. If intrathecal migration is suspected, an MRI of the targeted spinal level should be obtained before anticipated SCS replacement.

PACEMAKERS AND SCS

The interference and inhibition of the cardiac pacemaker can be caused by SCS. However, SCS can be used in a patient with a preexisting pacemaker if certain precautions are taken: (1) both devices should be programmed in bipolar mode; (2) the SCS frequency should be set at 20 Hz; (3) SCS programming should be performed using continuous electrocardiographic monitoring; and (4) the manufacturer's recommendations should be strictly followed and the input of a cardiologist is recommended.

CONTROVERSIES

SINGLE- VERSUS DUAL-LEAD SYSTEM

Adequate relief of axial low back pain using SCS remains a challenge. It is not clear if SCS is indicated for isolated axial low back pain or only for axial low back pain combined with lower extremity pain. If the goal of SCS is to cover low back pain and bilateral lower extremity pain, single- or dual-lead systems can be considered. Using a dual-lead system can potentially provide "deeper" electrical field penetration in the dorsal column and therefore provide better axial low back pain coverage.[29,60] North et
FIGURE 74.4 AP fluoroscopic view of dual lead system in thoracic area.

al.[28,61] have shown that there is no advantage to using the dual over single lead for axial low back pain and that a failure rate is higher in dual electrodes. However, the dual system is justified when it is expected that separate programming of two leads is necessary (Figure 74.4).

FOUR VERSUS EIGHT ELECTRODE SYSTEM

Both four and eight electrodes were shown to be effective in treatment of low back and lower extremity pain with no apparent advantages of one system over the other. Eight electrodes may have the potential advantage in case of the lead migration but this has not been shown in clinical trials. Putatively, the increased number of electrodes may offer more combinations for stimulation coverage but its clinical significance is not clear.

INTERNAL VERSUS EXTERNAL POWER SOURCE

An internalized, fully implanted power source offers apparent advantages. It is more convenient for the patient to use, it is aesthetically more appealing, and it does not require frequent external battery changes.

However, in certain situations, the external power source can be indicated. This applies to all the cases where high amplitudes of stimulation are needed during the trial phase. In particular, the required stimulation amplitude should be monitored when dual-lead systems are used. Dual-lead systems tend to empty batteries faster than a single-lead system even at modest stimulation amplitudes. In case an internal power source is used, these patients may require frequent battery replacements.

PERCUTANEOUS VERSUS LAMINECTOMY APPROACH

Although both approaches can be used, percutaneous placement of the SCS lead is a less invasive procedure, minimizing immediate complications and requiring less operating room time. Because percutaneous electrodes are

placed under monitored anesthesia care, adequate SCS coverage can be confirmed during permanent implantation. This has advantage over the laminectomy approach, which is generally done under regional or general anesthesia, which makes it difficult if not impossible to confirm appropriate stimulation coverage.

Nevertheless, the laminectomy electrodes provide several advantages over percutaneously placed one[47]: (1) they are anchored to the dura and thus have minimal chance of migration[62–64] and (2) they are in closer contact with the dura, and thus they do not cause unnecessary posterior epidural space stimulation.

CONCLUSION

The SCS is an excellent treatment modality for carefully selected patients with low back and lower extremity pain. It may be a treatment of choice for patients with FBSS. The main advantages of SCS are its minimal invasiveness, reversibility, and excellent studies supporting its use. In carefully selected patients, SCS is cost-effective in comparison with the medical approaches. However, further studies are needed to better identify patient selection criteria for SCS.

Intrathecal Pumps

Timothy R. Deer, MD

INTRODUCTION

Pain persisting after the expected time for healing is defined as chronic pain. More than 40 million people in the United States suffer from chronic musculoskeletal pain. Chronic low back pain is a major public health problem in the United States, serving as the second most common cause of hospital admissions. Each year, approximately $25 billion is spent on direct medical costs for low back pain. When indirect costs, such as lost productivity and economic hardship, are included, the figure exceeds $100 billion annually.[1] After an initial presentation of spine-related pain, 80 to 90% of patients resolve within 6 weeks with conservative treatment. Unfortunately, a number of these patients will have relapses while others will never recover fully. This can lead to a prevalence of low back pain of 40% at 1 year after initial presentation. Chronic pain after cervical injury, or whiplash, occurs in up to 45% of patients 1 year after initial presentation.

This epidemic of chronic spine-related pain syndromes leads to more than 600,000 spine surgeries and over 2 million interventional pain procedures per year. The costs of caring for these patients exceed those of coronary disease, cancer, and AIDS.[2] In another large group of patients, osteoporosis leads to long-term sequelae, with as many as 700,000 patients per year suffering from debilitating compression fractures. Unfortunately, despite the growing number of surgeries, injections, and alternative modes of treatment, a number of patients fail in both noncancer and cancer disease states. The increasing prevalence of chronic pain is due to those with noncancer pain, along with as many as 75% of patients suffering with cancer pain. This has led to an increase in the use of oral opioids.

The increased use of opioids has resulted in a consensus statement from the American Pain Society and the American Academy of Pain Medicine regarding the appropriate use of oral and transdermal medications.[3] Unfortunately, even when using these guidelines, a large number of patients fail with opioids over time. The most common causes of failure are unacceptable side effects or lack of efficacy. This has led to a growing number of patients becoming candidates for intrathecal drug delivery. In the past decade, there has been a growing problem of drug diversion and opioid abuse. The spreading epidemic of opioid abuse has also led many physicians to offer intrathecal therapies earlier in the course of therapy to avoid escalating opioid doses. Despite continued debate, these factors have helped chronic intrathecal therapy for the treatment of persistent pain of noncancer origin to gain acceptance. The use of these systems in cancer pain has become the standard of care in patients with severe pain who do not do well with conventional medical therapy.

HISTORY AND GENERAL PRINCIPLES

The use of intrathecal drug delivery systems (IDDS) to administer morphine intrathecally for the treatment of chronic pain was introduced in the early 1980s.[4] An IDDS consists of two implantable components: an infusion pump and an intraspinal catheter. The pump is usually placed abdominally in a subcutaneous pocket, while the catheter is inserted into the intrathecal space of the spine, tunneled under the skin, and connected to the pump. The pump reservoir is filled with medication by inserting a needle through a septum in the pump. Medication is delivered through the catheter to the intrathecal space.

The development of chronically infusing drug delivery systems has been a point of controversy in the medical community for three decades. In the early 1980s pioneers such as Penn and Coombs initiated this therapy for the treatment of intractable spasticity related to cerebral palsy and spinal cord injuries. This therapy then evolved to use in unrelenting cancer pain. Several years ago, the Food and Drug Administration (FDA) approved the use of preservative-free baclofen and preservative-free morphine in intrathecal solution for the treatment of moderate to severe spasticity and moderate to severe pain, respectively. Krames and Lanning[5] noted that morphine alone was unacceptable in many patients because of side effects, allergies, and lack of clinical success. In the last 20 years, research has been performed on several other drugs including intrathecal bupivacaine, hydromorphone, clonidine, and fentanyl. This led others to search for new agents, some of which have been very helpful, and some of which have led to toxicity and bad outcomes. Since the initiation of such therapies, we have learned about neurotoxicity and adverse outcomes that have changed the practice of interventional pain medicine. The last few decades have also been significant for the advancement of technology for both pumps and catheters. Since the work of the pioneers, many papers have been written on the acceptable drugs and techniques for the use of intrathecal therapies. This chapter reviews the critical points that may result in optimal outcomes with this therapy.

PHYSIOLOGY

The theory behind intrathecal drug delivery is that by directly depositing drugs into the cerebral spinal fluid (CSF), we can avoid the first pass effect. For example, it has been estimated that intrathecal morphine is 300 times as effective as oral morphine for equipotent pain treatment.[6] By direct drug action, the number of central nervous system (CNS)–derived side effects can be reduced. The effect of spinal opioid administration may be more complex than simply the delivery route. Eisenach et al.[7] recently concluded that spinal opioids caused the release of adenosine in humans. This effect appears to be caused by local opioid receptor activation of an opioid-adenosine mechanism. Further research is needed into this area as to the action of adenosine in the spinal cord.

The mechanism of action of intrathecal-administered opioids appears to be at the spinal cord level as well as at receptors in the supraspinal region. The supraspinal effect may lead to side effects despite the relatively low dose of medication delivered as compared with other routes.[8]

DISEASE STATES

The use of intrathecal catheters attached to totally implantable pumps first came to clinical utilization for the treatment of spasticity. Implantation for pain soon followed. The initial pain-related disease state in which this therapy was used involved cancer-related syndromes. In a recent study, Smith et al.[9] showed a major improvement using intrathecal devices in cancer pain when compared with comprehensive medical management in the areas of fatigue, level of consciousness, and survival. Despite this evidence of efficacy, the use of intrathecal pumps for cancer pain has shown no recent increases in requests from oncologists. This lack of increase in use in patients with cancer has resulted in cancer becoming a secondary use of this device.

Other disease states have been found to respond well to this therapy. Spinal disorders result in chronic disabling pain in many patients. Spinal stenosis, radiculitis, compression fractures, spondylosis, spondylolisthesis, foraminal stenosis, arachnoiditis, syrinx, and ankylosing spondylitis are only a few of the debilitating conditions that can result in severe pain in the cervical, thoracic, or lumbar spine. Intrathecal drug delivery has been used in each of these disease states. In more severe syndromes such as spinal cord trauma, spinal infarction, paraplegia, and cauda equina syndrome, the use of intrathecal therapy may involve treatment of both pain and spasticity.

In addition to spinal disease, other conditions may be appropriate for this treatment. Peripheral neuropathy, phantom-limb pain, rheumatoid arthritis, radiation neuritis, postherpetic neuralgia, post-thoracotomy syndrome, interstitial cystitis, and chronic pain of the abdomen and pelvis have successfully been treated by intrathecal drug treatment.[10] The development of new drugs will expand the efficacy of the therapy and also expand the number of diseases that may be amenable to the therapy.

PATIENT SELECTION

Proper selection of patients for this therapy is more important than technique, trialing, or management. The presence of an intrathecal pump in a patient who is not a good candidate for the therapy is doomed to fail, even if all parameters of clinical practice are at the highest level. In choosing the proper patient for intrathecal drug delivery several essential questions must be answered:

- Does the patient have an acceptable physiological explanation for the pain syndrome? Does the diagnosis warrant aggressive pain treatment?
- Has the patient failed less invasive therapies? What were those therapies? Are they documented in the record? Does this include physical therapy and oral medications?
- Are less invasive therapies unacceptable, not desired, or contraindicated?

- Does the patient have a life expectancy of 3 months or longer? This criterion is required for both patients with cancer and patients without cancer.
- Do the symptoms of pain affect the ability to function?
- Has the patient been reasonably compliant with past treatment recommendations?
- Does the patient have a contraindication to pump placement? Examples may include untreated coagulopathy, bacteremia, or localized infection.
- Is the patient psychologically stable?
- Has the patient had a successful neuroaxial trial? The physician should document acceptable symptom relief, side effects, and overall patient acceptance.
- Does the patient have reasonable expectations?
- Does the patient accept the risks of the procedure and future drug therapies?

In general the patient should meet some or all of the noted criteria. In the event that a patient does not meet these criteria, but other therapies have been exhausted, a pump may be placed at the discretion of the physician. In these rare cases the physician should consider other options, the risk-to-benefit ratio, and the possibility of obtaining a second opinion prior to proceeding. As noted, if the patient meets the appropriate criteria, a trial should be performed prior to placing a permanent pump.[11]

PSYCHOLOGICAL ASSESSMENT

Prior to pump placement many physicians treating non-cancer pain obtain a consultation with a psychologist to help finalize the selection process. Psychologists use interviewing, MMPI testing, Beck inventories, IQ testing, EQ testing, and other measurement tools to form an opinion of the patient's mental status and stability. Outcomes have been shown to worsen with the presence of untreated depression, untreated anxiety disorders, and suicidal or homicidal ideation. Outcomes have also been seen to be negatively influenced by the presence of untreated drug addiction. The presence of these factors is not seen as an absolute contraindication, but the problems should be treated and stabilized prior to going to a permanent implant. The presence of a personality disorder diagnosed as borderline, antisocial, or multiple should be viewed with extreme caution, and only implanted with a intrathecal pump in rare cases.[12] Psychological clearance is not needed in the patient with cancer pain; however, many of these patients may benefit from counseling to better cope with the disease process.

PUMP TRIAL

A patient trial for potential pump placement can be performed in several different clinical settings. The clinician must decide on the method of a single bolus or continuous infusion. Other decisions include anatomical position of the trial. Options include intrathecal or epidural trialing. Other considerations include length of trial, site of service, and medication selection for trialing. Recently, an expert panel met to discuss recommendations for trialing for pump placement. The panel included 19 experienced implanters, with a broad diversity of geographic locations, practice type, and specialties. The expert panel agreed that there is strong theoretical justification for a trial that mimics the conditions that will be achieved by the implanted system as closely as possible. Relevant parameters include (1) delivery site (intrathecal vs. epidural; spinal level); (2) delivery modality (infusion vs. bolus); (3) rate of infusion; and (4) dose/concentration range. [13]

A recent multicenter prospective analysis compared trialing methods in patients selected for an intrathecal drug delivery system. Deer and colleagues[14] analyzed the results of patient outcomes based on initial trialing success and outcomes at 1 year based on functional analysis, pain scores, quality of life ratings, and patient satisfaction. In each center the physician used the trialing method of choice based on patient profiles, usual clinical practice specific to the trialing physician, and primary pain type. To estimate primary pain type, the physicians were asked to classify the pain as nociceptive, neuropathic, or mixed. Trialing methods were grouped into single-shot intrathecal, continuous intrathecal, or continuous epidural. In the final analysis at 12 months post-implant it was determined that there was no statistical difference in trialing method in outcomes with nociceptive pain. In trialing for neuropathic syndromes, the initial success of trialing was significantly better if a continuous method was used. There was no difference in outcome between trialing via the epidural route as compared with the intrathecal route. It was interesting to note that the primary difference in patients with successful trials in neuropathic and mixed pain syndromes was the use of more than one agent to improve the success of the trial.

Continuous catheter trialing may be performed by placement of an epidural or intrathecal catheter. The FDA has approved morphine for continuous intrathecal infusion. Because of the regulatory approval, morphine is often the initial drug of choice for patient trialing. For patients with burning or lancinating extremity pain, some physicians will add a local anesthetic or alpha receptor-acting drug to improve the chances of trial success. With patients who have side effects from morphine or fail to achieve relief at reasonable doses, the drug infusate may be rotated to an alternative opioid.

Trialing success should include three significant outcomes:

1. The patient should have significant pain relief.
2. The patient should have controllable side effects.
3. In noncancer pain the patient should achieve some objective functional improvement.

TECHNIQUES

Once a patient has been selected for intrathecal therapy and an acceptable trial has been performed, a permanent placement is scheduled. Prior to going to the operating suite, the patient should have appropriate preoperative assessment. Preoperative laboratory assessment should be consistent with the American Society of Anesthesiologists Criteria for the selected anesthetic based on the patient's age and health status. In relation to the proposed procedure, an evaluation of the white blood cell count and differential, hemoglobin, platelet count, and metabolic profile should be obtained. In patients with diabetes, the patient should be encouraged to maintain appropriate control of serum glucose in the weeks preceding the implant. A hemoglobin A1C may be helpful in assessing compliance. If any high risks of infection exist such as a history of poorly controlled diabetes, AIDS, cancer, Addison's disease, prolonged oral steroid use, or infectious skin conditions, an infectious disease consult should be considered in the preoperative period.[15]

Several decisions and steps that are critical for a successful pump implant program are discussed below.

Antibiotic Prophylaxis

In the past the use of prophylactic antibiotics has been controversial. Over time the use of prophylactic antibiotics has become the standard of care in most cases. Practices vary in the antibiotic choice with the most common a third-generation cephalosporin or vancomycin. Oral antibiotics are given during the course of the trial in most cases, and for 7 to 10 days after permanent implant. Acceptable choices include cephalosporins, penicillin derivatives, and quinolones. Intraoperatively, it may be helpful to irrigate the wound with antibiotic solution. The most common choices are bacitracin, a polypeptide, or an aminoglycoside such as kanamycin. Modifications to antibiotic choices should be made based on common pathogens seen in the institution and community.[16]

Prepping, Draping, and Positioning

Patients should undergo a vigorous prep that is outside of the margins of the planned surgical field. It is also helpful to use an adhesive drape to prevent migration of the sterile field with patient movement. Common prepping solutions include chlorhexidine, alcohol, and iodophor solutions. Positioning should include vigilance to pressure points and peripheral nerves. The patient may be positioned in the prone position for catheter placement, but this requires repositioning for pocket creation. In the majority of cases the patient is placed in the lateral decubitus position, with the hips flexed, and the knees bent.

Catheter Placement

Once the patient is prepared the fluoroscopic image is used to properly identify anatomy and pathology of the spine. In most cases the point of entry will be below the level of L2. In rare cases the entry point will be at the level of the cord. In the event that the entry point is above L2, the patient should be conversant, and the angle should be as shallow as possible. If the patient experiences paraesthesias, the needle should be removed and repositioned. Prior to starting the case the physician should have a planned level for the catheter placement. Once the catheter is in place, a purse-string suture should be placed to help secure the tissue around the catheter, and a silastic anchor should be used to secure the catheter. Two theories are common regarding the appropriate level of catheter placement. Some clinicians choose to place the catheter tip as close to the primary pain generator as possible. This type of placement allows for the delivery of a lipophilic drug in an effective manner. Others suggest that the benefit of direct catheter placement is outweighed by the recently described problem of inflammatory catheter mass. Currently, no studies give a clear answer to this debate, and the decision remains a matter of physician judgment and preferred practice.[17]

Pocket Placement

The most common location for pump placement is the lateral anterior abdominal wall at the level of the umbilicus. In deciding the appropriate place for incision, one should consider the location of the anterior superior iliac spine, the rib, and the patient's preferred belt line. Anatomical considerations such as the presence of an osteotomy should be considered in the planning. The pump should be anchored with either suture loops or a Dacron pouch to avoid flipping. Prior to placing the pump in the pocket, it should be prepared based on the manufacturer's recommendations, and filled with the appropriate drug based on the trial response.

Hemostasis and Skin Closure

Prior to wound closure, great care should be taken to assure that hemostasis has been achieved. After extensive antibiotic irrigation of the newly created pump pocket, the wound should be retracted to allow good visualization.

This will allow the recognition of small venous and arterial vessel bleeders. If bleeders are identified, an appropriate technique should be used to control bleeding; options include the following:

1. Simple pressure may alleviate bleeding.
2. Sponges soaked in hydrogen peroxide 3% solution may be packed into the wound for 3 to 5 minutes. This may be helpful with very small vessels.
3. Electrocautery can be used to control more aggressive bleeding. Care should be taken in the application of cautery to limit its use to the specific vessel. Overheating of tissue can create skin trauma or seroma formation. This can lead to delayed healing, dehiscence, or infection of the wound.
4. Suturing a vessel is still the "gold standard." Once the vessel has been clamped with a hemostat, a simple suture or "figure of eight" type suture using 00 or 000 absorbable material on a noncutting needle can be used to stay the bleeding. If space allows, a simple tie may be used. Another method for hemostasis would the use of metal ligature clips. Just prior to insertion of the pump, the wound should be irrigated again and reinspected for hemostasis. Once the pump has been inserted the subcutaneous tissue and skin must be closed over the pump. The pump should fit snugly in the pocket but still allow the skin edges to be brought together without tension. If this cannot be achieved, further tissue undermining may be required. The subcutaneous tissue should be brought together using a 00 or 000 monofilament absorbable suture. When closing the wound, care should be taken to obliterate any "dead space." This can be done with careful suture placement using an interrupted or running suture. The skin edges should be touching slightly, everted, and then closed with a monofilament non-absorbable material or metal skin clips (Figure 75.1).

A bulky sterile pressure dressing should be applied over the wound. An abdominal binder could be used for compression and support, which may reduce the risk of seroma and bleeding. The use of antibiotic ointment may be of some help in preventing infection. Dressing changes may be performed daily, or only if dressings are saturated. This is a physician judgment issue.

POSTOPERATIVE CARE

The patient is generally seen 7 to 10 days postoperatively. At this time stitches or staples can be removed and adhe-

FIGURE 75.1 Pocket closure

sive strips applied to support the wound. The time may be extended in those patients who are immunocompromised or have a nutritionally poor status. Any signs of wound breakdown or infection should be approached aggressively.

SURGICAL COMPLICATIONS AND MANAGEMENT

The most important aspect in the management of complications is early recognition of the problem and quick action to remediate the problem. Bleeding at the wound site will be fairly self-evident, manifested by swelling, discoloration, and erythema. Treatment may include ice and compression, but may require surgical exploration. Infection may be a minor, limited, superficial problem, or may lead to a loss of the device and significant sequelae. Infection may present as elevated body temperature, purulent wound drainage, erythema, or frank pus. Urgent action is required to incise and drain the wound, identify the pathogen, and initiate antibiotics (Figure 75.2, Figure 75.3). The decision to excise the pump is based on the presence of necrotic tissue, the overall condition of the wound, and the condition of the patient. The collection of non-infectious fluid is called a seroma. Treatment may be limited to pressure dressings and time for reabsorption. If conservative treatment fails, a sterile aspiration of fluid may be required (Figure 75.4, Figure 75.5). Another cause of fluid collection is a hygroma. This represents a collection of CSF. The most common cause of hygroma is fluid seepage around the catheter entry point to the pocket. The
FIGURE 75.2 Early wound.

FIGURE 75.4 Aspiration.

FIGURE 75.5 Effusion 2.

problem can be treated by abdominal pressure, increased fluids, and caffeine. In addition to the complications noted, two disastrous problems must be identified if present. These include epidural hematoma, which may result in paralysis. Any change in the neurological exam postoperatively should be viewed as an emergency and an MRI should be obtained as soon as possible to rule out spinal cord compression. The presence of an intrathecal pump is not a contraindication to MRI, and should not delay the

use of this imaging modality. The second serious complication is the presence of neuroaxial infection. This may include meningitis or epidural abscess. Both of these diagnoses must be made in an expedient fashion to allow initiation of the appropriate treatment.

MEDICATION SELECTION

The FDA has approved morphine as the drug of choice for chronic intrathecal infusion in the United States. A survey in 1999 involving physicians from North America, Europe, and Australia showed that physicians use many other drugs in patients with chronic cancer and noncancer pain.[18] Based on available world literature and the information obtained from the survey, a consensus panel of experts created an algorithm for intrathecal use. This algorithm suggested using morphine as a first-line drug, followed by hydromorphone in patients with side effects from morphine. In patients with no side effects, but lack of analgesia with morphine, a combination of morphine with bupivacaine or morphine with clonidine was suggested as second-line treatment. In patients failing those combinations, a third-line therapy involved the use of hydromorphone with bupivacaine or clonidine, the use of morphine with clonidine and bupivacaine, or the use of more potent lipophilic opioids such as fentanyl or sufentanil.[19] In an update of the consensus algorithm in 2003, the panel elevated hydromorphone to first-line therapy along with morphine. This decision was based on recent studies in laboratory models showing safety that may be better than morphine. In a study of chronic infusion in a sheep model, hydromorphone was not associated with inflammatory mass formation. This may suggest this drug is safer in humans, although more extensive research is needed.[19]

Local anesthetics are often added to opioids in patients experiencing burning or lancinating pain. The drug with the most experience in clinical use is bupivacaine. Clinical experience shows the drug is safe and shows efficacy when compared with opioid alone. The drug is most commonly used at doses of 1 to 20 mg per day (Deer et al., 2002).[20] Work in the laboratory shows that bupivacaine is stable, compatible, and safe when administered via an implantable delivery system.[21] Tetracaine has shown signs of neurotoxicity and has been discouraged for clinical use. Ropivacaine has now been used clinically, but data on this drug are limited and its use should be approached cautiously.[22]

In a landmark study, Staats and colleagues[23] found that ziconotide provided clinically and statistically significant analgesia in patients with pain from cancer and AIDS. Ziconotide, formerly called SNX-111, works by selectively blocking N-type voltage sensitive calcium channels. In theory, this drug may provide relief in patients who have failed or do not tolerate opioids. This drug, which is formed by modification of a snail toxin, shows the possibilities of future non-opioid drug devel-

opment. Presley and colleagues[24] conducted a double-blind, placebo-controlled trial that comprised 257 patients with noncancer pain, 78% of whom had neuropathic pain. Pain relief was assessed for 5 or 6 days in a blinded fashion, followed by an additional 5- to 6-day maintenance period. Significantly lower Visual Analog Scale of Pain Intensity (VASPI) scores (mean percent change in VASPI score from baseline to titration phase; $P = 0.0002$) were reported by 31% of the ziconotide-treated patients, compared with 6% of the placebo-treated patients. Moderate to complete pain relief was achieved in 43% of patients in the ziconotide arm versus 18% placebo ($P = 0.001$). Patients who received ziconotide reported improved mood, sleep, and enjoyment of life, and were able to decrease their use of opioid compared with patients receiving placebo (mean of >300 mg/day morphine equivalents by +24.3% vs. –5.3%).

Opioid research has been limited in chronic noncancer pain. In a retrospective analysis of 29 patients who received intraspinal drug therapy for pain, 8 patients received fentanyl 10.5 to 115 µg/day for a mean duration of 31 months. These patients experienced an average of 68.4% improvement in pain and an average overall satisfaction of 3.25 on a scale of 1 (poor) to 4 (excellent).[25] Another retrospective study ($n = 122$) reviewed the complications associated with implantable drug delivery systems, including two patients with the combination of fentanyl and bupivacaine combination. In this study the group was seen to have minimal complications with this combination. The efficacy was 74% in the group compared with fentanyl alone.[26] Three studies, two prospective ($n = 24$ and $n = 70$) and one retrospective ($n = 47$), were performed to evaluate the use of methadone in neuroaxial infusion. The surveys involved both patients with cancer and patients without cancer; methadone was administered at total daily doses of 5 to 60 mg, and duration of treatment ranged from 3 days to 37 months. Overall effectiveness, based on greater than 50% reduction in pain only or pain reduction combined with improved quality of life survey scores ranged from 37.5 to 80%. Transient blurred vision was noted as an adverse event in one patient.[27–29]

Deer et al.[30] recently reviewed the use of intrathecal bupivacaine with and without opioids. They note that stability, bacteriologic studies, toxicology data, and clinical reports of infrequent complications support the safety of this regimen. Intrathecal bupivacaine, a clinically effective combination partner, was also noted to be more efficacious than epidural administration. The authors conclude that intrathecal bupivacaine is a safe and efficacious treatment for malignant/nonmalignant pain. They suggest that the data warranted further studies of compatibility with combination partners, and outcome analyses based on the source and mechanism of pain.

Hassenbusch et al.[31] report a 20-month prospective Phase I/II cohort study of 31 patients (6 with cancer pain, 25 with nonmalignant pain) who received intrathecal clonidine at a total daily dose of 144 to 1,200 µg/day (mean 872 µg/day). In the study, 22 patients (achieving >50% pain/symptom reduction without intolerable side-effects) who progressed through the dose escalation stage were evaluated. At 6 months, 77.3% (17/22) of this cohort achieved continued good pain relief, and 59% of the cohort (42% of the accrued study population) were considered long-term successes (mean follow-up 16.7 months). Consistently, clonidine dose did not change significantly over time in this group. Moreover, there was no change in patients' Karnofsky performance status. Inability to achieve long-term pain relief was related to inadequate pain relief ($n = 4$) and intolerable side effects (hypotension, $n = 2$; impotence, lethargy, and malaise, 1 each).[31]

A retrospective survey observed that only 2 of the 10 patients treated with clonidine alone (75 to 950 µg/day) had good pain relief after 7 to 11 months of intrathecal therapy. The addition of clonidine (75 to 950 µg/day) to either morphine 0.15 to 15 mg/day (5 patients) or hydromorphone 200 to 800 µg/day (10 patients) similarly yielded very limited effect; only 3 of these patients achieved long-term pain relief (7 to 11 months). Adverse events reported by Ackerman et al. include hypotension (5 patients), catheter complications (1 patient), sedation (3 patients), confusion (1 patient), constipation (1 patient), nausea (2 patients), pruritus (2 patients), and catheter-tip granuloma (1 patient). It is unclear whether the adverse events in this and other prospective studies were related to clonidine or opioid administration.[32]

In a prospective cohort study, Uhle et al.[33] report data from 10 patients with neuropathic pain syndromes (2 of whom had cancer pain) who received clonidine (average, 44 µg/day) in combination with morphine sulfate or buprenorphine. These patients realized a 70 to 100% reduction in pain. Four of eight patients with non-neuropathic pain also appeared to benefit from the addition of clonidine. The frequency of adverse events was hypotension (10 patients), fatigue (4 patients), dry mouth (3 patients), and impaired bowel (1 patient). Studies have shown that clonidine is stable in combination with morphine and when infused in intrathecal pumps over 90 days. Clonidine has also been shown to be stable at 90 days with bupivacaine and morphine. In animal studies there has been no evidence of neurotoxicity in preservative free midazolam. Continuous infusions in sheep and pigs have shown no changes in mental status or toxicity. In the sheep studies, the pain thresholds were improved and the overall ability to tolerate painful stimulus was improved.[34]

CLINICAL MANAGEMENT

The chronic successful management of intrathecal delivery systems requires a group of professionals working as a team with a compliant, motivated patient. The team

FIGURE 75.6 Continuous flow pump.

should include a physician leader who prescribes the therapy and makes clinical decisions based on patient response and side effects. Other members of the team should include nursing personnel, well educated in patient assessment and pump management; a pharmacist who is familiar with appropriate drug preparation and dosing; and support staff who assure proper materials are present for the refill. Refills should be performed by the physician or team member with appropriate training in refilling and, when appropriate, reprogramming the pump.

PUMP AND CATHETER TYPE

Pumps are of two basic types. In the constant-flow pump a pressurized, hydraulic mechanism drives the flow of drug into the catheter (Figure 75.6). In this type of pump there is no internal battery. The downside of a constant-flow pump is the inability to program the pump for bolus dosing and daily infusion variable doses, and the inability to obtain a history of infusion or reservoir volume.

In the programmable pump, an internal battery is used to drive a rotor to deliver drug to the catheter (Figure 75.7). In this type of pump the battery must be replaced over time. The advantage of this type of pump is the ability to rapidly change dose and boluses, and to track reservoir volume.

The catheter type selected is important in reducing the complications rate of the catheter. Catheters vary on the number of exit points at the end of the catheter. Catheters

FIGURE 75.7 Programmable pump.

also vary in the internal structure. Options include silastic materials or wire-reinforced catheters. The wire reinforcement theoretically limits the complications of catheter fracture and kinking.[35]

COMPLICATIONS

A large retrospective study involving 429 patients showed a high complication rate. In this report by Paice and colleagues,[36] 21.6% of patients show system malfunction. The most common reason for this problem was catheter related, including catheter kinking and fracture (Figure 75.8 and Figure 75.9). In a limited study of cancer patients Commbs and colleagues[37] report no complications, such as infection, catheter problems, or respiratory depression, in a very early study of a limited number of patients
FIGURE 75.8 Catheter kinking.
FIGURE 75.9 Catheter fracture.
FIGURE 75.10 Lateral of Fx.

receiving intrathecal therapies for cancer pain. There have been reports of migration of a catheter into the subdural space causing drug withdrawal. This diagnosis should be considered with cases of acute catheter failure. The diagnosis is made by catheter injection with post-injection computed tomography (CT) scanning.[38] As noted, the number of complications with catheters with wire reinforcement has been reported to be less than 1% over the life of the implant. This design avoids the risk of kinking and is more resistant to fracture (Figure 75.10).

Hormonal changes have been reported with long-term opioid use regardless of the route of delivery. Naturally occurring opioids diminish testosterone levels at both the central and end organ locations. The use of long-term sustained-release oral opioids has been shown to contribute to subnormal sex hormone levels.[39] Willis and Doleys[40] studied several patients receiving long-term opioids by intrathecal infusion for at least 1-year duration. In this group several patients experienced hypogonadism and fatigue related to clinically proven decreased testosterone. Many have hypothesized that there may be an effect on other hormonal systems as well, and more studies are needed to determine the extent of this problem.

Recently, another complication issue has led to a great deal of discussion in the pain management community: inflammatory mass or granuloma (Figure 75.11, Figure 75.12). This complication results from buildup of inflammatory material at the tip of the catheter. This condition leads to a compressive disorder that causes complications ranging from asymptomatic patients to catastrophic neurological sequelae. Coffey and Burchiel[41] analyzed 41 cases of inflammatory mass lesions in intrathecal drug infusion catheters. Their conclusions were that those requiring high-dose intraspinal opioids should be monitored closely for signs of this problem. They also concluded that early recognition may lead to prevention of neurological damage. Both physi-
FIGURE 75.11 Large thoracic.

FIGURE 75.12 Lateral of granuloma.

cians served on a consensus panel that made recommendations on the cause, prevention, diagnosis, and management of inflammatory mass.[17]

The true incidence of inflammatory mass in clinical practice is unknown. Coffey and Burchiel mention clusters of reports in their analysis. McMillan and colleagues[42] report a significant percentage in their practice. They report three of seven patients with confirmed inflammatory masses on diagnostic imaging. In one of these patients, left lower-extremity paralysis developed. The other two patients were treated conservatively with no complications. Deer[43] recently reported a much lower incidence in his group with only 3% of patients having inflammatory mass by diagnostic imaging. In this study, 208 consecutive patients underwent MRI or CT myelogram. In the cases that were recognized, no patients had any long-term sequelae.

The etiology of granuloma has been reviewed extensively. Based on work by Yaksh et al.,[44,45] the appearance of granulomas suggests an inflammatory reaction to an opioid. The mechanism may be related to a mitogen-activated protein kinase cascade that causes increased lymphocyte activity. This inflammatory reaction appears to dissipate once the offending opioid is removed. Some have suggested an allergy to silicone, but the absence of these lesions in patients receiving baclofen for spasticity argues against that thought.

It has been postulated that granulomas are a response to impurities in pharmacy-compounded medications; however, granulomas have been seen just as frequently in commercially purchased preparations.[41] Granulomas have been reported most commonly with morphine. Other drugs have also been implicated in causing this complication including hydromorphone, fentanyl, and ziconotide.[41,43] Clonidine has been theorized to have a protective effect in humans, although this has not been shown in any clinical study to date. Walker et al.,[46] who routinely combine clonidine with opioid, have reported no granulomas in Australia. Yaksh et al.[45] has shown a protective effect of clonidine in the dog model. More data are needed on the prophylactic effect of clonidine.

Admixtures of opioid with clonidine and/or bupivacaine have led to dose reduction in the opioid. Dosage reduction allows for lower concentrations of drug (because higher doses must be concentrated to allow for a reasonable period of time between refills). Indeed, not only is the drug that is infused thought to be important in the formation of granuloma, but also the concentration of drug. With morphine, the majority of cases have been described in patients receiving concentrations of 40 mg/cc or greater.

The same concentration-effect has been reported with hydromorphone; the majority of described cases received concentrations of 10 mg/cc or greater. Despite this increased incidence in patients with higher concentrations of drug, there are reported cases at markedly lower concentrations of morphine and hydromorphone. These granulomas, seen at low concentrations, suggest the need for vigilance in all patients.[47]

It is often noted that granuloma formation is more common in catheters with a single exit site. Catheters with single orifices allow for a high concentration of drug to settle at one point in the CSF. The theory suggests that the concentration gradient leads to an inflammatory reaction. New catheters with multiple drug exit sites may be safer. However, the issue has not yet been addressed in a randomized study. Indeed, because time is required for granulomas to become clinically significant, the possibility exists that the majority of granulomas have been noted with single-orifice catheters because these catheters have been in use the longest. If this is true, problems may become evident with multiple exit catheters in the future.[48]

The most controversial area in the etiology of granulomas involves the issue of catheter placement. The majority of granulomas have been reported in the area of the thoracic spine. This has led many to conclude that catheters should be placed in the lumbar or cervical region avoiding the site of most granuloma formation. The science behind this thought process involves the fact that CSF volume and flow in the region of the thoracic cord are relatively reduced, compared with other parts of the spinal cord. The ventral thoracic subarachnoid space has the longest region of low CSF flow within the entire intrathecal compartment.[49] This stagnation of flow has been postulated to cause higher concentrations of drug. The confounding issue in the catheter placement debate is the number of catheters placed in that region compared with the lumbar and cervical spine. For technical reasons, the number of current indwelling catheters is higher in the thoracic spine as compared with other regions. Therefore, it is difficult to be sure whether concentration effects explain the high number of granulomas seen in the thoracic spine.[17]

The possibility that granulomas result from a low-grade infection has also been considered. In animal studies, analysis of cytology and cultures shows no evidence of infection. The same can be said of tissue samples and catheter analysis in postoperative patients with granulomas. Many cultures have been performed in these patients and have been negative. Based on this information, it appears that infection does not play a role in the formation of granuloma.[17]

A retrospective cohort analysis of 23 patients with leg edema associated with long-term (greater than 24 months) administration of intrathecal morphine found an association between edema during neuroaxial infusion and the presence of leg edema and venous stasis prior to pump implantation; a dose–effect relationship for leg edema was suggested by these observations. The etiology of this leg edema has been theorized to arise from an effect on the pituitary. Opioids may have an effect on antidiuretic hormone, causing edema. Further research is needed to examine this issue.[50]

OUTCOMES

Outcomes in patients suffering from severe pain secondary to cancer have been very positive by physician report. Most studies have been retrospective or based on case reports. Smith and colleagues[9] report a multicenter, international, randomized, prospective study comparing intrathecal drug delivery versus comprehensive medical management. In this study the patients were randomized to the intent-to-treat group and then underwent a trial for intrathecal pump placement. The trials were performed based on the physician's normal technique. At 4 weeks after the enrollment of the patient, the data were analyzed based on the initial enrollment group. The results showed a clinically significant advantage of intrathecal pumps in overall toxicity (based on national cancer toxicity criteria), pain relief, fatigue, and level of consciousness. Perhaps the most impressive finding was a trend toward improved survival in the pump group ($P = 0.06$). This study suggests more patients with moderate to severe cancer pain should be considered for intrathecal drug delivery. In a large retrospective study involving both cancer (32.7%), and noncancer (67.3%) pain, a mean pain reduction of 61% was seen in both groups. In those patients with neuropathic pain, improved efficacy was reported when using drugs such as clonidine or bupivacaine. Minimal long-term adverse drug events occurred in this group.[36] One of the earliest outcome studies presented a negative impression of intrathecal infusions in patients with cancer. In this study, Commbs and colleagues[37] found in a small group of 14 patients that there was no difference in patients receiving intrathecal morphine when compared with other routes of delivery.

De Lissovoy and colleagues[51] found a positive outcome in cost-effectiveness. An analytic study with computer simulation was used to project outcomes in a group of patients with failed back surgery syndrome. In this model, a patient receiving intrathecal therapy would be cost-effective to society at 12 to 22 months when compared with alternative methods of treatment. It should be noted that in a more care-intensive patient such as an end-of-life cancer patient, Bedder et al.[52] have shown cost-effectiveness at 3 months when compared with epidural home infusion. Kumar et al.[53] published their analysis comparing conventional pain therapy with intrathecal drug delivery. In this 5-year study, the data were collected regarding function, hardware costs, professional fees, diagnostic imaging, nursing visits, hospitalization costs, and alternative medicines. The conclusion of this study was a cost-effectiveness of intrathecal therapies at 28 months. This is even more impressive when considering that the intrathecal therapy patients had improved function when compared with conventional treatment using the Oswestry Disability Index. The National Outcomes Registry for Low Back Pain has collected prospective data on outcomes for 136 patients with chronic low back pain who received neuroaxial infusion via implanted devices (morphine in 81% of patients). Patients were entered into the registry by a group of participating clinicians. Pain and function ratings were measured by the visual analogue scale and Oswestry Low Back Pain Disability Scale, respectively. Impressively, at the 12-month follow-up period both indices improved by more than 47% for patients with back pain and by more than 31% for those with leg pain.[14]

Willis and Doleys[40] in a retrospective evaluation of 29 consecutive patients with a follow-up duration of 31 months report an average 63% improvement in pain, 46% improvement in activity level, and 54% improvement in ease of performing activities. Paice et al.[36] also showed 61% relief in a large, retrospective, multicenter survey. In other studies, Tutak and Doleys[54] report a good or excellent outcome in 78% of the patients, and Krames and Lanning[5] report good or excellent outcome in 81% of patients. Other drugs also have been used for pain treatment in implantable systems. Van Hilten et al.[55] studied intrathecal baclofen for the treatment of painful dystonia in patients with reflex sympathetic dystrophy. They performed a double-blind, randomized, controlled, crossover of bolus intrathecal injections of 25, 50, and 75 mg of baclofen as well as placebo. The results showed that in six women, bolus injections of 50 and 75 mg of baclofen resulted in complete or partial resolution of focal dystonia of the hands but little improvement in dystonia of the legs. In chronic infusions, two of the patients with lower extremity dystonia improved. The conclusions made were that painful dystonia can be improved by intrathecal baclofen. This study, a double-blind, placebo-controlled

study, is limited based on the low number of patients enrolled for analysis.

Unfortunately, despite numerous studies of existing and novel drugs, outcome data pertaining to long-term neuroaxial infusion are limited. An algorithmic process to choose drugs based on clinical and animal studies must be a critical part of patient decision making. As new drugs are developed for intrathecal use, the medical community must continue to take a critical look at safety, efficacy, and indications.

COMPOUNDING

Infumorph® (preservative-free morphine sulfate sterile solution/Elkins-Sinn) is the only drug currently approved by the U.S. FDA for the intrathecal treatment of pain. In up to 65% of patients, morphine alone will fail to provide appropriate relief because of side effects, dose escalation, and failure of safe concentrated drugs to provide a reasonable length of time between device refills. This has led clinicians to use off-label drugs to treat patient's long term. Unfortunately, most commercially available drugs labeled for other uses are not acceptable for human use. The drugs are unacceptable because of the presence of preservatives, excipients, or unacceptable solubility at body temperature. It is important to note that drugs labeled as "preservative-free" may still be neurotoxic because of excipients or pH buffers. Another issue is the compatibility of drugs with intrathecal devices. Several drugs including dopamine, mitomycin C, cyclosporin A, apomorphine, meperidine, octreotide pH 4.11, interleukin II with 25 mg human serum albumin (HAS)/ml, and diamorphine have been reported to be incompatible with, and cause malfunction of, the SynchroMed Infusion System (Medtronic Neurological, Minneapolis, MN).

In an era in which the cost of drug development is high and the use of intrathecal drug infusions is challenged because of financial restraints, many pharmaceutical companies are unwilling to spend large amounts of revenue on this patient group. Because of the lack of acceptable drugs, drug compounding has become common practice in patients requiring polyanalgesia.

Drug compounding is defined as the mixing of ingredients to prepare a medication for patient use. Compounding is a complicated practice that requires vigilance with sterile technique and attention to drug solubility and drug compatibility. Incorrectly prepared products can lead to nerve injury, paralysis, and death when administered into the CNS.

The U.S. Pharmacopoeia and the American Society of Health-System Pharmacists have issued guidelines on compounded sterile products that have practical and legal significance. These guidelines apply to the compounding of solutions for neuroaxial drug delivery.[44,56,57] When a compounding pharmacy is chosen, it is important for patient safety that it comply with these guidelines.

FUTURE ADVANCES

Advances in intrathecal drug delivery will occur on many fronts. Developments in new drugs, devices, and catheters must occur for this therapy to gain wider acceptance. For new drugs to be considered they must be put through stringent evaluations. Recommendations include drug formulation, chemical stability/compatibility, pharmacokinetics, and toxicology during the development and approval phase.[58]

Current research on new drugs is promising. Tizanidine and gabapentin are two drugs of interest. In a dog model by Kroin et al.,[59] a comparison of tizanidine and clonidine at doses of 3.0 to 18.0 mg/day yielded equivalent analgesia on a thermal withdrawal test but greater toxicity hypotension, bradycardia, and bradyarrhythmias from the clonidine. An additional tizanidine toxicity study with 3 to 6 mg/day in dogs found no significant side effects (neurotoxicity, body weight, temperature, respiratory rate, heart rate, sedation, or motor coordination) or histopathologic effects (spinal cord gray and white matter).

The analgesic efficacy of intrathecal gabapentin has been evaluated in rodent models. Administered by bolus intrathecal injection (100 to 1000 μg), gabapentin reduced mechanical allodynia, neuropathic pain, and hyperalgesia in rats and chronic allodynia in mice. Gabapentin had no effect on acute nociceptive pain as assessed using the Phase I formalin test in rats or the hot-plate test in mice. In these rodent studies, the potency of gabapentin was markedly higher (greater than 10-fold) when the drug was administered intrathecally as compared with other routes of administration. Intrathecal administration yielded no effect on hemodynamics, but produced mild neurological toxicity at doses greater than 300 μg.[60-62]

The work on gabapentin is exciting when viewed in terms of a single agent; however, new data suggest it may act synergistically when administered with clonidine and agents acting at the NMDA receptor. In rat models, using a ligature model of neuropathic pain, the use of the drugs concomitantly was significantly better than either drug alone, or the additive effect of the drugs independently.[63]

Other exciting work is ongoing with hormonal therapies. Deer et al.[64] recently completed a double-blind, randomized study of intrathecal octreotide for the treatment of chronic pain. In the final analysis, the overall improvement versus placebo was not statistically significant. However, when the subset of patients with neuropathic pain was analyzed separately, a statistically significant improvement was seen. Other drugs that are currently undergoing clinical studies include aspirin, neostigmine, adenosine, methadone, Demerol, and NMDA antagonist.

CONCLUSIONS

The decision for a physician or practice to add intrathecal therapies should be approached with a great deal of thought. Once that decision has been made, a commitment must be made by the entire team. This includes physicians, nurses, support staff, and pharmacists. With proper use of intrathecal therapies, many patients who have no hope for improvement may receive treatment that significantly enhances quality of life. It is imperative that advances continue with intrathecal drugs, devices, and outcome measures.

Acupuncture and Traditional Chinese Medicine

James E. Williams, OMD, LAc, AP, FAAIM

INTRODUCTION

Chronic pain is one of the fastest growing health problems in the United States with an estimated one third of Americans suffering from pain at an annual cost of $80 billion to $100 billion (Eshkevari, 2003). It is also one of the most challenging conditions clinicians face and the most common reason patients seek alternative care. Acupuncture, of all alternative therapies, has considerable potential in the treatment and management of chronic pain. Much of the evidence on acupuncture is relevant and convincing, and suggests that in some cases it may be useful on its own while in others it may be part of an integrative approach to pain management. The integrative model may offer the most potential benefit to the patient. This chapter reviews and summarizes the scientific basis and clinical evidence for acupuncture and related traditional Chinese medicine modalities in the treatment and management of chronic and acute pain. It also discusses safety and the most common therapeutic course for conditions treatable by these therapies.

ACUPUNCTURE

Acupuncture and traditional Chinese medicine (TCM), the use of Chinese herbal medicines to treat disease and promote health, are collectively referred to as Oriental medicine (OM) and sometimes as East Asian medicine. With a history of several thousand years, OM is still widely practiced in Asia and has gained acceptance in Western countries. In fact, since the 1950s acupuncture has evolved

rapidly as a modern therapy. First in China and Japan, followed by other Asian countries, Europe, and lately North America, acupuncture is gaining the respect of both the public and medical sectors. Interest in TCM followed in the mid-1980s, stimulating a surge of basic research in antiviral compounds, immunomodulating compounds for cancer, and adaptogenic compounds for neuroendocrine regulation, as well as anti-inflammatory and analgesic compounds for pain.

In the United States, acupuncture caught the public imagination in 1971 when James Reston, a reporter for the *New York Times*, published an article about his experience in China. In 1973, the U.S. Food and Drug Administration (FDA) classified acupuncture needles as experimental medical devices. Acupuncture needles were reclassified as "safe and effective" in 1995. In 1997, the National Institutes of Health published a consensus statement, the *NIH Consensus Development Conference on Acupuncture*, reporting favorable findings for the use of acupuncture in a select number of conditions. With such achievements, it is understandable that between 1992 and 1998 the demand for acupuncturists nearly doubled, climbing from 5,525 to 10,512.

At present in the United States, roughly 3,500 physicians and 12,000 licensed acupuncturists use this medical specialty for the treatment of a wide range of illnesses including chronic pain. Currently, 50 acupuncture and OM schools train nonphysicians, and about 500 to 600 physicians train yearly to American Acupuncture Medical Association standards (Erickson, 2003). Costs for acupuncture treatments vary according to locale, specialization, and

experience of practitioners with an average range from $40 to $75 per visit. Workers' compensation and insurance fee schedules vary from state to state, but apply for those covered. However, most patients pay for acupuncture out-of-pocket.

Although now practiced worldwide, acupuncture has its roots in Chinese cosmology and philosophy. In this model, the universe is an orderly series of ever-changing cycles and events. Human biology is looked on as a reflection of the natural environment. For example, blood vessels are like rivers and fever or inflammation is likened to fire. Animating both the human and natural worlds is the non-Western concept of *qi*, an invisible but palpable energy pervading the body that flows in specialized networks or meridian systems and that is concentrated at specific sites along the course of those meridians — the acupuncture points (acupoints). Although *qi* and the meridians have defied scientific proof of their existence, they remain the central paradigm by which acupuncture is understood and practiced.

For now, most researchers leave the question of whether *qi* is real to philosophers and newly founded specialized fields such as human bioenergy, turning their attention to investigating the underlying neurophysiology of how acupuncture works. Practitioners are equally affected by a similar quandary as researchers: are *qi* and traditional theory necessary to achieve clinical success or can acupuncture be just as effective when performed as a medical technique based on neurophysiology or other Western methodology? Some acupuncturists base their practice on traditional Chinese medical philosophy; others combine points based on protocols matched to specific diseases; and some practitioners have suggested models integrating both Eastern and Western medical paradigms. Such modernized systems only utilize traditional acupuncture theory to the extent of selection of optimal therapeutic sites for the placement of needles, electrical stimulating devices, point injections, laser, or microcurrent stimulation.

Needle Mechanics

Traditionally, needle insertion is thought to stimulate and regulate the quality and flow of *qi*, described specifically in the acupuncture literature as *de qi* or needle sensation resulting in a particular numbing response that is associated with greater therapeutic effect. Because of the extreme thinness of acupuncture needles, specialized manual skill is required to insert it without bending. In some cases, an insertion tube made of stainless or plastic is used to keep the needle from flexing during initial insertion.

Once inserted, each needle is manually manipulated or electrically stimulated to maximize the needle sensation. Concurrent with needle insertion and manipulation, patients frequently report sensations in other areas of their body distant from the needle insertion site, which are known to correspond to meridians.

Scientific studies, on the other hand, contend that needle insertion has a wide range of neurochemical, immunological, and neurobiological effects. For example, inserting an acupuncture needle into normal tissue causes cellular disruption and corresponding immunological reactions. The multiple "mini-wounds" caused by needle insertion stimulate the release of growth factors such as platelet-derived growth factor, which induces DNA response and in turn promotes cell and tissue repair through increased protein synthesis (Filshie & White, 1998).

In the United States, acupuncturists favor pre-sterilized disposal needles in gauges between 0.12 and 0.30 mm in lengths from 15.0 to 60.0 mm. Depending on the area of the body treated and the technique employed, insertion depths range from 1 to 2 mm up to several centimeters, with an average depth of 14 mm. The number of needles used per treatment varies ranging from 2 to 12 on average.

Scientific Basis

Of all complementary and alternative therapies, acupuncture is the most researched, particularly for its use for pain management. Since 1976 numerous scientific studies have investigated the effects and possible mechanisms of acupuncture analgesia (AA) with a critical mass of acupuncture research accumulated between 1976 and 1988. By 2004, PubMed listings for acupuncture research included 8,916 papers of which 2,292 were related to pain. Bruce Pomeranz, a leader in acupuncture research, published more than 100 papers on AA. Other prominent researchers include Lixing Lao, Richard Hammerschlag, Jeanette Ezzo, Adrian White, Edzard Ernst, and Zang Hee Cho. In addition, research centers in China, Japan, South Korea, Hong Kong, Taiwan, and Singapore continue to contribute substantial information, as do centers in Germany and other European countries. Unfortunately, most of the results of this research is unavailable in English.

Basic Mechanisms

Chronic pain is thought to be the outcome of one or more causes: (1) ongoing nociception as from an unhealed fracture, a torn ligament, or chronic inflammation; (2) psychogenic factors without a known physiological basis; (3) stress-induced abnormal regulation of the hypothalamic-pituitary-adrenal axis; and (4) functional disturbances in the nervous system causing hypersensitivity without nociception as with sympathetically mediated pain. Acupuncture and related modalities, particularly electrostimulation, have the ability to regulate all four of these causes.

Acupuncture needling and electrical stimulation to acupuncture points have been shown to affect nociceptive,

proprioceptive, and autonomic nerve pathways. Both needle acupuncture and electroacupuncture (EA) increase enkephalin and dynorphin in the spine and mid-brain, and raise endorphins in the pituitary–hypothalamus complex. The flow of enkephalins in mid-brain stimulates the release of monoamines, serotonin, and norepinephrine in the spine. It is theorized that these substances are responsible for the inhibition of pain. As early as 1979, Han et al. found that serotonin turnover is increased with acupuncture, and conversely, when serotonin is depleted, the acupuncture analgesic effect is reduced (Han, Chou, Lu, Lu, Yang, & Jen, 1979). According to this hypothesis, needle stimulus acts to restore neurotransmitter chemical balance and thereby neutralizes pain initiated by a painful stimulus (Pomeranz, 2001).

Inflammatory mediators may also be involved in AA. Endorphins inhibit substance P, a short-chain polypeptide that functions as a neurotransmitter involved in pain and inflammation. Neuropeptides, such as substance P, are involved in the production of cytokines such as tumor necrosis factor-alpha, interleukin 1-beta, interleukin 2, and interleukin 6. These cytokines along with substance P are involved in the inflammatory cascade and influence the rate of wound healing (Delgado, McManus, & Chambers, 2003). The anti-inflammatory actions of acupuncture are linked to the complex interactions between substance P and beta-endorphin, which may influence the balance between proinflammatory and anti-inflammatory activity (Zijlstra, van den Berg-de Lange, Huygen, & Klein, 2003). EA has been shown to influence substance P in the dorsal vagal complex in rat models (Liu et al., 2004).

NEWER MODELS: GENE EXPRESSION

Part of the long-term effect of acupuncture beyond opioid changes may lie in gene expression. Several studies demonstrate that levels of c-Fos, a gene that produces a protein, which functions in the control of the transcription of DNA to mRNA, increase in affected brain areas following acupuncture. Usually the amount of c-Fos in cells is low until the cell is stimulated by a stressor. c-Fos is useful as a marker for increased cellular activity and has been studied in the expression of GABAergic and serotonergic activity in the brainstem and spinal cord (Maloney, Mainville, & Jones, 2000). In animal studies, acupuncture has shown to increase c-Fos expression in the hypothalamus (Medeiros, Canteras, Suchecki, & Mello, 2003), hippocampus (Kang et al., 2003), spinal cord (Kim et al., 2003), and pituitary gland (Pan, Castro-Lopes, & Coimbra, 1996). However, in a paper by Jiang et al., EA was found to inhibit c-Fos expression during brain injury (Jiang, Zhao, Shui, & Xia, 2004). As with many research models of acupuncture, it is possible that a regulatory effect may eventually be found in which acupuncture acts as both an agonist and antagonist for c-Fos expression.

NEUROENDOCRINE MODULATION

Neuromodulators and functional changes in the neuroendocrine system may also be involved in the acupuncture response and its ability to mediate pain. In one study, researchers demonstrated that melatonin combined with EA suggested a relationship between AA with an increase in pro-opimelanocortin (POMC) mRNA (Zhou, Yu, & Wang, 2001). POMC is a single precursor molecule for peptides such as melanocortin that effect energy homeostasis (Schwartz, Woods, Porte, Seeley, & Baskin, 2000). In another study, electrostimulation to auricular points increased plasma levels of growth hormone (Debreceni, 1991). Less is known on how the pituitary–hypothalamic complex functions than neural response; however, it is thought that acupuncture modulates hypothalamic release of β-endorphin and adrenocorticotrophic stimulating hormone by the pituitary (Masala et al., 1983). Studies suggest that both peptides continue to increase up to 80 minutes after acupuncture (Zhou et al., 2001). Dopamine may also play a role in chronic widespread pain (Wood, 2004) and may be increased by acupuncture (Han, Yoon, Cho, Kim, & Min, 1999). Neuronal circuits that influence hormone regulation in the hypothalamus, such as POMC expression, suggest at the complexity of neuroendocrine activity in the body. These and other studies suggest how acupuncture might play a neuroendocrine regulatory role in the management of pain.

IMAGING AND BRAIN SCANNING

Historically, acupuncture research seems to have taken on the technology of the times. After endorphins, a group of 10 neurotransmitters that activate opiate receptors, were discovered by Hughes and Kosterlitz in 1975 (Kosterlitz & Hughes, 1977), for more than a decade acupuncture researchers favored opioid models. In the early 1980s, neuroendocrine models were investigated. In the early 1990s, models of gene expression were explored. As computerized scanning technology became available in the late 1990s, researchers such as Alavi and La Riccia demonstrated by single photon emission computed tomography (SPECT) scan abnormal blood flow in some brain areas of patients with chronic pain, which normalized with acupuncture (Alavi & La Riccia, 1997). In a study of five patients with chronic pain, SPECT scanning employed before and after acupuncture treatment revealed thalamic asymmetrical blood flow, which was normalized after treatment coinciding with reported pain relief from the test subjects (Alavi, La Riccia, Sadek, & Lattanand, 1996).

More recently, using functional magnetic resonance imaging, Cho investigated models for acupuncture research using neuroimaging based on molecular science and pharmacokinetics. Although far from a unifying theory of how acupuncture works, such research provides

objective and quantitative analyses in an "East meets West" approach toward understanding the mechanisms of acupuncture.

In groundbreaking work, Cho examined needling response to acupoints LI4 and ST36, both commonly used sites for amelioration of pain in the upper and lower body, respectively, in normal subjects (Cho et al., 1998; Cho, Oleson, Alimi, & Niemtzow, 2002). Significant brain activity was noted in the brainstem, midbrain, and cerebral cortex. In further studies, Cho expanded acupoints to include UB67 on the foot, GB 37 on the lower lateral leg, and GB 43 on the lateral distal foot. Armed with promising results from his imaging studies, Cho formulated an acupuncture pain relief hypothesis involving higher cortical areas (Cho, 2001). In this model, the effects of acupuncture are mediated through the central nervous system affecting corresponding areas of the cerebral cortex where communication takes place, theorized principally in the hypothalamus, where further neural communication occurs resulting in pain modulation. This may also help to explain the healing effects of acupuncture on a wide range of diseases.

CLINICAL EVIDENCE

Although an overwhelming body of observational information in nonpeer-reviewed journals and books describes the effects of acupuncture and Chinese medicine, and the body of scientific research into the mechanisms of acupuncture is extensive and growing, the overall number of clinical studies remains small. The reason for this is twofold. First, initial efforts in acupuncture research have focused on amassing a sizable body of evidence evaluating the mechanisms of AA and establishing safety before conducting human trials. At the time, no one knew how acupuncture worked; therefore, animals were ethically acceptable models for investigation. Second, there are several inherent difficulties in acupuncture clinical research. These include whether single- or double-blinded studies are best, how to establish a true control group since sham acupuncture itself may have greater effect than placebo; and if placebo in fact is the standard against which acupuncture should measured (Hammerschlag, 2003).

Blinded, placebo-controlled trials may be the gold standard for studying drugs, but obviously acupuncture is not a drug and, if anything, is more like a surgical procedure. Perhaps the only reason clinical studies for acupuncture have been compared against placebo is because of the early stance of the American Medical Association that acupuncture was no more effective than placebo or that it was similar to hypnosis. It seems strange that this debate is still going on when the first NIH grant for acupuncture headed by Ulett delivered convincing evidence in 1983 that acupuncture successfully modulated experimental pain and was not hypnosis (Ulett, 1983, 1996).

In addition, assessing the adequacy of acupuncture trials emphasizes study design but, in the West, rarely addresses whether the method used was in fact sufficiently adequate to achieve effective results (White & Ernst, 1998). The problem of effectiveness arises because of the many different techniques and styles of acupuncture used by practitioners; some methods are more effective for certain conditions than others and some practitioners are more effective than others. Compounding this is that there are no definitive studies comparing one form of acupuncture with another, such as Chinese versus Japanese acupuncture, for the treatment of a specific condition.

Systematic reviews of existing acupuncture studies also suffer from a variety of problems. These include reviewers' bias, limited number of well-designed studies, and lack of clustering of similarly designed studies. In addition, until recently there was no method of assessing the adequacy of acupuncture treatments used in the studies. To address this concern, White and Ernst devised a checklist of data required in studies using acupuncture treatments, including specifics of patient posture, number of needles used, needle size, use of international standards for acupuncture point names and locations, and depth of insertion (White & Ernst, 2003). Defining universal standards for acupuncture studies is a significant step toward establishing evidence.

In contrast to these limitations, the Cochrane Collaboration rigorously reviews methodology and outcomes and is considered the leading method for summarizing evidence (Ezzo, 2003). To date, seven Cochrane Reviews have been completed on acupuncture for rheumatoid arthritis, asthma, headache, induction of labor, lateral elbow pain, low back pain, and smoking cessation, with reviews in progress on stroke, postoperative nausea and vomiting, Bell's palsy, chronic constipation, depression, opioid dependence, and osteoarthritis. The interest in evidence-based information on acupuncture is shown by the number of reviews conducted or in progress. However, due to lack of well-designed, placebo-controlled, and randomized studies available in English, results of these reviews are equivocal.

Several important areas of study in pain management with acupuncture remain to be investigated. Because acupuncture needle therapy is time and labor intensive, it is important to learn if electrical stimulation provides equal benefit (Ceccherelli, Gagliardi, Seda, Corradin, & Giron, 1999). If so, which type is more effective? Is auricular acupuncture, in practice much easier to administer to a patient, equal or better than whole-body needle acupuncture (Lein, Clelland, Knowles, & Jackson, 1989)? Does electrostimulation of auricular acupuncture points work better than manual auricular acupuncture? In one study comparing auricular acupuncture with electrical stimulation for the treatment of chronic cervical pain, continuous electrical stimulation of auricular acupuncture points sig-

TABLE 76.1
Selected WHO-Listed Pain Conditions

System	Condition
Dental	Toothache, post-extraction pain
Neurological	Headache, migraine, trigeminal neuralgia, peripheral neuropathies, intercostals neuralgia
Musculoskeletal	Cervicobrachial syndrome, "frozen" shoulder, "tennis elbow," sciatica, low back pain, osteoarthritis

nificantly decreased pain, improved psychological well-being, and improved sleep (Sator-Katzenschlager et al., 2003). The challenge for researchers has been in finding a fair and objective way to evaluate the clinical evidence of acupuncture so that the foundational studies necessary are rigorously conducted (Sherman & Cherkin, 2003).

EVIDENCE BASE FOR SPECIFIC CONDITIONS

Acupuncture is used for a broad range of health conditions. Chinese acupuncture textbooks list anesthesia during surgery, infectious diseases such as the common cold and malaria, respiratory conditions such as asthma and bronchitis, cardiovascular conditions such as congestive heart failure, diabetes, hyperthyroidism, facial paralysis, headache, mastitis, and many other conditions (Bensky, 1981). However, it was not until 1979 when the World Health Organization (WHO) upon review of traditional claims for acupuncture listed more than 40 conditions that are suitable for treatment by acupuncture (Table 76.1). However, these conditions were selected without strong evidence for their efficacy. They include conditions of the upper and lower respiratory tract; eye, ear, and dental problems, gastrointestinal disorders, neurological, and musculoskeletal pain.

In 1998, almost two decades after the WHO list, the NIH Consensus Statement on Acupuncture (NIH, 1998) concluded that there was substantial evidence for the efficacy of acupuncture for postoperative, chemotherapy-induced, and pregnancy-associated nausea and vomiting, and for postoperative dental pain (Table 76.2). In addition, the panel concluded that a number of conditions are acceptably treated with acupuncture although further research is necessary. These include addiction, stroke, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma.

Recent acupuncture literature suggests that many other pain conditions respond to acupuncture and related modalities including musculoskeletal pain, sciatica, urogenital pain, labor pains, neuropathy, facial pain, neck pain, and pain associated with malignancy (Filshie & White, 1998).

TABLE 76.2
NIH Consensus Statement on Acupuncture Listed Conditions

Conditions with Substantial Evidence	Acceptable Conditions for Treatment
Postoperative pain	Addiction
Chemotherapy-induced and pregnancy-associated nausea and vomiting	Asthma
Postoperative dental pain	Carpal tunnel syndrome
	Fibromyalgia
	Headache
	Low back pain
	Menstrual cramps
	Myofascial pain
	Osteoarthritis
	Stroke
	Tennis elbow

In a study of 73 patients with symptomatic osteoarthritis of the knee, acupuncture proved effective as long as 4 weeks after treatment (Singh, Berman, Hadhazy, Bareta, Lao, Zarow et al., 2001). In another study on knee osteoarthritis, psychosocial factors were measured in patients to study possible placebo effects of acupuncture. As in other arthritis studies, response to acupuncture was favorable, while no evidence of a link between psychosocial variables was found (Creamer, Singh, Hochberg, & Berman, 1999).

Acupuncture and EA have been found to ameliorate symptoms in men with chronic prostatitis and pelvic pain (Antolak, 2004) and renal colic (Antolak, 2004), dysmenorrhea (Thomas, Lundeberg, Bjork, Lundstrom-Lindstedt et al., 1995), and pelvic pain in women (Slocomb, 1984).

Chronic low back pain (cLBP) is a commonly seen condition in the pain clinic. Several studies show that acupuncture is useful in all age groups. In a 2003 randomized, controlled trial on subjects older than 60 years, Meng et al. (2003) found that acupuncture was effective and safe in older patients. In blinded, randomized, controlled studies comparing electrical stimulation with manual acupuncture, both therapies have been shown to be effective in managing cLBP (Kerr, Walsh, & Baxter, 2003). Policy setting studies are currently under way in Europe for the treatment of cLBP and osteoarthritis. To date, the largest study on cLBP is the German Acupuncture Trial for Chronic Low Back Pain study. In a multicenter, randomized, partially blinded trial 102 patients were treated. In another study 300 patients were studied for osteoarthritis under protocols developed by Acupuncture Randomized Trials, and another 300 subjects for cLBP (Brinkhaus et al., 2003). Results from these studies were due for release in 2004 but have not been published in time for inclusion here.

Studies comparing different treatments and combining modalities have also been performed. As orthopedists refer patients for physical therapy, most acupuncturists

TABLE 76.3
Comprehensive List of Pain Conditions Responsive to Acupuncture

Conditions with Substantial Evidence	Conditions with Reasonable Evidence or Consensus	Conditions Potentially Responsive to Acupuncture Based on Observational Studies
Postoperative dental pain	Carpal tunnel syndrome	Malignancy-associated pain
Headache	Fibromyalgia	Neck pain
Low back pain	Intercostal neuralgia	Neurofibromatosis
Osteoarthritis	Menstrual cramps	Neuralgia
	Migraine	Post-arthroscopic pain
	Myofascial pain	Reflex sympathetic dystrophy
	Peripheral neuropathies	Rheumatoid arthritis
	Tennis elbow	Sciatica
	Trigeminal neuralgias	

prescribe back exercises in addition to providing treatment. In one study combining EA and back exercises, 52 patients were treated with results indicating that the combination was effective in managing pain and reducing disability associated with cLBP (Yeung, Leung, & Chow, 2003). In a randomized trial with 115 patients comparing medication, spinal manipulation, and acupuncture for spinal pain, results suggest that manipulation may be better for short-term pain relief and increased mobility, but it does not provide the longer-term anti-inflammatory relief as does acupuncture or steroid medications (Giles & Muller, 2003). In a randomized, controlled trial on chronic neck pain, laser acupuncture was more effective than conventional massage therapy (Konig et al., 2003). Acupuncture is useful following musculoskeletal surgery as found in a controlled study on arthroscopic acromioplasty. Findings with 35 patients indicated lower postsurgical pain levels, less use of analgesics, increased range of motion, and a high rate of patient satisfaction (Gilbertson, Wenner, & Russell, 2003).

Malignancy-associated pain causes considerable suffering among cancer patients. In France, auricular acupuncture has been used to alleviate cancer pain for more than 30 years. In a randomized, blinded, controlled trial of 90 patients, statistically significant evidence was found for the reduction of pain intensity (Alimi, Rubino, Leandri, & Brule, 2000; Alimi et al., 2003).

Other conditions for which acupuncture has been shown to be effective include neurofibromatosis, low back pain of pregnancy, soft tissue disorders of the shoulder, rheumatoid arthritis, neuropathic pain following spinal cord injury, reflex sympathetic dystrophy, sciatica, and fibromyalgia (Table 76.3).

MERIDIAN SYSTEM AND ACUPUNCTURE POINT RESEARCH

The problem of solving or disproving the existence of *qi*, acupoints, and the meridians has been of little interest to Western researchers. However, because these concepts are the basis of acupuncture theory and practice, and derive from Chinese culture, Asian researchers have taken the challenge more seriously. *Qi* research is largely carried on in China and Japan, where it is culturally acceptable, with international conferences annually where results of studies are presented, little of which has been taken seriously by Western scientists. Detection of acupoints has focused on electrical conductivity or resistance, with researchers theorizing that acupoints should manifest at the dermal surface as sites of lowered resistance and increased conduction.

Since the 1950s, Chinese, Japanese, French, German, and Austrian researchers have developed devices that confirm this suggesting that acupoints are anatomically real but instead are part of a non-neurological system in communication with the nervous, endocrine, and immune systems: in a sense, a homeostatic system regulating the internal physiological milieu with the outer environment.

A number of electrical point detection devices are used by acupuncturists and researchers including Electro-Acupuncture According to Voll originally developed in Germany by Reinhold Voll in 1953. This system measures galvanic skin resistance at distal acupuncture points on the fingers and toes using a 1 volt, 6 to 12 microampere current. Ryodoraku, first researched in Japan by Yoshio Nakatani in 1951 and followed by Odo and Hyodo of the pain clinic at Osaka Medical College (Hyodo, 1980), is based on autonomic nervous system function and uses a 12 volt, 200-microampere current to measure points.

Validating the existence of acupuncture meridians is equally challenging. Based on animal models, Ma et al. hypothesize that a perivascular space around blood vessels independent of lymphatic vessels constitutes an interstitial space within loose tissue through which acupuncture-induced signals are transmitted (Ma et al., 2003). Motoyama's Apparatus for Meridian Identification device is under investigation for its diagnostic capabilities in

establishing meridian and organ system disturbances and as means of monitoring effectiveness of acupuncture intervention (Borg, 2003).

SAFETY

Acupuncture safety falls into several categories: transmission of infectious diseases, infection from unsanitary needles or improper clean needle technique, direct injury to tissue or organs from needle insertion, allergic reactions, and needle breakage within the tissue. Lao, Hamilton, Fu, and Berman (2003), in a systematic review of 98 published papers between 1965 and 1999, identified 202 cases of complications associated with acupuncture. The most common complication found between 1974 and 1988 was hepatitis B with 94 cases reported. There have been no epidemiological reports of transmission of hepatitis C virus or HIV through acupuncture.

Common side effects of acupuncture include pain from needling, anxiety, and syncope. First-time patients are most susceptible; therefore, to prevent syncope the supine position is recommended over the seated position. Hematoma is another possible side effect, as are light-headedness, tiredness, drowsiness, and induction of sleep during treatment. Transient, localized skin irritation including erythema is not uncommon in patients with allergic dispositions. All of these side effects can be significantly minimized by an experienced practitioner who explains each step of treatment to new patients, and applies localized massage to acupuncture points after treatment, applies pressure when a hematoma is observed, and makes sure patients are positioned in a comfortable manner on the treatment table. Bruising may also occur in patient with a tendency for easy bruising and in elderly individuals with aged and fragile skin. Because of their blood-thinning properties, precaution should be taken with patients taking drugs such as coumadin and aspirin (Peuker, White, Ernst, Pera, & Filler, 1999).

Some patients do not react favorably to acupuncture. These nonresponders may be deficient, genetically or otherwise, in opiate receptors (Peets & Pomeranz, 1978). Nonresponder results may be improved by the addition of DL-phenylalanine, an essential amino acid, at 750 to 1,000 mg daily to potentiate endorphin release (Hendler, 2001). Other factors influencing acupuncture efficacy are under investigation. In animal models, Lee et al. (2003) demonstrated that the analgesic effect of acupuncture is closely related to the amount of genetic expression of cholecystokinin-A receptors. Cholecystokinin is a peptide prehormone secreted from mucosal epithelial cells in the small intestine and produced by neurons in the enteric nervous system. It is widely distributed in the brain and may be the most abundant neuropeptide in the central nervous system.

Considering an estimated 5.4 million acupuncture visits in 1997 alone, the risks of acupuncture are small and the incidence of side effects minimal and uncommon. According to the 2002 National Health Interview Survey, the largest and most comprehensive survey of complementary and alternative medicine use by American adults, an estimated 8.2 million U.S. adults have used acupuncture safely (Barnes et al., 2004).

ACUPUNCTURE THERAPY

Acupuncture is both a practice and a technique. The practice of acupuncture rests upon several thousand years of empirical experience and an ancient, comprehensive theory of health and disease. The technique of acupuncture consists of inserting specialized stainless steel needles into specific sites on the body, manipulating these needles manually or with electrostimulation, and then removing them. Point selection is based on the condition, location, and symptoms, and is guided by the theory of practice. The procedure is repeated at subsequent visits for a course of treatment, which on average consists of between 5 and 10 visits.

In China, it is common to perform acupuncture in a series of 10 to 30 daily treatments for two to four courses, with a rest of several days to a few weeks between each course. In the West and particularly in the HMO environment, we cannot emulate this economically, which brings up the question of cost-to-benefit ratio. But what is the most effective number of treatments for specific conditions? It is well known that repeated treatment with acupuncture or low-frequency, high-intensity electrical stimulation as with transcutaneous electric nerve stimulation (TENS) produce cumulative benefit for the patient (Pomeranz & Warma, 1988). Due to this cumulative effect, Western practitioners find that 10 to 15 treatments provided two to three times weekly produce sufficient pain-modulating effects.

Needle insertion combined with electrical stimulation, heat from moxibustion, and massage to acupoints before or after insertion are common additions to traditional acupuncture. In fact, in China acupuncture is traditionally called *zhen jiu* meaning needle and moxibustion, which is the burning of a prepared form of *Artemesia vulagaris*, a mugwort species, indirectly to an acupoint or directly to a needle inserted into a point. Other modalities include injection therapy, adaptation of microcurrent stimulation to acupoints using small probes or pads, EA without needles, retention of magnets or interdermal needles, and laser therapy.

Acupoint injection therapy uses small dosages of vitamin B_{12}, herbal extracts, homeopathic medications, biological substances such as Botox, as well as anti-inflammatory pharmaceutical agents such as cortisone and analgesics for the treatment of pain. Often referred to as "wet" acupuncture (vs. "dry" when needle only is

employed), this method has a long history in Germany but is only in the early stages of use in the United States.

Microcurrent has been shown to reduce symptoms of muscle damage following competitive sports (Lambert, Marcus, Burgess, & Noakes, 2002), neck and shoulder pain (Kim, 2001), and other pain conditions (Wieder, 1991). Devices have been adapted specifically for the acupuncture clinic using handheld probes to identify and treat problem areas such as the temporomandibular joint and other small joints.

EA devices that do not use needles but that simulate results of acupuncture are attractive for use in the pain clinic. TENS has a long history of use in the pain clinic. Grant, Bishop-Miller, Winchester, Anderson et al. (1999) demonstrated statistically significant improvement with both TENS and acupuncture, with acupuncture offering additional benefits over TENS. Home use of TENS units can complement acupuncture treatments, especially when patients can come for treatment only once or twice weekly.

Correlations among acupuncture, auricular acupuncture, EA, and vagal response have long been speculated with research conducted on heart rate (Shi, 1997; White & Ernst, 1999) and gastric secretion (Noguchi & Hayashi, 1996), as well as in the treatment of pain. In particular, auricular acupuncture according to Nogier of France has received wide acceptance (Oleson, 2002). In a study of 90 patients with cancer pain, Alimi, Rubino, Leandri, and Brule (2003) demonstrated clear benefit using auricular acupuncture over placebo.

Magnets and interdermal needles retained subcutaneously have wide use in Asia; however, there is scanty evidence in the literature for their use. Interest in using magnets applied to acupoints is increasing in the United States and may play an adjunctive role by applying magnets to affected areas in patients with pain between treatments as with TENS. In one double-blind study, Hinman, Ford, and Heye (2002) found that patients with chronic knee pain had statistically significantly less pain than the control group. In another study on osteoarthritis of the knee, Wolsko, Eisenberg, Simon, Davis et al. (2004) demonstrated statistically significant efficacy of magnetic therapy as compared with placebo after 4 hours.

Low-power lasers (LPL) have been employed in Europe since the 1970s for the treatment of pain and the promotion of tissue healing. The most frequently used types are visible red light helium–neon gas lasers, infrared gallium–aluminum–arsenide lasers, and gallium–arsenide lasers. Irradiated tissue is not heated as with surgical lasers. Trials involved LPL for pain have been conducted for trigeminal neuralgia (Walker & Akhanjee, 1985), postherpetic neuralgia (Moore, Hira, Kumar et al., 1988), rheumatoid disease (Oyamada & Izu, 1985), and myofascial pain. LPL therapy has been adapted for stimulation of acupoints as "needleless" acupuncture. Although the mechanisms behind laser efficacy remains poorly under-

stood, there is wide acceptance among acupuncture professionals for tissue-healing, reduction in soft tissue inflammation, and in some cases, reduction of pain.

TRADITIONAL CHINESE MEDICINE

Traditionally, Chinese herbal medicine has been used in Asia for a wide range of acute and chronic pain conditions such as osteoarthritis, rheumatoid arthritis, cervicalgia, low back pain, headache, fibrositis and myositis, neuritis, and other pain conditions. Herbal drugs have been shown to exert antioxidant activity, modulate cytokines and chemokines, effect gene expression, and regulate the inflammatory cascade. Modern Chinese herbal preparations include concentrated extracts, standardized dry extracts, and injectable medications. Numerous traditional Chinese herbal medicines have been shown to have analgesic and anti-inflammatory activity in the laboratory and in animal models. These include *Panax ginseng radix*, *Scutellaria radix*, *Aconiti radix*, *Stephaniae tetrandrae radix*, and others.

Ginsenosides Rb1, Rb2, Rd, Rf, Rg1, and Rg3 have antinociceptive effects on substance P–induced pain models (Choi, Han, Han, Lee, & Suh, 2003). In a study involving *Aconiti* and *Stephaniae*, analgesia was demonstrated in a rat model (Li, Zhang, & Qin, 2000). In another animal model, the flavanoid wogonin derived from *Scutellaria* inhibited inflammatory-associated enzymes much as cyclooxygenases (Chi, Lim, Park, & Kim, 2003).

However, few randomized, controlled clinical studies on large numbers of subjects have been performed. Because safety and drug–herb interactions are a controversial topic, until further investigation provides sufficient data on efficacy and safety, the practice of using Chinese herbal compounds in the integrative pain clinic should be avoided.

CONCLUSIONS

Both medical and traditional acupuncture are effective and safe methods for the treatment and management of chronic pain. Although a unifying model of the scientific mechanisms of acupuncture reconciled with TCM theory and modern human bioenergy hypotheses remains illusive, researchers continue to investigate the evidence underlying acupuncture. Further investigation is required for use of Chinese herbal preparations before they are integrated into common use in the pain clinic. It may be that bringing Western and Chinese medical paradigms into concert with each other, both in the research and clinical setting, will provide the necessary relevance needed to learn how they can benefit patients and fully integrate acupuncture and related traditional Chinese medicine therapies into the pain clinic.

Aromatherapy for Pain Relief

Alan R. Hirsch, MD

INTRODUCTION

In explaining the persuasive attraction of alternative medicine, Kaptchuk and Eisenberg (1998) note, "The fundamental premises are an advocacy of nature, vitalism, science, and spirituality." Use of aromatherapy has burgeoned along with the other forms of complementary and alternative medicine. As of 1997, out-of-pocket money spent for alternative medicine products and services was $27 billion and equaled that for all out-of-pocket U.S. physician services (Yager, Siegfried, & DiMatteo, 1999). There has been a growth of 900% in the use of aromatherapy from the 1980s and 1990s (Kessler, Davis, Foster et al., 2001). Pain, including headache, is one of the most common reasons for seeking complementary alternative medicine treatment (Eisenberg, David, Ettner et al., 1998), and in particular aromatherapy because it is suggested that, "almost all essential oils have some analgesic properties" (Gatefoss, as quoted in Buckle, 1999b).

DEFINITIONS

One of the difficulties in understanding aromatherapy is that it means different things to different people. One part of its definition that is agreed upon is that aromatherapy uses odorous compounds to promote health and healing (Kaptchuk & Eisenberg, 1998). Beyond this, opinions differ. Aromachologists speak of using odors not to treat disease, but to promote wellness. Aromatologists believe in ingestion of the substance being used as well as its inhalation (Price & Price, 1995). Many aromatherapists believe in using massage and topical application coinci-

dent with inhalation (Tisserand, 1977, Wood, 2003). In this chapter, aromatherapy for pain relief is defined as the use of odorants as inhalants. This definition excludes any effects of ingestion or percutaneous absorption, although this may be significant depending on the method of application (Weyers & Brodbeck, 1989). This definition is consistent with the literature indicating that real aromatherapy involves the uptake of fragrant compounds only through inhalation, not by other methods (Buchbauer, 1993). As defined, aromatherapy is also independent of any coincident, noninhalational therapies, such as massage, interpersonal interaction, or bathing.

Many in the aromatherapy community believe that natural or essential oils are effective and that artificial synthesized compounds are not. However, in the treatment of neurologic and psychiatric diseases, the literature does not substantiate this dichotomy (King, 1994). No distinction will be made herein between the use of synthetic as opposed to naturally occurring oils.

BACKGROUND

Why is the concept of aromatherapy under consideration today? One reason is its history. Throughout the ages, odorants have been used to treat various diseases. More than 5,000 years ago the Egyptians treated disease using odors (Lindsay, Pitcaithly, & Geelen, 1997), and 3,500 years ago the Babylonians used odors to exorcise demons of disease (Roebuck, 1988). The ancient Aztecs also used odors to treat disease. Aromatherapy has known no cultural or geographic boundaries. Virtually all cultures have fumigated the sick (Buchbauer, 1993).

ANATOMY OF OLFACTION

Neuroscience provides insight into the mechanisms by which odors may influence behavior and neurologic functioning.

There is an anatomic basis for the belief that odors can affect the brain and behavior (Brodal, 1969). Once an odor passes through the olfactory epithelium, it stimulates the olfactory nerve, which consists of unmyelinated olfactory filia. The olfactory nerve has the slowest conduction rate of any nerve in the body. The olfactory filia pass through the cribiform plate of the ethmoid bone and enter the olfactory bulb. During trauma, damage often occurs in this bulb (Hirsch & Wyse, 1993). Different odors localize in different areas of the olfactory bulb.

Inside the olfactory bulb is a conglomeration of neuropil called the glomeruli. Approximately 2,000 glomeruli reside in the olfactory bulb. Four different cell types make up the glomeruli: processes of receptor cell axons, mitral cells, tufted cells, and second-order neurons that give off collaterals to the granule cells and to cells in the periglomerular and external plexiform layers. The mitral and tufted cells form the lateral olfactory tract and establish a reverberating circuit with the granule cells. The mitral cells stimulate firing of the granule cells, which, in turn, inhibit firing of the mitral cells. A reciprocal inhibition exists between the mitral and tufted cells. This results in a sharpening of olfactory acuity.

The olfactory bulb receives several afferent projections, including the primary olfactory fibers, the contralateral olfactory bulb and the anterior nucleus, the prepiriform cortex (inhibitory), the diagonal band of Broca (with neurotransmitters acetylcholine and gamma amino butyric acid [GABA]), the locus coeruleus, the dorsal raphe, and the tuberomamillary nucleus of the hypothalamus.

The olfactory bulb's efferent fibers project into the olfactory tract, which divides at the olfactory trigona into the medial and lateral olfactory stria. These project to the anterior olfactory nucleus, the olfactory tubercle, the amygdaloid nucleus (which, in turn, projects to the ventral medial nucleus of the hypothalamus, a feeding center), the cortex of the piriform lobe, the septal nuclei, and the hypothalamus, in particular the anterolateral regions of the hypothalamus, which are involved in reproduction. The neurotransmitters by which the olfactory bulb conducts its information include glutamate, aspartate, *N*-acetyl-aspartyl-glutamate, cholecystokinin, and GABA.

The anterior olfactory nucleus receives afferent fibers from the olfactory tract and projects efferent fibers, which decussate in the anterior commissure and synapse in the contralateral olfactory bulb. Some of the efferent projections from the anterior olfactory nucleus remain ipsilateral and synapse on internal granular cells of the ipsilateral olfactory bulb.

The olfactory tubercle receives afferent fibers from the olfactory bulb and the anterior olfactory nucleus. Efferent fibers from the olfactory tubercle project to the nucleus accumbens as well as the striatum. Neurotransmitters of the olfactory tubercle include acetylcholine and dopamine.

The area on the cortex where olfaction is localized, that is, the primary olfactory cortex, includes the prepiriform area, the periamygdaloid area, and the entorhinal area. Afferent projections to the primary olfactory cortex include the mitral cells, which enter the lateral olfactory tract and synapse in the prepiriform cortex (lateral olfactory gyrus) and the corticomedial part of the amygdala. Efferent projections from the primary olfactory cortex extend to the entorhinal cortex (area 28), the basal and lateral amygdaloid nuclei, the lateral preoptic area of the hypothalamus, the nucleus of the diagonal band of Broca, the medial forebrain bundle, the dorsal medial nucleus and submedial nucleus of the thalamus, and the nucleus accumbens.

It should be noted that the entorhinal cortex is both a primary and a secondary olfactory cortical area. Efferent fibers, from the cortex, project via the uncinate fasciculus to the hippocampus, the frontal cortex, and the anterior insular cortex (next to the gustatory cortical area). This may explain why temporal lobe epilepsy that involves the uncinate often produces parageusias of burning rubber, known as uncinate fits (Acharya, Acharya, & Luders, 1996).

Some of the efferent projections of the mitral and tufted cells decussate in the anterior commissure and form the medial olfactory tract. They then synapse in the contralateral parolfactory area and contralateral subcallosal gyrus. The exact function of the medial olfactory stria and tract is not clear. The accessory olfactory bulb receives afferent fibers from the bed nucleus of the accessory olfactory tract and the medial and posterior corticoamygdaloid nuclei. Efferent fibers from the accessory olfactory bulb project through the accessory olfactory tract to the same afferent areas, for example, the bed nucleus of the accessory olfactory tract and the medial posterior corticoamygdaloid nuclei. It should be noted that the medial and posterior corticoamygdaloid nuclei project secondary fibers to the anterior and medial hypothalamus, the areas associated with reproduction. Therefore, the accessory olfactory bulb in humans may be the mediator for human pheromones (Hirsch, 1998b).

Some unique aspects of the anatomy of the olfactory system are worth mentioning. Smell is the only sensation to reach the cortex before reaching the thalamus. The only sensory system that is primary ipsilateral in its projection, olfaction does not depend upon the cortex, as has been demonstrated in decorticate cats (Dusser de Barenne, 1933).

Neurotransmitters of the olfactory cortex are multiple, including glutamate, aspartate cholcystekinin, luteinizing hormone releasing factor, and somatostatin. Furthermore, perception of odors causes modulation of olfactory neurotransmitters within the olfactory bulb and the limbic

system. Virtually all known neurotransmitters are present in the olfactory bulb. Thus, odorant modulation of neurotransmitter levels in the olfactory bulb, tract, and limbic system intended for transmission of sensory information may have unintended secondary effects on a variety of different behaviors and disease states that are regulated by the same neurotransmitters. For example, odorant modulation of dopamine in the olfactory bulb/limbic system may effect manifestations of Parkinson's disease. Non-olfactory mesolimbic override to many of the components of Parkinson's disease have been well documented, for example, motoric activation associated with emotional distress and fear of injury in a fire (Adams, Victor, & Roper, 1997).

EMOTIONAL AND BEHAVIORAL EFFECTS OF ODORS

Odors can affect behavior by acting as alternative sensory stimuli. The phenomena of visual system modification of the movements of Parkinsonian gait through the visual stimulation of lines placed on the floor (Dietz, Goetz, & Steddings, 1990) are an example of alternative stimuli. Other sensory input, including pain, has been shown to inhibit the Jacksonian march in epilepsy (Gowers, 1881, cited in Efron, 1957). Similarly, odors may act as competing sensory stimuli during an uncinate seizure (Efron, 1957). It seems possible that other sensory input, including odors, could modify Parkinson's disease as well as other neurologic conditions, including pain, by acting as competing sensory stimuli.

Using another mechanism of action, odors can affect behavior and mood by producing a primary effect on the emotions of the individual (Ersser, 1990). This is different from a direct neurophysiologic effect on the limbic system. Rather, the odor can change the mood of the individual, which then has secondary neurologic effects. For example, mood or level of alertness can affect the perceptual threshold of a stimulus, including the perception of pain (Loring & Meador, 2001). A soldier who is severely wounded in battle may continue to fight and not feel pain until the battle is over. Studies also suggest that persons in a positive state of mind are less bothered by pain (Fields, 1967). Thus, aromatherapy's analgesic effect may be due to its ability to induce happiness.

Substantial evidence exists that odors can affect mood (Broughan, 2002). As early as 1908, Freud stressed the importance of olfaction on emotion in his description of a patient with an obsessional neurosis.

By his own account, when a child, he recognized everyone by their smell, like a dog, and even when he was grown up he was more susceptible to sensations of smell than other people … and I have come to recognize that a tendency towards osphresiolagnia which has become

extinct since childhood may play a part in the genesis of neuroses.

In a general way I should like to raise the question whether the inevitable shunting of the sense of smell as a result of man's turning away from the earth and the organic repression of smell pleasure produced by it does not largely share in his predisposition to nervous diseases. It would thus furnish an explanation for the fact that with the advance of civilization it is precisely the sexual life which must become the victim of repression. For we have long known what an intimate relation exists in the animal organization between the sexual impulse and the function of the olfactory organs.

Of all the sensations, olfaction is the one most intertwined with limbic system functioning (MacLean, 1973). The profuse anatomic and physiologic interconnections through the olfactory bulb, stria, and nuclei to the olfactory tubercle, and from there to the prepiriform cortex, the amygdala, and numerous other limbic system structures elucidated earlier support this (Brodal, 1969).

Smells are described differently from other sensory modalities, adding credence to their connection to emotion. Other sensory modalities are first described cognitively; a picture, for example, is identified as being of a ship, a woman, or a house and only secondarily is it described affectively: "I like," or "I dislike it" (Ehrlichman & Halpern, 1988). But odors are first and foremost described affectively: "I like," or "I dislike" it.

The olfactory/limbic/hippocampal connections help to explain olfactory-evoked nostalgia, the phenomenon whereby an odor induces a vivid recall of a scene from the distant past (Hirsch, 1992). In 86% of 989 subjects queried, certain odors triggered vivid associations analogous to a flashbulb memory. Classically, an event must induce strong emotions for deposition of such memories to occur (Brown & Kulik, 1977; Squire, 1987). By directly stimulating the limbic system, odors also can act as the inducing agent. This phenomenon was vividly described by Proust (1934), who wrote that the aroma of madeleine dipped in tea evoked a flood of memories and nostalgic feelings. Olfactory-evoked recall is usually a positive experience, but it can be negative, as in the olfactory flashbacks of post-traumatic stress disorder (Kline & Rausch, 1985). Hence, it seems possible that olfactory-evoked nostalgia may affect pain because approximately 90% of these memories are associated with strong affective tones (Laird, 1988).

Odorants' effect on mood may be mediated through more short-term influence — through a Pavlovian conditioned response. In this mechanism, a recent exposure to an odor is linked to a mood or behavioral state, and when the odor is reintroduced, this same emotional tone also returns (Broughan, 1998; Engen, 1991). This suggests that for each person the same odor will have a different effect because the emotions paired with the odor will be unique,

dependent on each individual's past experiences and memories (Van Toller & Dodd, 1988). Superimposed on individual preferences are cultural mores, trends, and prohibitions, which also act to guide members of each culture for use of specific odors for group occasions, like incense in a church or cotton candy at a carnival (Classen, Howes, & Synnott, 1994). In these situations, specific odors are more likely to be associated with specific emotions common to their respective cultural groups — i.e., happiness with cotton candy and contrition with incense (Broughan, 1998). Thus, not only will there be cultural differences from odor to odor in terms of preference and use, but even within the culture, there will be individual variability (Davis & Panboro, 1982).

The above brings to the forefront the question of how odors exert an impact on behavior or mood. The answer can be represented by either of two constructs: the lock and key theory or the general affective theory of odors.

THE LOCK AND KEY THEORY OF ODORS

The lock and key theory of odors (also called the systemic effect theory) (Buchbauer, 1993) suggests that odor acts very much like a specific neurotransmitter, a drug, or an enzyme. In this paradigm, an odorant has a specific effect on behavior or emotion — one odor for one emotion or one odor for, at most, a few emotions. Thus, an odor could be viewed like a medication in the pharmacopoeia. For example, in the world of neurology, propranolol is used for modulation of essential tremor, migraine headache, and anxiety. However, one would not use propranolol as a treatment for insomnia, dementia, or multiple sclerosis. The lock and key theory suggests that specific odors have specific effects. This theory has been proposed in virtually every book about aromatherapy in which specific odors are recommended for specific health effects (Cunningham, 1995; Damian & Damian, 1995; Feller, 1997; Keville & Green, 1995; Price, 1991; Price & Price, 1995; Schnaubelt, 1995).

An argument supporting the lock and key theory is that odorants exert central nervous system (CNS) effects outside a subject's conscious awareness. In test animals, the more lipophilic an odor is, the greater its sedative effect. In addition, steric differences in odors create different effects despite similarities in perceived odor and volatility (Buchbauer, 1993; Buchbauer et al., 1993). In humans, conscious detection is not necessarily required for an odorant to have its effects. For example, subliminal aromas of vanilla enhances mood (Lorig, 1994) and the subliminal aromas of mixed flowers increase both the perceived value and the desire to buy inanimate objects (Nike shoes) (Hirsch & Gay, 1991).

According to the lock and key theory, odors act as a drug (Buchbauer, 1993) with a potentially pharmacologic mechanism of action. The odorants are integrated in the membrane of the cells causing an increase in membrane volume due to disruption of the membrane lipids. This leads to electrical stabilization of the membrane, thus blocking the inflow of calcium ions and suppressing permeability for sodium ions. As a result, action potential production is inhibited, which induces narcosis or local anesthesia. At higher concentrations of odorant, the conductivity of potassium ions is reduced. It also is possible that the odorants act on protein kinase C, which could affect the spontaneous rhythm of nerve cells (Buchbauer, 1993).

This mechanism of action is further supported by established pharmacology for the action of the target organ, in this case, a drug on the brain. If the odorant did not directly infiltrate the olfactory neurons and then spread transaxonally to specific neural nuclei as has been postulated (Buckle, 1993, 1999a), inhalation of an odorant would have to produce measurable levels in the blood, sufficient to pass through the blood–brain barrier. Parts per billion levels in blood have been seen after minimum inhalation of oils of rosemary (Kovar, Gropper, Friess et al., 1987), sandalwood (Jirovetz, 1992), and lavender (Buchbauer, Jirovetz, Jäger, Dietrich et al., 1991; Jellinek, 1998/1999). Stimpfl et al. (1995) demonstrated that this does occur in humans. One subject inhaled 1,8-cineol for 20 minutes, which produced a linear increase of 1,8-cineol in the blood, up to 275 ng/ml, a level high enough to allow penetration of the blood–brain barrier (Stimpfl et al., 1995).

Battaglia (1997) postulates that part of the efficacy of aromatherapy for analgesia lies in its pharmacologic effects: anti-inflammatory and prostaglandin-inhibiting properties. Göbel, Schmidt, and Soyka (1994) suggests that antinociceptive influences of aromas are derived either through afferent segmental inhibition at the posterior horn or through central efferent inhibition, or through a combination of these.

THE GENERAL AFFECTIVE THEORY OF ODORS

An alternative theory, the general affective theory of odors, also called the reflectorial effect theory (Buchbauer, 1993), holds that an odor experienced as hedonically positive induces a positive, happy mood, and when in a happy mood, an individual does almost everything better, and pain is less bothersome. For example, when a person feels happy, it is easier to learn and to sleep, and headaches are less frequent. According to the general affective theory, a single odor could have a multitude of diverse effects, thus affecting virtually all behaviors.

The major premise that hedonically positive odors induce happier moods was demonstrated by Alaoui-Ismaili et al. (1997); 44 subjects inhaled five odorants, namely, vanillin, menthol, eugenol, methyl methacrylate, and propionic acid. Six autonomic nervous system parameters were recorded: skin potential, skin resistance, skin

temperature, skin blood flow, instantaneous respiratory frequency, and instantaneous heart rate. Evaluation of these parameters demonstrated a pattern consistent with known emotional states. Hedonically pleasant odors evoked mainly happiness and surprise, and unpleasant ones induced mainly disgust and anger (Alaoui-Ismaili et al., 1997).

Miltner et al. (1994) also showed that exposure to odors could change emotions in the same direction as the hedonic valence of the odor. Using the startle reflex amplitude as a physiologic indicator of emotional valence, he found that the odor of hydrogen sulfide increased the startle reflex amplitude and the odor of vanillin reduced it.

Aromatherapists recognize the affective impact of odors as the mechanism of action. Buchbauer notes, "A pleasant odor has always been, and still is, an important factor for people to feel good, and feeling well is synonymous with good health. Therefore, we can conclude that all substances which are able to create a certain amount of well-being and well-feeling possess therapeutic properties and, therefore, can be called therapeutic agents" (Buchbauer, 1990). The general affective theory of odors might be extended to include non-odorants in the pharmacologic arena, such as Valium. Valium may be useful for virtually all medical conditions because reducing anxiety makes conditions such as chronic pain, movement disorders, or insomnia less bothersome. Hence, an entire branch of medicine could be built around Valium: "Valiotherapy." If one ascribes aromatherapeutic results to the general affective theory as the mechanism of action, it follows that any odor that one likes induces a happier state and, hence, would have a positive effect on any disease. Again, the concept could be expanded beyond odors to any environmental stimuli, for example, a bird singing or a pretty landscape. A *Star Wars* movie might induce happiness in some observers and could be seen as inducing a positive mood state. The positive mood might lead to a reduction in pain, anxiety, and negative feelings. One could then categorize this as a form of alternative therapy: "Lucastherapy!" Thus, reliance on the general affective theory of odors implies that virtually any sensory stimulus could be used as a therapeutic tool. This largely trivializes the definition of therapy.

Another problem with the general affective theory of odors is that the same odor, in different contexts, may induce opposite emotional tones (Sugawara, Hino, & Kawasaki, 1999). In "The Invalid's Story," Mark Twain compares the disgust at the odor of a rotting corpse to the delight at the smell of cheese (Clemens, 1882). The odors were the same but perceived to be from different sources. This suggests that an odor that is contextually appropriate in one situation might be considered totally inappropriate in another. Smelled in a positive context, it would be appreciated as hedonically positive and would enhance a positive affective state; smelled in a negative context, it would be perceived as hedonically negative and would, thus, induce a negative affective state. Therefore, the same odor could produce opposite mood states and opposite effects. This suggests that it is the perception of the odor rather than the odor itself that is essential in the mechanism of aromatherapy (Broughan, 1998). This was demonstrated for neroli, which had either an activating or an opposite, deactivating response, depending upon whether the subject believed it was a floral or a citrus-based aroma (Torii, 1996).

A variant of the general affective theory is that odors may induce a mood more congruent with the demands of the external environment. For example, if the external environment requires that the individual be alert, the odor induces awareness of this; therefore, the individual responds by becoming more alert. Alternatively, if the external environment is such that it is more appropriate to be relaxed, the odor induces that awareness and the individual responds by becoming more relaxed. Evidence for the validity of this variant comes from studies of muguet odor. Where the external demand is for a greater degree of relaxation, individuals do become more relaxed, and in an environment where they are required to be more alert and vigilant, they become more alert. Warm, Dember, and Parasuraman (1991) demonstrated this effect of odorant-induced recognition of affective demands. A total of 40 subjects underwent vigilance tasks for 40 minutes during which they received periodic 30-second whiffs of air or one of two hedonically positive fragrances: muguet (independently judged as relaxing) or peppermint (independently judged as alerting). Those who received either the relaxing or alerting fragrance detected more signals during the vigilance task than the unscented air controls ($p = 0.05$).

This odorant-induced congruence of mood may also be applied to the pharmacologic agent diazepam or Valium. Valium can induce opposite mood states in the same individual at different times. It can reduce anxiety to enhance concentration on a test, or it can reduce concentration to act as a soporific when the same individual is suffering with insomnia.

A corollary to the general affective theory is that hedonically negative odors or malodors have a negative effect on mood (Baron & Thomley, 1994). If this were true, the simple elimination or masking of malodors with neutral or hedonically positive odors would induce positive effects; in this paradigm, in the hospital setting, the true aromatherapist is actually the hospital janitor!

Literature supports the deleterious and cephalogenic effects of hedonically unpleasant odors. Miner (1980) described some health effects of exposure to the odor of livestock waste. They included annoyance, depression, nausea, vomiting, headache, shallow breathing, coughing, insomnia, and impaired appetite.

One of the malodorous pollutants that has been studied, trichloroethylene, a universally present air pollutant, can cause cephalgia (Hirsch & Rankin, 1993). Acute exposure to nitrogen tetroxide can cause cephalgia (Hirsch, 1995a) and chronic neurotoxicity (Hirsch, 1995d). Acute exposure to chlorine gas can cause neurotoxicity (Hirsch, 1995c). In 1991, Neutra et al. reported that people living near hazardous waste sites suffer more physical symptoms during times when they can detect malodors than when they are unaware of them. Shusterman (1992) demonstrated that even at levels considered nontoxic, chemical effluviums can cause physical symptoms.

Health effects of malodors can be divided into six categories: respiratory, chemosensory, cardiovascular, immune, neurologic, and psychologic.

Respiratory. Individuals with asthma are especially affected by malodors. Any strong odor may induce an attack in persons with unstable asthma, and even in people without asthma, malodors have been demonstrated to affect the cardiorespiratory system. Increased ambient oxidant levels correlate with slower cross-country running times in high school students (Wayne, Wehrle, & Carroll, 1967).

Chemosensory. Chronic exposure to malodors from pulp mills can cause permanent olfactory loss (Maruniak, 1995).

Cardiovascular. Certain malodors can induce an adrenocortical and adrenomedullary response leading to elevated blood pressure and a subsequent increase in stroke and heart disease (Evans, 1994).

Immune. Immune function may be compromised either directly, as a result of olfactory/neural projections to lymphoid tissue (Evans, 1994), or indirectly, as a result of malodor-induced depression or other negative mood states (Weisse, 1992).

Neurologic. Chronic exposure to intermittent malodors from a U.S. Navy dump site in Port Orchard, Washington, induced cortical and subcortical dysfunction, which was manifested by encephalopathy: limbic encephalopathy and cephalgia (Hirsch, 1995b). Both ambient NO_2 and SO_2 impair visual adaptation to darkness and sensitivity to brightness, and increase alpha wave desynchronization on electroencephalogram (EEG) (Izmerov, 1971).

Psychologic. Recognized for centuries and noted by Freud and others, psychologic effects of odors vary widely among individuals. Persons under major stress are particularly vulnerable to the psychologic effects of ambient malodors (Evans, 1994). Persons with a distorted or impaired olfactory sense may be annoyed by odors that other persons usually consider pleasant (Evans, 1994).

Certain bad odors irritate nasal passages. Resultant trigeminal stimulation releases adrenaline, leading to a tense and angry state. Thus, bad odors can trigger aggression that may then be covertly expressed. For example, in one experiment college men were instructed to apply electric shocks of varying intensity to their colleagues, supposedly for the purpose of training them. When bad odors were present, the subjects chose to inflict greater degrees of pain upon their colleagues (Rotton et al., 1979). Another example involves air pollution. On days when malodorous air pollution is high, the number of motor vehicle accidents increases, indicating that people drive more aggressively in a polluted environment (Ury, Perkins, & Goldsmith, 1972).

Various studies show how mood and well-being suffer in the presence of malodors. Residents exposed to the effluvium from nearby commercial swine operations reported that they suffered increased tension, fatigue, confusion, depression, and anger, and that their vigor decreased (Schiffman et al., 1995). According to one study (Rotton et al., 1978) ambient pollutants decreased personal attraction. In a German urban area, the moods of young adults fluctuated in synchrony with the daily fluctuations in quality of environmental air, a pattern especially marked among more emotionally unstable individuals (Brandstatter, Fuhrwirth, & Kitchler, 1988). Further, daily diary entries of women in Bavaria showed that variations in their psychologic well-being coincided with variations in ambient air quality. The correlation was particularly marked among women suffering from chronic diseases such as diabetes (Bullinger, 1989a, 1989b). In Israel, negative health effects were significantly associated with levels of urban pollution (Zeidner & Schecter, 1988).

The number of family disturbances and the number of 911 emergency psychiatric calls also were linked to malodors in the environment, as determined by ozone levels (Rotton & Frey, 1985). In several cities, the number of psychiatric admissions paralleled the quality of environmental air (Briere, Downes, & Spensley, 1983).

In a study of the malodorous emanations from a mulching site southeast of Chicago, it was found that on days when the miasma wafted from the site to the school across the street, children at the school demonstrated increased behavioral problems (Hirsch, 1998a).

Malodorous ambient SO_2 levels correlate with psychiatric admissions, child psychiatric emergencies (Valentine et al., 1975), and behavioral difficulties with decreased cooperation (Cunningham, 1979). Ambient NO_2 levels covary with psychiatric emergency room visits (Strahilevitz, Strahilevitz, & Miller, 1979). In nonsmokers, the odor of cigarette smoke has been demonstrated to exacerbate aggressive behavior (Jones & Bogat, 1978).

The fatigue and annoyance caused by ambient malodors undoubtedly reduce individuals' capacities to function normally. Their abilities to tolerate frustration and pain, to learn, and to cope with other stressors are impaired. In one laboratory study, subjects exposed to unpleasant odors experienced increased feelings of helplessness (Rotton, 1983).

CONTRADICTORY THEORIES

If the general affective theory of odors is true, a single odor can induce a positive mood in one person and a negative mood in another. This negates the lock and key theory in which odors' effects are produced outside of conscious awareness. Robin et al. (1999) demonstrated this using eugenol. Eugenol, which is often associated with the smell of dental cement, was rated pleasant by nonfearful dental subjects and unpleasant by fearful subjects ($p = 0.036$). Changes in subjects' autonomic nervous system measurements were consistent with their emotional states; 19 subjects were exposed to eugenol while recording six autonomic nervous system parameters, including two electrodermal, two thermovascular, and two cardiorespiratory. The results of 7 subjects with high dental fear were compared with those of 12 without such fear. Those with dental fear had a stronger electrodermal response ($p = 0.006$), suggesting that eugenol triggered different emotional responses depending on the unpleasantness of the subject's past dental experiences. Thus, the same odor can have different effects depending on the past experience of the individual (Robin et al., 1998).

On the other hand, if the lock and key theory is true, and an odor's behavioral effects are produced independent of affective reaction, this negates the general affective theory of odors. Ludvigson and Rottman do just that, demonstrating that the scent of lavender enhances mood state while impairing arithmetic reasoning ($p = 0.01$) (Ludvigson & Rottman, 1989).

Given the previous information, several factors must be taken into account in reviewing the literature regarding efficacy of aromatherapy in the treatment of pain. Can odors elevate mood as the general affective theory maintains or do they act in a lock and key fashion? Were the odors tested considered hedonically positive by each subject? This question is essential because what is hedonically positive for one person can be hedonically negative for another, and an odor that is hedonically positive at one concentration may be hedonically negative at another (Distel et al., 1999). Was an associated change in mood independent of the desired effect? Was there a placebo control group (Miller et al., 2004)? Was it a single-blind or double-blind procedure? Was the subject size sufficient to obviate falsely positive test results? Did the subjects of the experiment have a normal or near-normal sense of smell?

Could suggestion have an effect? This is particularly relevant because various studies suggest that as in traditional pharmacologic intervention (Flaten, Simonsen, & Olsen, 1999), odors have both placebo and nocebo effects as demonstrated by Knasko, Gilbert, and Sabini, (1990). Knasko and co-workers subjected 90 people to water vapor sprayed in a room; 30 subjects were told that the water vapor odor was pleasant, 30 that it was unpleasant, and 30 that it was neutral. Those who had been told that the odorant was pleasant reported being in a better mood than did the other two groups ($p = 0.05$). Subjects who had been told the odor was unpleasant reported having more health symptoms ($p < 0.0003$). The strong effect of belief over actuality in the perception of odor pleasantness (Martin, 1996) begs the question, if a scent is even needed at all for the aromatherapy's effects to occur or is it enough just to have the belief that an effective aroma is present (Buckle, 1999b). Martin posits, "If an odour is not required, simply the manipulation of belief, the use of odour in aromatherapy becomes redundant."

Were the experiments controlled not only for the effect of suggestion, but also for the effect of expectation of outcome? It seems possible that persons with a positive view of aromatherapy, and who believe that odors can have a positive effect, will be more predisposed to experience a positive effect from odors because of their bias independent of any true effect of the aroma (Broughan, 1998/1999). The effect of expectation has been demonstrated neurophysiologically by Lorig and Roberts (1990) who measured the contingent negative variation (CNV) of the EEG in 18 subjects presented with a mixed odor of lavender, jasmine, and galbanium. They found CNV amplitude for the mixed odors varied depending on what the subjects were told about the odorant ($p = 0.05$).

One way of eliminating expectancy effects is by using subjects with no preconceived notions of efficacy of aromatherapy for pain relief. One such group is infants and young children. A variety of studies of aromatherapy for pain relief have been performed on this population.

In one study, 20 HIV-infected hospitalized children aged 3 months and older were provided Roman chamomile and *Lavandula angustifolia* for pain relief and comfort (Styles, 1987). While it was reported that all the children responded well to these blends with a reduction of need for analgesic drugs and relief of chest pain, muscle spasm, and peripheral neuropathy associated pain, the exact amount and responses were not described and no statistical analysis was provided.

The effect of aromas to reduce pain has also been evaluated in even younger children. Full-term newborns displayed *no* reduction in pain expression in response to a painful heelstick when presented the aroma of maternal milk (Mellier et al., 1997; Rattaz et al., 2001), unfamiliar milk, or lavender (Kawakami et al., 1997).

In another study 51 preterm infants (average 32-weeks gestational age) assessed at 1 week postnatal age had no reduction in crying in response to heelstick pain during exposure to the pre-familiarized odor of vanillin or the novel, unfamiliar odor of vanillin as compared with a no odor control (Goubet, Rattaz, Pierrat, Bullinger, & Lequien, 2003). In response to a less severe painful stimuli (venipuncture), those exposed to the familiar odor of vanillin had a reduction in perceived pain as displayed by no increase in crying as compared with baseline. Thus, the familiar odor of vanillin prevented preterm infants from crying during mild pain, but had no effect on more intense pain, whereas the same aroma, if unfamiliar, had no effect on either painful situation. This implies that vanillin's analgesic effect was based not on the inherent properties of the vanillin, but rather, on the perception of the odor as familiar. Familiar odors may reduce pain because there is a preference for familiarity early in life, or from odor-induced affective memory and an associated happy (non-painful) mood state.

Did the experimenter consider the effect of social desirability whereby subjects try to please the examiner by biasing their answers (Visser, 1999)?

Were the subjects' individual personality factors, which could influence their response to odors, taken into account (Warrenburg & Schwartz, 1990)? For example, those with field dependence tend to be more susceptible to the effects of external cues like ambient aromas on affect and mood state, than field independent personalities, who are more influenced by their own internal milieu and more resistant to impact of ambient aroma (Ehrlichman & Bastone, 1992; Goodenough, 1978; Jellinek, 1998/1999).

In an analysis of all randomized controlled clinical trials of aromatherapy referenced in Medline, Embase, British Nursing Index, CIS-CO, and AMED from June 1999 back to the origin of each database, no studies that had independent replication for the treatment of pain were found in *any* language (Cooke & Ernst, 2000). The authors suggest that use of aromatherapy for anxiety is best considered "a pleasant diversion," and for pain or any other indication, "is not supported by the findings of vigorous clinical trials."

In light of the above, one must be circumspect regarding articles touting aromatherapeutic efficacy in the treatment of pain. Because the basic physiologic mechanism of aromatherapy's antinociceptive effect has not been fully established, skepticism seems all the more appropriate.

As a general rule, pain can be positively influenced by improving the patient's mood or allaying anxiety. Virtually all pain is made worse with depression and/or high anxiety. If these moods can be ameliorated by aromatherapy, it would suggest that aromatherapy could have a positive role in treating pain (Ching, 1999). Aromatherapy's analgesic effects may be secondary to its anxiolytic effect because relaxation or anxiolysis reduces perception

of pain (Buckle, 2001). Thus, aromas may act like diazepam, which activates GABA-mediated inhibitor neurons in the amygdala (LeDoux, 1996). True lavender may induce anxiolysis through a similar mechanism (Tisserand, 1993).

But, do aromas have efficacy as anxiolytics or antidepressants? Aromatherapists recommend numerous odors as anxiolytics, including chamomile, cypress, orange blossom, lavender, marjoram, rose, sandalwood, clary sage (Tisserand, 1977), basil, bergamot, cedarwood, geranium, jasmine, juniper, neroli, petitgrain, ylang-ylang (Damian & Damian, 1995), melissa (Feller, 1997), benzoin, camphor, cardamom, fennel, frankincense, nutmeg, parchouly, peppermint, pine, rosemary, rosewood (Keville & Green, 1995), mandarin, lemon verbena (Schnaubelt, 1995), neroli, and juniper berry (Price, 1991).

Studies of the effects of odorants on anxiety have relied primarily on individuals' self-appraisals of their feeling state. In one instance, apple/nutmeg odor associated with the task of performing certain mathematical calculations led to an attenuated increase in anxiety as determined by subjects' self-reports and blood pressure measurements (Warren & Warrenburg, 1993).

In a nonrandomized, uncontrolled study of eight female day hospital psychiatric patients with anxiety with depression, psychotic depression, or schizophrenia, unnamed oils reduced self-reports of anxiety and depression, although no statistical analysis was performed to demonstrate this (Edge, 2003).

Aromatherapy induced a self-reported relaxed state in five patients with stroke and one patient with spinal injury in a nonrandomized uncontrolled study (Papadopoulos, Wright, & Ensor, 1999). Again, no statistical analysis of efficacy was provided. These results should also be viewed skeptically as olfactory ability was not determined in these subjects and olfactory ability is frequently impaired after a stroke (Murphy et al., 2003) and after spinal cord injury (Hirsch & Cleveland, 1998).

Similarly, the odor of green apple eased the anxiety of being in a space-deprivation booth for six normosmic subjects as demonstrated in a double-blind, controlled, randomized experiment (Hirsch & Gruss, 1998).

Not all studies of the impact of aromatherapy on anxiety have shown positive results, even when outcome parameters were based only on self-appraisals. Among 66 women awaiting surgical abortion, 10 minutes of inhalation of a mixture of the essential oils of vertivert, bergamot, and geranium was no more effective at reducing pre-procedure anxiety than inhalation of the placebo hair conditioner, based on self-reports on a verbal anxiety scale (Wiebe, 2000).

Physiologic evidence is even less conclusive regarding the potential of odorants as anxiolytics. Lavender odor was found to reduce the CNV among perfumers, and the lavender correlated with a more relaxed state (Torii, 1988).

This change on the CNV, however, may also indicate a distracting effect of the odorant (Warren & Warrenburg, 1993). The physiologic manifestations of the anxiolytic effects of the odors of nutmeg–apple, mace, valerian, neroli (orange flowers), and lavender have been demonstrated (Brodal, 1969; Roebuck, 1988). EEG studies support observations that lavender increases alpha waves posteriorly, which is associated with relaxation (Acharya et al., 1996).

Mild reduction in systolic blood pressure, an indicator of anxiolysis (Langewitz, Ruddel, & VonEiff, 1987), with inhaled odors was assessed in a double-blind, controlled, randomized fashion in normosmic and anosmic, awake and anesthetized adults (Allen, 1929). No significant effect was noted with inhalation of hedonically positive odors, but inhalation of an irritant (ammonia) caused an increase in blood pressure.

Studies have also addressed the anxiolytic effects of aromatherapy in the clinical setting with, at best, ambiguous results. In a case-controlled study of 36 men with public speaking anxiety, jasmine and apple spice were no more effective than the odorless control condition in reducing speech anxiety (Spector et al., 1993).

Likewise, no clear efficacy has been demonstrated for aromatherapy for anxiety reduction in patients confined to the hospital. Aromas of marjoram, lavender, rose, eucalyptus, geranium, chamomile, and neroli were used in combination with massage and music therapy to treat 69 terminally ill patients (Evans, 1995). An 80% rate of success, defined as "deriving benefit in some way," was found, but this must be viewed critically for the following reasons: statistical significant was not determined; treatments ancillary to the aromatherapy included talking, massage, or music may have been the true agents; concomitant medical treatment, for example, pharmacologic agents used to decrease pain, may have been the agent of beneficial effects which were misattributed to aromatherapy; different odors were used for each subject; and no consideration was given to hedonics, olfactory ability, a control group, randomization, expectation bias, or examiner bias.

In 122 patients in intensive care, aromatherapy with massage was no more effective than either massage alone or no treatment (the control subgroup) in either subjective perception of aromas ($p > 0.05$) or physiologic parameters of anxiety (systolic blood pressure, respiratory rate, and heart rate) (Dunn, 1992; Dunn, Sleep, & Collett, 1995).

Similarly, a randomized, double-blind trial of aromatherapy with two different species of lavender and massage was performed on 24 postoperative intensive care cardiac patients. No statistically significant self-perceived anxiolytic effect for either species of lavender was found ($p = 0.09$) (Buckle, 1993).

The same results were documented with inhaled neroli aroma combined with massage in 100 1-day post-operative intensive care cardiac patients (Stevensen, 1994). In this randomized, controlled study, again, no statistical significance was found in physiologic parameters of anxiety (heart rate, systolic blood pressure) or subjects' self-perceptions of anxiety as reported in a modified Spielberger State Trait Anxiety Inventory (STAI) self-evaluation questionnaire.

Wilkinson (1995) also used the STAI and the psychologic scale of the Rotterdam Symptom Checklist (RSCL) to assess anxiolytic effects of aromatherapy. In the study, 51 patients with cancer receiving palliative care were randomly assigned to receive three sessions of either full-body massage with carrier oil only or full-body massage with carrier oil and 1% Roman Chamomile essential oil. Upon completion of the sessions, there was no statistically significant effect ($p = 0.08$) of aromatherapy with massage as opposed to massage alone on the psychologic scale of the RSCL or the STAI. Definitive evidence validating aromatherapy in anxiolysis remains to be seen.

Depressed mood is associated with exacerbation of states of pain, and with reduction of depression with elevation of mood, there is a reduction of perception of pain. Thus, if aromatherapy can reduce depression, associated pain would also be expected to be reduced.

A variety of odorants, including basil, bergamot, chamomile, frankincense, geranium, jasmine, lavender, neroli, patchouli, peppermint, rose, sandalwood, ylang-ylang (DeGroot, 1996), clary sage, grapefruit, lemon, mandarin orange (Damian & Damian, 1995), camphor, hyssop, melissa, petitgrain, pine, thyme (Feller, 1997), coriander, helichrysum, rosewood, vetivert (Keville & Green, 1995), marjoram, and thyme (Walji, 1996), have been advocated for the treatment of depression (Tisserand, 1977).

However, scientific studies of aromatherapy for elevation of mood have yielded disappointing results. A mixed citrus odor (a combination of lemon oil, orange oil, bergamot oil, and *cis*-4-hexenol) was applied to the ambient air for 4 to 11 weeks in the rooms where 12 men were hospitalized for DSM-III-R major depression (Komori et al., 1995). During this time, antidepressant medications were reduced or eliminated for 11 of the 12 men and kept constant for another 8 control patients whose rooms were not perfumed. The criteria for medication tapering were not informal, but rather, on a clinical basis. Comparing effects of odorant and antidepressant treatment versus antidepressant treatment alone, the odorant had no statistically significant effect on objective measures of depression including the Hamilton Rating Scale for Depression, a self-rating depression scale, and the number of days of hospital treatment. Despite this, the results of the study are difficult to interpret because levels of antidepressants were not kept constant. Furthermore, olfactory ability was never assessed and because many antidepressants impair olfactory ability, this is particularly important (Estrem &

Renner, 1987). Also, depression itself is associated with olfactory impairment (Hirsch & Trannel, 1996).

Kite, Maher, Anderson et al. (1998) suggested that aromatherapy significantly improved depression as determined by the Hospital Anxiety Depression Scale ($p < 0.001$) and reduced parameters consistent with adjustment disorders and major depressive disorders. These results must be viewed critically for the following reasons: (1) Of 89 entrants, only 58 (65%) completed the study, an indication that the dropouts may have been treatment failures. (2) The majority of subjects (74%) had breast cancer and were receiving oncologic therapy including radiation therapy or surgery. Olfactory ability was not assessed, yet chemotherapy, radiation therapy, and simply having breast cancer (estrogen receptor positive type; Lehrer, Levine, & Bloomer, 1985) are associated with olfactory impairment (Hirsch & Bailey, 2004). Thus, any positive results could be spurious and unrelated to the aromatherapy. The experimental design supports that this may have been the case. (3) No control group was provided; therefore, mood improvement could have been due to the coincident improvement of the underlying disease state. (4) Aromatherapy was not provided alone, but along with massage and empathic therapeutic sessions, either of which might have been effective. (5) One third of the patients concomitantly received counseling and some were on antidepressants, both of which could improve depression. (6) In all, 20 different essential oils were used, alone or in various combinations. The odors were different for each subject and changed during the course of treatment in more than one third of the cases. Thus, even though relief of depression was reported, the effects of the odorants are indeterminate. Thus, primary anxiolytic or antidepressant influence as a mechanism of aromatherapy antinociceptive effects is, at best, tenuous.

However, a dissociation between analgesic and antidepressant/anxiolytic effects of aromas have been seen, suggesting aromas antinociceptive action may be mediated through nonlimbic mechanisms. Stevensen demonstrated this dissociation in a study of 50 post-cardiac surgery intensive care patients, half of whom underwent 20 minutes of foot massage with plain vegetable oil, while the other half had foot massage with neroli essential oil (Stevenson, 1992). While the aromatherapy group had a marked reduction in anxiety, a significant reduction of pain was not observed.

This same analgesic–anxiolytic dissociation was demonstrated in a study of 40 healthy (8 to 25 years old) volunteers (Marchand and Arsenault, 2002). In this experiment, thermal nociception was induced through immersion of the hand for 3 minutes in a hot (46 to 48°C) circulating bath, 10 different times per subject. During each epoch, in a randomized fashion, a different essence was presented for inhalation: massage oil, orange water, aftershave, distilled water, baby oil, vanilla extract, white

vinegar, perm product (hair care), and zonalin (a dentistry product). For the 20 men, there was no significant effect of aromas on pain perception. For the women, however, pain perception was significantly reduced in the presence of pleasant aromas. In both men and women, no correlation was found between mood and pain perception, suggesting analgesic effects of aromas are through other mechanisms such as distraction or even more specific action: both pleasant touch and odors activate the same region in the orbitofrontal cortex, and thus, odors may act to stimulate cortically mediated pain-inhibiting pathways (Francis, Rolls, Bowtell et al., 1999).

Possibly, aromas act to reduce pain through distraction — by focusing attention away from the pain, central supraspinal inhibition occurs and perceived pain is less (Adams, 1998; Buckle, 1999b). Distraction has been suggested as the mechanism whereby lavender suppresses contingent negative variation magnitude (Torii et al., 1988). If this is aromatherapy's antinociceptive mechanism of action, almost all aromas should be effective and those of higher intensity or with greater trigeminal component should be even more effective because they have greater distracting qualities. However, use of essential oils as trigeminal stimulants for pain relief has not been heretofore evaluated.

Another posited mechanism of action of aromatherapy is through potentiation of the analgesic effect of orthodox pain medication (Buckle, 1999b). To date, no studies have been published that substantiate this claim.

AROMATHERAPY FOR VARIOUS PAIN CONDITIONS

Given the above, let us review the literature discussing the antinociceptive effects of aromatherapy in specific complaints and diseases.

HEADACHE

Nontraditional therapies, such as acupuncture, massage, and biofeedback, are frequently used in the management of headache (Matteliano, 2003).

Historically, odors have been recognized to have analgesic effects. When Roman soldiers returned from battle, they placed bay leaves in their baths to reduce their pains (Genders, 1972). In ancient Greece, the Corinthian physician Philonides recommended pressing cool, scented flowers against the temples to relieve headaches (Genders, 1972).

In contemporary lay literature, a multitude of unsupported claims are made for headache and pain reduction using specific odorants. These claims do not indicate whether the mechanism of action is primarily analgesic, soporific, or anxiolytic. Suggested odorants include benzoin, chamomile, lavender, and rosemary for pain (Mantle,

1996); cloves for dental pain (Price & Price, 1995); wintergreen for muscle pain (Göbel et al., 1995; Price & Price, 1995); menthol, ginger, lemongrass, rosewood, clary sage (Damian & Damian, 1995), cajeput, tea tree, juniper, pepper, and rose (Walji, 1996) for headaches (Price & Price, 1995); lavender (Passant, 1990; Waldman et al., 1993), *Lavandula angustifolia, Chamaemelum mobile, Ocimum basilicum, Origanum majorana, Rosmarinus officinalis* (Price & Price, 1995), eucalyptus (Damian & Damian, 1995), and true melissa (Price, 1991; Keville, 1999) for migraine; sweet marjoram for catamenial migraine (Lim, 1997); mentha × piperita for "headache caused by digestive disorder" (Price & Price, 1995); Roman chamomile, lemon, lavender, and peppermint for migraine related to digestion (Lim, 1997); peppermint and eucalyptus for tension headache (Saller, Hellstein, & Hellenbrecht, 1988; Waldman, 1993); basil, cardamom, and eucalyptus radiata for sinus headaches (Worwood, 1995); helichrysum, chamomile, marjoram, and lavender for neuralgia (Keville & Green, 1995).

Experimental studies of odors for pain management are few. Hirsch and Kang (1998) studied 50 chronic sufferers whose headaches met International Headache Society (IHS) criteria. Upon olfactory testing, only 31 demonstrated normal olfactory ability. Green apple odor was given in an aromatherapy inhaler. Only 15 subjects found the odor hedonically pleasant. In this open-label, non-blinded study, subjects served as their own controls. The control condition consisted of resting in a dark, quiet room, and the experimental condition involved inhaling the green apple odor while resting in the same dark, quiet room. Results indicated that green apple odor produced no statistically significant improvement over simple resting in a dark, quiet room. However, in the subgroup of 15 subjects who liked the odor, there was a statistically significant reduction in the severity of the headache ($p < 0.03$). Therefore, the efficacy of the green apple odor was hedonically dependent. Subjects who liked the smell experienced a statistically significant reduction in the severity of the headaches, but patients who disliked the smell experienced no significant improvement.

The mechanism of the odor's action in reducing headaches in these 15 patients is subject to speculation. The odor may have induced a variety of psychologic effects. The therapeutic result may have been mediated through Pavlovian conditioning. For example, the respondents may have consciously or unconsciously associated (Kirk-Smith, Van Toller, & Dodd, 1983) the green apple odor with past anxiolytic or pain-alleviating experiences so that the association reproduced this same effect during the headache episodes. The odor also might have worked through olfactory-evoked recall, because olfactory-evoked recall is usually pleasant and associated with a positive mood state. The green apple scent, by inducing a positive mood state in the 15 patients, could thus have reduced

perception of pain (Fields, 1967). This corresponds with the general affective theory of odors described previously.

The lack of response in those who found the green apple scent unpleasant indicates that hedonics was more important than the particular odor used. This does not preclude the possibility of a neurophysiologic effect of the odor, including a change in serotonin, dopamine, acetylcholine, norepinephrine, GABA, gastrin, beta endorphin, or substance P, all of which are known to be modulators of headache, including migraine (Willis & Westlund, 1997). Because these neurotransmitters exist within the olfactory bulb, they could, theoretically, be influenced by odors (Anselmi et al., 1980; Appenzeller, Atkinson, & Standefer, 1981; Foote, Bloom, & Aston-Jones, 1983; Gall et al., 1987; Haberly & Price, 1978; Halasz & Shepherd, 1983; Hardebo et al., 1985; Igarashi et al., 1987; Leston et al., 1987; Macrides & Davis, 1983; Mair & Harrison, 1991; Moskowitz, 1984; Nattero et al., 1985; Shipley, Halloran, & Torre, 1985; Sjaastad, 1986; Zaborsky et al., 1985). Alternatively, aromatherapy's analgesic effect may be mediated in the nucleus accumbens by way of dopamine, serotonin, and norepinephrine (Buckle, 2001).

Despite its hedonic dependence, green apple odor may have worked somewhat like pharmacologic agents used in the treatment of headache, for example, amitriptyline or propranolol, by modifying the neurotransmitters in the pain pathway. In patients who disliked the odor, a strong negative mood state may have been induced that overwhelmed the odor's neurophysiologic effect. Therefore, the pain was not alleviated.

Göbel also studied the effects of odors on headaches (Göbel et al., 1994, 1995). In that study, 32 healthy subjects underwent a double-blind, placebo-controlled, randomized crossover study of the effects of peppermint oil, eucalyptus, and ethanol. The odors were used in different combinations on various measures of headache pain, including the relaxation of pericranial muscles and contingent negative variation. In this study, three applications of odorant were placed on the skin of the forehead and temples at 15-minute intervals using a small sponge. After 45 minutes, parameters were assessed. To avoid factors of circadian rhythm, all testing took place between 3 and 6 P.M. To prevent subjects from recognizing the presence or the absence of odors and thereby breaking the double-blind nature of the study, "traces" of peppermint oil and eucalyptus oil were added to all applications. Eucalyptus had no effect. Peppermint combined with eucalyptus and ethanol relaxed pericranial muscles ($p < 0.05$) as did a combination of peppermint and ethanol. The most reduction of pain sensitivity as measured by algesimetry was from a combination of peppermint oil and ethanol. Regulation of pericranial muscles was a postulated mechanism of action of the peppermint.

This study has several potential problems. Because the traces of peppermint and eucalyptus were sufficient to

cause olfactory response, they also may have been sufficient to produce an effect, although they were described as inert. Hence, the authors may not have tested the particular odors they thought they were testing. Furthermore, no parameter was measured to determine whether the effect was based on hedonics, to eliminate any influence of the general affective theory of odors. No assessment was made of subjects' olfactory abilities, nor was the preconceived notion or the expectancy effect addressed.

The author postulated that the odors, through a peripheral mechanism in the gate control theory of pain, acted by segmental inhibition of the posterior horn (Göbel et al., 1995). However, this same pathway could have been activated totally independently of the odors. The experimental procedure of applying the odors by rubbing cold oils on the skin may, in and of itself, have influenced the pain pathway. The cold stimuli could have induced firing of A-delta fibers, which would have increased blood flow in the skin and created a counterstimulus to reduce the headache pain. Alternatively, the inhalation of odors may have affected central serotonergic systems leading to a change in mood state and, thus, a reduction in pain (general affective theory of odors).

In another study, Göbel and colleagues found aromatherapy with peppermint oil was effective in treating tension headaches meeting IHS classification (Göbel et al., 1996). Peppermint oil was applied locally in a randomized, placebo-controlled, double-blind, crossover fashion; 10 g of peppermint oil and 90% ethanol were used. The placebo was 90% ethanol solution to which traces of peppermint oil were added for blinding purposes. During their headache attacks, peppermint oil was applied across the foreheads and temples of 41 patients. The application was repeated after 15 and 30 minutes. Compared with the placebo, peppermint oil significantly reduced headache intensity after 15 minutes ($p < 0.01$). The analgesic effect equaled that of 1,000 mg of acetaminophen. Very few studies that claim to have demonstrated efficacy of aromatherapy have been as carefully performed (Woolfson & Hewitt, 1992).

Another possible mechanism by which peppermint may relieve headache is by noncompetitive inhibition of serotonin and substance P (Saller et al., 1988). Odors may inhibit headaches by acting as calcium channel blockers. *Romarinus officinalis*, for example, has been demonstrated to relax tracheal smooth muscle by way of its calcium antagonistic property (Aqel, 1991).

OTHER PAIN CONDITIONS

Aromatherapy has been suggested as a treatment option for a variety of nonheadache acute and chronic pain conditions. Foremost among these is the pain association with labor and delivery (Jardine, 2002; Reid, 2001).

Among 635 postpartum women with acute perineal pain (Dale & Cornwell, 1994), use of lavender in the daily bath was compared with an aromatic placebo consisting of 2-methyl-3-isobutyl tyrosine diluted in distilled water. Of the women, 217 received lavender, 213 synthetic, and 205 control. This study demonstrated no statistically significant effect of using lavender in treating perineal pain.

In a retrospective, nonrandomized, nonblinded, non-placebo-controlled study, the analgesic effect of aromas was assessed in 534 women in labor and delivery pain (Burns & Blamey, 1994). Essential oils assessed included, individually or in combinations of up to four: lavender, clary sage, peppermint, eucalyptus, chamomile, frankincense, jasmine, rose, lemon, and mandarin. They were either administered through inhalation or directly placed on the skin, with or without massage. Expectation effect was encouraged: only those who wanted aromatherapy were chosen and the subjects themselves chose the aroma combination and the method of application. Despite this bias, this study did not support any antinociceptive properties of aromatherapy; there were 225 uses of analgesia before use of essential oils, compared with 624 uses after essential oil application.

In another study, Burns (Burns, Blamey, Ersser et al., 2000) assessed the effect of the same 10 aromas on labor pain among 564 women as compared with a nonaromatherapy control group. Aromatherapy was administered through inhalation, massage, footbath, cutaneous application, or perineal lavage and spray; 54% of those who used lavender and 64% of those who used frankincense reported efficacy in pain reduction, and fewer women required epidural analgesic when aromatherapy was used to reduce anxiety and pain. These results remain suspect because no statistical analysis, randomization, blinding, or control for expectation bias was performed, nor was olfactory ability assessed. Furthermore, their data revealed internal inconsistencies. They report that 7% of 8,058 mothers or 564, used aromatherapy to relieve pain, but later state that *only* 537 administrations of essential oil for pain were provided!

In an attempt to determine efficacy of complementary and alternative therapy for pain management during labor, assessment of aromatherapy was performed through an analysis of all published and unpublished randomized controlled trials that appeared in the Cochrane Pregnancy and Childbirth Group Trials Register (*The Cochrane Library,* Issue 2, 2002), Medline (1966 to July 2002), Embase (1980 to July 2002), and Cinahl (1980 to July 2002) (Smith, Collins, Cyna, & Crowther, 2003). Only one trial of aromatherapy was found that met these criteria (Calvert, as referenced in Smith, 2003). This was a double-blinded, randomized study involving 22 multiparous women with a singleton pregnancy, who, for pain relief, received either the essential oil of ginger, the essential oil of lemongrass, or both. These were applied by bath. There was no statis-

tically significant effect of any of the aromas as measured by the McGill pain visual analogue scales or in the use of pharmacological pain relief. This study suggested the absence of efficacy of aromatherapy for labor pain.

An open-label, non-placebo-controlled study of *Vitex agnus-castus*, applied dermally (presumably at a level high enough for an inhalational effect) for menopausal and perimenopausal symptoms was performed (Lucks, 2003). Of the 52 volunteers, 4 to 6 noted reduced period pain; 1 to 2 volunteers complained that odorant precipitated headaches. Despite that some subjects were as old as 73 years, where more than one half have olfactory deficits (Doty, Newhouse, & Azzalina, 1985), olfactory ability was never assessed. It is unclear if any effect at all seen in this study was due to the aromatherapeutic benefit of *Vitex agnus-castus* as opposed to the topical effects, or even due to the tactile sensory stimulation which occurred on application.

Aromatherapy for pain reduction has been evaluated in the intensive care unit as well. In a study that was not randomized and not double blinded, Woolfson and Hewitt (1992) gave aromatherapy and massage in 20-minute sessions twice a week to 12 patients (Hewitt, 1992). Another 12 patients received massage only. The aromatherapy patients were massaged with lavender oil in an almond oil base. The other patients were massaged with almond oil only. Observations were recorded at the beginning and end of each 20-minute session and 30 minutes after treatment. All sessions were conducted in midafternoon. Approximately 50% of the patients were in the coronary care unit and the others were in intensive care units; 50% of the patients were artificially ventilated. The authors state that 50% of the aromatherapy patients and 41% of massage-only patients reported a decrease in pain. This is somewhat misleading, however. That six patients responded to aromatherapy and five patients responded to massage without aromatherapy is clearly not a statistically significant difference. If anything, these results indicate that aromatherapy was no better than massage alone. Given their selection of patients, however, one would not have predicted that aromatherapy would be effective, because the pathway for olfactory input is compromised by artificial ventilation.

In the previously described randomized, controlled trial of massage with either plain vegetable oil or with essential oil of neroli in postcardiac surgery intensive care unit patients, Stevensen actually demonstrated greater pain reduction with the plain vegetable oil! (Stevensen, 1994).

Oncology patients have also sought analgesia from aromatherapy with mixed results. In an open-label, non-randomized, noncontrolled study, eight women with lymphoedema associated with breast cancer underwent aromatherapy with lavender coincident with at least six 20- to 30-minute therapeutic massages. Three women reported a reduction of pain (Kirshbaum, 1996). All but one did not even notice the aroma. This is not surprising as estro-

gen-positive breast carcinoma is associated with olfactory impairment (Lehrer et al., 1985). Thus, in this study, it is unclear how much of the results were due to the massage rather than the aroma.

Seven men and one woman with glioblastoma multiforme or anaplastic astrocytoma were treated with massage combined with lavender or with Roman chamomile. No statistically significant effect was found for relief of pain, anxiety, or depression (Hadfield, 2001).

Over a 3-year period, an unknown number of inpatient and outpatient oncology patients underwent a total of 769 treatments with massage with a variety of essential oils including *Lavandula angustifolia, Aniba rosaeddora, Citrus sinensis, Santalum album, Pelagonium gravedlens, Cupressus sempervirens,* and eucalyptus globules (DeValois & Clarke, 2001). After each treatment, patients rated their perception of pain relief; 31% of outpatient treatments and 20% of inpatient treatments were reported to improve pain. However, this study is severely limited because it is unclear which aroma was used and the subject size is unknown — the same subject may have undergone treatment many times, with each time counted separately, thus biasing the results.

In a study already referenced regarding possible efficacy of aromatherapy for depression, 89 patients with heterogeneous forms of cancer underwent six sessions of aromatherapy combined with massage and empathetic talking and, in some, reflexology (Kite et al., 1998). A blend of between one and four (median three) essential oils was used and in more than one third, a change in the oils occurred at least once during the treatments. Lavender, chamomile, geranium, juniper, bergamot, jasmine, and rose were the most frequently used of 20 different oils provided. Two thirds completed the study, the majority being women with breast cancer who were also receiving oncological treatment. While 69% (11 of 16) reported "significant improvement in pain," it is unclear what this truly means because no statistical significance was provided, exact aromas used are not reported, no control group was established, and results could have been produced with "empathetic talking" alone without the aromatherapy.

Among 17 cancer hospice patients, pain level was measured in response to 1 hour of lavender aromatherapy as compared with no treatment and a water humidifier control; lavender aroma had no statistically significant effect in reducing pain and was no more effective than plain water, or even no treatment at all (Louis & Kowalski, 2002).

On the other hand, 1% Roman chamomile reduced pain and anxiety ($p < 0.003$) among 51 patients with cancer, 76% of whom had metastases. A blend of lavender, marjoram, and rosemary was found to "show significant effectiveness" after treatment by 44 aromatherapists, based on responses on patient questionnaires (Yamada, Kando, Kim et al., 2001).

Arthritic and osteoarthritic pain is said to be responsive to a variety of aromatherapeutic agents including lavender, angustifolia, eucalyptus, black pepper, ginger, Roman chamomile, rosemary, myrrh, and rosemary, juniper, and birch are recommended for "stiff muscles" (Urba, 1996).

In 100 patients with pain of the periarticular system (Krall & Krause, 1993), treatment of from 10 to 20 days compared the efficacy of mint oil with that of hydroxy-ethylsalicylate gel. The mint oil was put into a gel and applied topically. Of the patients and physicians, 78% thought that mint therapy was highly effective and 50% of patients and 34% of physicians thought that hydroxy-ethylsalicylate gel was highly effective. None of the confounding parameters previously mentioned, such as olfactory ability, expectation, and hedonics, was addressed in this study.

Negative results were found in a study of the effects of massage with and without lavender on nine patients with rheumatoid arthritis (Brownfield, 1998). Although subjects who received lavender with massage were able to reduce their analgesic usage, no statistical significant reduction of pain as measured on a visual analogue scale as a result of massage alone or coincident with lavender administration was found.

In response to a Web page survey about fibromyalgia, 60 (90% female, 97% white) sufferers responded to questions about alternative medicine treatment. Of 10 who admitted to use of aromatherapy, 9 thought it had some effectiveness on treating symptoms (Barbour, 2000). It is difficult to assign much credence to this study because (1) bias may have existed in self-selected respondents, (2) symptom relief may have been for fatigue, depression, or anxiety, and *not* pain, (3) what aromas, methods of distribution, and coincident therapies used are unknown, and (4) no statistical significance regarding efficacy was able to be generated from this study.

RISKS

Before using aromatherapy in pain management, consideration must be given to the potential risks of the treatment. Adverse reactions from inhalation can occur among patients with diseases that predispose them to the development of side effects, and among the population as a whole as well.

Certain diseases make their sufferers particularly susceptible to adverse effects of aromatherapy. Approximately 40% of migraineurs report osmophobia, whereby an odorant induces a migraine headache (Blau & Solomon, 1985). A wide range of odorants can act as such triggers, depending on the individual. These triggers include perfume, cigarette smoke, and food odors (Hirsch & Kang, 1998).

Those with asthma, upon exposure to common odors, can suffer a worsening of their respiratory status independent of their olfactory ability (Burfield, 2000). In a survey of 60 patients with asthma, 57 (95%) described respiratory symptoms upon exposure to common odors including insecticide (85%), household cleaning agents (78%), cigarette smoke (75%), fresh paint (73%), perfume and cologne (72%), automobile exhaust or gas fumes (60%), and cooking aromas (37%). Room deodorant and mint candy also can cause respiratory distress (Shim & Williams, 1986). Four subjects who underwent an odor challenge with four squirts of a popular cologne all had an immediate decline in 1-second forced expiratory volume (18 to 58% reduction) (Shim & Williams, 1986).

Among persons who suffer complaints consistent with multiple chemical sensitivities, 24% of the men and 39% of the women note that odors precipitate their complaints (Miller, 1996). However, double-blind studies fail to demonstrate odorant-induced multiple chemical sensitivity symptoms (Ross, Whysner, Covello et al., 1999).

A variety of essential oils are said to be able to precipitate seizures in individuals with epilepsy. Whether these effects can occur by inhalation alone as opposed to ingestion or by percutaneous absorption is unclear. Proconvulsant odorants are said to include rosemary (Betts, 1994; Tisserand, 1977), fennel, hyssop, sage, wormwood (Millet et al., 1981; Tisserand, 1977), thuja, and cedar (Millet et al., 1981).

Inhalation of odorants can produce measurable levels in the blood (Lis-Balchin, 1997; Stimpfl et al., 1995), and because many common fragrances contain naphthalene-related compounds (including menthol and camphor), persons with G6PD deficiency may be at risk from aromatherapeutic exposures (Olowe & Ransome-Kuti, 1980). In neonates, dermal application has demonstrated this, but in adults it remains only a theoretical risk for inhalational aromatherapy.

Because aromatherapeutic inhalation of essential oils can produce detectable levels of the oils in the blood, these compounds, like any pharmacologic agents, could induce adverse drug–drug interactions in persons on medication. Such interactions could enhance metabolism of anticonvulsants or pain medications, for example, thus predisposing a patient with epilepsy to have a seizure or a patient with chronic pain to withdraw from medication. Jori, Bianchetti, and Prestini (1969) demonstrated this potential. Inhalation of eucalyptol by rats increased microsomal enzyme systems, thus decreasing the effect of pentobarbital.

While odorants can produce harmful side effects among persons suffering or predisposed to disease, they can injure the healthy population as well (Hosokawa & Ogawa, 1979). Airborne-induced allergic contact dermatitis is a recognized result of aromatherapeutic inhalation of tea tree oil (melaleuca oil) (DeGroot, 1996). Examples

of common melaleuca oil allergens include *d*-limonene, aromadendrene, alpha-terpinene, 1,8-cineole (eucalyptol), terpinen-4-ol, *p*-cymene, and alpha-phellandrene. Because of the highly volatile nature of essential oils, their common constituents and cross-sensitization, DeGroot (1996) postulated that the same airborne-induced contact dermatitis could occur with several other essential oils including lavender and a mixture of eucalyptus, pine, and peppermint. Bridges suggested that if odorants can sensitize the respiratory system as they do the skin, they might not only exacerbate asthma, but might actually precipitate asthma (Bridges, 1999).

There is even the potential of sedation to the point of apnea in newborns when aromatherapy is used during the process of childbirth (Lis-Balchin, 1997). Some oils even appear to be carcinogenic (Ernst, 2001, Wisneski & Havery, 1996).

Substantial risks of aromatherapy introduced through a noninhalational route also exist. Toxicity of ingestion and topical application of aromatic essences has been well described and can involve multiple organ systems including cutaneous, renal, gastrointestinal, respiratory, hepatic, and neural, depending on the rapidity and means of administration, dosage, and specific oil used (Guba, 2000; Patel & Wiggins, 1980). Some adverse dermatologic effects of cutaneous application of aromatic essences result from their phototoxic and photomutagenic properties, as seen with oil of bergamot (Kaddu, Kerl, & Wolf, 2001). Dermal application not only can induce a cutaneous allergic response, but also, as with camphor, may be absorbed transdermally inducing toxic blood levels with associated gastrointestinal distress, hepatic toxicity, and even CNS manifestations including encephalopathy, delirium, and seizures (Rampini, Schneemann et al., 2002). Topical application of fragrances in rats has been demonstrated to produce not only blue discoloration of internal organs, but also neurotoxicity (Eiermann, 1980).

CONCLUSION

With aromatherapy, just as with any therapeutic tool, practitioners must weigh the relative risk/benefit ratio in deciding on its use in the treatment of pain.

Having spent the last two decades investigating the scientific basis of aromatherapy and having published more than 100 peer-reviewed articles in this area, the author does not believe that the scientific literature supports, nor the risk/benefit ratio justifies, use of aromatherapy in pain management at present. This is a fluid position, and as more studies are performed delineating the efficacy of aromatherapy, ultimately it may become a valid part of the therapeutic armamentarium. Until such time, this form of alternative medicine in the treatment of pain cannot be recommended.

Homeopathy

Michael W. Loes, MD, MD (H), and Dana Ullman, MPH

INTRODUCTION

Many books and papers have been written about the healing powers of homeopathy (from Greek *homoios,* meaning "like" or "similar"). It is practiced around the world. What is it? What do I need to know about it? How does it work? Should I, as a pain management physician, learn enough about it to integrate it into my pain practice?

WHAT IS HOMEOPATHY?

Homeopathy's philosophical roots go back to ancient Greek physicians, especially Galen and Hippocrates. In their writings, they spoke, in general terms, about the ability of *like* substances having the ability to cure the symptoms that diseases cause. This concept is the most fundamental kernel of homeopathic ideas and is known as "the law of similars." The healing agent — the "like cures like" substance — is known as the *similimum.*

Conventional medicine teaches that symptoms are caused by the illness, whereas homeopathy understands the symptoms as the body's natural reaction in fighting infection or responding to stress. Homeopathy seeks to stimulate rather than suppress symptoms, thereby enhancing and creating a curative response.

Homeopathy as a medical discipline was developed by the German physician, Samuel Christian Friedrich Hahnemann (1755–1843). At an early age, his father recognized that Samuel had a talent for languages, and by the time he finished secondary school, he likely had mastered nearly a dozen. He soon earned a modest income doing medical translations, and these undertakings introduced him to some of the early classical medical texts.

He completed a formal medical degree, but from the onset, he was openly critical of many common therapies of his day such as bloodletting for fevers, leeches for infections, purgatives, toxins, and the use of various religious exorcisms. He was appalled by surgeries done in squalid conditions where postoperative complications were the norm. Hence, over a fairly short period of time, Dr. Hahnemann alienated one group of practitioners, and attracted another, who became his avid followers and began doing things differently. Homeopathy was born.

The principles that form the foundation of homeopathy are eloquently penned in *The Organon of Medical Art* which underwent five editions during the lifetime of Dr. Hahnemann, and a sixth edition was published after his death. It lays out 291 concepts that are referred to as the natural principles of cure. It is exhaustive, and worthy of intense study. The more modest goal here is to acquaint the reader with this science and art of medicine. The information is introductory, but key references and sources are provided as best places to go to explore farther. Your interest will expectantly rise. Some of you will dig deeper learning to use homeopathy, or at the very least, incorporate some of the concepts that are universal to health and healing.

KEY PRINCIPLES

The basic assumption of homeopathy is that symptoms of illness are defenses of the body in its efforts to fight infection and adapt to stress. Instead of using medicinal agents to inhibit or suppress symptoms, homeopaths look to find a substance that would cause, in deliberate overdose, the *similar* symptoms that the sick person is experiencing. The

homeopath then prescribes the identified substance in specially prepared minute or infinitesimal doses.

Homeopaths determine what symptom and disease states a medicine is effective in treating based on research in toxicology. Homeopaths conduct experiments called "provings," in which human subjects are given repeated doses of a substance in order to find out what it causes (and thus what it can cure). These provings are conducted on healthy subjects only because sick people, by definition, are exhibiting various symptoms, and the purpose of a proving is to determine what symptoms a specific substance causes. Please note that provings are conducted with homeopathic doses of substances making them much safer for clinical experiments. However, because such small doses are used, not every person who participates will be exhibit symptoms.

Homeopathy is part of "vitalistic medical thought," although this underlying premise is not a perquisite for using homeopathic medicine clinically. Vitalism assumes that there is an underlying force in the human body that unifies it and that works in coordinated fashion to defend itself against the various infective agents and stresses to which the human organism is prone. The concept of vital force has alternative names: *chi, ki, prana, kundalini*, life essence, life energy, vitality. Even the Romans had a name for it; they called it *élan vitale*.

Homeopathy is holistic in that the homeopath believes that no one organ of the body can be sick without affecting the person as a whole, and that the mental, emotional, and the physical states of the person create symptoms that are a part of the overall disease the person is experiencing. Each person has his or her own syndrome of symptoms.

Homeopaths utilize extremely small and specially prepared doses of various substances from the plant, mineral, animal, and chemical kingdoms. These drugs are manufactured by FDA-recognized drug manufacturers, and they are primarily regulated as over-the-counter drugs.

THE LANGUAGE OF HOMEOPATHY

As with other alternative systems, certain terminology needs introduction as one begins to study homeopathy. Let us start with three terms: *remedy, potency, succession.*

A remedy is the prescription given by the homeopath after a comprehensive case history has been conducted. The remedy contains an amount of a substance that is intended to begin the healing. These substances are generally animal, vegetable, or mineral substances — *but not always*. A list of remedies is categorized in the *Materia Medica* and contains nearly 2,000 possible substances. The similimum is the remedy that best matches the disease spectrum. There are multiple pharmaceutical companies that produce remedies of unquestionable purity. Boiron, Dolisos, Heel BHI, Standard Homeopathic, and Hahnemann Laboratories are notable examples.

Potency refers to the number of times that a medicinal substance has been diluted with double-distilled water in either 1:10 or 1:100 ratios. A 1× potency is called a tincture. A 2× is when 1 cc of this solution is taken and then diluted to 10 cc. When a solution is diluted 1:100 once, it is called a 1C, and when it is diluted again 1:100, it is a 2C, and so on. The aqueous solution is vigorously shaken between each dilution. This shaking is called *succussion*. Serial dilutions render progressively greater potencies, and clinical experience has discovered that the more a substance is potentized, the longer it acts, the deeper it acts, and, in general, fewer doses are generally needed. "Low potency" remedies are generally 1× or 1C to 12× or 12C. "Medium potency" remedies are generally 13× or 13C to 30× or 30C. "High potency" remedies are generally above the 30th potency. In following the tradition of Roman numerals, potencies that have been potentized 1,000 times are called 1M and when they have been potentized further ($1/100 \times 1/500$) they are called LM potencies, and at 100,000 times, they are called CM. Potency designations can also be understood in logarithm scale: 1×, 1C could be expressed as 1×10^6, 1×10^7.

WHAT DOES A HOMEOPATHIC PHYSICIAN DO?

When a homeopathic physician evaluates a patient, major emphasis is placed on the history and, in particular, the symptoms experienced. They are categorized in meticulous detail, not only in severity, but also in order of appearance. The crux of the *Organon's* Principle 7 is that a disease can only be known by its symptoms. When the categorization is done, the spectrum of illness is known, and it must be matched to a similimum (Principle 28) by comparing the illness's spectrum with those of known substances in the *Materia Medica,* which refers to books in which the "materials of medicine" are described based on information derived from provings as well as from clinical practice.

EMPHASIS

> *The symptom spectrum in the illness must match as closely as possible to the known toxic spectrum of the substance in the* Materia Medica *that was determined when the substance was tested in a* healthy *person as part of a proving.*

In *classical* homeopathy, a *single* remedy — known as the similimum — is selected. When it is selected, the potency needs also to be prescribed, as well as giving directions on when and how to take it.

In *modern* homeopathy, low-potency combination homeopathic remedies are often used. A number of rem-

edies will be combined to treat common illness such as an upset stomach, headaches, the flu, or backaches. Homeopathic physicians who are more traditionally trained in homeopathy will often scoff at combination products that are more disease driven than individually attended. It needs to be appreciated that homeopaths treat individuals, not diseases. As soon as the Western concept of disease is introduced, the uniqueness of this therapeutic approach is lessened and likely rendered less effective. If one were to ask a homeopathic physician how many diseases there are, he or she would undoubtedly answer that the number of diseases is equal to the number of living people in "dys-ease." Each person is unique, and how illness forms in each person is individually determined. Hence, the practice of homeopathy, at least classically, is always directed toward the individual person.

CONCURRENT POLITICAL EVENTS IN EVOLUTION IN THE EARLY 20TH CENTURY

- The flu epidemic of 1918, where homeopathy had established itself as better than conventional treatment in at least in one epidemiological mode (Suits, 1985)
- The rise of the American Medical Association (AMA) and its government mandate to control medical education
- The birth of psychiatry, especially the champions of psychoanalysis and cognitive behavior therapy
- The industrial revolution and its assembly-line production style which not only caused new kinds of injuries, but extended exposures to specific chemicals, and may have created the image of "assembly-line" medical care
- The development of the food industry and the problems of contamination
- The early celebrated discoveries of a burgeoning pharmaceutical industry
- The labor-intensive nature of individualized homeopathic care which did not fit into 20th century medicine that emphasized quick visits and drug prescriptions

At a critical time in American history, homeopathy did not have the unity or political power to survive. It was driven underground and nearly annihilated by multiple opposing factors, both from within and outside of its ranks.

THE NEXT STEP

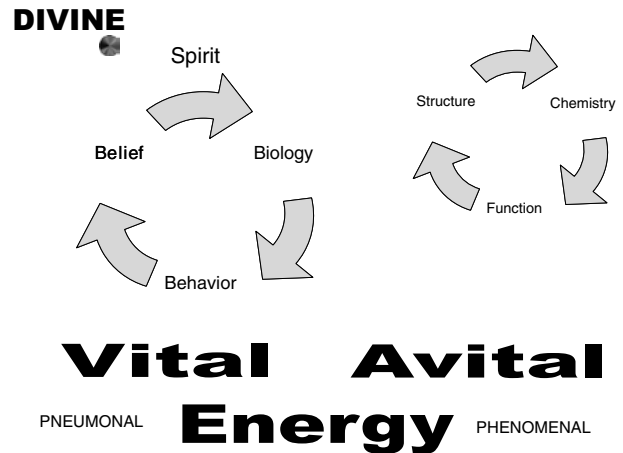
If you, as a pain management physician, nurse, or other type of health care provider, are to appreciate the beauty and discipline of homeopathy, you need to assess your belief system about holistic health and healing. Many of


FIGURE 78.1 Relationship of homeopathy to avital disciplines.

you, in my experience, have developed or have had to develop "unconventional" views because people hurt — *they really suffer*. Prescribing drugs to decrease "nociception" (pain receptors firing) and using advanced neuromodulation techniques are often not enough. Either the patients ask or we, as pain management health care providers, personally begin exploring acupuncture, hypnosis, herbs, and just maybe — homeopathy.

Figure 78.1 illustrates where most homeopaths would place their therapeutic model of health and disease. It needs to be understood that there is a basic separation between sciences that are "avital" and those that are "vital." Physical sciences are avital: math, physics, chemistry, astronomy, computer science. The cause and effect reactions that one investigates are "phenomenal" — can be observed, are generally capable of being reproduced on an experimental basis. Predictability models can be developed. The avital interrelationships address structure, function, and chemistry and are usually defined by mathematical equations. Physical laws are observed, and under laboratory conditions, the information can be confirmed. Many physicians never go beyond these mechanical relationships. Their thinking tends to be mechanistic and reductionistic by design, exemplifying that the whole is the sums of the parts and when a part goes bad, fix it.

For the physician who believes that health is "vital," a new set of relationships exists: beliefs, emotions, spiritual energy, a living biology, and functional behaviors. Relationship can be viewed as back and forth or circular as can the former relationships, but the key is that we have a living relationship — one that is homeodynamic, rather than homeostatic. Some philosophers, most notably Emmanuel Kant, have called this area of inquiry the "pneumonal" or the breath of existence. When a homeopathic physician performs an evaluation, there is assessment of vitality, "aliveness," and very specific lines of questioning are used to do this. The goal is to assess the composite energetic picture of the patient and then choose

a similimum that approximates what is being seen at that point in time.

HOMEOPATHIC MEDICINE AND RESEARCH

Most physicians assume that there have not been good clinical studies to test the efficacy of homeopathic medicines. This is simply not true. A review of 89 worthy clinical studies was published in *The Lancet*, and this review found that, on average, those patients given a homeopathic medicine were 2.45 times more likely to experience a positive result than those given a placebo (Linde, Clausius, & Ramirez et al., 1997). This review of research evaluated various experiments that tested the efficacy of homeopathic remedies in the treatment of hay fever, asthma, migraine headaches, ear infections, upper respiratory infections, rheumatoid arthritis, diarrhea, indigestion, influenza, childbirth, postsurgical complications, varicose veins, sprains and strains, among many others.

In 1991, the *British Medical Journal* published an extensive review article on the efficacy of homeopathy (Kleijnen, Knipschild, & Riet, 1991). The authors pulled from reputable medical journals, scientifically designed clinical studies on homeopathy. In that review, 107 trials were identified and evaluated, rendering a summary conclusion that 77% of the trials showed that homeopathy worked.

The greatest body of clinical research testing homeopathic medicine has concerned conditions in the field of allergy, the vast majority of which has shown highly significant results (Taylor, Riley, Llewellyn-Jones et al., 2000). In their efforts to answer if research in homeopathy is reproducible, a team of physicians and scientists determined that the answer to this question is in the affirmative (Reilly, Taylor, Beattie et al., 1994)

In the treatment of people with influenza, three trials were conducted using a popular homeopathy influenza medicine called "Oscillococcinum." All of these trials were multicentered, placebo controlled, and double blind (Cassanova, 1992; Ferley, 1989; Papp, 1998); two of the three trials were also randomized. Each of these trials was relatively large in the number of subjects (487, 300, and 372), and each of these trials showed statistically significant results.

In addition to double-blind, placebo-controlled research; there is also a body of outcomes research evaluating consecutive cases of patients suffering from specific conditions. One international study involved 30 clinicians in six clinics, in four countries, who enrolled 500 consecutive patients with upper respiration tract complaints, lower respiratory tract complaints, or ear complaints (Singh, Riley, Fischer, & Singh et al., 2001). Of those receiving homeopathic care, 82.6% of patients experienced improvement while only 68% of those receiving a conventional medication experienced a similar degree of improvement. Within 3 days, 67.3% of homeopathic

patients experienced improvement, whereas only 56.6% of patients given conventional medicine experienced improvement. Even within 24 hours, 16.4% of homeopathic patients improved compared with 5.7% in the conventional group.

A satisfaction survey designed at the Royal London Homeopathy Hospital was sent out to 541 adult patients who had had at least three clinical visits. In all, 506 of these were completed, of which 499 were suitable for evaluation (Sharples & van Haselen, 1998). Of these patients, 63% had had their main problem for more than 5 years, and as a result of treatment rendered, 80% reported that their main problem had very much, moderately, or slightly improved and 90% were satisfied or very satisfied with their care. Of the 262 patients who had been concomitantly using a conventional drug, 29% had stopped the drug and 84.3% had decreased their usage since receiving homeopathic care.

In addition to the various above-described clinical trials and outcome studies, there are also numerous basic science studies that have been conducted, including one laboratory study that was replicated by four independent groups of researchers. Four groups of researchers and scientists at Queens University of Belfast, the University of Utrecht (Netherlands), University of Florence (Italy), and Catholic University of Louvain (Belgium), conducted the same experiment using various homeopathic potencies of histamine (15C to 19C) (Belon et al., 2004). A total of 2,706 experiments were conducted using "flow cytometry," which is an automated technology that objectively measures histamine release from basophils. The researchers found that these homeopathic doses of histamine had a substantially significant effect on inhibiting the effects of IgE ($p < 0.0001$). References to various other basic science studies have been published elsewhere (Bellavite & Signorini, 2002; Ullman, 2004).

The controlled clinical studies discussed next are worthy of attention to physicians who specialize in pain management.

ARTHRITIS

Two research reviews on arthritis and homeopathy have concluded that there is a body of evidence to suggest that homeopathic medicine, either individually prescribed or used in homeopathic formulae, can provide relief for people with rheumatoid disease (Jonas, Linde, & Ramirez, 2000) or osteoarthritis (Long & Ernst, 2001).

One study addressing patients with rheumatoid arthritis was published in the *British Journal of Clinical Pharmacology* (Gibson, Gibson, MacNeill et al., 1980) and found that 82% of patients prescribed an individually chosen homeopathic medicine experienced some relief of their arthritis pain, while only 21% of patients prescribed a placebo experienced a similar degree of relief. Another

study comparing the results of a homeopathic remedy was found to be safer and more effective than the conventional comparison drugs (Shealy, Thomlinson, Cox, & Borgmeyer, 1989).

A newer study that was not a part of the previous reviews compared a homeopathic topical application with a convention nonsteroidal anti-inflammatory drug. This randomized, double-blind trial found that the homeopathic topical gel was as effective as piroxicam gel (van Haselen & Fisher, 2000). This trial evaluated the treatment of 172 osteoarthritis patients over 4 weeks, applying either a homeopathic gel or piroxcam gel three times daily. The homeopathic gel contained Symphytum, Rhus tox, and Ledum.

BACK PAIN

When a patient has back pain, there are simple homeopathic medicines that in clinical experience are worth trying although as in conventional medical trials, the problem with this group of patients is that these individuals have multiple and varied symptoms, and various degrees of trauma, degeneration, and dysfunction. Given these concerns, nonetheless, there is at least one study to support this assertion, which compared a homeopathic topical gel with a conventional pain-relieving gel (Stam, Bonnet, & van Haselen, 2001). This trial compared a homeopathic gel (Spiroflor SRL: containing tinctures of Sympthytum officinale, Rhus tox, and Ledum) with conventional medication: Cremor® Capsica Compositus (CCC). There were 161 subjects in this trial and the findings showed significant pain improvement in both groups and found that the homeopathic gel had fewer adverse events (11% vs. 26%) or adverse drugs reactions (4% vs. 24%).

CARPAL TUNNEL SYNDROME

Eight small carpal bones make up the wrist along with the multiple muscles, tendons, and joints that connect them giving us strength, dexterity, and optimal function. A common idiopathic or overuse syndrome, called carpal tunnel syndrome, was the test group for 37 patients during recovery from their tunnel release surgery. They were treated with either placebo or Arnica 6X in tablet and Arnica ointment (5%). Those patients given this homeopathic medicine had a statistically significant reduction in postoperative pain after 2 weeks when compared with patients given a place ($p < 0.03$; Jeffrey & Belcher, 2002).

EARACHES

Earaches are at present the most common ailment for which American parents take their children to a physician, and there is growing controversy about the effectiveness of antibiotics in the treatment of this common ailment (Cantekin, 1998). Homeopathy provides a safer and often more effective treatment.

A randomized double-blind, placebo-controlled study prescribed individualized homoeopathic medicine or placebo to 75 children (Jacobs, Springer, & Crothers, 2001). There were 19.9% more treatment failures in children given a placebo than those given an individually chosen homeopathic medicine. Diary scores showed a significant decrease in symptoms at 24 and 64 hours after treatment in favor of those given a homeopathic medicine. What was particularly impressive about these results was that improvement from homeopathic medicine occurred within the first day.

Another study providing evidence of rapid resolution of ear infection in children given a homeopathic medicine involved 230 children (Frei & Thurneysen, 2001). These children were given an individually chosen homeopathic medicine. If pain reduction was not sufficient after just 6 hours, another individually chosen homeopathic medicine was prescribed. These researchers found that 39% of patients experienced sufficient pain reduction in the first 6 hours and another 33% after 12 hours. This improvement was 2.4 times faster than in children prescribed a placebo.

FIBROMYALGIA

Researchers in England found that patients with fibromyalgia were a varied group with differing symptoms but that there was one homeopathic medicine, more than any other, that seems to be indicated (Fisher, Greenwood, & Huskisson, 1998). This medicine, Rhus toxicodendron, was found to be indicated in 25% of patients with fibromyalgia. The researchers found 30 patients who seemed to fit the symptoms of Rhus tox, and they were given a homeopathic dose of this medicine in the 6C potency. The researchers found that there was a significant degree of improvement in the reduction of pain and tender points and improved sleep when the subjects were taking the homeopathic medicine, as compared with when the subjects were taking a placebo ($p < 0.005$).

A more recent study appeared in *Rheumatology* (Bell et al., 2004), representing research from the University of Arizona. Collaborating with local homeopathic physicians, 62 patients with fibromyalgia were enrolled using a double-blind, randomized, placebo-controlled study design. Patients received either an oral daily dose of an individually chosen homeopathic medicine in LM potency or a placebo. Patients were evaluated at baseline, 2 months, and 4 months. The study found that patients receiving the homeopathic treatment experienced a 25% or greater improvement in tender point pain on examination, as compared with those who were given a placebo ($P = 0.008$). After 4 months, the homeopathic patients also rated the "helpfulness of the treatment" — connoting positive well-being. Again, the patients who received homeopathy rather than placebo felt that they were helped ($P = 0.004$). Another interesting point in this study was that

because this was an individualized treatment protocol, the number of different "placebo remedies" was greater in the placebo group than in the true homeopathic group, likely because positive benefits were not being seen, and the clinicians were changing remedies.

One of the most intriguing aspects of the above study was that the researchers gave the first dose of the homeopathic medicine (or placebo) via olfaction (smelling the liquid dose of the medicine or placebo). Each patient was hooked up to electroencephalography (EEG) monitor at the time of this first dose, and the researchers found a statistically significant difference in the EEG readings of those patients given a homeopathic medicine as distinct from those given a placebo. This objective evidence along with the significant clinical improvement in the homeopathic patients presents a strong case for homeopathy.

HEADACHES

The scientific evidence for the efficacy of homeopathic medicines in the treatment of headaches is mixed. Two studies have shown beneficial results (Brigo, 1987; Straumsheim, Borchgrevink, Mowinckel et al., 2000), but two other studies have shown that homeopathic medicines are no better than placebo (Wallach, Haeusler, Lowers et al., 1997; Whitmarsh, Coleston-Shields, & Steiner, 1997). Noteworthy is that the two studies showing positive results trended toward younger patients and those whose duration of suffering was less than in the studies showing negative results.

Despite these results, it makes sense to try homeopathy due to homeopathic medicine's history of safety.

HEAD INJURY

A randomized and double-blind study of people with mild traumatic head injury showed a statically significant difference in patients given an individualized homeopathic medicine for pain relief as compared with those given a placebo (Chapman, Weintraub, Milburn et al., 1999).

COMMONLY USED HOMEOPATHIC MEDICINES FOR PAINFUL CONDITIONS

Arnica (mountain daisy): This medicine is the most common homeopathic medicine for injuries to soft tissue and pre- and postsurgery (the 1000th potency is preferred); this remedy is also thought to reduce shock of injury or from surgery.

Hypericum (St. John's wort): This remedy is the first medicine to consider for injuries to the nerves or to parts of the body rich with them, including the fingers, toes, back, and eyes. Any injury with shooting pains should be given this remedy.

Belladonna (deadly nightshade): This is for rapid and violent onset of throbbing pain (arthritis, headaches, menstrual) arising with flushed face and/or skin; symptoms are aggravated by tough jarring and especially by motion, and warm wraps relieve them.

Bryonia (wild hop): Headaches or arthritis syndromes that are aggravated by any motion; some relief of pain comes from lying still, heat, direct pressure, and lying on one's painful side.

Ruta grav (rue): Injuries to the elbow or knee; serious injuries to connective tissue, deep achy pain in the joints, especially the back, worse in cold damp weather, worse when lying down, better with movement.

Rhus tox (poison ivy): This medicine is the most common remedy for sprains and strains after the use of Arnica during the first 24 hours. It is especially indicated when a person experiences a "rusty gate" syndrome, that is, pain on initial motion, which is reduced gradually as the patient continues to move. It is also often given to people with the flu, arthritis, or fibromyalgia who experience this similar rusty gate syndrome.

(*Note:* It is the low potencies of these commonly used homeopathic preparations that are commonly prescribed: 3X,12X, 30X, 6C, 12C, 30C.)

HOMEOPATHY (GLOBAL)

Homeopathy is so popular in certain countries that it is no longer appropriate to consider it "alternative medicine" there. Approximately 30 to 40% of French physicians use homeopathic medicine, about 20% of German physicians use these natural medicines, and 45% of Dutch physicians consider them effective (Fisher & Ward, 1994). According to the 1986 survey in the *British Medical Journal*, 42% of British physicians surveyed refer patients to homeopathic physicians (Wharton & Lewis, 1986), and it is now considered to be much higher.

In addition to these impressive statistics, homeopathy is particularly popular in India where there are more than 120 5-year homeopathic medical schools. Homeopathy is also popular in Greece, Pakistan, Brazil, Argentina, Mexico, and South Africa.

Clinical Applications of Massage Therapy in Pain Management

Joe Durant, NCTMB

INTRODUCTION

From acupressure, neuromuscular therapy, and Swedish massage to Trager approach and Hellerwork, there are numerous forms and names of touch therapy on the market. Each incorporates its own special twist, technique, or theory and has its own following of practitioners who find that therapy to be most effective for specific disorders. From a practical standpoint all bodywork systems incorporate various techniques of massage in one form or another, and as such, massage represents one of the oldest known and most easily applied forms of healing. Utilization of massage ranges from massage therapists to nurses, physical therapists, and physicians and is one of the few therapies that can, in many cases, be safely and easily applied by a patient or family member.

The mechanisms of and research into the effects of massage fall into one or both of two categories: direct mechanical effects or reflexive effects.

DIRECT MECHANICAL EFFECTS

These include local effects in the area of massage such as the inactivation of a myofascial trigger point, increased local circulation, or increased range of motion.

Myofascial Trigger Points

Point-specific massage techniques can effectively eliminate the referred pain and local tenderness associated with myofascial trigger points (Hanten et al., 2000). This point

lends tremendous support to the use of massage for chronic musculoskeletal pain.

Soft Tissue Healing

Massage that uses heavy pressure promotes the healing process in tendonitis in part by increasing the number of fibroblasts in the area of treatment (Davidson et al., 1997; Gehlsen, Ganion, & Helfst, 1999), suggesting that the healing effects of massage come in part from the controlled application of microtrauma.

Range of Motion

Massage can have significant effects on range of motion in areas such as the lower extremity (Wiktorsson-Moller et al., 1983) and low back (Hernandez-Reif et al., 2001) as well as more specific single joint areas such as the shoulder (Watson, Dalziel, & Story, 2000). The conclusion is that massage either manually stretches muscle tissue or stimulates stretch receptors, which allows muscles to stretch once motion is applied.

Muscle Soreness

Delayed-onset muscle soreness from maximal muscle contractions can be significantly reduced by the application of one massage treatment (Hilbert, Sfornzo, & Swenson, 2003). Soreness resulting from constant spasm can be reduced by the application of massage as well as overall muscle tension (Naliboff & Tachiki, 1991).

H-Reflex

Massage has an inhibitory effect on the H-reflex in muscles that appear to originate from stimulation of deep (not cutaneous) mechanicoreceptors (Morelli, Chapman, & Sullivan, 1999).

Muscle Performance

Massage applied to fatigued muscle can increase their follow-up performance when compared with muscles that have only been allowed to rest — suggesting a strong influence on local circulation (Rinder & Sutherland, 1995).

REFLEXIVE EFFECTS

These include effects removed from the site of massage, such as increased blood flow to the intestines by massaging the feet, or systemic effects, such as decreased blood pressure and anxiety (Moyer, Rounds, & Hannum, 2004) and even improved immune system functioning (Diego et al., 2001).

Pain Relief

Repeated massage treatments bring about antinociceptive effects that can be reversed by an oxytocin agonist, suggesting that the long-term antinociceptive effects of massage are at least partly tied to the oxytocinergic system (Lund et al., 2002). Massage increases levels of beta endorphins, strengthening the position that massage can affect pain through the opiate receptor system within the body (Kaada & Torsteinbo, 1989). Further evidence supporting this theory is that acupoint stimulation can potentiate the effects of morphine (Yuan et al., 2002). Multiple massage applications can reduce level of depression and the delayed assessment of pain, suggestive again of effects on the endogenous opiate system (Lund et al., 2002).

Pressure

The effects of massage can depend on the amount and type of pressure. Moderate, light, and vibratory massage all reduce anxiety. But while light and vibratory massage can increase heart rate and overall arousal measures (via electroencephalography), moderate pressure massage decreases heart rate and arousal (Diego et al., 2004), and deep massage can increase heart rate temporarily (Delaney et al., 2002).

Sympathetic Arousal

A single application of general massage and acupoint stimulation can reduce blood pressure, heart rate, and anxiety state (Kober et al., 2003; McNamara et al, 2003; Moyer et al., 2004) — a definite reflexive effect applicable to sympathetic arousal from pain.

Edema

Persistent edema can be reduced through massage (Howard & Krishnagiri, 2001). The inference here is that fluid circulation through the body can be strongly influenced by massage.

Nausea

Massage of specific acupuncture points or reflexology zones can be targeted to influence very specific goals, such as the reduction of nausea (Roscoe et al., 2003), which supports the position that a trained massage practitioner can reflexively influence but also physiological functions.

Immune System

Immune system functioning can be improved by massage (Diego et al., 2001; Ironson et al., 1996), lending support to the use of massage during cancer and HIV/AIDS for more than palliative applications.

Constipation

Massage can be used to treat chronic constipation (Bishop et al., 2003; Ernst, 1999), which is very significant for patients who have become constipated via the use of opiates to control their pain.

Although most types of massage focus more on one of the two effects, one would be hard pressed to argue that most therapies do not incorporate elements of both direct mechanical and reflexive effects. Even therapies such as acupressure will have a mechanical effect on the tissue at the point of pressure application, not forgetting that acupuncture points and myofascial trigger points have at least an 80% correlation rate (Travell & Simons, 1983). Although many effects of massage have been uncovered, the explanation of why properly applied massage triggers these effects is still an elusive one research is just beginning to uncover.

MYOFASCIAL PAIN

Few other works have influenced the clinical practice of massage therapy as strongly as the two-volume set, *Myofascial Pain and Dysfunction: The Trigger Point Manual*, by Drs. Janet Travell and David Simons. With in-depth descriptions of trigger point location, patterns of referred pain, and techniques and stretches for treating muscles, the volumes are an essential reference for anyone who is serious about treating chronic muscular pain. A brief review of the volumes clearly suggests almost all types of pain are reflected in one way or another in the muscular system, even if the source of the pain lies elsewhere such as in a diseased organ.

A myofascial trigger point is defined by Travell and Simons as: "A hyperirritable spot, usually within a taut band of skeletal muscle or within the muscle's fascia that is painful on compression and that can give rise to characteristic referred pain, tenderness and autonomic phenomena" (Travell & Simons, 1983). Research has shown that between 45 and 54% of healthy, asymptomatic young adults were found to have latent trigger points in the shoulder girdle musculature (Sola, Rodenberger, & Gettys, 1955). Given the frequency with which trigger points occur, one certainly cannot deny the often significant role they can play in the pain cycle if they become active via chronic strain or a traumatic event. Currently, there are four hypotheses that attempt to explain findings at trigger points (Rivner, 2001):

1. Trigger points are found at the muscle spindle.
2. Trigger points represent hyperactive end-plate regions.
3. Trigger points are representations of focal dystonia.
4. Trigger points do not exist.

For the purpose of pain management, it is enough to recognize that myofascial trigger points do exist, that they can create extremely painful conditions for patients, and that they can be treated via manual pressure or massage (Hanten et al., 2000; Hou et al., 2002).

To illustrate the severity of the pain that can be perpetuated by trigger points, consider a case with which the author was recently presented. A female in her mid-30s was diagnosed with a herniated disc at C5–6 (confirmed via magnetic resonance imaging, MRI) and posterior cervical pain on the left as well as pain down the left arm into the fingers. She failed conservative treatment including physical therapy, cervical traction, pharmacological interventions (including oral steroids and muscle relaxants), and bed rest. The patient underwent surgery having an anterior cervical fusion with plating at C5–6. Several weeks after surgery, the patient presented in a complete panic with symptoms that had recently manifested during the recovery phase as being virtually identical to the initial pain she had prior to surgery. She was convinced that either surgery had failed or that she had somehow done something to compromise the surgery. An examination revealed the presence of several myofascial trigger points in the left scalenes that when palpated, duplicated her neck pain and referred pain down her arm to her hand and fingers. A course of neuromuscular massage, electrotherapeutic point stimulation (ETPS^SM) by the author and trigger point injections by the neurosurgeon were successful in eliminating the trigger points and thereby the pain. Despite elimination of the offending pressure on the nerve root, the myofascial component of the pain perpetuated itself until it was addressed with physical input to break the cycle. It has been suggested that many cases of "failed back" after surgery can be traced to the presence of untreated trigger points (Travell & Simons, 1983).

Simons and Mense (2003) note that myofascial trigger points typically either follow acute muscle overload (such as a car accident) or develop gradually over time with repetitive or prolonged muscle contractions. It has been demonstrated that trained clinicians can reliably determine the precise location of trigger points within muscles (Sciotti et al., 2001). Clinical trials have also demonstrated that "ischemic compression" can effectively eliminate myofascial trigger points and the referred pain that accompanies them (Hanten et al., 2000; Hou et al., 2002). It is a reasonable assumption that massage therapy is a viable option to incorporate into the treatment of chronic musculoskeletal pain. Massage has been shown to be an effective treatment for muscular shoulder pain (van der Dolder & Roberts, 2003) and should therefore be applicable to other muscular problems that cause pain.

Fibromyalgia is certainly a disease that often includes myofascial. When treating fibromyalgia, the previously noted effects of deep massage on increasing heart rate and other autonomic functions should be taken into consideration as fibromyalgia does, from an observational point of view, appear to be a disorder of sympathetic upregulation.

STRUCTURAL CONSIDERATIONS

There are many schools of massage such as Rolfing, Alexander technique, and neuromuscular therapy that promote the idea that simply eliminating myofascial trigger points is not enough. Postural distortions from adaptive muscle shortening (from dysfunctional biomechanics) that chronically strain the antagonist muscles must be addressed if one is to eliminate the source of the trigger points. Trigger points are considered more of a diagnostic indication of a problem rather than the primary source of the problem. Consider the following simplified example as an illustration of how including structural theories will affect treatment.

A patient presents with chronic posterior shoulder and mid thoracic pain between the medial border of scapula and the spine. Upon examination, palpation reveals the presence of trigger points in the right rhomboids that, when pressed, replicate the pain pattern the patient has been experiencing. Visual exam reveals that the right shoulder is protracted and the right scapula winged out slightly when compared with the left. When supine, the patient's right shoulder is elevated off the exam table but the left is flat. In explaining his case history, the patient notes that there has never been any major trauma to the right shoulder. The patient also reveals that he works with computers for long hours every day and that his right arm is always reaching forward for hours at a time while he uses the mouse.

In this case, massage used to eliminate the myofascial trigger points in the right rhomboids will most likely result in only temporary relief of the pain. The protracted shoulder, slight winging of the scapula, and failure of the right shoulder to lie flat on the table while the patient is supine are all indications of a shortened pectoralis minor muscle (Kendall, McCreary, & Provance, 1983). In this case, the shortened pectoralis muscle puts chronic strain on its antagonist, the rhomboids, which then develop trigger points and cause pain. From a structural standpoint, massage techniques will be used to eliminate the trigger point in the rhomboids. Massage techniques will also be used to lengthen the chronically shortened pectoralis minor muscle and overlying fascia. (There are entire systems that have been developed to specifically address the fascia such as the myofascial release methods taught by John Barnes, physical therapist.) Even addressing the shortened pectoralis will not be enough to keep the pain from recurring. The patient must reorganize his workstation so that using the computer mouse does not entail reaching forward in such a way that the pectoralis minor is allowed to adaptively shorten again. Stretches should also be performed periodically that promote retraction of the shoulders.

The above example is highly simplified for the purpose of clear illustration, and it must be noted that real cases are typically much more complex. The recognition and treatment of postural distortions caused by adaptive shortening in muscle from dysfunctional biomechanics is a key concept for anyone attempting to use massage therapy in the treatment of chronic musculoskeletal pain. Without this key recognition, the patient can become locked into a revolving-door type of dependency on the practitioner simply for the short-term relief of trigger point–related pain, which, as noted, can be merely a symptom of the problem. In these situations patients may give up because of the cumulative cost and frequency of massage treatment, and may say that they tried massage but "it just didn't work." The failure is not with the massage, but its improper application.

So important is the role of recognizing and treating postural distortions that some systems of structurally based massage such as Rolfing insist on a set series of treatments to align the body structurally before they will provide localized treatment of pain.

Even integrative treatments such as ETPS incorporate treatment of core postural muscles such as the iliopsoas group and piriformis/lateral hip rotators (Weiner, 2002). Hocking suggests that chronic contraction of core postural muscles imbalance the hips and sacrum. This imbalance will cause upregulation of the autonomic nervous system via uneven muscular tension levels along the spine and pressure on nerve roots and elevate acetylcholine levels along dermatomes. Muscles then can become depolarized and the chronic pain cycle maintained.

As Sigmund Freud is rumored to have said, "Sometimes a cigar is just a cigar" — with the implication that it is rarely ever the case. Sometimes local massage will completely eliminate muscular pain, but in cases of long-term chronic pain, it is strongly suggested that some type of postural distortion is at work to perpetuate the condition. Entire sections of physical therapy reference books, such as in *Muscles Testing and Function* (Kendall et al., 1983), are often devoted to the role of posture and pain, and make an excellent addition to the library of the practitioner.

SPECIFIC PAIN DISORDERS

BACK PAIN

If one reviews the database of the National Library of Medicine, it quickly becomes clear that back pain has been one of the most thoroughly researched areas in the efficacy of massage. "Back pain" is a very broad term covering conditions ranging from trigger points to the effects of disk herniation. However broad the term may be, there is very good evidence supporting the use of massage for treating back pain. Massage has been found to be both safe and cost-effective in treating back pain (Cherkin et al., 2003). A literature review found massage to be an effective treatment for low back pain (Furlan, 2002), and it is at least as effective as acupuncture (Cherkin et al., 2001; Hurley, 2001). Techniques range from cryomassage (Gusarova, 2000) to standard massage (Cherkin et al., 2001; Predye, 2000), and can be effective in treating back pain. Neck pain and massage does not appear to have been researched as well but treatment is along the same lines and has been shown effective (Luo & Luo, 1997).

Theoretically, back pain can be treated on a number of different levels with massage. General massage techniques and reflexology can be used to bring about reflexive changes in the body's response to pain. Using massage to eliminate myofascial trigger points is another avenue of treatment that would certainly be worth pursuing. A structural approach is also strongly recommended. Consider the potential benefits of releasing muscles around a bulging disc — muscle contractions create pressure, and by releasing the pressure, one could potentially influence the amount of disc bulge. Also from a structural standpoint, consider the patient who has habitually stood on the right leg to protect an old ankle injury in the left foot. The right quadratus lumborum could shorten, pulling the pelvis into an abnormal position. With the pelvis in an abnormal position muscle tension in the paraspinal muscles would be unequal from left to right as the body compensated to maintain a straight posture. The chronic strain on one side of the paraspinals could certainly lead to the formation of trigger points, which in turn create pain. Neck pain could even originate from a low back postural distortion. As was noted earlier, massage can affect muscle length and ten-

sion so it would certainly be logical to attempt to correct the postural distortion by treating the shortened muscles. The topic of neck pain treated specifically by massage does not appear as frequently in research as back pain. As the neck is simply an extension of the spine and its musculature, it would be reasonable to apply the same supporting research to massage in the treatment of neck pain.

HEADACHES

Migraine headaches are estimated to affect 27.3 million people annually and tension-type headaches even more (Landy, 2004). While massage therapy is not generally the first route most people take to alleviate their pain, there is strong evidence suggesting that massage can be effective in treating both conditions. There is an inherent problem in that most people normally cannot take time for massage when a headache occurs, and it may be dangerous to attempt driving while in the throes of a severe migraine or tension headache. The strength of massage therapy in the treatment of headaches lies in preventing them and reducing the intensity of future headaches.

The exact mechanism by which massage is helpful for headaches is uncertain. The effectiveness of massage for headaches cannot be predicted by psychological testing (Wylie, Jackson, & Crawford, 1997), suggesting that the effects of massage go beyond some imagined process in the minds of easily influenced patients.

As studies have confirmed the effectiveness of both reflexology and Swedish-type massage for both tension and migraine headaches (Hodges, 1990; Launso, Brendstrup & Arnberg, 1999; Lemstra, Stewart, & Olszynski, 2002; Lipton, 1986; Puustjarvi, Airaksinin, & Pontinen, 1990; Quinn, Chandler, & Moraska, 2002), one may infer that an overall reduction in stress via massage may play a significant role. Certainly, properly applied local techniques such as myotherapy and neuromuscular therapy for inactivating myofascial trigger points that are known to refer pain into the head (Travell & Simons, 1983) may also be a factor. Long-term effects on migraine headaches have been achieved, with studies indicating that 81% of patients treated were still receiving benefit 3 months posttreatment (Launso et al., 1999). Again, the practitioner is urged to look for postural distortions that may be perpetuating trigger points around the head and neck.

PREGNANCY

Pregnancy is a time when many medications for painful conditions such as migraine headaches or even general pain disorders may very well be contraindicated. As has been previously discussed, massage is an effective tool for the management of migraine headaches as well as musculoskeletal pain. Certainly massage should not be the only intervention in the absence of pain medication; all

appropriate modalities should be integrated, but massage is an obvious choice.

Although many antidepressants are characterized as safe during pregnancy, the author has seen in his clinical practice many women who choose to stop taking these medications while pregnant. As previously mentioned, massage has shown to be effective in lowering anxiety and improving overall quality of life. Pregnancy is a time when massage can certainly be employed to offset the effects of not taking medication that controls anxiety contributing to depression. A simple 20-minute massage applied twice per week has been shown to decrease leg and back pain, increase sleep, and decrease anxiety and urinary stress hormone (norepinepherine) (Field et al., 1999). As a further benefit, the same study subjects had fewer complications during labor, and their infants had fewer postnatal complications.

During labor therapeutic and acupressure related massage has been shown effective in reducing pain and anxiety. Manual stimulation of the acupoints Large Intestine (LI) 4 and Bladder (B) 67 have been shown to reduce pain during the first stage of labor (Chung et al., 2003). Ice massage of LI4 was shown by Waters (1995) to reduce labor pain and by Melzack to reduce back pain and was a key study in the development of the gate control theory of pain (Melzack & Wall, 1965). LI4 is located in the web of the thumb approximately one third of the distance distally from the junction of the metacarpal — it should be quite tender to a pincer grip between the thumb and forefinger (Hocking, 1999). B67 is located at the lateral edge of the base of the nail of smallest toe — if a straight line were drawn across the proximal base of the nail and down the lateral border of the nail, the meeting point is B67 (quite tender to palpation with the tip of a ballpoint pen) (Hocking, 1999). Therapeutic massage applied during labor has also been shown to reduce pain during the latent (3 to 4 cm dilation), active (5 to 7 cm), and transitional phases (8 to 10 cm) (Chang, Wang, & Chen, 2002).

It must be strongly suggested that massage during pregnancy be applied by or monitored by a trained massage practitioner as well as the attending physician. Strong evidence to support this recommendation comes from cases of cranial hemorrhages occurring in Pacific Islander infants in Auckland, New Zealand. Infants of Pacific Islanders were found to have a 60% greater chance of being stillborn than European or Maori infants (Becroft & Gunn, 1989). Traditional massage practices were thought to be at the heart of the problem and warnings about traditional massage at antenatal clinics resulted in a significant decrease in still births progressively over several years. Contraindications for massage, such as deep vein thrombosis and preclampsia, should be closely screened for prior to initiating any massage during pregnancy (Waters, 1995). Although there are no studies to support negative effects of manually stimulating acupoints

during pregnancy, thousands of years of experience should be heeded. The following acupoints should be avoided during pregnancy massage (Waters, 1995):

- Spleen (SP) 6: Located four fingers above the apex of the medial malleolus and hooked slightly behind the fibula (Hocking, 1999)
- Stomach (ST) 36: Located (with the knee flexed at 90°) four fingers below the patella halfway between the peak of the tibia and the head of the fibula (Hocking, 1999)
- LI4: Located in the fleshy web between the thumb and forefinger (Hocking, 1999) mentioned above as helpful for labor pain, but should be avoided during earlier stages of pregnancy

CANCER

Cancer is a disease in which there are multiple roles for the application of massage. Not only can there be a great deal of pain associated with the disease itself, but the treatments can have a multitude of side effects including pain and nausea. In addition to pain, there can be an understandable level of anxiety as patients are attempting to have quality of life and organize their affairs in order in the face of a potentially lethal disease. Massage can be utilized as a tool to improve the above-mentioned aspects and may even improve immune functioning.

The benefits of massage in cancer are clearly mostly of a reflexive nature and reflect effects that are generalized throughout the body. Therapeutic massage and reflexology have both been found effective in improving the pain experience of patients with cancer (Ferrell-Torry & Glick, 1993; Post-White et al., 2003; Smith et al., 2002; Stephenson, Dalton, & Carlson, 2003; Walach, Guthlin, & Konig, 2003). It must be pointed out that cancer is one of the few situations that incorporate elements of nociceptive, inflammatory, and neuropathic pain and as such the pain-relieving benefits of massage can be short lived, sometimes not lasting 3 hours (Stephenson et al., 2003). The possible short-term duration of pain control may be attributed to the fact that there is constantly new damage being done by the disease. Despite the shortcomings, massage can still be effectively used as a nursing intervention and function in much the same way that breakthrough medication is used when pain peaks.

Because massage does increase plasma levels of beta-endorphins (Kaada & Torsteinbo, 1989), it could conceivably potentiate the effects of opiates given for pain control. From a speculative basis one might infer that pain resulting from visceral–somatic referrals (Travell & Simons, 1983) from pancreatic and other organ cancer might be reduced by the application of massage to soft tissue in the area of referred pain. The author can vouch for this theory based on personal experience with patients suffering with organ cancer.

Overall quality of life can be significantly affected by proper application of massage. In a study involving more than 200 subjects, massage along with healing touch were found to decrease the intake of nonsteroidal anti-inflammatory drugs over a 4-week period as well as to decrease mood disturbances and fatigue in patients receiving chemotherapy (Post-White et al., 2003). In the same study, blood pressure, heart rate, respiratory rate, and anxiety were all significantly reduced as a result of massage therapy. Simply put, the less anxiety, the better the quality of life that someone may have left.

During cancer treatment chemotherapy is an often used modality, and the nausea that has been known to accompany it can significantly affect the quality of life of the patients who may have only limited time. It has been demonstrated that something as simple as a 10-minute foot massage (Grealish, Lomasney, & Whiteman, 2000) or finger pressure over two pairs of acupoints (Dibble et al., 2000) can influence both the frequency and the intensity of nausea. These simple techniques can easily be taught to spouses or family members of patients with cancer and most certainly can be learned by nursing staff in medical facilities that treat cancer.

The role of massage in cancer care can be a controversial one, as cancer is often noted as a contraindication for any type of massage that may affect circulation (Werner, 1998). Because massage can be very effective in facilitating the movement of lymph through the body, conceivably cancer cells could be moved through the lymph nodes by improper application of massage (Cheville, et al., 2003; Howard & Krishnagiri, 2001; Williams et al., 2002). Certainly in cases where there are conditions such as neutropenia and thrombocytopenia the intervention of a trained massage practitioner under the care of the treating physician would be advisable if massage was being considered (Werner, 1998). The risk of possibly worsening the plight of the patient with cancer must be balanced with the known benefits of massage especially when one considers that the number of natural killer cells in the immune system can be increased as well as the ratio CD4/CD8 lymphocytes (Diego et al., 2001; Ironson et al., 1996; Iwama & Akama, 2002). Strengthening the immune system can be accomplished simply by administering daily dry towel rubdowns for 10 minutes (Iwama & Akama, 2002) or with general massage therapy (Diego et al., 2001).

In an investigation into the habits of insured cancer patients (Lafferty et al., 2004), it was found that 11.6% of enrollees filed claims for some type of complementary or alternative medical (CAM) intervention. It was noted that CAMs are in no way replacing conventional providers but that many insured cancer patients will use CAMs in addition to conventional cancer treatments. The benefits

of massage in cancer are demonstrated in a number of different areas, and this is clearly a disorder where the integration of touch therapy can make a tremendous contribution to the overall care of the patients. HIV/AIDS has not been well researched in terms of massage therapy but the immune system effects as well as the reflexive reduction of pain and anxiety are equally applicable and should be considered as part of the care regimen.

Lymphedema

Lymphedema can come as a result of mastectomies or a variety of circulatory disorders. Regardless of how it appears, it can extremely painful as fluid pressure builds up in the limb tissue and stretches the skin far beyond its normal range. The author has seen simple cases of edema from a knee injury put so much pressure on the nerves that patients lose feeling in their feet. Consider the long-term effects of chronic edema on nerve function, proper oxygenation, and infection. Fortunately, massage techniques for lymphedema are effective measures in reducing swelling (Cheville et al., 2003; Howard & Krishnagiri, 2001; Williams et al., 2002). The techniques promote the movement of lymph out of the limb, and once this is done, compression garments can be used to prevent a recurrence.

Respiratory Circumstances

There are a number of circumstances that while not strictly pain conditions, warrant mention for treatment via clinical massage as they involve elements that can and often do cause pain. The chronic strain placed on the respiratory musculature of patients with COLD (chronic obstructive lung disease) certainly qualifies as an area where pain can strike. The author has treated many patients with extremely tender intercostal muscles, scalenes, and upper trapezius muscles who have reduced diaphragm capability and are overusing accessory muscles of respiration. Most specifically, breathing disorders such as asthma and COLD have shown positive responses to massage techniques. The chief benefit of these techniques is that when therapeutic doses of medication are either contraindicated or already at maximum dosage, additional benefit and possible medication reduction can be achieved. Because corticosteroids are known to decrease muscle function, it can be self-defeating to increase the medication of a patient who is already suffering from breathing problems. Indeed, there is significant evidence that reflexively applied therapy such as acupressure can significantly improve dyspnea experienced by patients with chronic obstructive pulmonary disease (COPD) (Wu et al., 2004).

The practice of treating the diaphragm via direct pressure from under the ribcage has long been taught in neuromuscular therapy courses but has been little researched. The underlying theory of neuromuscular massage is that

it is possible to release spastic and chronically shortened muscles via manual therapy. It has been shown via MRI that the diaphragm does flatten in patients with COPD, ostensibly because the muscle has shortened over time. Neuromuscular massage was found to be effective in treating moderate COLD (including panlobular emphysema, centrilobular emphysema, chronic bronchitis, and interstitial lung disease, Beeken et al., 1998). Part of the therapy involves manual pressure on the diaphragm in an effort to promote stretch in the muscle. Significant changes in breath holding (as much as 100%), peak flow, heart rate, and oxygen saturation were demonstrated after neuromuscular therapy. As COLD affects an estimated 30 million people in the United States alone, further research into this field is certainly warranted (Petty, 1990).

Asthma is another arena in which clinical massage warrants a close look. One would be hard pressed to argue with the avoidance of corticosteroid use when possible — especially in children whose bodies are still developing. Successful research in treating asthma via manual techniques is noted by Kuznetsov as early as 1980 (Kuznetsov et al., 1980). A study comparing the benefits of massage versus progressive muscle relaxation in children with asthma (Field et al., 1998) showed significant improvements in not only anxiety, but forced vital capacity (24% increase), forced expiration volume (57% increase), and peak expiratory flow rate (30%). One of the most impressive points about this study was that massage was not rendered by therapists, but by the parents of the children involved in the study, and the treatment itself took only 20 minutes per day. It is in giving patients and their families an active role in treating a given disorder that integrative techniques provide one of their most important functions. Acupressure as well has been shown to be an effective tool in overall quality of life for patients with asthma (Maa et al., 2003). In the treatment of asthma, massage does not have noticeable effects in only one treatment (Robertson et al., 1984).

INTEGRATIVE HEALTH CARE

As effective as massage therapy can be when applied clinically in pain management, it cannot be stressed enough that it should be an integrated part of the continuum of care, not an isolated therapy. Chronic pain is very often a complicated process that may involve not only the area of pain, but postural distortions or biomechanics that perpetuate the pain as well as psychological factors such as depression that may impede a patient's ability to actively participate in elements of treatment such as home stretching or exercise.

Throughout the literature, one will encounter studies that demonstrate the effectiveness of multidisciplinary interventions to treat various disorders such as migraines (Lemstra et al., 2002) and back pain (Cottingham & Mait-

land, 1997). The future of pain management lies in the successful integration of standard medical care and complementary therapies. If simple massage could heal all chronic pain, then everyone with chronic pain would be lined up for massage — but no one therapy or technique stands on its own as the answer to chronic pain. There are many hybrid therapies being developed today that incorporate elements of several systems. A good example of this is ETPS[SM], which incorporates elements of acupuncture, electrotherapy, myofascial release, and structural theory, and achieves impressive results when combined with standard physical therapy such as doubling outcomes (Freed, 2002). There is no room for isolationists or purists in the treatment of pain. A willingness to work cooperatively with other doctors and therapists and to integrate techniques is essential if patients with pain are to benefit. One might look to the example of successful integration of "cutaneous stimulation" (massage) into the emergency room and the positive effects on pain reduction (Kubsch, Neveau, & Vandertie, 2001).

Considering that the practice of massage in one form or another stretches back to our earliest recorded history, it is surprising how little research has actually been done in the field. That trend does appear to be changing as studies on the effects of massage appear in the literature more regularly. There is a definite need for more research into specific techniques of massage, and those who utilize massage are strongly urged to become more involved in the research process.

Interdisciplinary Approaches to Treating Myofascial Pain Syndrome

Nancy Shaw, CMTPT, MS, and Pamela F. Kozey, CMTPT, BEd

INTRODUCTION

Myofascial trigger point pain and dysfunction are probably the foremost causes of chronic pain in this country. Conservative estimates of reported cases indicate that 23 million of the U.S. population have one or more chronic disorders of the musculoskeletal system (Alvarez & Rockwell, 2002). Musculoskeletal disorders are the main cause of disability in the workforce and the leading cause of disability in age-related groups (Mense, Simons, & Russell, 2001). In actuality many practitioners report studies indicating as many as 74 to 85% of the cases seen contain a primary organic diagnosis of myofascial pain (Strauss, 2004). Other studies, however, report 37 to 65% with localized myofascial pain (Strauss, 2004). Because the disorders can be treated very successfully, why do we continue to see myofascial pain and dysfunction increasing and growing to epidemic proportion? Part of the problem lies in the continued misunderstanding and blurring of diagnoses, especially between fibromyalgia, chronic fatigue, and myofascial pain syndrome. Without the proper diagnosis, there cannot be proper treatment. And, even with proper diagnosis, one needs proven guidelines for treatment to ensure a positive result.

Janet G. Travell, M.D., a noted pioneer in the field of myofascial trigger point pain and dysfunction, engineered a comprehensive, yet simple, treatment protocol. This protocol, although simple, takes time — time to listen to the patient's account of what has transpired over years of muscle use and misuse; time to unravel the patient's habits, adjustments, and accommodations to movement and activity over the years; time to listen about the work, family, and other stressors, both good and bad, that have had an impact on the patient; and time to investigate the nutritional, mechanical, postural, endocrine, and other perpetuating factors that affect the patient. As Shakespeare said, you need to "look with your ears."

The treatment protocol established by Travell (personal communication) is shown in Table 80.1. It is this protocol with an interdisciplinary approach that is the focus of this chapter.

HISTORY OF MYOFASCIAL TRIGGER POINT THERAPY

Medical studies and findings in the literature on trigger point myofascial pain and dysfunction have often been confusing due in part to the terminology used in definition and reporting. Early tracings reveal the literature divided into three major groups and show a remarkable progression of findings. German literature, seen in the writings of Froriep, Schmidt, Lange and Eversbusch, and Kraus, seems to hold the most extensive works of the late-19th and early-20th century (Shaw, 1987; Travell & Simons, 1983). They associated the acute and chronic pain with palpable tender areas related to soft or non-articular rheumatism, identifying palpable hard nodules, tender areas responding to forceful pressure treatment. The turn of the last century highlighted continued research from Great Britain, including Gowers, Kellgren, Stockman, and Llewellyn and Jones, which revealed original fibrositis literature, along with varying explanations (myogeloses and interstitial myo-fibrositis) (Shaw, 1987; Travell & Simons,

TABLE 80.1
Travell's Seven-Step Myofascial Trigger Point Treatment Protocol

It is the utilization of the trigger point therapy as a treatment protocol, not as a modality, that leads to its ultimate success

Step	Action
1.	**Medical diagnosis**
	Medical history
	Elimination of pathology
	Differential diagnosis
2.	**Patient history**
	Family
	Vocational
	Social
	Avocational/exercise
	Illnesses/accidents
	Medications
	Nutrition
3.	**Pain documentation**
	Verbal
	Diagrammed
4.	**Range of motion**
	Pain site
	Functional unit
	Secondary and compensatory areas
5.	**Perpetuating factors**
	Mechanical stresses
	Nutritional inadequacies
	Metabolic and endocrine inadequacies
	Postural stresses: Sleeping, sitting, standing, driving
	Sleep disturbances
	Sleep apnea
	Home and workstation ergonomics
	Psychological
6.	**Trigger point therapy**
	Trigger point pressure release
	Intermittent coolant with stretch
	Injection
7.	**Specific muscle stretch retraining**

To eliminate any one of these steps in treating myofascial pain and dysfunction can lead to treatment failure!

Note: From Travell, personal communication.

1983). Adler added the concept of pain referring away from the pain source, and Kellgren further established referred pain arising from the tender areas of the muscle (Shaw, 1987; Travell & Simons, 1983). The mid-20th century evidenced American literature making major contributions to the understanding of the syndrome in the works of Travell, Sola, Rinzler, Bonica, and Kraus and thus the emergence of myofascial pain syndrome, myofascitis, trigger points,

and myalgia (Shaw, 1987). The late-20th century saw renewed research by Simons, Mense, Hubbard, Gunn, Baker, Jaeger, and others encompassing soft tissue and tended toward designations of fibrositis, myofascial pain, fibromyalgia, psychogenic rheumatism, myofascitis, tension myalgia, and fibromyositis (Mense, Simons, & Russell, 2001). During the mid- to late-20th century Janet G. Travell published more that 40 papers on the myofascial genesis of pain, myofascial trigger points, documenting the specific pain referral patterns, and theorized the self-sustaining characteristic mechanism of trigger points (Travell & Simons, 1999). Her early work became a respected source of information and still holds that respect.

Travell, the clinician, developed a treatment protocol that set the standard for the treatment of myofascial pain and dysfunction, or myofascial pain syndrome. That protocol is the focus of this chapter. It is a protocol that has stood the test of time and has an outstanding success rate if performed in its entirety without shortcuts or alterations. The multiplicity of the terminology, however, continues to add confusion and needs to be clarified if differential diagnosis and, thus, treatment are to be correctly directed. A listing of the more important definitions that pertain to the material in this chapter follows:

- **Arthritis:** Inflammation of a joint marked by pain, redness, swelling, and heat. Osteoarthritis is a degenerative joint disease and is a noninflammatory condition with a gradual and subtle onset. Pain is an early symptom, usually made worse with exercise (*Dorland's Medical Dictionary*, 1982, p. 47).
- **Chronic pain:** Long-standing (weeks, months, years) pain but not necessarily incurable (Travell & Simons, 1983). A complexity of life changes that produce altered behavior and that may persist even after the cause of the pain is eliminated constitutes the chronic pain syndrome (Zohn, 1988).
- **Fibromyalgia syndrome:** A common medical condition characterized by widespread pain and tenderness to palpation at multiple anatomically defined soft tissue body sites (Yunus & Rachlin, 1994).
- **Muscle cramp:** Involuntary shortening activation of the muscle resulting in pain and limited motion.
- **Muscle pain:** An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (Mense et al., 2001).
- **Muscle spasm:** Increased tension with or without shortening of a muscle due to nonvoluntary motor nerve activity. One cannot voluntarily

release or relax this spasm (Travell & Simons, 1983, p. 4).

- **Muscle stiffness:** Discomfort with movement of a joint (Mense et al., 2001).
- **Muscle strength:** The contractile force of the muscle.
- **Muscle stretch:** To draw out to full extent or beyond normal functioning limits of the muscle.
- **Muscle tone:** The muscle in its resting tension, clinically determined as resistance to passive movement (Mense et al., 2001).
- **Myofascial pain syndrome:** Pain and/or autonomic phenomena referred from active myofascial trigger points with associated dysfunction (Travell & Simons, 1983). A regional pain syndrome accompanied by trigger points (Yunus & Rachlin, 1994).
- **Referred trigger point pain:** Pain arising in a trigger point, but felt at a distance, often completely remote from its source (Travell & Simons, 1983).
- **Tender point:** A general term expressing focal pressure pain sensitivity, i.e., tenderness limited to a point usually not larger than about 1 cm. Tender points are not defined by any additional specific attributes (Fischer & Rachlin, 1994).
- **Trigger point:** A focus of hyperirritability in a tissue that when compressed is locally tender and if sufficiently hypersensitive, gives rise to referred pain and tenderness and sometimes to referred autonomic phenomena and distortion of proprioception (Fischer & Rachlin, 1994; Travell & Simons, 1983). The exquisitely sensitive area, the trigger point, refers pain to a remote "reference pain zone" that is specific to each trigger point (Fischer & Rachlin, 1994).
- **Trigger point pressure release:** Slowly applied pressure to a trigger point. Once resistance is met, the pressure is sustained until a change in the muscle is felt. This process may then be repeated. This is a new term replacing "ischemic compression" in trigger point deactivation.

BACKGROUND

Skeletal muscle is the largest single organ of the human body. Aside from varying ways of counting muscle divisions, it is generally agreed that there are approximately 500 muscles in the body. Any one of these muscles can develop trigger points that refer pain or, in lesser states of activity, cause dysfunction. The contracted muscle fibers, if left without an opposing muscle to pull them back to a neutral position will remain in a shortened state, vulnerable to daily wear and tear. The muscles develop memories of functioning short, just like learning a bad golf swing. They develop trigger points, and elicit pain to distal areas of the body. Ongoing function in a contracted or partially contracted state leads to chronicity of the trigger point pain. Yet, the medical profession, in general, has not addressed this basic muscle phenomenon. Perhaps this is true because there is nothing "wrong" with the muscles, they have simply "learned" to function incorrectly, i.e., in a shortened functional range of motion. Just as there are many small components to a bad golf swing, there are many factors contributing to patterns of incorrect muscle functioning and to the resultant trigger points eliciting pain.

In a perfect scientific, medical world there would be specific, objective tests that would determine the cause of myofascial pain and dysfunction. Although interventional modalities such as electromyography (EMG), muscle biopsy, ultrasonography, surface EMG, and thermography have been studied and used with varying success (Alvarez & Rockwell, 2002), currently there are no specific laboratory tests or imaging techniques for the diagnosis of myofascial pain and dysfunction. Certainly there are none that can compare with the comprehensive evaluation by the clinician. There have been major steps, however, taken in the study of the epidemiology, pathophysiology, pathogenesis, and therapeutic options for what is now termed myofascial pain syndrome (Strauss, 2004). These studies have helped eliminate the notion of benign chronic pain as primarily psychological in nature or associated with "malingering." The studies have established the legitimacy of myofascial pain syndrome in the medical profession. In conjunction with the above studies, a great deal can be gained from the subjective pain assessment tools including, Visual Analogue Pain Scales, the McGill Pain Questionnaire, and pain diagrams (Straus, 2004). With such growing research and support tools, why does there continue to be such a lack of double-blind studies verifying an effective treatment protocol? To understand the very nature of the complexity of myofascial pain and dysfunction dictates the answer to that question. Travell noted that approximately 75% of treatment success lies in the addressing of the multitude of perpetuating factors and in the stretch neuromuscular retraining. Perpetuating problems may be due to mechanical stressors, postural stressors, nutritional inadequacies, systemic metabolic and endocrine inadequacies, psychological/stress factors, chronic infection, functional stressors, and complications of the above, e.g., nerve impingement, sleep disturbance, and environmental and food sensitivities. Because addressing these perpetuating factors in their entirety is critical to treatment success, double-blind research would necessitate finding a group of individuals with exactly the

same perpetuating factors complaining of the same pain problem and another group for the control. This is not going to happen. Yes, we could find a group exhibiting, for example, the same back pain but that group would not present with the exact same perpetuating factors. While some aspects of treatment may be measured by group evaluation (e.g., use of nutritional supplementation), the very nature of the myofascial trigger point pain syndrome with its myriad of perpetuating factors unique to each individual does not lend itself to the research of double-blind studies that are requested. Should this inability to conduct double-blind study research negate the validity of myofascial trigger point therapy? Of course not. It simply means we must rely on the research of Simons, Hubbard, Mense, and others to identify the location and nature of trigger points, their mechanism of activation and deactivation, and strategies for prevention of recurrence. We must rely on a proven treatment protocol to establish treatment success.

INTERDISCIPLINARY APPROACH

Myofascial trigger point therapy (MTPT) lends itself to an interdisciplinary approach of dealing with neuromuscular pain conditions. The first step in the MTPT protocol requires a diagnosis of myofascial pain syndrome or fibromyalgia. A licensed health care provider such as a physician, chiropractor, osteopath, or dentist makes a diagnosis and recommends MTPT. This step usually rules out any systemic illness or neurological or orthopedic problems.

In addressing perpetuating factors, myofascial trigger point therapists work in conjunction with a variety of health care practitioners. A common referral would be to a chiropractor or osteopath. Body workers release and balance muscles/fascia. The chiropractors and osteopaths adjust and align joints. The newly released and balanced muscles will rapidly revert to their old patterns if joints are not aligned properly. The opposite is also true. If we adjust and align joints without releasing taut bands and trigger points, the imbalanced muscles will pull the joints out of alignment again. A team approach working with both muscles and joints is usually more effective and requires a shorter treatment regimen.

Following is a partial list of other health providers with which body workers collaborate on a regular basis:

- Allergists
- Dentists
- Endocrinologists
- Homeopaths
- Kinesiologists
- Naturopaths
- Nutritionists
- Physiatrists
- Physical therapists
FIGURE 80.1 Anatomy of a muscle fiber. Microscopic anatomy of an individual skeletal muscle fiber (cell). Note the striated (striped) appearance of the muscle fiber and the myofibrils. From *Basic Human Anatomy* (2nd ed.), by A. P. Spence, 1986, Menlo Park, CA: Benjamin/Cummings. Reproduced with permission.

- Podiatrists
- Psychiatrists, psychologists, social workers
- Rheumatologists
- Chiropractors
- Osteopaths

It is vital that myofascial trigger point therapists work closely with these other professionals to provide the most holistic care possible. To ignore a piece of the puzzle will result either in a failed attempt to relieve myofascial pain or in pain that returns shortly after treatment.

A more detailed discussion of perpetuating factors appears later in this chapter.

MUSCLE ANATOMY

The structure and activity of a motor unit must be understood to recognize a disruption of normal function. This disruption or pathology is the cause of myofascial pain and dysfunction. The following is a cursory overview of the anatomy and physiology of the skeletal muscle.

Each muscle, in descending order of magnitude, consists of muscle fibers, myofibrils, sarcomeres, and myofilaments (Figure 80.1). The sarcomeres are the main contractile mechanisms of the muscle. They are made up of thick and thin filaments. The thick filaments are composed of proteins called myosin. The thin filaments are composed of proteins called actin, tropomyosin, and troponin (Figure 80.2) (Spence, 1986). It is the sliding action of these two filaments that actually causes the contraction. The sliding is a result of a series of rowing actions between the projections or heads on the myosin filament and attachment sites on the actin filament. Relaxation occurs when the myosin heads detach from the actin filament (Mense et al., 2001).

But what causes muscles to contract? The site where the terminal branch of the alpha-motor axon links with the muscle fiber is called the motor end plate or neuromuscular junction (Figure 80.3). When an action potential
FIGURE 80.2 Myosin and actin filaments. (a) Thick filament, (b) thin filament, (c) longitudinal section of filaments. From *Basic Human Anatomy* (2nd ed.), by A. P. Spence, 1986, Menlo Park, CA: Benjamin/Cummings. Reproduced with permission.

arrives at this junction, the axon releases acetylcholine (ACh). The ACh diffuses across the synapse to the muscle cell membrane and causes a change in the membrane at the junction of the muscle cell (Mense et al., 2001). This change results in the generation of a stimulatory impulse that spreads over this plasma membrane and into the interior of the muscle cell by way of *t* tubules. This impulse excites the sarcoplasmic reticulum causing it to release calcium ions (Ca^{2+}). This constitutes the initiating event for muscle contraction (Griggs, Mendell, & Miller, 1995; Mense et al., 2001; Spence, 1986).

In the resting muscle, the tropomyosin masks the binding sites (for the myosin heads) on the surface of the actin molecule. The rise in Ca^{2+} concentration causes the tropomyosin chain, which is wrapped around the actin, to move from its blocking position. The myosin heads can then bind with actin in a rowing motion. This movement pulls the actin filament toward the middle of the sarcomere thereby shortening it (Mense et al., 2001).

Adenosine triphosphate (ATP) provides the energy required for muscle contraction. In a resting muscle cell, an ATP molecule binds to the projection (club-shaped head) on the myosin molecule. The myosin head also contains ATPase, an enzyme that splits ATP into adenosine diphosphate (ADP) and phosphate (P) plus energy. Actin activates the ATPase in the presence of magnesium (Mg) ions. Consequently, as soon as the tropomyosin chain moves and the myosin heads make contact with the actin filaments, ATP is split. This released energy then separates the myosin heads from the actin (Mense et al., 2001).

If intracellular Ca^{2+} remains high, the myosin heads will again attach to the actin with the flexing motion. When the concentration of Ca^{2+} drops, the attachments no longer occur and tropomyosin once again blocks the binding sites. The calcium pump returns the Ca^{2+} to the sarcoplasmic reticulum, until ACh spikes again (Mense et al., 2001).

ANATOMY AND PHYSIOLOGY OF A TRIGGER POINT

Trigger points (TrPs) have been difficult to understand because there has been no method of studying them. Often, differences in terminology have made it difficult to know if investigators were even dealing with the same condition. Our current understanding of trigger points results from the convergence of two independent lines of investigation, one electrodiagnostic and the other histopathologic. Fitting together the lessons from each led Mense and Simons to postulate a theory called the *Integrated Hypothesis*. It is now becoming clear that the region we are accustomed to calling a TrP, or a tender nodule, is a cluster of numerous microscopic loci of intense abnormality. These loci are scattered throughout the nodule. The critical TrP abnormality now appears to be neuromuscular dysfunction at the motor end plate of an extrafusal skeletal
FIGURE 80.3 Anatomy of a motor end plate. From *Muscle Pain: Understanding Its Nature, Diagnosis, and Treatment,* by S. Mense, D. G. Simons, & I. J. Russell, 2001, Baltimore: Lippincott/Williams & Wilkins. Reproduced with permission.
FIGURE 80.4 Dysfunctional motor end plate. From *Muscle Pain: Understanding Its Nature, Diagnosis, and Treatment,* by S. Mense, D. G. Simons, & I. J. Russell, 2001, Baltimore: Lippincott/Williams & Wilkins. Reproduced with permission.

muscle fiber, making myofascial pain caused by TrPs a neuromuscular disease.

The primary dysfunction hypothesized here is an abnormal increase (by several orders of magnitude) in the *production and release of ACh* packets from the motor nerve terminal under resting conditions. The greatly increased number of miniature end plate potentials (MEPPs) produces end plate noise and *sustained depolarization of the postjunctional membrane* of the muscle fiber. This sustained depolarization could cause a *continuous release and inadequate uptake of calcium ions from local sarcoplasmic reticulum* and produce *sustained shortening (contracture) of sarcomeres.* Each of these four italicized changes would increase energy demand. The sustained muscle fiber shortening compresses local blood vessels, thereby reducing the nutrient and oxygen supplies that normally met the energy demands of this region. The increased energy demand in the face of an impaired energy supply would produce a local energy crisis, which leads to the release of sensitizing substances that could interact with autonomic and sensory (some nociceptive) nerves traversing that region. Subsequent release of neuroactive substances could, in turn, contribute to excessive ACh release from the nerve terminal, completing what then becomes a self-sustaining vicious cycle (Mense et al., 2001; Figures 80.4 through 80.6).

Two types of myofascial trigger points have been identified. The central TrP occurs in the belly of the muscle at the dysfunctional motor end plate. The attachment trigger points occur where myofascial tissue attaches. The dysfunction at the motor end plate results in a contraction knot, which can produce a palpable nodule, thus the central TrP. The remainder of the sarcomeres is stretched into a taut band of very tense muscle fibers. As the tightened sarcomere pulls on the attachment points, it causes a disruption of these fibers, resulting in tenderness and swelling (Mense et al., 2001).

INTRODUCTION TO TRAVELL'S SEVEN-STEP PROTOCOL

Mennell states that medicine is not just a matter of taking pharmaceuticals. Nor is it merely an exercise in high technology. "The successful practice of medicine is still based on arriving at a correct diagnosis of the cause of each patient's symptoms; this is still dependent on listening, observing, feeling and thinking. The result of thinking is enhanced by experience. No computer is able to touch. Observation is the action of many human capabilities a machine cannot possess" (Mennell, 1991, p. 1).

With Mennell's philosophy in mind, it is imperative that any clinician or therapist perform the entire treatment protocol to ensure successful resolution of myofascial pain syndrome. It is the utilization of the trigger point therapy as a treatment protocol, not as a modality, that leads to its ultimate success. To eliminate any one of the steps in treating myofascial pain and dysfunction can lead to treatment failure.

In the process of stepping through the Travell protocol, we will also show how certain steps are distinctly different from a traditional therapy protocol.

STEP 1: MEDICAL DIAGNOSIS

Medical History

A thorough medical history and physical examination must be conducted to eliminate possible sources of the musculoskeletal pain other than myofascial trigger points. The presence of myofascial pain syndrome does not rule out other hidden conditions that may be contributing to the pain. The diagnosis of these conditions (Table 80.2) must be addressed in the initial evaluation.

Elimination of Pathology

While eliminating any underlying pathology, it is important to remember, however, that myofascial trigger points can coexist with any other condition and be a significant contributor to the pain being experienced. As long as other medical conditions, if they exist, are being treated, it is most valuable to treat the trigger points and engage in muscular retraining to eliminate that pain component.

Differential Diagnosis

Table 80.3 indicates the percentage of patients with another diagnosis who also had myofascial trigger points that contributed to their problems. Often the overall pain experienced is significantly reduced with trigger point elimination, indicating the pain was not just from the coexisting condition. For example, arthritic joint pain is often the result of inflammation occurring at the point of the tendon joint attachment where muscles are functioning at a shortened range of motion, pulling on and irritating

TABLE 80.2
Differential Diagnosis in Medical Evaluation

Musculoskeletal Diseases:
- Arthritis: Osteoarthritis, rheumatoid arthritis, gout
- Myopathy: Painless weakness of proximal muscles
- Focal inflammation of musculoskeletal structures: Trigger points refer to regions where tendons, ligaments, and bursae are located

Neurological Diseases:
- Identified by motor and/or sensory deficits in the distribution of the afflicted nerve
- Motor findings include atrophy, weakness, diminished or absent reflexes
- Sensory changes are described as numbness, tingling, pins and needles, burning, and sensory distortions

Visceral Diseases:
- Somatovisceral effects: Active trigger points in the abdominal wall muscles can disturb visceral function, e.g., gastrointestinal including but not limited to constipation, diarrhea, cramping, irritable bowel syndrome, leaky gut syndrome, and esophageal reflux
- Viscerosomatic: Visceral disease can refer pain to skeletal muscles and activate satellite trigger points

Infectious Diseases:
- Viral
- Bacterial
  While the presence of symptoms other than pain may indicate a nonmyofascial component, there may be activation of trigger points within the painful regions, which may then persist after recovery from the infectious illness.

Endocrine Disorders:
- Hypothyroidism
- Hyperthyroidism
- Adrenal fatigue
- Wilson's disorder
- Hypoglycemia

Autoimmune Diseases:
- Chronic fatigue syndrome
- Fibromyalgia
- Systemic lupus erythematosus
- Mononucleosis

Nutritional Disorders:
- Systemic candidiasis
- pH imbalance
- Vitamin and/or mineral inadequacies

Psychogenic Disease:
- Clinical depression
- Bipolar
- Anxiety

Sleep Disorders:
- Sleep apnea
- Inadequate sleep maintenance
- Inadequate restorative sleep

Note: From N. Shaw, unpublished, 1988.

TABLE 80.3
Percent of Pain Patients Harboring Concomitant Myofascial Trigger Points

Diagnosis	No. of Patients	% with MTrPs
Cervicogenic headache	80	100
Reflex sympathetic dystrophy	84	82
Fibromyalgia	19	100
Chronic intractable benign back pain	90	96.7
Chronic intractable benign neck pain	34	100

Note: From "Myofascial Pain Syndrome: A Short Review," by S. Strauss, *The Medical Acupuncture Webpage,* Retrieved January 2004 from http://users.med.auth.gr/~karanik/english/articles/mayofac.html..

TABLE 80.4
Myofascial Versus Fibromyalgia

Myofascial Pain Syndrome	Fibromyalgia
Equal number men and women	About 4:1 ratio women over men
Trigger Points	Tender Points
• Local tenderness	• Local tenderness
• Taut band	
• Local twitch response	
• Jump sign	
Singular/multiple body quadrant/specific	Multiple body quadrants/generalized
May occur in any skeletal muscle	Occurs in specific locations that are symmetrically located
Specific pain referral patterns	No pain referral pattern
Decreased range of motion	No decreased range of motion
	Hypermobility
20% also have fibromyalgia	72% also have active TrPs
Resolves with treatment	Chronic

Common to Both Conditions

Sleep deprivation
Fatigue
Pain made worse with activity
Depression/anxiety
Muscle stiffness

Note: From N. Shaw, unpublished, 2003.

attachments. Accompanying trigger points refer pain to the joint area. The inflammation can be treated but if the shortened muscle continues to tug at the joint attachment and trigger points continue to refer pain to the joint area, the problem will not be eliminated.

Another differential diagnosis needing attention is the ongoing blurring of myofascial pain syndrome with fibromyalgia. These are two distinct entities. These conditions often coexist and may interact with one another. "As many as 72% of fibromyalgia patients also have some myofascial pain syndrome but the reverse is not necessarily so. Only 20% of myofascial trigger point pain patients also exhibit fibromyalgia symptoms" (Strauss, 2004, p. 2; Table 80.4). Until greater skill is developed in recognizing, understanding, palpating, and defining myofascial trigger points, there will continue to be misdiagnoses.

Considerable effort has been made to establish guidelines for the differential diagnosis of common medical conditions and myofascial pain syndrome and to highlight common associated symptoms. This provides immeasurable direction for medical evaluation, proper diagnosis, and thus, properly directed treatment. Table 80.5 delineates common medical diagnoses and the trigger points/muscles causing some of the same pain symptoms.

After a diagnosis of myofascial pain syndrome, it becomes important for the clinician to educate the patient while performing the initial but specific myofascial evaluation. Since other medical conditions have been addressed, let the patient know that if the pain experienced relates strongly to locomotor activity and body positioning, it is probably musculoskeletal in origin!

STEP 2: PATIENT HISTORY

Personal information, family makeup, vocation, stressors, activities, hobbies, relaxation and fun activities, vacations, and the like will help the clinician understand how much the pain is disruptive to the patient's lifestyle. This infor-

mation indicates the place pain is playing in the patient's life, both good and bad; identifies aspects important to the patient; and helps set treatment goals.

Family History

The makeup of the family structure may give insight to stressors that are affecting the patient with myofascial pain syndrome. Infants or very young children need to be carried, often in awkward positions. They often have very sporadic sleep schedules, frequently awake and requiring attention during the night. Older children have to be driven numerous places for activity involvement, times varying from very early morning to later in the evening. Difficult teens may require special efforts. Aging parents living with children require mental, physical, and emotional adjustments for the family. Long work hours and long work weeks often provide little time for relaxed interaction with spouses and children. All of these situations can provide stress, require muscle accommodations, and lead to sleep deprivation and general mental and physical fatigue, which can perpetuate a myofascial pain syndrome.

Vocational History

It is helpful to know the nature of current and previous work situations. The mental, emotional, and physical demands of

the patient's work need to be evaluated. Can commute time, work schedules, breaks, deadlines, postures, meals, and personnel interactions be refined to make a less-demanding, yet productive work environment? It is often the patient's own pressure in the work situation that is detrimental.

Vocational status of the patient is important in determining the patient's desire to maintain active employment in the same field or identifying alternative goals that become part of the treatment plan. Physical and mental demands at work and the hours required might be contributing to the perpetuation of the pain problem. Ergonomics of the workstation need to be evaluated.

Exercise

Explain that movement and exercise are essential to optimal health. They are essential to unimpaired function of the musculoskeletal system. Conditioned muscles are less vulnerable to trigger point development as long as stretch has been included to maintain a balance necessary to normal activity. Specific movements and stretch neuromuscular retraining will be an integral aspect of the treatment program. It will require patient compliance and commitment to ensure treatment success.

Nutrition

Dietary evaluation helps assess the likelihood of nutritional inadequacies and eating habits, e.g., skipping meals, that may interfere with treatment success. This topic is covered more completely in the perpetuating factor section.

Social History

In what social activities is the patient involved? Do these activities involve family, spouses, friends, or co-workers? Are activities sedentary or more active in nature? Are the activities and the people involved ones that lead to relaxation, stress relief, and just plain fun?

Avocational History

Does the patient have hobbies or outside interests? Are these activities sedentary or active? Do the hobbies require different muscular demands than the patient's job or other activities?

It is important for the patient to have time and space to be involved in a number of activities that allow body movement to be varied. This helps alleviate overuse, underuse, and abuse of muscles, and allows for healthy function.

Illness and Accident History

Illnesses, accidents, and surgeries begin to give a picture of muscle stresses and traumas that are a part of the patient's history. There may even be a myofascial compo-

nent behind some of the traumas (e.g., falling frequently because of sternocleidomastoid trigger points resulting in disruptive equilibrium). This information certainly points to some of the cumulative precipitating factors of trigger point development and the ongoing muscle tension that results in myofascial pain syndrome.

Medications

Note medications the patient is currently taking, those previously taken, and how long they have been taken, and indicate the efficacy of each. This will give insight into medical care already received and lessen the duplication of evaluative and treatment efforts. It will also indicate other medical conditions being treated and reveal unnecessary drug clutter, patient dependency on the drugs, and the patient's pain perspective.

STEP 3: PAIN DOCUMENTATION

After establishing myofascial pain and dysfunction with the patient and recording general information, the clinician must then perform an extensive and specific myofascial evaluation with the patient. Clinical features associated with myofascial trigger point diagnoses involve several components. Travell differentiates three phases of refractory chronic myofascial pain. In phase 3, stiffness, dysfunction, and decreased range of motion arise from latent trigger points, which cause no pain unless palpated. In phase 2, increased less irritable trigger point activity gives rise to intermittent pain upon movement and upon taking certain postures. Generally, only some activities aggravate the pain so patients quickly learn what movements or activities to avoid. These are, however, active trigger points, both primary and satellite. In phase 1, the most involved active trigger point activity results in pain on motion and at rest and can be continuous and intense with little relief even with medication. Because the pain is constant and intense, the patient often cannot identify specific movements or activities that increase the pain (Travell, Fricton, & Awad, 1990). When addressing the pain specifically with the guidelines unique to the Travell myofascial trigger point, protocol treatment can be divided into three phases as seen in Table 80.6: (1) pain documentation, (2) treatment, and (3) rehabilitation.

To begin the initial evaluation of the patient with pain, general information is necessary to establish a working basis for the patient and the clinician. The history of the pain must be thorough, establishing when the pain began, how it began, its intensity and duration, what increases or decreases the pain, and what helps or aggravates the pain. Pain perception should be put in perspective. When there are multiple pain areas, it is important to establish to which pain the patient's response applies. Defining the patient's perception of what causes the pain influences the patient's

---

TABLE 80.5
Common Pain Diagnoses Frequently Unrecognized as Originating from Myofascial Trigger Points in Specific Muscles

	Initial Diagnosis	**Some Likely Trigger Point Sources**
1*	Acute stiff neck	Levator scapulae
		Sternocleidomastoid
		Upper trapezius
2	Angina pectoralis (atypical)	Pectoralis major
3	Appendicitis	Lower rectus abdominis
4*	Arthritis of shoulder	Infraspinatus
5*	Arthritis of hip	Tensor fasciae latae
		Quadratus lumborum
6*	Arthritis of knee	Rectus femoris
		Vastus medialis
		Vastus lateralis
7	Atypical angina	Pectoralis major
8	Atypical facial neuralgia	Masseter
		Temporalis
		Sternal division of sternocleidomastoid
9	Atypical migraine	Sternocleidomastoid
		Temporalis
		Posterior cervical
10	Back pain, middle	Upper rectus abdominis
		Thoracic paraspinals
11	Back pain, low	Lower rectus abdominis
12	Bicipital tendonitis	Long head of biceps humerus
13	Chronic abdominal wall pain	Abdominal muscles
14	Dysmenorrhea	Lower rectus abdominis
15	Earache (enigmatic)	Deep masseters
16*	Earache — normal drum	Clavicular division of sternocleidomastoid
17	Epicondylitis	Wrist extensors
		Supinator
		Triceps brachii
18	Frozen shoulder	Subscapularis
19*	Heel spur	Soleus
20	Myofascial pain dysfunction	Masticatory muscles
21	Occipital headache	Posterior cervicals
22*	Pelvic pain	Coccygeus
		Levator ani
23	Postherpetic neuralgia	Serratus anterior
		Intercostals
24	Radiculopathy, C6	Pectoralis minor
		Scalenes
25	Scapulocostal syndrome	Scalenes
		Middle trapezius
		Levator scapulae
26*	Sciatica	Posterior gluteus minimus
		Piriformis
27	Subacromial bursitis	Middle deltoid
28*	Subdeltoid bursitis	Infraspinatus
		Deltoid
		Supraspinatus
29	Temporomandibular joint disorder	Masseter
		Lateral pterygoid
30	Tennis elbow	Finger extensors
		Supinator

response to treatment and compliance in addressing perpetuating factors and prescribed home program. Demonstrate that the pain is of muscle trigger point origin and refocus the patient's attention from pain to function. It can almost work against the treatment process to have the patient keep a "pain log," which focuses the patient on the pain rather than on more positive movements not causing pain and on improvements in function.

Verbal Description

The patient's description of the pain gives the clinician insight into the patient's pain perception, the pain's impact on the patient's daily functioning, the psychological mindset of the patient regarding the pain, and the accuracy of the patient's understanding of the pain. It is helpful to know the patient's view of the pain if the clinician is to be successful in educating the patient regarding pain origin and perpetuating factors, and the patient's role in treatment and rehabilitation.

Pain Diagram

The site of the pain or pains is documented on a pain chart to ensure an exact representation of the pain location. It is preferred the clinician do the charting as patients

tend to exaggerate the boundaries of the pain site due to the seemingly all inclusiveness of the pain sensation. The clinician's recording of the pain pattern also establishes a good working relationship with the patient. Upon recording the pain pattern described by the patient, the clinician shows the pain chart to the patient to verify its accuracy. The patient can concur as to the accuracy or make adjustments. The clinician establishes a clear "I am listening" working relationship with the patient. This is important in obtaining patient compliance with future directives during treatment. Only if the pain patterning is exactly represented can the clinician identify which trigger points in which muscles are key or primary. For example, at least six muscles refer pain to various aspects of the medial border of the scapula. Identifying "exactly" where the pain is helps determine which muscle may be harboring the most primary trigger points, thus identifying the pain source. Once the pain site is identified, the clinician determines the trigger point source and begins to develop the treatment progression. Generality of pain location = identifying the incorrect muscle/trigger point = misdirected trigger point treatment. Exact pain location = identifying the correct trigger point = proper trigger point treatment.

STEP 4: RANGE OF MOTION TESTING

When evaluating range of motion, it is imperative that comprehensive range of motion be conducted. This will involve areas of active, latent, satellite, and compensatory trigger points. The patient generally has made movement adjustments or accommodations for the pain, or avoids certain movements as a guarding mechanism to avoid pain. The clinician will often find quite a discrepancy from the patient's right and left range of motion. This difference will help dictate not only treatment detail but also the neuromuscular rehabilitation as a balance of function is sought (see Table 80.7 for a joint measurement chart).

Pain Source Versus Pain Site

When evaluating the patient's pain, the clinician may focus on the pain site but must also focus on the anticipated trigger point source of the pain. Pain site alone gives a distorted view of the comprehensiveness of the pain problem and leads to temporary but "quick fix" or unresolved pain elimination.

Range of Motion Testing Versus Strength Testing

Range of motion evaluation is recommended instead of strength testing. If there is decreased range of motion, there will, of necessity, be decreased strength as only partial contractual/functional potential is available. Any weakness at this point is considered pseudo-weakness. The pain is a result of an unwanted tension/contraction in

the muscle, i.e., trigger point. If strength testing is performed before full functional range is obtained, contraction is added to the muscle memory, thus increasing pain and weakness. Simons has pointed out the value of range of motion as diagnostic criteria. Measurement of increased range of motion becomes a useful objective measurement of treatment progress. It is an inexpensive measurement and can be objectively measured with a goniometer, protractor, or inclinometer. This range of motion evaluation will also serve as a differentiation with fibromyalgia as the restriction is characteristic of myofascial pain and dysfunction while hypermobility is common in fibromyalgia (Simons, 2003). Once range of motion is addressed in treatment with deactivation of trigger points and return of muscle length, then strength can be evaluated to determine needed areas of improvement. A balance of strength–stretch is the optimal outcome.

STEP 5: PERPETUATING FACTORS

Perpetuating Factors Versus Precipitating Factors

Perpetuating factors, in many ways, become more important factors than the precipitating factors in the treatment of myofascial pain and dysfunction. There can be one culminating event that results in the patient's current pain condition; but more often, a patient will express having experienced pain intermittently over an extended period of time. The latest episode, however, was worse, lasted longer, and eventually became chronic. If, however, one looks at the cumulative nature of muscle tension over time, i.e., muscle contraction/relaxation but no concerted effort to stretch regularly = gradual muscle shortening = shortened muscle functional memory = trigger point = pain, it is more accurate to identify not one but a series of uses, misuses, and abuses. This functional shortening is usually followed by conscious or unconscious adaptations or adjustments of the patient's function and posturing. Perpetuating factors and the adaptations that become habit continue to reinforce poor functional efficiency and extend the pain problem. Travell often indicated treatment success was directly proportional to eliminating perpetuating factors so appropriate neuromuscular retraining could be achieved without reactivating trigger point activity. Travell and Simons dedicated 50+ pages to perpetuating factors, leaving additional detail of each factor to the clinician. Travell often stated that Chapter 4, Vol. I on perpetuating factors was the most important chapter in *Myofascial Pain and Dysfunction: The Trigger Point Manual*. Figure 80.7 elaborates the categories of perpetuating factors in the treatment of myofascial pain and dysfunction.

One of the greatest needs for the interdisciplinary team in the diagnosis and treatment of myofascial pain and dysfunction is for addressing these perpetuating factors. The broad range of perpetuating factors necessitates

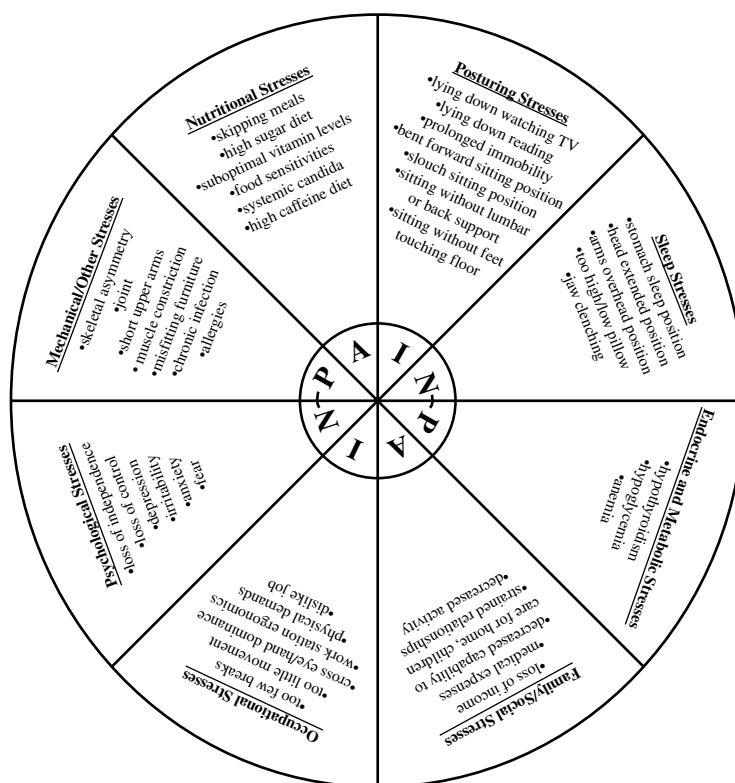
the expertise of a number of health care professionals including, but not limited to, acupuncturists, chiropractors, dentists, homeopaths, internists, manual therapists, naturopaths, neurologists, nutritionists, osteopaths, podiatrists, physiatrists, psychologists, psychiatrists, pulmo-nologists, and rheumatologists. It is important to address many of the perpetuating factors identified in the initial evaluation to set the best possible stage for treatment. Unattended, these perpetuating factors undermine the results of trigger point release. Released, but reactivated


FIGURE 80.7 Common myofascial perpetuating factors. (From Shaw, unpublished, 1992.)

by perpetuating factors, interference brings frustration to both the patient and the clinician. One simply treads water with no resolution of the pain. Table 80.8 helps delineate the role of some of the various practitioners that may be needed in the treatment of the perpetuating factors of myofascial pain syndrome.

Mechanical Stresses

Introduction

Mechanical stressors, most commonly skeletal asymmetry and disproportions, perpetuate trigger points in most patients with persistent myofascial pain syndrome (Travell & Simon, 1983). Disproportional mechanical stressors include short upper arms and Dudley Morton's foot. Asymmetry includes small hemipelvis and leg length discrepancy. Other mechanical stressors can include hypermobility, structural scoliosis, and cross eye–hand dominance.

Lower Limb-Length Inequality

Lower limb-length inequality (LLLI), commonly referred to as a short leg, is a major perpetuating factor of trigger points in the quadratus lumborum musculature. Usually LLLI is not a precipitating factor but rather only comes into play when the quadratus lumborum suffers the activation of a trigger point. In some instances a heel lift under the short leg is all that is necessary to resolve the back pain. In other instances (when pain is long-standing or

several painful episodes have occurred), the trigger points must be released first.

In Travell and Simons book, *Myofascial pain & dysfunction: The lower extremities, Vol. 2,* the authors explain in detail the procedure for measuring LLLI by radiographic measurement. For our purposes, we detail the clinical testing of leg length.

When a short leg is suspected in the patient with low back pain, clinicians recommend that the patient first be examined for quadratus lumborum trigger points and, if present, that they be inactivated. An attempt to measure LLLI in the presence of trigger point shortening of the quadratus lumborum is likely to produce a misleading result (Travell & Simon, 1983).

The undressed patient stands with the back to examiner and with both knees straight. The feet are placed approximately 6 inches apart, and an estimate of leg length difference is made by palpating the iliac crests or posterior superior iliac spines. An approximate correction is placed beneath the short leg, making sure that the patient finds it comfortable. Pages of a pad or small magazine are convenient. The patient is distracted for a minute or two and is encouraged to relax and let the weight settle on both feet. As the muscles are relieved of their attempt to compensate for the difference in leg length, they release their protective control and relax. It is then possible to accurately compensate any remaining LLLI by adding correction until pelvis and shoulders are level and, most impor-

tantly, the spine is straight. The efficacy of the lift can be tested using applied kinesiology or the lift can be moved under the long leg. In either case, the patient can feel and see the difference (Travell & Simon, 1983).

Some additional points of examination are helpful. The arm on the side of the short leg tends to hang away from the body, while the arm on the other side rests against it. Narrowing at the waist and bulge of the hip appear greater on the side of the long leg. The border of the gluteal fold appears lower on the short side. Skin folds are present or more numerous in the flank of the concave side of the lumbar spine (Travell & Simon, 1983).

The clinician should be cautious when using the heel lifts. They should be avoided if the lumbar spine is not flexible. The senior author of this chapter has found that supporting what looks like the longer leg in a person with a pronounced or structural scoliosis has had beneficial effects. This takes some of the stress off the musculature supporting the structural imbalance. This is not always true, and patients must be followed closely to make sure that a bad situation does not become worse. Regardless of the size of the discrepancy, the heel lift initially should not be more than 1/4 inch high. A lift that is higher than that is too much for the body to handle all at once. As the body adjusts, more lift can be added. Anything more that 1/2 inch requires a lift that covers the whole foot. Preferably, the lift should be built into the sole of the shoe (Chaitow & DeLany, 2002, p. 328).

It is also recommended that during the course of treatment, which may include chiropractic or osteopathic adjustments, the LLLI be checked regularly. Adjustments should be made in the height of the lift when appropriate.

Small Hemipelvis

Patients with a pelvis that is small in its vertical dimension on one side tend to sit crookedly, leaning toward the small side. They often cross one knee over the other to lift up the low side in attempt to even the iliac crests and balance the body. The quadratus lumborum is the muscle primarily affected by axial distortions in the lumbar region. In addition, the scalene and sternocleidomastoid muscles of the neck are heavily overloaded by the tilt of the upper thorax. These are not the only muscles affected, but they are the major ones (Travell & Simons, 1983).

For examination, the patient should be seated on a hard, flat surface with the back and buttocks exposed, in a position to be observed from behind. The feet should be high enough that the patient can slip the fingers between the thigh and the front edge of the seat. Examination of the pelvis, back, and shoulders is similar to that for a short leg, with specific attention paid to scoliosis, position of the posterior superior iliac spine, the relative heights of the iliac crests, and tilting of the shoulder-girdle axis. If, through examination, it is found that the pelvis is twisted,

this obliquity should be corrected prior to correction with a butt lift (Travell & Simons, 1983).

The amount of seated correction for a small hemipelvis is determined by adding increments of lift beneath the ischial tuberosity on the small side until the spine is straightened and the pelvis is leveled. The correction determined on a hard surface must be approximately doubled for a moderately soft chair, and tripled for a very soft sofa (Travell & Simons, 1983). Once a patient becomes comfortable with the correction, all muscles having been balanced and structure aligned, the patient may want to make various sizes of ischial lifts with attractive covers to leave on chairs or seats that are used regularly, i.e., desk chair, car seat, sofa, or favorite reading chair.

Morton Foot Structure or Long Second Metatarsal

Dudley J. Morton described the Morton foot structure. It is not to be confused with the metatarsalgia of Morton's neuroma, described by Thomas G. Morton.

The Morton foot has a relatively long second and short first metatarsal bone. This may perpetuate pain in the low back, hip, thigh, knee, leg, and dorsum of the foot. These patients consistently give a history of weak ankles; they say that they frequently have turned and sprained these joints (Travell & Simons, 1983).

When the first metatarsal is relatively short, the second metatarsal bears more weight. Not only is the second metatarsal longer, but because of this foot structure, it is located a bit more toward the plantar surface of the foot. As a result, the foot, balanced on the second metatarsal during weight bearing, rocks as if on a knife-edge. To compensate for this, most people modify their gait so that the lateral side of the heel and the medial side of the sole show excessive wear. Usually the foot is slightly externally rotated on heel strike and during stance phase. The ankle rocks inward (pronates) everting the foot at the ankle during and after the stance phase. The knee swings in toward the other knee as the thigh internally rotates (Travell & Simons, 1983).

The authors have observed that people with severe pronation often walk with their knees rubbing up against each other. Those with slight or moderate pronation add one more movement to the post stance phase. The knee moves laterally trying to regain the correct position over the foot.

The gait usually activates myofascial trigger points in the posterior gluteus medius muscle. The rocking foot also places a great strain on the peroneus longus muscle. Taut bands of these trigger points may entrap the peroneal nerve against the fibula immediately below its head, producing numbness and tingling across the dorsum of the foot and sometimes motor weakness with foot drop. Other muscles with activated trigger points are posterior gluteus minimus, vastus medialis, tensor fascia latae, iliotibial

band, sartorius, tibialis anterior, and extensor digitorum longus (Travell & Simons, 1983).

This syndrome is greatly aggravated by a shoe that is tight because it is too small or has a tight cap over the toes, and by high heels or shoes with pointy toes. Also, shoes should bend relatively easily at approximately the head of the metatarsals. Some shoes do not bend at all or they bend at the toes. This will be detrimental to a normal gait (Travell & Simons, 1983).

To examine for Morton foot structure, the clinician should flex the toes so that the metatarsal heads are prominent. By marking the heads with a pen, the long second metatarsal becomes obvious. Remember to measure the metatarsal heads and not the toe length. A long second metatarsal does not necessarily correlate with a long second toe. The long web between the second and third toes is characteristic of Morton foot structure. Because of the abnormal distribution of weight, most individuals with a Morton foot will develop calluses. They occur under the head of the second metatarsal, lateral to the fifth metatarsal under the medial side of the head of the first metatarsal, and on the medial side of the great toe along the interphalangeal joint (Travell & Simons, 1992; Figure 80.8).

To correct for the Morton foot structure, Morton recommended inserting into the shoe a leather insole with a leather build up of 1/8 to 3/16 inch under the head of only the first metatarsal bone. He also added a pad of sponge rubber behind the first to fifth metatarsal heads, which supported the shafts of all five metatarsal bones. In the office one can simply use two thicknesses of Molefoam (Dr. Scholl's Molefoam, distributed by Schering Plough Healthcare Products, Inc., Memphis, TN) under the first metatarsal head. If the heel of the shoe is too wide for the foot, a felt pad can be added along the medial side of the heel (Travell & Simons, 1983).

If the Morton foot structure is accompanied by excessive pronation or structural misalignment, a referral to a podiatrist and/or chiropractor is in order.

Short Upper Arms

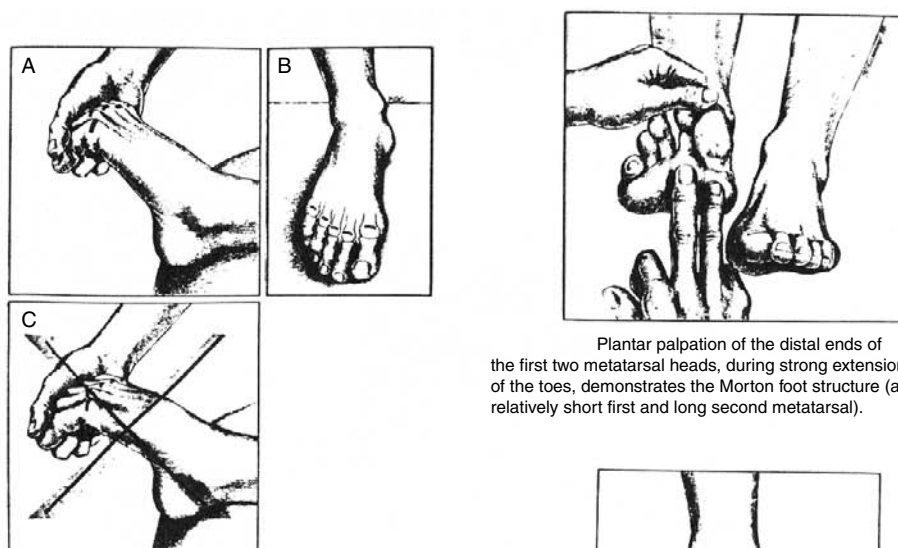
Shortness of upper arms is a rarely recognized, but not uncommon, source of muscle strain and perpetuation of trigger points in the shoulder girdle musculature (Travell & Simons, 1983). If the shoulder–elbow segment of the upper extremity is short in proportion to the rest of the body, the elbows do not reach the iliac crests when subject is standing with elbows bent at a 90° angle. When the person is sitting, the elbows fail to reach the armrests of the usual chair. This structural anomaly places undue stress on the upper trapezius, levator scapulae, and scalenes, thus perpetuating trigger points in these muscles. If a person spends an unduly long period of time leaning down to rest arms on the armrest, other muscles, such as the quadratus lumborum, can be affected.

Chairs, sofas, car seats, etc. that a patient uses regularly should have the arms built up so that elbows rest on them without the patient's leaning to one side, pushing shoulders up, or having the weight of the arms exerting a constant pull on the shoulder girdle musculature.

Hypermobility

"Double jointed" or "loose ligaments" are two other names for hypermobility. This condition is frequently overlooked because clinicians are trained to look for reduced, not increased, range of motion (Travell & Simons, 1992). Hypermobility stresses the muscles because they are constantly working to stabilize joints. A person with this perpetuating factor presents a complicated picture. The complete MTPT protocol does not apply when dealing with these patients.

When there are trigger points in the muscles that cross hypermobile joints, the trigger points should be inactivated using techniques that do not extend the muscles to maximum length (Travel & Simons, 1992). Normal MTPT pressure release techniques call for a muscle to be placed on a limited or partial stretch during this procedure. The full passive stretch after pressure should be eliminated. Trigger point pressure release at the attachment trigger points, vapocoolant with stretch of the affected muscles, and a stretch rehabilitation program done with great frequency are counterproductive when treating these patients. Instead, the central trigger points in the belly of the muscle must be released and the muscle must be stretched manually (massage therapy). Also, the patient should *not* be given a stretch rehabilitation program to do at home. Experience teaches that a stretch program may actually cause more pain than it relieves. A muscle-specific strengthening program coupled with manual stretching and limited joint movement during the treatment phase will provide the most relief. Strengthening acts to stabilize joints; think football players who destroy ligaments in their knees. Their rehabilitation program consists of strengthening the muscles around the knee to stabilize it. People with hypermobility syndrome must stabilize all joints by strengthening and balancing the muscles around them.

Another method for stabilizing the joints is prolotherapy. Hackett pioneered the use of controlled irritation of relaxed ligamentous tissues to achieve proliferation with minimal scarring, with a view to enhancing stability of the weakened structures (Chaitow & DeLany, 2002). The key to success was increased collagen formation and hyperplasia of the ligament tissue without evidence of histological damage. This is accomplished by the injection of a solution of tissue irritant into the connective tissue. The most common appears to be a glucose solution. The resulting proliferation of ligamentous tissue serves to strengthen and stabilize the joint. It is recommended that these two treatment methods be attempted before enter-


Examination of the Morton foot structure. *Black marks* locate the metatarsal heads in all positions. A, medial side view, good technique: flexion of the toes at the metatarsophalangeal joints and neutral position of the metatarsals proximally. B, standing weight-bearing position. *Black marks* clearly reveal the relatively short first and long second metatarsals. C. incorrect way of marking the metatarsal heads: the metatarsal bones are also flexed proximally at the tarsometatarsal joints, restricting flexion of the toes at the metatarsophalangeal joints.

Plantar palpation of the distal ends of the first two metatarsal heads, during strong extension of the toes, demonstrates the Morton foot structure (a relatively short first and long second metatarsal).

The long web between the second and third toes is characteristic of the Morton foot structure (a relatively short first and long second metatarsal).
Calluses frequently associated with the Morton foot structure. The second toe usually extends farther from the foot than the first toe when the second metatarsal is longer than the first metatarsal. Thick calluses may develop under the head of the second metatarsal, and lateral to the head of the fifth metatarsal. Another callus occurs under the medial side of the head of the first metatarsal and still another usually appears on the medial side of the great toe along the interphalangeal joint.

FIGURE 80.8 Screening for Morton's foot structure.

taining surgery for hypermobile joints (Chaitow & DeLany, 2002).

Cross Eye–Hand Dominance

Cross eye–hand dominance occurs when a person's right hand and left eye are dominant or vice versa. To determine which eye is dominant, have the patient perform the following test. Extend arms in front, palms facing away, at approximately eye level. Form a small triangle with the thumbs at the bottom and the web between thumb and forefingers serving as the sides. Keeping both eyes open,

look through this triangular opening at an object across the room. This object should just obscure the opening. While holding this position, close one eye and then the other. When the object remains in approximately the same place, the eye that has remained open is the dominant eye. When the dominant eye is closed, the object appears to shift to one side or the other, and, in some instances, seems to move out of the opening completely.

People with this perpetuating factor (PF) frequently complain of upper back and neck pain and headaches. Patients should be instructed in ways to avoid various

postural positions. Most of us have been taught that, when writing, the paper should be situated under the dominant hand and forearm and slightly toward the dominant hand side of the centerline of the body. In order for the dominant eye to focus on the work, the head tilts or rotates toward the side of the dominant hand. Holding one's head in this rotated or cocked position causes the muscles on one side of the neck and upper back to be held in a shortened position. On the other side the muscles are put on a constant stretch. Either or both of these positions can perpetuate neck and upper back pain and headaches. A simple solution to this problem is to move the paper more in line with the nondominant hand or to the midline of the body.

Other suggestions to thwart this perpetuating factor are as follows:

1. At the computer workstation, place work to the side of the dominant eye.
2. In the theater, concert, or lecture hall sit on the side of the dominant hand. In other words, left eye dominant people should sit on the right side of the theater, and vice versa.

Nutritional Inadequacies

Vital in the treatment of myofascial pain syndrome are strong, adequate levels of vitamins and minerals. Travell and Simons state that nearly half of patients seen for chronic myofascial pain require attention to inadequate nutritional levels in order to obtain lasting pain elimination. They also state that without sufficient levels of vitamins and minerals the body needs to make metabolic adjustments because coenzyme vitamins are limited. There is good reasoning to state that "normal" serum levels of nutrients are not necessarily "optimal" tissue level (Travell & Simons, 1983). To ensure optimal myofascial syndrome resolution, it is important to set the treatment stage with optimal levels of tissue nutrition.

Vitamin and mineral levels lower than required for good muscle health may come from decreased food intake, decreased supplementation, decreased absorption, decreased utilization, increased metabolic requirements, and increased exertion. Elderly individuals face these same complications along with increased destruction in the body and a less efficient functioning system. Once educated by the clinician, the patient with myofascial pain can address some of the very basic nutritional problems. Issues to include in patient education follow:

- Many patients with chronic myofascial pain skip meals, usually breakfast, but frequently breakfast and lunch. Their rationale for this is that they are not hungry in the morning, do not have time to eat in the morning, and are too busy for lunch. It is critical to begin the day, especially the workday, with nutrients for muscle function and ongoing muscle rehabilitation. Nutrients from the previous evening's meal have been used during the night and reserves are just not available. Many afternoon headaches have been traced to skipping breakfast and lunch.
- Many patients with chronic myofascial pain are using empty nutritional foods as fillers, for example, coffee or coffee and a bagel for breakfast: donuts, pastries, pretzels, crackers, coffee, and sodas at work. Carbohydrates of refined flour, refined sugar, and coffee not only provide no nutritional value to the system, but often use nutrition to digest them. Eating these foods fills the patients and interferes with more nutritious fruits, vegetables, and protein. Many an afternoon's increase in pain, and particularly an increase in headaches, comes from the abundance of high filler foods and high sugar intake.
- Many patients with chronic myofascial pain, in spite of the rise in the high-protein, low-carbohydrate diets gracing the market, are not eating adequate protein for good muscle function, particularly protein without undue high saturated fat. For most people breakfast does not include protein during the work week. Breakfast tends to be cereal (refined), bagel (nutritionally empty and refined), breakfast bars (high sugar and fat), breakfast drinks (high sugar), or nothing. Lunch may be a salad with vegetables (but no protein), sandwich (protein but refined flour bread), fast food (protein but high fat), pasta (nutritionally empty and refined), etc. Of course, there are those who eat well, but the patients routinely seen for chronic pain tend to eat high glycemic index and sugar foods. The recommended protein may be a small amount (e.g., four to five almonds) but the frequency of the protein tends to even the metabolism and provided the necessary impetus for muscle function efficiency.
- Many patients with chronic myofascial pain eat a diet high in refined sugar. The average American now consumes 152 pounds of sweeteners/sugars annually, a rise of almost 1,500% in the last 200 years (Gittleman, 1996)! The evolution of our bodies does not even begin to progress at a rate that would allow them to deal with the changes sugar causes internally. Besides being an extremely nutritionally empty additive, refined sugar creates an imbalance in the synergistic balance of minerals. Our own minerals are used just to digest it. Minerals are necessary for protein metabolism and proper muscle function. The mineral imbalance results in muscles being more vulnerable to tension and spasm.

- Sugar weakens the immune system primarily by upsetting the synergistic balance of minerals. It interferes with the transport of vitamin C in the body. Vitamin C inadequacy can result in aching muscles and joints. With frequent prescriptions of antibiotics as a result of the illness from a weaken immune system and patients eating a diet high in refined sugar, it is not uncommon to find patients with chronic myofascial pain suffering from systemic *Candida*. The overgrowth of bacteria can result in many diffuse symptoms including many experienced by the patient with myofascial pain: fatigue, lethargy, insomnia, lack of concentration, muscle weakness, muscle achiness, dizziness, depression, and anxiety.
- Many patients with chronic myofascial pain are eating foods and combining foods in such a way that results in an acidic pH in the system. "Muscle movement takes place because of the body's use of the gravity force of attraction and repulsion. The background pH maintains the balance of forces that allows chemical reaction to take place" (Judd & Judd, 2004, p. 125)
- Many patients with chronic myofascial pain, for some of the reasons mentioned above, harbor inadequate levels of vitamins and minerals, particularly B_1, B_6, B_{12}, folic acid, C, calcium, iron, and potassium. When testing for nutritional levels, it is critical to understand that "normal" serum vitamin and mineral levels does not assure "optimal" nutritional levels. "The prevalence of unrecognized hypovitaminosis is distressingly high" (Travell & Simons, 1983, p. 115).

Vital to the successful treatment of myofascial pain and dysfunction is the resolution of nutritional inadequacies.

- **B_1 Inadequacy** can result in an increased susceptibility to myofascial trigger points and a resistance to local treatment. (See Table 80.9 for signs and symptoms of marginal deficiency in B_1, thiamine.) Perhaps this is due to the need for thiamine for many steps in the process of energy production (Teitelbaum, 2001). B_1 levels are easily detected using the aluminum–magnesium alloy long period tuning fork. According to Travell and Simons this reveals the graded loss of vibratory perception in relation to fiber length. The greater the discrepancy between the distal (big toe) and proximal (hand), the greater the deficiency of B_1 (Travell & Simons, 1983).

- **B_6 Inadequacy (**See Table 80.10 for signs and symptoms of marginal deficiency of B_6, pyridoxine.)
- **B_{12} Inadequacy (**See Table 80.11 for signs and symptoms of marginal deficiency of B_{12}, cobalamin.)
- **Vitamin C Inadequacy (**See Table 80.12 for signs and symptoms of marginal deficiency of vitamin C.)
- **Folic Acid Inadequacy (**See Table 80.13 for signs and symptoms of marginal deficiency of folic acid.)
- **Calcium Inadequacy** results in decreases in muscular contracture mechanism and increases in trigger point irritability.
- **Potassium Inadequacy** decreases rapid repolarization of the nerve and muscle cell membranes following an action potential (Travell & Simons, 1983).
- **Iron Inadequacy** decreases oxygen transport to and within muscles.
- **Magnesium Inadequacy** decreases contractile mechanism of myofilaments (Travell & Simons, 1983).

Metabolic and Endocrine Inadequacies

Sonkin and Rachlin state, "Failure to recognize a metabolic cause of myofascial symptoms may result in prolonged, ineffective therapy, visits to a variety of therapists, and occasionally one or more fruitless surgical procedures" (1994, p. 45). While all metabolic inadequacies affect skeletal muscles and may be the cause of trigger points, the clinician may most often need to evaluate the patient for hypothyroidism (see Table 80.14). Patients who are even borderline low hypothyroid experience diffuse weakness and stiffness particularly of the shoulder girdle, trigger points, dry skin and hair, cold intolerance, weight gain, and muscle cramps. Because the primary function of the thyroid hormone is the control of cellular metabolism, the patients with myofascial pain are more susceptible to trigger points due to an inadequate supply of energy for muscle contraction. According to Weintraub's statement from the National Institutes of Health (NIH): "Thyroid hormone resistance syndrome may affect thousands of unsuspecting Americans" (Weintraub, 1991). In the face of current evidence correlating symptoms of hypothyroidism with unresolved myofascial trigger points, it seems reasonable to offer a low therapeutic trial of replacement thyroid, which is frequently effective (Sonkin & Rachlin, 1994). In hyperthyroidism, on the other hand, active trigger points are uncommon.

TABLE 80.9
Vitamin B$_1$ (Thiamine)

Clinical Evaluation of Marginal Deficiency

Symptoms	Signs	Laboratory Findings
Dry Beriberi		
Pain localized to any body areas, related to physical overload	Active trigger points in muscles refer pain and tenderness patterns that match pain complaints	RBC: Transketolase activity diminished
	Ankle jerks — sluggish or absent	
Paresthesias bilateral	Impaired vibratory perception: (higher	Low T4 (RIA)
Lower extremities — Primary	threshold) greatest compared with hands; least	Low thyroid function improved by thiamine
Upper extremities — Secondary	compared with feet, compared with hearing (in	supplement
Difficulty in making simple decisions	relation to nerve fiber length)	
Constipation	Motor	Serum cholesterol mid to high normal
	Weakness of muscles on exertion	
Calf cramps — any time		Anemia infrequent
Sleep impaired	Sensory	
	Dysesthesia	
Tinnitus, if also niacin deficiency		
No cold intolerance unless thyroid and/or folate deficiency/inadequacy		
Wet Beriberi		
Edema, cardiac	Pitting edema of feet, ankles, lower legs	
Shortness of breath		
Tachycardia, resting		

Factors Contributing to Thiamine Deficiency

Tea drinking at meals (tannin binds thiamine and prevents absorption)
Antacids at meals
Diet low in coffee, fresh nuts, potatoes
Alcohol, high intake

Note: Thyroid medication increases metabolic need for thiamine and may precipitate severe thiamine deficiency. From J. G. Travell, unpublished, 1987.

Hypoglycemia

Hypoglycemia is a metabolic disorder that aggravates myofascial trigger point activity and reduces or shortens the positive response to specific myofascial therapy. Recurrent hypoglycemic attacks perpetuate myofascial trigger points. There are two kinds of hypoglycemia, fasting and postprandial. They occur for different reasons, but present the same symptoms. Both of these disrupt the energy supply for muscle contraction, thereby perpetuating pain and dysfunction (Travell & Simons, 1999).

The initial symptoms of hypoglycemia or of increased epinephrine are usually sweating, trembling and shakiness, a fast heart rate, and a feeling of anxiety. Activation of sternocleidomastoid trigger points may cause headache and dizziness (Travell & Simons, 1999).

Insulin Resistance

Insulin resistance has been mentioned in relation to the perpetuating of myofascial trigger points in relation to menopause and the luteal phase of the menstrual cycle. It has been linked to a decrease in estrogen levels (Lowe, 2000). In the past estrogen replacement has been suggested to decrease insulin resistance. Recent research findings linking estrogen replacement with increased levels of breast cancer would mitigate against this course at this time.

In Syndrome X, there appears to be a genetic defect that causes resistance of the skeletal muscle cells to insulin. The insulin receptor may be the defective locus. Researchers have found reduced numbers of insulin receptors in skeletal muscle cell membranes in obese subjects, only some of whom have diabetes. The resistance involves desensitization due to excess exposure of cell membranes to insulin (Lowe, 2000).

The authors cannot emphasize enough the part that metabolic disorders play in perpetuating myofascial trigger point pain and dysfunction. In the case of stubborn pain problems, patients should be referred for a complete endocrine workup.

TABLE 80.10
Vitamin B$_6$ (Pyridoxine, Pyridoxal)

Clinical Evaluation of Marginal Deficiency

Symptoms	Signs	Laboratory Findings
Chronic pain, anywhere in body, often head and neck	Active myofascial trigger points refer pain in patterns that match patient's complaints; only transient relief by trigger point therapy	Serum vitamin B$_6$ low Urinary vitamin B$_6$ and tryptophan decreased
Motion sickness (boat, car, airplane)		Symptoms promptly relieved by therapeutic trial of vitamin B$_6$ moderate dosage (100 mg daily)
Nausea and vomiting first trimester of pregnancy		
Fatigue, lethargy	Anemia	Microcytic or macrocytic
Weakness	Ankle jerks reduced	Peripheral neuropathy
Muscle twitching	Vibratory perception diminished	
Soreness of wrist, tingling in first three digits	Carpal tunnel syndrome, atrophy thenar muscles	Median nerve compression by carpal ligament
Skin scaly, greasy patches	Seborrheic dermatitis	Vitamin B$_6$, cofactor for many enzymes, complex actions
Lips dry, fissures	Chelosis	
Sore tongue	Glossitis	
Kidney pain, attacks due to renal calculi	Oxaluria and oxalate kidney stones	Genetic defect, corrected by lifetime vitamin B$_6$ supplement 200–300 mg/day
Impaired vision	Eye, dislocation of lens	Genetic defect, homocystinuria, relieved by lifetime vitamin B$_6$ 300–500 mg/day
Cardiac dysfunction	Thrombosis of arteries and veins, cardiac failure	
Convulsions, newborn		Mother deficient in vitamin B$_6$

Tissue Reserves of Vitamin B$_6$ Depleted by
Contraceptive pill
Isoniazid (antitubercular)
Levodopa (for Parkinson's disease)
Alcohol

Note: From J. G. Travell, unpublished, 1987.

Posture: Sleeping, Sitting, Standing

Postures patients use during the day and at night can reinforce or counteract any treatment being administered. The best treatment, with the best neuromuscular retraining, can be undone by habitual positions that compromise muscle resting neutrality. Have patients bring photographs of themselves in their various sleep positions, sitting, watching television, using the computer, work positions, driving, and any other things they do frequently. The clinician will never get the same information from interacting verbally with the patient that can be obtained from the pictures. Their beds, pillows, chairs, sofas, sewing, working in the yard or on the car, workstation postures cannot be adequately described. The pictures are all telling!

Sleeping posture is one of the most common postural perpetuating factors maintaining trigger point activity. Stomach sleeping with head rotation results in significant contraction of the trapezius, levator scapulae, sternocleidomastoid, and posterior cervical muscles. If these muscles already harbor latent or active trigger points, the rotated position reinforces the "learned" shortened function of the muscle. The opposing muscles are on significant stretch and can react with a rebound effect when the head is returned to neutral. The arms in the stomach sleep position are often raised in an overhead position. This shortens the levator scapulae and splenius cervicis, lifts the rib cage and scapulae, and thus shortens the scalenii, serratus anterior and posterior, and the rhomboid major and minor. Other muscles, pectoralis, latissimus dorsi, coracobrachialis, and rotator cuff, are also in compromised positions. Looking at the trigger point pain patterns, it is no wonder the patient wakes during the night or in the morning with a headache, stiff neck, and back pain. Stomach sleeping usually places the feet in plantar flexion, thus contracting the calf muscles. Leg cramps and the beginnings of plantar fasciitis can result. Stomach sleeping is out! Place a tennis ball below the xiphoid process held in place loosely by an ace bandage. When the patient rolls onto the stomach, the tennis ball applies pressure to the solar plexus that knocks the air out of the patient. It only takes a couple of times of trying this before the stomach sleep habit is tamed.

A half side, half stomach sleep position further compromises neutral positioning by rotating the hips and flex-

TABLE 80.11
Vitamin B$_{12}$ (Cobalamin)

Clinical Evaluation of Marginal Deficiency

Symptoms	Signs	Laboratory Findings
Muscle pain and stiffness, often in low back and lower extremities	Active trigger points in muscles refer pain and tenderness in patterns that match pain complaints	Serum vitamin B$_{12}$ low (not optimal); 1,000 is optimal — no known toxic effects to injections of B$_{12}$
Ticklish	Startle reaction (body jump) to light touch	Subacute combined degeneration of spinal cold, without anemia if folic acid tissue reserves are adequate
Paresthesias of lower extremities bilateral; later of upper extremities		
Hypersensitive to noise	Hyperacusis	Pernicious (megaloblastic) anemia, but only if acid deficiency also exists
Fatigue and weakness	Ankle jerks hyperactive, Babinski reflex may be present	
Poor balance	Position sense impaired (positive Romberg sing)	
Diarrhea, often bowel disease (Crohn's sprue)	Tongue coated white (malabsorption)	Lack of gastric intrinsic factor (Schilling test positive) and achlorhydria with malabsorption (decreased hydrochloric acid)
		Microscopic abnormalities of gastric epithelium
		Stool examination may show fish tapeworm, which eats vitamin B$_{12}$

Note: Supplements with vitamin B$_{12}$ stimulate the metabolism of bone marrow and increase the need for folic acid. From J. G. Travell, unpublished, 1987.

ing one leg. This torque position on the quadratus lumborum and abdominal obliques and the sustained shortening of the iliopsoas create a setting for active trigger point low back, hip and groin pain. Side sleeping using pillows or similar props in front of the body will help break this torqued, flexed position.

Side sleeping can be used if one stays in a neutral position without curling into a fetal position and without rounding the thoracic and cervical spine with a head forward translation. The curled position shortens the pectoralis major and minor, especially if the top arm is allowed to fall in front of the body or with the arms curled or flexed at the elbow and wrist. This is often a precursor to carpal tunnel syndrome from the shortened biceps, brachialis, and forearm flexors and shortened scalenii. The lower arm should not be elevated overhead under the pillow or head, which affects the same muscular as in the overhead arm position of stomach sleeping. The side position should allow for the shoulders to be down/in a neutral position. Also shortened in the fetal position are the rectus abdominis and iliopsoas, both with low back/lumbosacral trigger point pain patterns. The legs should be extended almost straight with the body in neutral position.

Back sleep position if often difficult for patients but usually maintains the most neutral position of the body.

The pillow should be under the head, not the shoulders, and should hold the head in straight alignment. Contoured and special material pillows can be used, if they fit! It is not uncommon, however, to find these pillows fit only a few patients accurately. Note that the head should not be held flexed, extended, or laterally flexed. A small pillow or elevation can be placed under the knees to reduce lumbar strain. Minimize calf plantar flexion strain by loosening the covers at the end of the bed or by placing a pillow at the bottom to hold the covers off the feet.

Sitting posture should maintain neutral positioning. Hip, shoulder, and ear should be in a straight-line alignment. When a slouched or rounded posture is taken, the head juts forward. This results in considerable strain on the posterior cervical musculature as it attempts to hold the weight of the head against gravity. The cervical curve begins to straighten resulting in undue stress on the posterior disk space. The rounded posture shortens the anterior musculature, particularly the pectorals, coracobrachialis, anterior serratus, and rectus abdominis. The antagonists are strained on stretch to maintain posture.

The rounded/slouched sitting posture positions the pelvis in a posterior tilt. If the posture becomes habitual, there can frequently be ligamentous changes which tend to maintain that posterior tilt when standing. This significantly limits iliopsoas range of motion.

TABLE 80.12
Vitamin C (Ascorbic Acid)

Clinical Evaluation of Marginal Deficiency

Symptoms	Signs	Laboratory Findings
Post-exercise stiffness, aching muscles and joints, several hours or next day after exercise	Generalized muscle soreness and restricted motion, with trigger points related to regions of acute pain	Low plasma vitamin C (0.6% too low)
Easy bruising (minimal trauma)	Ecchymoses, spotty capillary oozing after needle prick	Capillary fragility increased
Bleeding gums	Petechiae	
Tissue healing slow	Scar formation incomplete: pressure sores	Collagen formation impaired
Subject to cold and infections, postnasal discharge, chronic		Vitamin C prevents replication of viruses
Active allergies	Asthma, hay fever	Adrenal output of corticosteroids improved by vitamin C supplement (2.3% adrenal output parallels vitamin C levels)
Smokes or exposed to cigarette smoke	Smoker's odor Post-nasal discharge, chronic	Smoking reduces vitamin C content of adrenal gland
Fatigue	Pallor, anemia	Iron-deficiency anemia, or macrocytic if either folic acid or vitamin C is low
No paresthesias	Ankle jerks normal	
Male infertility		Sperm in semen stick together

Vitamin C is Destroyed by
Heat — boiling, cooking food
Exposure of food, or person's skin, to fluorescent lighting
Mixing with antacids in stomach

Note: Vitamin C improves absorption of iron and utilization of folic acid. From J. G. Travell, unpublished, 1987.

Sitting in reclining chairs or propped up with cushions while lying on the sofa watching television or reading causes the head to be in a forward and/or flexed position, even if supported. There is a stretch strain on the posterior cervical musculature and a contraction in the anterior musculature. If this becomes a habitual posture, the lower thoracic spine flattens and the upper thoracic spine becomes extremely kyphotic with extension of the cervical spine. Once ligamentous changes begin to accommodate this posture, it becomes quite a challenge to return to normal positioning.

Standing posture is often the culmination of sitting, lying, and sleep postures. To maintain normal standing alignment may require releasing anterior musculature, strengthening weakened overstretched muscles, utilizing joint mobilization, and redeveloping a kinesthetic perception of what "normal" is. Feldenkrais and Alexander techniques are helpful with redefining proper body positioning and movement.

Home and Workstation Ergonomics

Occupational perpetuating factors involve the interaction of humans, machines, and the environment. Our main interest is the human and how we interact with tools, machines, and environments. The science of ergonomics evolved to address these issues.

Ergonomics recognizes four important facts:

1. Machines and equipment should be designed and prescribed based on recognized human characteristics.
2. Tasks should be structured to enhance ease, efficiency, and safety.
3. Job demands and human capabilities should be matched.
4. People must be made aware of the environment within which they perform (Khalil et al., 1994, p. 488).

As a therapist involved in treating people with acute or chronic pain, the clinician must consider a person in his or her workplace whether that be inside or outside the home. As was mentioned previously, a vital tool for diagnosing the problems inherent in the interaction between human and workplace is photographs of the patient at his or her workstation along with an explanation of the tasks performed. Through these the clinician is able to make suggestions regarding changes in work habits and postures.

TABLE 80.13
Folic Acid

Clinical Evaluation of Marginal Deficiency

Symptoms	Signs	Laboratory Findings
Intolerance to cold (primary)	Low basal body temperature (taken in morning before getting out of bed, or any physical activity, even shaking thermometer)	Serum folate in lowest quartile of "normal average range, or below lower limit of "normal"
Headache and neck pain	Active trigger points in neck and masticatory muscles refer pain and tenderness in patterns that match pain complaints	Spinal fluid folate may be lower than serum folate (blood–brain barrier)
Restless legs, nocturnal, no pain	Dry skin	Serum cholesterol low
No nocturnal calf cramps (night cramps more often low vitamin E)	Bodyweight low	Anemia marginal (may or may not be macrocytic, is microcytic)
Diarrhea, episodic		
Indigestion, gas, and bloating	Abdominal examination normal	Stool examination normal
Pain not aggravated by rainy weather	No weight gain with rainy weather	
No paresthesias	Ankle jerks normal	
	Vibratory perception threshold normal	

Drug-Related Folate Deficiency

Antiepileptic (Dilantin)
Antitubercular (Isoniazid)
Antacids after eating
Alcohol ingestion affecting liver function and therefore decreased folate

Note: From J. G. Travell, unpublished, 1987.

Without a doubt, as computer use has increased, the pain problems associated with this task are increasing rapidly. The conditions have been variously called carpal tunnel syndrome, repetitive strain injury, cumulative trauma, or overuse syndrome. Regardless of the name used to describe this condition, there are two basic activities responsible for the problem. One is holding the muscle in a relatively fixed position, often under load, for prolonged periods. The other is a repetitive movement that gives the muscle incomplete recovery time (Mense et al., 2001). Both are present in computer users who spend long, uninterrupted periods at a workstation. In addition to computer users, assembly line workers also suffer from repetitive strain injury. As companies try to increase productivity or cut costs, they may speed up the line or reduce the number and length of breaks. This is a recipe for disaster for the company and the worker. The worker may develop a chronic pain condition. However, the company loses money to absenteeism and workers' compensation insurance premiums. Every effort should be made to ensure a healthy work environment for employees.

Occupational therapist Barbara Ingram-Rice (1997) lists the following risk factors in the development of carpal tunnel syndrome:

- Computer use (or any work requiring repetitive finger dexterity) for more than 2 to 4 hours per day

- Infrequent rest breaks (suggests 3 to 5 minutes every 30 minutes to stretch the neck, shoulders, and upper extremity)
- Hypermobile joints, as their instability makes these joints more susceptible to injury
- Poor posture, including rounded shoulders and forward head, which encourages nerve entrapment
- Poor technique with activity/work such as holding the phone to the ear with the shoulder, poor sitting postures, or a computer screen set at a less than ideal angle or distance
- Sedentary lifestyle, leading to overall decreased fitness level
- Stressful work environment, leading the person to work harder, not smarter
- Arthritis, diabetes, thyroid disease, or other medical conditions that can accentuate the individual's response to repetitive strain
- Long fingernails, causing awkward use of fingertips
- Excessive alcohol or tobacco consumption, decreasing the body's ability to repair tissue damage
- Obesity, as increased adipose tissue may decrease tunnel space and an overweight person is less likely to properly fit the furniture asso-

TABLE 80.14
Hypothyroidism

Clinical Evaluation of Marginal Hypometabolism

Symptoms	Signs	Laboratory Findings
Intolerance to cold	Low basal body temperature Cold feet and hands	Basal metabolic rate (BMR) low; 97.7–98.5 adequate, 97.0–97.5 marginal, below 97.0 definite
Chronic pain, made worse by mild overload and cooling the body		
Poor sleep and morning stiffness	Active trigger points in muscles, more often in lower extremities; only brief relief by trigger point therapy	Serum T4 (thyroxine) in lowest quartile of "normal" (average range, or lower — most helpful to see)
Intolerance to heat (decreased perspiration)	Perspiration negligible	TSH normal; serum cholesterol high (unless also folic acid inadequacy)
Skin coarse, but often well lubricated with skin cream (dry skin)	Skin rough, thickened over heels and areas of friction	Serum creatine phosphokinase (CPK) high
Hair "won't take a wave"	Hair dry, brittle (eyelashes may be broken/short; eyebrows may be very sparse and/or nonexistent in outer 1/3 of brow)	
Pain worse before and during rainy weather (very typical)	No palpable edema weight gain (fluid) with rainy weather (not cardiovascular)	Water content of muscles increased with humidity and low barometric pressure
Fatigue	Pallor	Anemia, normocytic unless also folic acid inadequacy (macrocytic)
Exhaustion by end of day (decreased muscle stamina)		Blood count shows low % of leukocytes and high % of monocytes
Constipation		
Poor resistance to infections		
Overweight or underweight	Slim underweight person often hyperactive	Body movement generates heat
No paresthesias (unless vitamin B_1 inadequacy)	Ankle jerks normal except for slow relaxation phase	
Tachycardia	Normal blood pressure	Electrocardiographic changes suggestive of myocardial disease
Menses irregular, excess bleeding, or amenorrhea	Occasional hypertension corrected by thyroid supplement	
	Fibrocystic disease of breast	Mammogram, biopsy positive

Thyroid Function Depressed by
Thiamine inadequacy
Radiation of thyroid gland or of person's body

Note: From J. G. Travell, unpublished, 1987.

ciated with the job (Chaitow & DeLany, 2000, p. 394)

For the "risk" factors listed above, we can substitute the phrase "perpetuating" factors. All of these must be addressed when treating a person with computer or repetitive motion-driven pain syndromes.

Sleep Disturbances

Sleep disturbances for the patient with myofascial pain may be due to a number of factors. It is important to identify whether the problem is one of getting to sleep or sleep maintenance. Identify possible reasons for the sleep difficulty. Reasons may include stress, mind or physical exercising activity before going to bed, sleeping too much during the day, eating before going to bed, sleep apnea, or conditions such as hypothyroidism or adrenal fatigue. Identify the severity of the sleep disturbance. If pain is the main interfering factor to sleep, deactivating trigger points along with muscular retraining will be most helpful. Restorative sleep becomes a major factor needing to be addressed if pain is to be eliminated.

Impaired sleep, regardless of the cause, severely affects the body's ability to resolve pain conditions. Impaired sleep conditions include insomnia, sleep apnea, and alpha-delta sleep anomaly.

There are three different kinds of insomnia:

1. The inability to fall asleep
2. The inability to stay asleep
3. A combination of the two (Starlanyl & Copeland, 1996, p. 115)

Sleep apnea means a temporary cessation of respiration. The tissues in the throat relax to the point where airflow is obstructed and the sleeper stops breathing momentarily (Starlanyl & Copeland, 1996). This usually involves the inability to exhale. The sleeper is aroused or comes to a shallower level of sleep and then takes an explosive breath. This arousal has been known to happen up to 100+ times per hour and can make the sleeper feel fatigued and achy upon awakening in the morning.

Alpha-delta sleep anomaly is caused when the alpha waves of nonrestorative sleep interfere with the restful continuous delta waves of deep sleep.

Regardless of the type of sleep impairment, there are ramifications, as muscles that should be repaired and maintained by sleep are not. Moldofsky and Scarisbrick (1976) found muscle tenderness and a sense of physical tiredness in the morning in healthy university students when the slow wave non-REM (rapid eye movement) sleep had been disrupted throughout the night. This finding demonstrates the basis for a vicious, self-perpetuating cycle. The painful muscles can interrupt sleep, and disrupted sleep can make the muscles more painful (Travell & Simons, 1999, p. 226). Pain can prevent a person from falling asleep or wake a person during the night. Change in sleep position or remaining in one position too long can cause sleep interruption.

Impaired sleep can be a precipitating or a perpetuating factor in muscle pain and dysfunction. It is still unclear whether the pain of fibromyalgia syndrome (FMS; Bennett et al., 1995) causes impaired sleep or impaired sleep contributes to the development of this debilitating pain syndrome. In the case of myofascial pain and dysfunction, a lack of sleep is an important factor in perpetuating pain. In order for the manual therapy and stretch to be effective, the therapist must deal with the sleep impairment. This may require a temporary sleep aid, which can range from over-the-counter antihistamines and herbal treatments to prescription medications. If the pain of trigger points causes the sleep disruption, trigger point release and restoration of a pain-free full range of motion are the quickest way to unimpaired sleep. In most instances, as the pain decreases, the length of time of uninterrupted sleep increases.

Psychological

The psychological state of the patient can be complex and yet blurred. Many patients with chronic pain have been to numerous physicians and pain clinics, have endured many types of treatment, and often still do not have any answers to their problem. The initial most valuable aspect of treatment we can give these patients is an unambiguous diagnosis of treatable myofascial pain syndrome. Teaching the patients their involvement in the treatment process begins to give them control over pain rather than the pain victimizing them. Depression, anxiety, frustration, anger, and even stoicism begin to lessen once there is positive direction and movement in treatment. Table 80.15 covers various mind-sets one may encounter when treating myofascial pain syndrome.

Step 6: Trigger Point Therapy Treatment

When identifying the responsible trigger point, the clinician finds evidence of a palpable band in the affected muscle. It may be difficult to feel, however, if it is a deeper muscle and overlying muscles are also shortened and contain trigger points. Within the palpable taut band the examiner identifies spot tenderness. This will present as a very precise, small area within the taut band. The patient may elicit an exclamation or actually flinch as pressure is exerted on the point of tenderness. This jump sign does not need to be, nor should be, elicited with undue/extreme pressure. Patients will often identify the pain elicited as the very pain they have been experiencing, and this identifies the trigger point.

Using a sustained pressure on the trigger point will elicit the pain referral pattern. The length of time holding the sustained pressure may vary from trigger point to trigger point and from patient to patient depending on the muscle contraction, depth of the trigger point, and the condition of the patient's tissues. According to Vecchiet in Travell and Simon (1999), subcutaneous tissue was found to be tenderer than the skin over the trigger point. The manual palpation identification of the trigger point still remains somewhat subjective, as it will vary with the amount of pressure applied to the taut band and with the skill of the examiner. Interrater reliability study results are shown in Table 80.16. Gerwin, in furthering Travell's work, has implemented seminars addressing the issue of skill development of identifying trigger points and in the injection technique used for treatment. The palpative physical examination focuses on the area of pain and discomfort but with an eye to observing total body movement, evidence of movement with mental guarding, posture, gait, weaknesses, and instability.

Myofascial Origin Versus Symptoms

Treating symptoms can certainly give pain relief to the patient, but when the pain results from myofascial trigger points, symptom relief masks the underlying source of the pain and treatment relief is temporary. Perhaps symptom treatment, added to treating the pain site rather than the pain source, is why the pain has become a chronic pain syndrome. It seems the critical question to ask is "why

TABLE 80.15
Psychological Mind-Sets of the Patient

Negative	a.	Patient's focus is on every negative aspect of the pain syndrome
	b.	Clinician should not ask "how are you?"
	c.	Talk and ask in positives
	d.	Give positive assignments
	e.	Turn patient's negative statements into positive ones
Depressed	a.	Patient has decreased self-image
	b.	Don't support patients feeling sorry for themselves
	c.	Give assignments reaching out to others
Benefits from the pain	a.	Give assignments reaching out to others
	b.	Set goals — *what* the patient wants in terms of work, social, self; *when* they want to accomplish these goals
	c.	Set responsibility for getting better on the patient with compliance to sessions, perpetuating factors, home program
Give up	a.	Loss of hope/victim mentality
	b.	Patient education, e.g., explaining there may not be an instant resolution but there is no damage
	c.	Set small goals
	d.	Note small advances
Good sport syndrome	a.	Patient pushes through pain and is proud of it
	b.	Patient education — constant reaggravation delays pain resolution
	c.	Ask — *why* pushing through wanting to keep self-image or other people's image, job, family, insecurity
	d.	Give relaxation assignments
Anxious/fearful	a.	Patient education — realistic vs. unrealistic aspects of the pain
	b.	Address the anxiety and fear directly — what is the patient really fearing?
	c.	Address exaggerated view of pain — worst-case scenario and best-case scenario
	d.	Glass half full/half empty view
Acceptance	a.	Conditioned reflex thinking patient views pain as "just the way I am; everyone in the family has it
	b.	Set patient responsibility of actions and habits independent of family habits
Misunderstanding	a.	Patient believes problem is structural, e.g., herniated disc, arthritis, pinched nerve
	b.	Patient believes there is damage that may or may not heal

Note: From N. Shaw, unpublished, 1988.

TABLE 80.16
Interrater Reliability of Examinations for Trigger Point Characteristics, Kappa Values

Examination	Wolfe et al.	Nice et al.	Njoo et al.	Gerwin et al.	Mean
Spot tenderness	0.61		0.66	0.84	0.70
Jump sign		0.70			0.70
Pain recognition	0.30		0.58	0.88	0.59

Referred pain	0.40	0.38	0.41	0.69	0.47
Twitch response	0.16		0.09	0.44	0.23
Mean	0.35	0.38	0.49	0.74	

Note: From *Muscle Pain: Understanding Its Nature, Diagnosis, and Treatment,* by S. Mense, D. G. Simons, & I. J. Russell, 2001, Baltimore: Lippincott/Williams & Wilkins. Reproduced with permission.

are the symptoms there, of what are they the result?" If we look at the "why" of the pain, we address the source of the pain and can treat toward permanent pain elimination. The treatment of myofascial pain syndrome addresses all of the primary and secondary pain and dysfunction problems, including perpetuating factors. It is actually possible that a major perpetuating factor needs to be a focus of change *before* the actual physical treatment begins. Otherwise, the perpetuating factor may continue to reactivate trigger points and interfere with any lasting pain relief (i.e., there is pain reduction for a few hours or days, but the pain returns at the same level or even worse).

The myofascial trigger point origin is determined by unraveling the totality of all trigger point referral patterns documented during the intake (primary, satellite, and compensatory). Treatment of only the primary trigger point does not eliminate the satellite and compensatory trigger points and their referred pain. The patient may notice the pain shifting to another area.

Pain Elimination Versus Pain Management

To address the primary, satellite, and compensatory trigger points and the associated functional units takes time and cannot be cut short if pain resolution, not pain management, is the treatment goal. The focus of the treatment must be pain resolution, with the gradual elimination of pain medications, muscle relaxants, antidepressants, and sleep medications used for the symptom relief of the myofascial pain and dysfunction. To eliminate the symptoms without eliminating the trigger point source and perpetuating factors of the pain leads to prolonged treatment and short-term relief. Short-term relief often means eliminating activities and/or movements that tend to increase the pain. On the other hand, pain elimination expands what the patient can do both in daily activities as well as outside activities. For a myofascial pain syndrome to become chronic, Travell suggested the clinician has, in some way, missed a piece of the pain puzzle. Although symptoms for a particular episode may be abated, if the myofascial pain syndrome returns, the treatment has not been sufficient to eliminate the source of the problem. Contrary to popular practice Travell looked to the clinician to refocus on the complex, whole patient and work with the patient to determine the missing pieces of pain resolution.

Total Trigger Point Treatment Versus Pain Site Treatment

The pain site is generally the point of trigger point referral; it is not the source of the primary trigger point. Satellite trigger points have become just as much a component of the chronic myofascial pain problem as the original primary factor. Muscle guarding implicates other muscles not originally part of the pain. Perpetuating adjustments and accommodations to the pain brings other muscles into the pain situation. The involvement does not end until the entire chain of trigger points has been evaluated and treated.

Total Patient Treatment Versus Pain Site Treatment

The critical fact here is that the clinician is treating a person, not a pain, not a shoulder, nor a knee or elbow. If, in fact, perpetuating factors are as important a factor as has been reported, it is the whole person that must be considered in treatment.

Movement Versus Rest

Passive and active movement is necessary in the release and retraining of the muscles involved in myofascial pain and dysfunction. The rest and inactivity often prescribed allow the musculature to stay, and even increase, contracture, thus perpetuating the problem. If you do not go golfing, the bad golf swing will never be an issue. If you do not move a muscle, it may not hurt but it certainly has not learned a new functioning length.

Hands-on Treatment Versus Mechanical Treatment

While the modalities of ultrasound, electric stimulation, traction, and biofeedback can certainly be helpful in the relaxation of muscles and may be necessary partners of the interdisciplinary team, they do not serve to deactivate trigger points, do not redirect/retrain muscle function, and do not allow for the all important aspect of "touch" in the therapeutic process. Travell worried that the treatment of myofascial pain and dysfunction would become "too high tech" and "too low touch." Mechanical treatments are modalities, only part of a full treatment protocol.

Heat Versus Cold

Heat, rather than ice, is used in the treatment of myofascial pain syndrome. Of course, with an immediate acute situation, as compared with the chronic pain problem, ice is used initially for the reduction of swelling and inflammation. Once the pain has become a chronic situation, ice on the involved pain area serves to act as a local anesthetic agent but also adds to the contracture of the muscles. It is too much contraction in the muscle that is already the problem, so additional contraction is to be avoided. The heat increases circulation, stimulating muscle relaxation and, thereby, increasing nerve and vessel efficiency. Heat is an adjunct to the trigger point release, not an agent of their release.

Trigger Point Pressure Release (Barrier Release)

The clinician, having identified the trigger point and placing the affected muscle on slight stretch, slowly applies a sustained compression, gradually increasing the pressure until resistance is felt. At the point of resistance the patient will usually feel some discomfort. It is important that the clinician not increase the pressure as that can actually traumatize the muscle, causing it to tighten to guard or protect from further pain. As the trigger point releases, a slack in the muscle occurs and the pressure can be slightly increased to the new point of resistance. This layering into the muscle effectively releases the trigger point without undue discomfort for the patient.

Spray with Stretch

The spray with stretch method of releasing a trigger point has been called a variety of names. They include spray and stretch, stretch and spray, vapocoolant with stretch, and intermittent coolant with stretch. In an effort to be as simple and yet as precise as possible, the term "spray with stretch" is used in this chapter. It is important to remember that spray is the distraction, and stretch is the action (Travell & Simons, 1983). To stretch before spraying will only aggravate the trigger point and increase pain. It will also cause a protective contraction and reflex spasm of the muscle, all of which will obstruct further elongation of the muscle.

In order for spray with stretch to be effective, the patient must be as relaxed as possible, in a comfortable and supported position (Travell & Simons, 1983). The room should be warm, and the patient should be wrapped in or covered with a blanket except for the part to be treated.

The muscle to be treated should be immobilized at one end. The patient should be instructed in the reasoning and methodology used. An explanation regarding spraying the source as well as the site of the pain is important. To mitigate fear of the unknown, the clinician should demonstrate by spraying vapocoolant on himself or herself and then on the patient in an area far from the pain site.

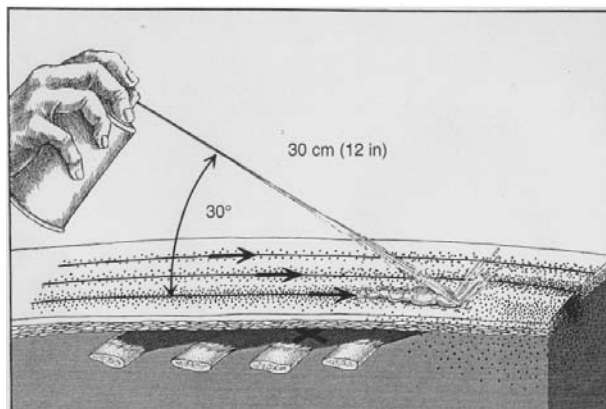
Having prepared the patient, the clinician proceeds to the actual procedure. Initial sweeps of the vapocoolant are applied over the muscle being treated and continued over the complete pain pattern to begin releasing muscle tension before taking up the slack to lengthen the muscle toward its stretch position. The spray is applied in parallel sweeps *only* in the direction of the referred pain. This spray procedure can be repeated until full muscle length is achieved or no further progress occurs. However, any given area of skin should be covered only two or three times before rewarming. After the skin is rewarmed, several cycles of full active range of motion complete the spray with stretch treatment (Travell & Simons, 1999).


FIGURE 80.9 Positioning for using vapocoolant. From *Myofascial Pain and Dysfunction: The Trigger Point Manual* (2nd ed., Vol. 1), by J. G. Travell & D. Simons, 1999, Baltimore: Williams & Wilkins. Reproduced with permission.

The nozzle of the spray bottle or can should be fully engaged. Any partial opening of the nozzle results in dripping coolant on the patient. For those who still have some bottles of Fluori-Methane (Gebauer Company, Cleveland, OH), the technique requires that the bottle be held upside down. The newly developed Instant Ice (Gebauer Company) can be held upright or at a slight angle. The stream of the spray should describe a path that is at a 30° angle to the skin and approximately 12 inches from the point of impact (Figure 80.9). The spray should be applied at a rate of 4 inches per second. The farther away the spray bottle/can, the cooler it feels. For patients who have difficulty dealing with the intensity of the cold, speed up the rate of the sweep and move the spray can closer. The Instant Ice, which is somewhat cooler than Fluori-Methane, should be held closer to the skin (3 to 7 inches away; Travell & Simons, 1999).

Injection

Trigger point injections are indicated for quick relief of acute, subacute, or chronic myofascial pain, for substitution of narcotic medication, for restoration of functional impairment due to myofascial trigger points, or for supplemental therapy of chronic myofascial pain to facilitate its recovery. The trigger point is identified in the taut band, sterile skin preparation is made, and the needle is inserted rapidly where a local twitch response is elicited upon needling the trigger point. The clinician senses a grabbing of the tissue around the needle upon penetrating the trigger point (Hong, 1994).

It is imperative that physicians be trained in the palpation, identification, and ultimate location of trigger points before the injection technique can be effective in treating myofascial pain syndrome. Ngoo and Gerwin have shown good interrater reliability if practitioners are

experienced and trained (Gerwin et al., 1997; Ngoo & Van der Does, 1994).

It is critical to note, once again, that the trigger point release, by whatever method, is just one step in treating myofascial pain syndrome.

STEP 7: SPECIFIC MUSCLE STRETCH RETRAINING

Rehabilitation is seen as a primary factor in the success of the myofascial trigger point protocol. Muscle retraining is imperative to the successful return of functional efficiency.

Stretch Versus Strength Rehabilitation

Stretch is an absolute in myofascial therapy rehabilitation. While we all agree that muscle weakness is a symptom of myofascial syndrome, it must be viewed initially as a pseudo-weakness. If the muscle is in a sustained muscle contracture with shortened range of motion function, it will, of necessity, have shortened contracture potential and, therefore, weakened function. To add contracture through strength rehabilitation before full stretch range is accomplished simply reinforces the habitual contracted patterning of the muscle and weakens it further. Starling's law states "length means strength." The specific stretch rehabilitation establishes new lengthened muscular patterning and returns full functional efficiency. Then, if the muscles are weak, a strength-stretch program can be instituted for the patient.

"No Pain" Range of Motion Versus "Pain for Gain" Range of Motion

The "no pain" range of motion is emphasized in stretch retraining of muscles in a chronic myofascial pain syndrome to help eliminate the rebounding effect of the exercise. It is important for the patient to respect the current potential of the muscle and not to push into the pain range. Movement/stretch is performed to the point of feeling initial stretch, even if the patient is capable of stretching beyond that point. This allows for a relaxed acceptance of the movement and the beginnings of a new established range of movement for the muscle. If the patient is in pain when performing the stretch retraining, the muscles are reaggravated rendering the release of the trigger points ineffective. "Pain for gain" range of motion may be necessary for some postoperative, prolonged immobilization or disease conditions but further activates trigger points or results in a rebound guarding for the patient with chronic myofascial pain.

Muscle Retraining Versus Muscle Conditioning

Muscle retraining is different from muscle conditioning. Muscle retraining is designed to reestablish full-length functioning of muscles that have been in a shortened contracted pattern of function. Muscles "learn." In myofascial pain and dysfunction the muscles are not injured, which is why objective testing generally reveals no indication of the pain source. A magnetic resonance imaging (MRI) image or a radiograph does not reveal the source of a bad golf swing or any other incorrect muscle function. The muscles, instead, are functioning incorrectly in learned shortened patterning. Do something long enough and it becomes habit, whether good or bad. Muscles frequently performing to newly acquired movement potential will establish a functioning pattern that becomes automatic. When trigger points have been deactivated, perpetuating factors resolved, and muscle function established at full range of motion, pain is eliminated.

Once range of motion is returned to the muscle and pain eliminated, muscle conditioning is introduced. This should be done in the context of the patient's interest and previous activity involvement. Working back into a balance of strength and stretch, reintroducing graduated participation in activity, and progressing to full daily and recreational activity should be implemented with patient input as to schedule, interest, and realistic compliance. The patient should be compliant and committed to the rehabilitation program. If it does not interest the patient, if it is not realistic within the structure of the patient's life, it is not going to happen. It is imperative the patient and clinician work together to create a workable and interesting rehabilitation program.

Stretch Principles

1. Patient in a relaxed, comfortable position
2. Stretch slowly at a pace that incorporates natural momentum
3. Two repetitions; it is the frequency that retrains the muscles, and this eliminates fatiguing the muscle resulting in a rebound guarding
4. Every 1 to 1 1/2 hours; frequency leads to a functioning habit
5. Hold long enough to take a deep inhalation and exhalation; this has a relaxing effect and the body accepts the movement without guarding
6. No pain range of motion; this allows acceptance of the motion for the patient mentally and physically
7. Stretch bilaterally

The clinician's goal is to establish a neuromuscular retraining program that:

- Can be performed anywhere
- Takes literally only a couple of minutes to perform

- Is individualized to the specific physical and mental needs of the patient
- Incorporates movement leading toward the activities of interest to the patient

If the program is workable, the commitment by the patient is much greater.

Trigger point deactivation in the treatment setting is well documented in the medical literature to include trigger point injections, intermittent coolant with stretch, and sustained compression. While trigger point deactivation is obviously a critical aspect of treatment, remember it is the interdisciplinary team — the physiatrist diagnosing, ordering appropriate lab work, and performing the trigger point injections; the podiatrist involved in forefoot varum; the rheumatologist dealing with endocrinological problems; the pulmonologist involved in sleep disturbances; the psychologist addressing emotional or behavioral components; the manual therapists performing trigger point release and addressing basic perpetuating factors and neuromuscular retraining; the chiropractor or osteopath correcting structural imbalances — that, working together, resolves myofascial pain and dysfunction.

SUMMARY

Checklist for Successful Treatment of Myofascial Pain Syndrome

- Perform proper differential diagnosis
- Set appropriate atmosphere for treatment
  Room and patient warm
  Patient relaxed
  Clinician not hurried
- Obtain adequate history
- Communicate adequately with patient
- Assure treatment conditions favorable
  Patient not ill with cold, flu, unduly fatigued, etc.
  Patient not highly emotional
  Patient not highly anxious
- Address all perpetuating factors
- Utilize correct technique
- Treat all categories of trigger points
- Treat at an appropriate pace
- Remove aggravating factors
  Sitting in drafts, driving long distances without breaks, etc.
- Recognize compensatory mechanisms/movements
- Utilize correct and complete stretch program
- Correctly prioritize rehabilitation program
- Reintroduce activity realistically
- Give adequate and complete patient education

- Obtain patient compliance
- Recognize conditioned reflex
- Treat with an interdisciplinary approach

REFLECTIVE THOUGHT

While there remains some controversy in allopathic physician circles regarding the roles of osteopathy, chiropractic, and complementary medicine, one study after another documents the merits and contributions of those interventions when properly applied (Materson, 2001).

There are two types of physicians — those that are free men and those that are slaves. The slaves, to speak generally, are treated by slaves, who pay them a hurried visit, or receive them in dispensaries. A physician of this kind never gives a servant any account of his complaint, nor asks him for any; he gives him some imperial injunction with an air of finished knowledge, in the brusque fashion of a dictator, and then is off in haste to the next ailing servant.… The free practitioner attends free men, treats their diseases by going into things thoroughly in a scientific way; and takes the patient and his family into his confidence. Thus he learns something from the sufferers, and at the same time instructs the invalid to the best of his powers. He does not give his prescriptions until he has won the patient's support.… Now which of the two methods is that of the better physician or director of the bodily regimen?

Role of Naturopathy in Pain Management

Rick Marinelli, ND, MAcOM, and Harry Adelson, ND

INTRODUCTION

The purpose of this chapter is to introduce the reader to the profession of modern naturopathic medicine in North America, outline its underlying principles and history, describe the emerging specialty of naturopathic pain medicine, and give the reader a cursory overview of a sampling of its traditional and emerging treatment modalities.

Naturopathic medicine is defined as a distinct system of primary health care — an art, science, philosophy, and practice of diagnosis, treatment, and prevention of illness (U.S. Department of Labor, 2003). Naturopathic doctors (NDs) are primary health care providers who combine contemporary conventional scientific knowledge with a spectrum of natural and conventional medicine modalities; they are the physician-level practitioner trained in the broadest range of conventional and natural medicines. Naturopathic medicine is distinguished by the principles that underlie and determine its practice rather than by its broad treatment modalities. These principles are based on the objective observation of the nature of health and disease, and are continually reexamined in the light of scientific advances. The treatment modalities used, although broad, are consistent with these principles and are chosen on the basis of patient individuality. The guiding principles of naturopathic medicine are as follows:

1. The healing power of nature (*vis medicatrix naturae*)
2. Identify and treat the cause
3. Treat the whole person
4. First do no harm
5. Doctor as teacher
6. Prevention

Modern NDs are trained at accredited, 4-year, postgraduate, residential naturopathic medical programs, which require an undergraduate degree with standard premedical coursework. The curriculum of the first 2 years closely mirrors that of conventional medical schools (M.D. or D.O.) in the basic sciences, conventional diagnostics, pharmacology, and minor surgery. The third and fourth year of training divides the student's time between clinical in-patient and out-patient rotations and additional class work in therapeutic nutrition, botanical medicine, homeopathy, naturopathic manipulative therapy, natural childbirth, classical Chinese medicine and acupuncture, hydrotherapy, and psychology. Postgraduate medical education is available to NDs, but is not required by all states that license NDs.

HISTORY OF NATUROPATHIC MEDICINE

The word *physician* is from the Greek root meaning nature. Hippocrates formulated the concept *vis medicatrix naturae* — the healing power of nature. This concept has long been at the core of indigenous medicine in many cultures around the world and remains one of the central themes of naturopathic philosophy to this day.

Vincent Priessnitz is credited with the creation of the European tradition of hydrotherapy in the early to mid-1800s. It is believed that he discovered the concept of the healing power of water through the observation of animals in the wild that would soak injured limbs in streams. Priessnitz developed large sanitariums, which were hugely popular, but bitterly opposed by the medical community. His work was furthered by Father Sebastian Kneipp, who added to Priessnitz's "water cure" the use

of medicinal herbs; exercise therapy; a wholesome, balanced diet; and "regulative" therapy, a system of organizing daily life in accordance with biological rhythms (Kirchfeld & Boyle, 1994).

In the 1890s, Benedict Lust, a German immigrant living in the United States, fell ill with tuberculosis. He returned to Germany to undergo Father Kneipp's water cure and was successfully healed. Father Kneipp instructed Lust to formally bring this type of medicine to the United States. Kneipp's medicine already existed in the United States among German immigrants, but it was Lust who was the first to be officially mandated by Lust to bring nature cure to the United States. Lust sensed the need to Americanize Kneipp's principles (i.e., Kneippism) and make it acceptable to Americans. He is credited as the "Father of Naturopathy." Lust chose the word *naturopathy* to describe this practice of medicine, a word coined by Sophie Scheel, an instructor at a New York homeopathic college. Lust realized that to be taken seriously, he would need formal medical training, so he attended medical school and was licensed as an M.D. This is an important point, as it demonstrates American naturopathy's foundation in Western scientific tradition. Lust additionally received D.O. and D.C. degrees during his medical career. He founded the American School of Naturopathy in New York City in 1901 and the American Naturopathic Association, as well as the periodical *The Naturopath* in 1902. It is important to note that the American School of Naturopathy, much like modern naturopathic schools, was based on contemporary medical curriculum with the addition of natural healing modalities. Henry Lindlahr, M.D., was an early student of Dr. Lust and is credited as the founder of "scientific naturopathy." He founded a number of sanitariums, which would treat patients with natural therapies only after a thorough, state-of-the-art conventional diagnostic workup had been completed (Kirchfeld & Boyle, 1994).

Naturopathic medicine quickly became popular and widely available throughout the U.S. in the early 20th century. In 1920, there were 10 naturopathic medical schools and approximately 20,000 practicing naturopathic physicians. The discovery and increasing use of "miracle drugs" such as antibiotics, the institutionalization of a medical system based primarily on high-tech and pharmaceutical treatments, as well as the ever-existing schism in the naturopathic profession between "traditional" naturopaths (who tend to have bias against scientific medicine) and "modern" naturopaths (who view themselves as hybrids) — all of these led by midcentury to the decline to near extinction of naturopathic medicine (Kirchfeld & Boyle, 1994).

John Bastyr, D.C., N.D., is credited as the "Father of Modern Naturopathy." In 1956, at the time that naturopathy was near extinction, Dr. Bastyr and a small number of other dedicated physicians created the National College

of Naturopathic Medicine (NCNM). Although homeopathy and spinal manipulation had been a treatment of naturopathic medicine for decades, it was Dr. Bastyr who brought these two modalities into the forefront of the naturopathic curriculum during his presidency in the early years of NCNM. Additionally, because his father was a pharmacist, and Dr. Bastyr had often worked in the pharmacy, he held a pragmatic view about the use of pharmaceuticals. Once, when asked by a student, which of the healing modalities was "the best," his response was, "The one that works." Naturopathic medicine is in no way philosophically opposed to conventional medicine; the role of the ND is to offer safe and effective treatments to those patients who seek naturopathic medicine and are candidates for naturopathic care.

Currently in the United States, the naturopathic medical profession is blossoming into maturity. Its infrastructure is based on a national association (the American Association of Naturopathic Physicians), federally accredited educational institutions, professional licensing by an ever-growing number of states, national standards of practice and care, peer review, and an ongoing commitment to state-of-the-art scientific research.

Those most opposed to naturopathic medicine cite a lack of scientific data to justify deviation from conventional care. However, the Office of Technology Assessment of the U.S. Congress has estimated that fewer than 30% of the procedures currently used in conventional medicine have been rigorously tested (Astin et al., 1998). One reason most naturopathic therapies are not considered "evidence-based" is that the majority were introduced prior to the advent of the randomized, controlled clinical trial (RCT). Such limitations are evident in conventional medicine as well; however, they are often overlooked due to the apparent or established effectiveness of a particular treatment. The common and accepted use of antithrombotic agents for cardiovascular diseases and their complications (myocardial infarction, stroke, pulmonary embolism, and death) is a good example. Three of the agents that had been prescribed by allopathic physicians for millions of patients every day, warfarin, aspirin, and heparin, were introduced prior to the era of randomized clinical trials and had widespread use for many years before they were validated by RCTs (Relman & Weil, 1999). However, few physicians would have argued that these were unconventional treatments simply because they had not yet gone through RCTs. Furthermore, natural substances are not patentable, and there is little financial incentive for corporate funded research. Nonetheless, every year sees and an ever-growing amount of meaningful data demonstrating or refuting safety and efficacy of complementary and alternative modalities.

As stated above, modern naturopathic medicine is defined by its principles and philosophy, not by its treatment modalities. NDs borrow from all of the medical

sciences to achieve wellness in each individual patient. Frequently, the modalities used by NDs are not proprietary to naturopathy. The specialty of "Naturopathic Pain Medicine" is currently evolving. We discuss a selection of modalities used by NDs, which is by no means exhaustive.

INTERNAL NATUROPATHIC MEDICINE FOR PAIN

In the tradition of Kneippism, the naturopathic treatment of any condition, painful or otherwise, is always based on lifestyle modification. Exercise, a healthful diet, and psychological health are the foundations upon which any treatment plan is built.

EXERCISE

Despite a poor rate of patient compliance, NDs recommend exercise to patients with pain. In one study, general practitioners gave written advice on physical activity during usual consultations. For every 10 written prescriptions for exercise, at 12 months only 1 person achieved and sustained 150 minutes of moderate or vigorous leisure activity per week. In these compliant patients, measures of self-rated general health, vitality, and pain improved significantly (Elley et al., 2003).

Fibromyalgia and chronic fatigue syndrome fall under the spectrum of chronic multisymptom illnesses. This constellation of syndromes is often defined by chronic pain, unremitting fatigue, cognitive difficulties, and various other symptoms. In treating these illnesses, a prescription for exercise is often overlooked by health care practitioners. Research has shown that exercise is quite beneficial in reducing pain and fatigue in this population and should be included as part of a multimodal therapy regimen (Ambrose, Lyden, & Clauw, 2003; King et al., 2002; Valim et al., 2003).

Beyond its use in treatment of pain syndromes, physical activity also effectively decreases the risk of many chronic disorders. Numerous studies have convincingly demonstrated that moderate levels of physical activity greatly reduce the incidence of many chronic health conditions, most notably type II diabetes mellitus, obesity, cardiovascular disease, depression, and many types of cancers (Chakravarthy, Joyner, & Booth, 2002).

Also, strength training in elderly people has been shown to have beneficial effects on risk factors for age-related diseases and pain. In addition to improved strength, function, endurance, muscle mass, and power, strength training has been shown to reduce insulin resistance, decrease both total and intra-abdominal fat, increase resting metabolic rate, prevent the loss of bone mass density, reduce risk factors for falls, and reduce pain (Hurley & Roth, 2000).

DIET

Whole-food diets high in fiber, quality protein, essential fatty acids, fruits, vegetables, and minimally processed, low-insaturated fats and trans-fatty acids are recommended by NDs. Although humans have remained primarily unchanged genetically since before the agricultural revolution, our diet and lifestyle have become progressively more divergent from those of our ancestors. Accumulating evidence suggests that this mismatch between our modern diet and lifestyle and our Paleolithic genes plays a substantial role in the epidemics of obesity, hypertension, diabetes, and atherosclerotic cardiovascular disease. Humans evolved on a diet high in lean protein, polyunsaturated fats (especially omega-3 fatty acids), monounsaturated fats, fiber, vitamins, minerals, antioxidants, and other beneficial phytochemicals. Anthropological studies have shown hunter–gatherers generally to have been healthy and largely free of the degenerative diseases common in modern societies (O'Keefe & Cordain, 2004). Although prehistoric humans had shorter life expectancies than modern humans, much of their mortality arose from conditions that we are now able to prevent or cure.

Generally, NDs do not recommend vegetarian or vegan diets; rather, they recommend healthful meat choices as part of a healthy diet. From the data currently available, it appears that the intake of meat itself is not a risk factor for degenerative disease, but rather the risk stems from the intake of excessive saturated fat. Unlike wild game meat, which is low in total and saturated fat and relatively rich in polyunsaturated fatty acids, meat from modern domesticated animals is high in saturated fat. There is some evidence that diets high in lean red meat can actually lower plasma cholesterol, contribute significantly to tissue omega-3 fatty acid, and provide a good source of iron, zinc, and vitamin B_{12} (Mann, 2000).

Vegetarian diet is, however, recommended in rheumatoid arthritis and other autoimmune conditions. Studies have shown patients with rheumatic conditions benefit from the vegan diet rich in antioxidants, lactobacilli, and fiber (Hanninen et al., 2000; Nenonen et al., 1998).

PROTEOLYTIC ENZYMES

Naturopathic training includes an in-depth study of botanical preparations. The botanical medicines used in the treatment of pain can be categorized, just as with pharmacologic preparations, into analgesics, anticonvulsants, antidepressants, anti-inflammatories, anxiolytics, sedatives, and alteratives/adaptogens. Some of the most commonly used botanical medicines for pain are bromelain, cayenne, feverfew, ginger, gingko, boswellia, corydalis, and guggulipid. A systematic review of the literature aimed at determining the clinical efficacy of botanical medicines for rheumatologic conditions suggests that herbal remedies have symptomatic effects beyond pla-

cebo. A review published in *Rheumatic Diseases Clinics of North America* concluded that phyto-anti-inflammatories have considerable potential in the symptomatic treatment of rheumatic disorders (Ernst & Chrubasik, 2000).

Bromelain is one such botanical medicine frequently recommended by NDs. It is viewed as an alternative to nonsteroidal anti-inflammatory drugs (NSAIDs). Bromelain is the collective term for enzymes (principally proteolytic) derived from the pineapple plant, *Ananas comosus,* and a member of the Bromeliaceae family. Pineapple has been used as a folk medicine for centuries. Its traditional uses have been as a digestive aid or to promote the healing of wounds.

Bromelain can function as a digestive enzyme, and there is research suggesting that it may also have wound healing, anti-inflammatory, antidiarrheal, and anticarcinogenic effects. Bromelain's anti-inflammatory action is believed to be from activation of proteolysis at site of inflammation, fibrinolysis via plasminogen-plasmin system, depletion of kininogen, inhibition of inflammatory prostaglandins, and induction of prostaglandin E1.

Bromelain mainly comprises cysteine proteases, with smaller amounts of acid phosphatase, peroxidase, amylase, and cellulase. Bromelain contains at least four distinct cysteine proteases. The principal stem protease is called stem bromelain or stem bromelain protease. Two additional proteases found in the stem are called ananain and comosain.

The therapeutic use of proteolytic enzymes is both empirically based and supported by scientific studies. Studies of the use of proteolytic enzymes in rheumatic disorders have mostly been carried out on enzyme preparations consisting of combinations of bromelain, papain, trypsin, and chymotrypsin. The results of various studies (placebo-controlled and comparisons with nonsteroidal anti-inflammatory drugs) in patients with rheumatic diseases suggest that oral therapy with proteolytic enzymes produces analgesic and anti-inflammatory effects (Leipner, Iten, & Saller, 2001). In some studies, proteolytic enzymes were shown to be as effective as NSAIDs while producing fewer side effects (Klein & Kullich, 1999; Wittenborg et al., 2000). Bromelain has been shown in a pilot study to be helpful in the treatment of mild acute knee pain (Walker et al., 2002) and, in an open case observation study, to be effective in speeding the healing time of blunt injuries to the musculoskeletal system (Masson, 1995).

Bromelain and proteolytic enzymes, therefore, seem a reasonable treatment option for patients suffering mild to moderate pain from inflammation, especially in light of its safety profile as compared with NSAIDs.

INTRODUCTION TO NATUROPATHIC THERAPEUTIC INJECTION (NTI)

In the treatment of painful conditions, oftentimes modalities more invasive than lifestyle modification, prepara-

tions taken by mouth, spinal manipulation, and acupuncture are needed, especially in patients who wish to avoid chronic use of pain medications. For this reason, injection therapies are increasingly employed by NDs practicing naturopathic pain medicine.

In response to this growing trend, the Naturopathic Academy of Therapeutic Injection (NATI) has been formed, with the following primary objectives:

1. To hold NDs practicing therapeutic injection to the highest standards of practice through board certification
2. To protect the public's safety
3. To advance the science of injection therapies in the context of a naturopathic pain medicine clinical practice

It is important to note that minor surgery is part of the core naturopathic curriculum, and NDs are trained in the management of the spectrum of possible adverse reactions to in-office procedures. Injection therapies increasingly used by NDs include intravenous micronutrient therapy (IVMT), myofascial trigger point injection, regenerative injection therapy (RIT), and mesotherapy.

INTRAVENOUS MICRONUTRIENT THERAPY

IVMT and, more specifically, the "Myers' cocktail" (Table 81.1) is a popular treatment modality among NDs and other physicians practicing complementary and alternative medicine (Gaby, 1998). No exact figures currently exist reflecting the extent of utilization of this modality; however, members who routinely treat patients with IVMT have been reported by a range of national medical associations, including the American College for Advancement in Medicine (ACAM), the American Association of Naturopathic Physicians (AANP), the American Holistic Medical Association (AHMA), the American

TABLE 81.1
Contents of the Myers' Cocktail

Magnesium sulfate (50%)	5 ml
Calcium gluconate (10%)	3 ml
Hydroxocobalamin (1,000 μg/ml)	1 ml
Pyridoxine hydrochloride (100 mg/ml)	1 ml
Dexpanthenol (250 mg/ml)	1 ml
B-complex 100*	1 ml
Vitamin C (222 mg/ml)	10 ml
Sterile water	20 ml

* B-complex 100 contains the following per each ml: thiamine HCl, 100 mg; riboflavin, 2 mg; pyridoxine HCl, 2 mg; panthenol, 2 mg; niacinamide, 100 mg; benzyl alcohol, 2%.

Academy of Pain Management (AAPM), the Great Lakes College of Clinical Medicine (GLCCM), and the International Society of Orthomolecular Medicine (ISOM). Data obtained by an online survey of members of these organizations suggest that IVMT has been widely used for a variety of conditions, most often fibromyalgia syndrome (FMS) and chronic fatigue syndrome (CFS), with reports of consistently positive results; survey data pertains to some reported 12,000 patient experiences. Despite its popularity, no controlled trials of IVMT efficacy and only one trial investigating the mechanism of action of the Myers' cocktail (Lonsdale, Shamberger, Stahl, & Evans, 1999) have been conducted. At the time of this writing, there is one National Institutes of Health–funded, double-blind, placebo-controlled, randomized trial being conducted on the use of IVMT in the treatment of fibromyalgia, but data are not yet available. The exact mechanism of action of IVMT is unknown apart from the effects of the individual constituents.

Alan Gaby, M.D., popularized the use of the Myers' cocktail. We refer the reader to the article by Gaby, "Intravenous Nutrient Therapy: The Myers Cocktail" (Gaby, 2002) in which he discusses his many years of experience using the Myers' cocktail for the treatment of, among many other conditions, status asthmaticus, migraine, CFS, FMS, acute muscle spasm, upper respiratory tract infections, chronic sinusitis, seasonal allergic rhinitis, and cardiovascular disease.

IVMT has the ability to achieve serum concentrations of micronutrients unobtainable with oral or intramuscular administration. The highest serum vitamin C level reported after oral administration of pharmacological doses is 9.3 mg/dl, however, intravenous (IV) administration of 50 g/day of vitamin C resulted in a mean peak plasma level of 80 mg/dl (Blanchard, Tozer, & Rowland, 1997). Similarly, oral supplementation with magnesium has been shown to minimally affect serum magnesium levels, whereas IV administration can double or triple the serum levels (Okayama, Aikawa, Okayama et al., 1987; Sydow, Crozier, Zielmann et al., 1993).

Much of the benefit of Myers' cocktail in the treatment of painful syndromes is believed to be derived from the magnesium content (Gaby, 2002). Magnesium administered intravenously has been shown to ameliorate pain in a number of conditions (Anand, 2000; Crosby, Wilcock, & Corcoran, 2000; Koinig et al., 1998; Mauskop et al., 1995a, 1995b, 1996; Tramer et al., 1996; Xiao & Bennett, 1994). Magnesium is important for more than 300 different enzyme reactions and, in healthy states, magnesium levels are second only to potassium intracellularly (Groff, Gropper, & Hunt, 1995). Magnesium has been found to be low in the serum (Eisinger et al., 1994, 1996) and erythrocytes (Eisinger et al., 1994) and high in the hair (Ng, 1999) of patients with FMS, suggesting some imbalance of magnesium regulation in this population. Gaby

hypothesizes that the reduced levels of intracellular magnesium found in patients with FMS play a role in the etiology, and in order to adequately replenish the cells with magnesium, it is necessary to attain extremely high levels in serum, possible only with IV administration (Gaby, 2002).

Migraine headache appears to share some features with FMS, such as irregularities of serotonin (Nicolodi & Sicuteri, 1996), extensive dysregulation in pain modulation, and generalized hyperalgesia (Okifuji, Turk, & Marcus, 1999). Similar to patients with FMS, patients with migraine have been found to have reduced red and mononuclear blood cell magnesium levels (Mazzotta et al., 1999). Two double-blind studies have shown that chronic oral magnesium supplementation may reduce the frequency of migraine headaches (Mauskop & Altura, 1998), and one pilot study demonstrated that IV magnesium can resolve an acute migraine (Mauskop et al., 1995b). Magnesium concentration plays a role in the modulation of serotonin receptors, nitric oxide synthesis and release, and a variety of other neurotransmitters (Groff et al., 1995).

Reed (1990) found parenteral magnesium therapy to have a beneficial effect in treating two groups of patients: those with acute sprains, contusions, or soft tissue injuries and those with chronic muscular complaints including myofascial pain, relapsing soft tissue injuries, and FMS.

Based on research to date, some conjecture can be made regarding the role of magnesium. However, the roles of the other constituents of the IVMT solution have not been investigated extensively. Nonetheless, vitamin B_{12} injected intramuscularly has been used experimentally to treat CFS, a syndrome closely associated with FMS (Goldenberg et al., 1990). In one unblind trial, 2,500 to 5,000 µg of vitamin B_{12}, given by injection every 2 to 3 days, led to improvement in 50 to 80% of a group of people with CFS, with most improvement appearing after several weeks (Lapp & Cheney, 1993). It has been suggested that oral or sublingual administration does not achieve the effects seen with injectable B_{12} (O'Dowd, 2000).

The potential for adverse reactions from IVMT lies mainly in the method of administration rather than the substance(s) administered (Bier, 2000). Any type of IV therapy holds some risk of local effects (hematoma, thrombosis, phlebitis, thrombophlebitis, infiltration, extravastion, local infection, venous spasm) and/or systemic complications (septicemia, circulatory overload, pulmonary edema, air embolism, speed shock, catheter embolism). These complications are rare and are avoided by using proper technique and thorough screening of patients for whom IV therapy is contraindicated (Phillips, 1997). There exist reports of allergic reaction to the thiamin (B_1) found in the B-complex solution. Reaction to thiamin, although extremely rare, most often manifests as a hypersensitivity reaction (Morinville, Jeannet-Peter, & Hauser, 1998; Stephen, Grant, & Yeh, 1992). A preliminary test for sen-

sitivity to thiamin is considered "best practice." Otherwise, there are no known serious side effects of IVMT. Providers of IVMT have not observed other known toxic effects of vitamin and mineral excess with the exception of hypotension due to too rapid a magnesium administration, easily avoided by observation of the patient's state (Gaby, 1998). Avoidance and management of adverse reactions to IVMT are taught in naturopathic medical school.

Previously, an erroneous belief linked the intake of large amounts of vitamin C with the formation of oxalate-type kidney stones because of the metabolic conversion to oxalic acid. If the amount of oxalic acid in the urine increases as the dose of vitamin C increases, it was postulated that a prolonged intake of large amounts of vitamin C might cause kidney stones. There exist, however, no data to support this speculation, and in fact, data clearly refute this idea (Johnston, 1999). Curhan et al. (1999) conducted a 14-year-long study to examine the association between the intakes of vitamins B_6 and C and risk of kidney stone formation in 85,557 women. They found that a high intake vitamin B_6 was inversely associated with risk of stone formation and vitamin C intake was not associated in any way with risk.

Myofascial Trigger Point Injection

MFTPI as originally described by Travell & Simons (1983) is an accepted modality in the treatment of soft-tissue, musculoskeletal pain. We refer the reader to the chapter in this volume by Gerwin and Dommerholt, which thoroughly outlines the modality. MFTPI is included here merely to illustrate that it is a modality routinely used by NDs practicing naturopathic pain medicine, and to discuss a common adaptation not proprietary to NTI, the addition of cobalamins (vitamin B_{12}) to the MFTPI solution.

While there is currently no direct evidence to justify the use of B_{12} in MFTPI solution, because of the known biochemical functions of the cobalamins and a small number of animal studies demonstrating their antinociceptive properties, it is used by some NDs and other practitioners of MFTPI and merits further discussion.

A number of animal studies have been conducted demonstrating the antinociceptive properties of thiamine, pyridoxine, and cyanocobalamin either alone (Franca et al., 2001; Fu et al., 1988; Leuschner, 1992), or used concomitantly with diclofenac (Jurna, 1998; Kuhlwein, Meyer, & Koehler, 1990; Reyes-Garcia et al., 1999; Vetter et al., 1988). One rat study showed that coadministration of diclofenac with either thiamine (B_1) or pyridoxine (B_6) resulted in an antinociceptive effect similar to that of diclofenac alone. On the other hand, coadministration of cyanocobalamin significantly increased diclofenac-induced antinociception (Reyes-Garcia et al., 1999).

While it is well known that vitamin B_{12} deficiency can cause fatigue, there exist data indicating that individuals who are not deficient in this vitamin experience increased energy after injections of vitamin B_{12} (Bjorkegren, 1999; Ellis & Nasser, 1973; Lapp & Cheney, 1993). Oral or sublingual B_{12} supplements are believed by some to be unlikely to obtain the same results as injectable B_{12}, because the body's ability to absorb large amounts is relatively poor (O'Dowd, 2000). Observational studies (Hutto, 1997) have found as many as 30% of patients hospitalized for depression to be deficient in vitamin B_{12} (Pennix et al., 2000).

Apart from the common practice of adding B_{12} and other pharmaceutical-grade natural substances, whether botanical, nutraceutical, or homeopathic, to the MFTPI solution, all other aspects of the technique, namely, the indications, contraindications, and techniques, are consistent with the teachings of Travell.

Regenerative Injection Therapy

In simplest terms, RIT (also known as prolotherapy) is the injection of a hypertonic solution containing local anesthetic directly into damaged connective tissues with the purpose of triggering an inflammatory response in order to allow the body's natural healing mechanisms to take place (Linetsky, Miguel, & Saberski, 2001). RIT is very clearly described in Linetsky's comprehensive chapter in this publication, and we refer the reader to Chapter 62 for an exploration of the science of RIT. RIT is of particular interest to NDs practicing naturopathic pain medicine, because it is believed that it directly addresses the cause of pain and allows the body to naturally heal itself.

While there currently exists a paucity of data examining RIT, one of the best-constructed trials was conducted by Reeves and Hassanein in 2000. They found that intra-articular injection with 10% dextrose resulted in clinically and statistically significant improvements in pain associated with knee osteoarthritis. Blinded radiographic readings at 1-year post-treatment demonstrated improvement in several measures of osteoarthritis severity. Additionally, it was found that anterior cruciate ligament laxity, when concurrently present in this patient group, improved as well (Reeves & Hassanein, 2000).

A common naturopathic interpretation of RIT/prolotherapy is the addition of glucosamine sulfate (GS) to the injected solution in the treatment of degenerated connective tissue. GS taken orally has been shown to be effective in the treatment of the pain associated with osteoarthritis of the knee as well as in the delay of the progressive degeneration (Braham, Dawson, & Goodman, 2003; Matheson & Perry, 2003; McAlindon et al., 2000; Pavelka et al., 2002). Glucosamine, formed in the body as glucosamine-6-phosphate, is the most fundamental building block required for the biosynthesis of glycolipids, glycoproteins, glycosaminoglycans, hyaluronate, and proteoglycans. The mechanism of action of GS in reversing

joint degenerations appears to be due to its ability to act as an essential substrate for, and to stimulate the biosynthesis of, the glycosaminoglycans and the hyaluronic acid backbone used in the formation of the proteoglycans found in the structural matrix of the synovium. After an oral dose, glucosamine concentrates in the liver, where it is incorporated into plasma proteins, degraded into smaller molecules, or used for other biosynthetic processes. Although absorption is very high, a substantial quantity of the absorbed glucosamine is probably modified or degraded to smaller compounds, such as H_2O, CO_2, and urea (Setnikar et al., 1993).

From these data, it is intriguing to NDs to inject GS directly into degenerated joints, ligaments, and tendons. NDs are not alone in injecting GS. Klein et al. (2003) conducted a pilot study to test the potential effectiveness of intradiscal injection therapy using an RIT solution, which included GS in the treatment of intervertebral disc disease. The study included 30 patients with chronic intractable discogenic low back pain. Affected lumbar intervertebral discs were injected with a solution of glucosamine and chondroitin sulfate combined with hypertonic dextrose and dimethylsulfoxide (DMSO). Assessment of pain and disability was completed before treatment and 12 months after the last treatment. Although the results were statistically insignificant for the 30 patients as a whole, 17 of the 30 patients (57%) improved markedly with an average of 72% improvement in disability scores and 76% in visual analogue scores. The other 13 patients (43%) had little or no improvement. Patients who did poorly included those with failed spinal surgery, spinal stenosis, and long-term disability (Klein et al., 2003). Derby et al. (2004) also conducted a pilot study where they compared "intradiscal restorative injections" containing GS to intradiscal electrothermal treatment (IDET) in the treatment of discogenic disc pain and found restorative injections to be slightly more effective than IDET in reported pain 6 to 18 months post-procedure and much improved in cost–benefit ratio.

Yelland et al. (2004) conducted a trial on RIT for low back pain. They assessed the efficacy of a prolotherapy injection versus the injection of saline with or without an exercise protocol in the treatment of chronic nonspecific low back pain in 110 patients. Their findings demonstrated significant and sustained reductions in pain and disability occur with ligament injections, irrespective of the solution injected or the concurrent use of exercises (Yelland et al., 2004). These data suggest that the mechanism of action of RIT may be found more in the mechanical disruption and subsequent local inflammation caused by the manipulation of the needle and stimulation of intracellular growth factors by the compression of cells by the injected solutions than by any specific chemomodulation caused by various ingredients used. However, more study is needed.

MESOTHERAPY

Although mesotherapy and its applications to pain and sports medicine are almost entirely unheard of in the United States, it is widely popular and available around the world. It is an emerging modality in naturopathic pain medicine and is of particular interest because of its apparent safety, tolerability to patients, and seeming efficacy.

History of Mesotherapy

In 1952, a French physician, Dr. Michel Pistor, administered 10 ml of procaine intravenously in an attempt to abort an acute asthmatic attack in a patient. While the treatment did not improve the patient's respiratory status, upon follow-up the patient reported a significant improvement in his impaired hearing. Soon after, Pistor began experimenting with superficial injections of procaine around the ear of deaf patients and reported some success. Soon his practice was full of hearing impaired patients seeking treatment. His results in curing deafness were mixed; however, many of these patients had improvement in seemingly unrelated concomitant conditions such as eczema of the auditory canal, temporomandibular joint pain, and tinnitus, which can be related to deafness (LeCoz, 1993).

Pistor continued experimenting with superficial injections of procaine for the treatment of various disorders, and in 1958 he published an article, which stated, "the action on the tissues originating from the mesoderm is so extensive that these treatments should be called mesotherapy." This was the first time the term *mesotherapy* appeared in print. Pistor proposed the basic premise of mesotherapy to be the "smallest dose, infrequently, in the correct location" (LeCoz, 1993).

The mesoderm is one of three embryologic histological classifications: endoderm, mesoderm, and ectoderm. The cells of the endoderm eventually develop primarily into the internal organs. The cells of the mesoderm level develop into dermis and hypodermis, fatty tissues, and the musculoskeletal system. The ectoderm develops into, among other tissues, the brain and epidermis. The term *mesotherapy* therefore is in reference to injecting into the dermis and hypodermis, which originates from the mesoderm (although some mesotherapy techniques involve injecting the epidermis, which originates from the ectoderm). The mesoderm exists only in embryos; there is no mesoderm layer of the human skin, a common erroneous belief among English-language mesotherapists.

The French Society of Mesotherapy was formed in 1964 and consisted of 12 members. The first international conference on mesotherapy took place in 1976. This was also the year mesotherapy was first used in in-patient settings in France. In 1981, Dr. Jacques LeCoz introduced mesotherapy into the sports medicine program at the National Institute of Sports in Paris. The French Academy

of Medicine officially recognized mesotherapy as a legitimate treatment modality within conventional medicine in 1987.

Currently, mesotherapy is considered mainstream medicine in France with more than 16,000 practitioners. It has been incorporated as an integral treatment in the specialty of sports medicine (Laurens, 2000) and pain management (Roch, 2000) in France as well as in other countries around the world (Belhocine & Oussedik, 2000). Apart from the French Society of Mesotherapy, some of the more established national mesotherapy associations or societies are in Algeria, Argentina, Belgium, Brazil, Canada, Colombia, Great Britain, Germany, Greece, Israel, Italy, Mexico, Portugal, Russia, Switzerland, Spain, Tunisia, Turkey, and Venezuela. Mesotherapy is also becoming widely popular in Asia with new national associations and societies being formed every year. In France, mesotherapy is primarily used for pain management and sports medicine, but the aesthetic procedures are very popular as well (LeCoz et al., 1994).

In the United States, mesotherapy as an aesthetic procedure is just now beginning to gain attention, and a number of professional associations are forming with a primary focus on cosmetic applications. Mesotherapy had been used in France for cosmetic purposes long before making its way to the United States. The French have always been ahead of the United States in cosmetic procedures; they developed liposuction and chemical peels. Mesotherapy has been used in the treatment of cellulite since the 1960s (LeCoz et al., 1994). Unfortunately, in the United States, pain management and sports medicine applications go largely ignored.

Basic Tenets of Mesotherapy

Mesotherapy is defined by its unique style of injection: various superficial injections using specialized short needles and specific injection techniques directly over the site of the affected structure (LeCoz et al., 1994). There are broad-ranging treatment protocols and philosophies regarding which substances are injected, including conventional medicines, botanical medicines, homeopathic medicines, or micronutrients.

The basic premise of mesotherapy is that solutions injected intracutaneously remain in the injected area longer because they are slower to be cleared by general circulation than a deeper injection. Further, it is felt that the injected solutions continue to penetrate the deeper tissues. Kaplan (1985) injected calcitonin marked with a radioisotope and found upon serial scans that the more superficial the injections, the longer the solution remained in the area. LeCoz and DuPont (1993) conducted an experiment on patients scheduled to undergo arthroscopic surgery of the knee. The subjects were divided into three groups. The first group received intraepidermic papules of a diluted NSAID, the second group received injections of the same amount of the same solution using 4-mm needles, and the third group similarly received deep intramuscular injections. At hours 1 and 3 post-injection, venous blood draws were performed to determine serum levels of the NSAID. It was found that uniformly, the shallower the injection, the less of the substance was found in venous circulation at both 1 and 3 hours post-injection. During arthroscopy, synovial biopsies were performed, and all groups were found to have NSAID present, although levels were not determined (LeCoz and Dupont, 1983). Mesotherapy, therefore, appears to be a novel technique to administer medicines where the skin acts as a natural time-release system.

There are three primary mesotherapy injecting techniques: *intradermic* (also called "point by point"), *nappage* (French for "covering"), and *epidermic*. Intradermic was first described in the context of mesotherapy by Pistor. It is very simply the injection of 0.02 to 0.05 cc of solution after inserting a 4-, 6-, or 12-mm needle its entire depth. Intradermic injections are generally 1 to 2 cm apart, and few are given. *Nappage*, first described by Bourguignon and Ravily (Mrejen & Perrin, 2003), is a more superficial technique that takes practice to master. With the syringe held at a 45° angle from the skin while applying positive pressure on the syringe's plunger, the practitioner uses a rapid flicking of the wrist technique, which can resemble shaking a salt shaker or the action of a sewing machine. In *nappage*, a 4-mm needle is used and is not fully inserted, perhaps only 0.5 to 2 mm deep, with only a drop of solution injected at each site at approximately 0.5-cm intervals. In this way, one is able to infuse a large area of skin with the solution. The third technique is epidermic, first described by Perrin in 1996 (Mrejen & Perrin, 2003). As the name implies, this is the most superficial of the techniques, and frequently the needle does not even puncture the skin. A 12-mm (or 1/2-inch) 30-gauge needle, bevel up and at a very steep angle (approximately 160°), is dragged along the skin while light positive pressure is applied to the syringe's plunger. The needle will bend slightly from the angle and the pressure. Some practitioners will use a slight "bouncing" action, which will cause minor pinpoint bleeding. Epidermic technique will cause a shallow groove in the uppermost layers of keratinized epithelial cells and place a bead of solution into that groove. When done correctly, there is no bleeding, but one is able to see the solution quickly absorb into the skin. Epidermic technique is done in a grid pattern at 1-cm intervals over the entire affected area. Care must be taken. If the epidermic technique is applied too aggressively, it can leave scars.

As practiced in France for sports medicine and pain management, a mesotherapy solution is generally a base solution with the addition of whichever medication is indi-

cated. The base solution is a local anesthetic and a drug from the vasodilator class.

The local anesthetic most commonly used in France for mesotherapy is either lidocaine 1% or procaine 1%, always without epinephrine. Local anesthetics are administered simply for their anesthetic properties, believed to be longer acting when injected superficially. As taught by the French Society of Mesotherapy, lidocaine is generally indicated for treatment of acute conditions, whereas procaine is indicated for chronic conditions because of its additional vasodilatory properties (*Mosby's Drug Consult*, 2005).

In France, there are many more pharmacologic preparations classified as vasodilatory than are available in the United States. The drug of this class that is most frequently used in France is buflomedil (Fonzylane). The only FDA-approved medication in the United States that is used in France that resembles this category is pentoxifylline (Trental). Pentoxifylline, approved for the treatment of intermittent claudication, improves the flow properties of blood by decreasing its viscosity and improving erythrocyte flexibility, thereby enhancing tissue oxygenation. Pentoxifylline has been shown to increase leukocyte deformability and to inhibit neutrophil adhesion and activation. Tissue oxygen levels have been shown to be significantly increased by therapeutic doses of pentoxifylline in patients with peripheral arterial disease (*La Phamacopee en Mesotherapie,* 2001). Mesotherapists believe that by increasing microcirculation of localized tissue beds, elimination of metabolic waste is more efficient and there is an increase in the delivery of the mesotherapeutic solutions as well as oxygen and nutrients in general circulation, thereby encouraging healing. Injecting pentoxifylline mesotherapeutically is believed to exercise its therapeutic effect for a continued period of time compared with per os or a deeper injection (LeCoz, 1993).

Upon this base solution of local anesthetic and vasodilatory preparation, a treatment-specific medication is added. The choice of medication is based on the condition treated and the philosophy of the practitioner (i.e., allopathic medications vs. homeopathic medications or other natural substances). In the case of muscle spasm, a muscle relaxant is used; in the case of acute inflammation, an NSAID; in depression, amitriptyline and magnesium are injected into specific acupuncture points. French mesotherapists have found that when injected mesotherapeutically, a much smaller amount of medication (generally 1/60th of the recommended oral dose) is needed to achieve therapeutic benefit. This has the added benefit of avoiding the risk of adverse side effects encountered with normal oral doses.

Of particular interest is the French mesotherapists' liberal use of salmon calcitonin (sCT) in the treatment of a broad spectrum of chronic pain disorders. sCT is best known as an antiosteoporotic agent, but its analgesic effects in the treatment of acute osteoporotic fracture have been well documented (Gennari, 2002; Lyritis et al., 1999; Mehta, Malootian, & Gilligan, 2003; Silverman & Azria, 2002). Further studies have examined the anti-nociceptive properties of sCT for a range of disorders including advanced metastatic malignancy (Allan, 1983; Mystaki-dou et al., 1999; Szanto et al., 1986), reflex sympathetic dystrophy (Appelboom, 2002), phantom-limb pain (Simanski et al., 1999; Wall & Heyneman, 1999), and diffuse sclerosing osteomyelitis of the humerus (Donnelly & Doyle, 1993). One animal study demonstrated the ability of sCT ability to potentiate the analgesic effect of amitriptyline and paroxetine (Ormazabel et al., 2001).

The mechanisms of analgesic action of sCT are believed to be multifactorial (Azria, 2002), and an anti-inflammatory action has been suggested (Azria, 2002). Studies in animals and in humans demonstrate that in some, but not all cases, sCT increases plasma beta-endorphin levels (Franceschini et al., 1993), and it is possible that specific binding sites for sCT exist in the brain (Lyritis & Trovas, 2002).

It merits mention that while the clinical use of sCT is relatively safe, it is not without risk of side effect or adverse reaction. Nausea, with or without vomiting, and local inflammatory reactions at the site of injection are encountered in approximately 10% of patients receiving sCT. Flushing of face or hands, skin rashes, nocturia, pruritus of the ear lobes, feverish sensation, pain in the eyes, poor appetite, abdominal pain, edema of feet, and salty taste have been reported in patients treated with sCT. Administration of sCT has been reported in isolated cases to cause hypersensitivity reaction (*Mosby's* Drug Consult, 2005).

Currently, the majority of scientific data in the field of mesotherapy regarding the treatment of pain and sports medicine are in the French language and consist of clinical case series. One such clinical case series showed mesotherapy to be beneficial in the treatment of 65 patients suffering from chronic thoracic back pain from arthritis, spinal stenosis, and sprain/strain that was not adequately controlled using conventional methods (NSAIDs, narcotic analgesics, muscle relaxants, and physiotherapy; Smail, 2000). Another paper describes the results of treatment of 267 cases of degenerative arthritic pain and shows mesotherapy to be an effective and reasonable treatment option, especially in light of the complete absence of adverse side effects or reactions in the treatment group (Leah da Silva & Mesquita, 2000). Another paper describes the mesotherapeutic treatment of 210 patients with various soft tissue musculoskeletal pain whose pain was not satisfactorily controlled with conventional methods. These patients were treated mesotherapeutically with local anesthetics, NSAIDs, sCT, and a nonsedating centrally acting muscle relaxant (thiocolchicoside), and again showed

mesotherapy to be a reasonably effective treatment option, especially in light of poor patient toleration of the most commonly used interventive option, injection of corticosteroids (Chos, 2000). Another paper that describes the use of mesotherapy on 132 cases of patients with back and neck pain that had not been ameliorated by at least 3 months of conventional treatment shows mesotherapy to be a promising treatment option in terms of safety and efficacy (Messedi-Kamoun, Ben Salah, & Dziri, 2000). Mesotherapy has been shown to be helpful in a variety of commonly seen sports medicine conditions, such as Achilles tendonitis (Bourit & Guerin, 2000).

A systematic review and descriptive analysis of the current data and better-constructed, large-scale trials are needed. However, mesotherapy appears to be a promising modality in the treatment of a spectrum of painful disorders. It is of particular interest in the field of naturopathic pain medicine, because of its seeming safety profile and tolerability to the patient.

CONCLUSION

Many patients with pain seek alternative health care because of philosophical leanings or dissatisfaction with conventional care. Naturopathic physicians specializing in naturopathic pain medicine and board-certified by NATI have a large armamentarium of traditional and cutting-edge modalities available to them. According to the data available, naturopathic pain medicine appears to be safe, effective, and potentially cost-effective.

Section IX

Electrical and Magnetic Therapies

Mark V. Boswell, MD, PhD, Section Editor

82

Electromedicine

Subrata Saha, PhD, and Ajay R. Kashi, BDS (MS)

INTRODUCTION

HISTORY

Electromedicine can be defined as the study of different types of electrical therapies used for the treatment of various medical ailments. Electromedicine has been practiced for hundreds of years, according to the historical data available. In the early years after the death of Christ, a growing interest in the use of electricity and magnetism was observed. This practice of electricity and magnetism for healing dates back more than 3,000 years (Basford, 2001), when sick people were treated with these methods. During the same time period, it was known that the electrical powers of fish (e.g., electric eels) influenced clinical medicine as a possible cure for ailments like headache and gout (Basford, 2001).

The discovery of the magnetism by Pliny the Elder (A.D. 23–79) (Basford, 2001) from stones that harbored attractive forces is the basis of the modern-day magnet. During the medieval age, the church played an important role in the progress of magnet therapy for medical ailments (Basford, 2001). Faith played an important role in most of the scientific research at least until the 17th century. Peregrinus in 1289 showed scientifically the workings of the magnet and did not commit to mystic forces (Basford, 2001). During the Renaissance and the Middle Ages, the magnet was used to treat a variety of medical ailments, and retrieve foreign bodies such as knives and arrowheads. Paracelsus (1493–1542) proposed a "push–pull" theory of treating disease. He suggested that when the south pole of a magnet is held near the head and the north pole near the abdomen of patients with epilepsy, it would cure the disease essentially by

pushing and pulling the disease from the body (Basford, 2001).

By the late 1800s, physicians across the United States were using electricity for treating pain regularly, although there was almost no scientific data or literature to support or to justify its use. The discovery of specific points on the body surface, which cause the underlying muscles to contract, was an important finding. These specific points on the body are now known as the "muscle points" or "motor points." Electrical stimulation of the motor points leads to contractions of the underlying muscles, much like contraction of the muscle during exercise. It is thought that contraction of muscles in this manner can lead to the alleviation of pain in a particular region of the body. Motor points are considered important anatomical landmarks for the application of electrodes of the electrotherapy devices. Another important finding is the ongoing research in the 18th- and 19th-century psychiatric therapies, during which it was assumed that vagus nerve stimulation by the application of electricity through the skin greatly disturbed the hypothalamic hormone vasopressin. This approach was used to treat affective disorders (Leonard, 2004).

Electrotherapy in the 20th Century

The popularity of electromedicine in America increased after the Civil War (Basford, 2001). A wide variety of electrical and magnetic devices were available at the beginning of the 20th century. All devices claimed to relieve patients having pain from various ailments. However, there was no universally accepted system or guidelines to justify these claims made by various electrical device manufacturers. Many physicians were using these devices even though they did not know their scientific

basis, and they were not trained formally in the use of such devices (Basford, 2001). Use of such devices was a very popular mode of treatment for pain during this period.

The advent of electrotherapeutics gained wide acceptance by the medical community in the 20th century. The hot debate regarding the scientific basis of such devices did little to tarnish the reputation of some of these devices, such as the Electreat, which used shocks similar to those of the torpedo fish (Basford, 2001). Although many devices used were considered false and endorsed by quacks, the popularity of electromedicine remained in mainstream medicine. It faced criticism from many quarters and its use waxed and waned for most part of the 20th century.

Modern Clinical Electromedicine

Research and development in the field of electromedicine slowed in the early 20th century because of claims of quackery and unscientific basis for the functioning of these devices. Gradual acceptance of electrical therapies has made possible the use of certain devices in mainstream medicine currently to treat a wide range of conditions by using devices such as transcutaneous electrical nerve stimulation (TENS), cranial electrical stimulation (CES), and transcranial electrotherapy. Modern-day electromedicine is used to treat painful conditions associated with the head and neck, back pain, pain associated with other conditions, orofacial pain, dental pain, postsurgery pain, and post-irradiation pain associated with cancer. The following section focuses mainly on the use of electromedicine for the treatment of pain. Brief discussion about its other uses is also included.

Interaction of Electricity with the Brain

To understand the interaction of electricity with the brain, one must think that there is some sort of a connection or a link between the cells of the brain (neurons) and electricity (in this case, the signals or stimulation received by the neurons involved). In other words, an electromagnetic field may act in the same way as a hormone on the cell membrane.

Mechanism Involved in Electromedicine

The interplay of the frequency, wavelength, intensity, and the location of the electrical input to facilitate specific effects in the human body is the basis for the physiologic action behind electromedicine. Certain electrical impulses in humans help to facilitate some bodily functions including, but not limited to, healing (Kirsch & Lerner, 1990). Mimicking the electrical impulses occurring in us can produce specific physiologic effects (Kirsch & Lerner, 1990).

OVERVIEW OF THE HUMAN NERVOUS SYSTEM

The nervous system in humans can be divided mainly into two different systems:

1. The central nervous system or CNS, which is the portion of the vertebrate nervous system consisting of the brain and the spinal cord and
2. The autonomous or autonomic nervous system or ANS, which is the part of the nervous system regulating involuntary actions, like those of the intestines, heart, glands, etc.; the ANS is further subdivided into the sympathetic and parasympathetic nervous system.

Primary Afferent Axons

Primary afferent axons are nerves that transmit information from touch or pain to the spinal cord and brain; they are nerve fibers connected to different types of receptors in the skin, muscle, and internal organs. The diameter of the nerve fiber correlates to the speed with which information travels in it; i.e., the thicker the nerve fiber, the faster the information travels in it. In some forms of electrotherapy, such as TENS therapy, specific fibers are activated. In the later part of this chapter, the different types of TENS devices/mechanisms are discussed in relation to the activation of specific nerve fiber types. Before proceeding to presentation of the types of TENS affecting various nerve fibers, an overview of the main types of fibers in the human body is shown in Table 82.1.

A-alpha nerve fibers transmit information related to proprioception (the ability to sense stimuli arising within the body/muscle). A-beta nerve fibers transmit information related to touch. A-delta and C-nerve fibers transmit information related to pain and temperature. However, the information travels faster in A-delta fibers compared to the C-fibers because the A-delta fibers are bigger in diameter than the C-nerve fibers. C-nerve fibers transmit information related to pain and temperature.

As electromedicine is principally used to treat pain, it is important to be familiar with the anatomical structures in the body responsible for transmitting impulses, such as pain, touch, and pressure to and from the periphery of the body to the brain and spinal cord. These are known as the afferent and efferent nerve fibers, and their functions are

TABLE 82.1
Main Nerve Fibers in the Human Body

Fiber Type	Aα	Aβ	Aδ	C
Diameter (μm)	13–20	6–12	1–5	0.2–1.5
Speed (m/s)	80–120	35–75	5–35	0.5–2.0

as follows. The afferent nerve fibers carry signals inward to a central organ or section, as nerves that conduct impulses from periphery of the body to the brain or spinal cord, and the efferent nerve fibers carry signals or impulses away from a central organ or section. In other words, they carry impulses away from the CNS. It has been hypothesized that electrotherapy devices interact with electrical signals of the brain. The brain waves are involved in normal functions of the body, such as gamma brain waves or fast brain waves, which operate at 40 Hz and are involved in higher mental activity such as perception and consciousness. Similarly, beta brain waves operate at 25 Hz and are present in the fully awake state; alpha brain waves operate at 10 Hz and are present during sleep, prayer, light meditation; theta brain waves operate at 3 Hz and are associated with astral travel, remote viewing; and, finally, delta brain waves operate at 0.5 Hz and are associated with deep meditation. The brain waves can be recorded by an EEG (or electroencephalogram) machine.

TYPES OF ELECTROMEDICINE

Electromedicine uses different devices for various forms of treatment to treat different conditions affecting one's body (Kirsch & Lerner, 1990). Briefly, the treatments can be classified as follows:

1. Transcutaneous electrical nerve stimulation, or TENS
2. Cranial electrotherapy stimulation, or CES
3. Microcurrent electrical therapy
4. Electro acutherapy
5. Auricular medicine

Magnets and acupuncture are popular modes of treating pain symptoms (Grant, Miller, Winchester, Anderson, & Faulkner, 1999; Karp, 2004). The theory behind the use of magnets in pain management is that the magnet reacts with the iron in the blood to increase blood flow and promote healing. In many recent studies, it has been shown that magnet therapy may show positive effect in certain patients and for certain conditions, but it may not show any beneficial effect in a significant number of patients (Karp, 2004). Magnet therapy has been used for many painful conditions such as foot pain, low back pain, and carpal tunnel syndrome (Karp, 2004). The placebo effect may play an important role in magnet therapy. Karp (2004) states that the decrease in pain reported by subjects wearing magnetic devices was not statistically significantly different compared with placebo-treated groups. However, in a study by Weintraub (Table 82.2), 450 Gauss multipolar magnetic insoles were used in 141 subjects and placebo insoles were used in 118 patients to treat symptomatic diabetic peripheral neuropathy, with constant symptoms for at least 6 months. The results of this study showed

TABLE 82.2
Results of Study Using Magnetic Insoles and Placebo Insoles in Treatment of Diabetic Peripheral Neuropathy

	Treatment Group	Placebo Group
No. of patients	141	118
Type of insole	450 Gauss multipolar magnetic insole	Placebo insole
Burning	12% reduction	3% reduction
Numbness and tingling	10.5% reduction	1% increase

Source: Data from Karp, J., *Biomechanics,* 73, 2004.

TABLE 82.3
Treatment Results from Subgroup of Patients

	Treatment Group	Placebo Group
Percentage of pain reduction in a subset of patients with baseline severe pain	32%	14%
Percentage of pain reduction in a subset of patients with foot pain	41%	21%

beneficial effect of the magnet therapy (Table 82.2 and Table 82.3).

Table 82.3 shows the results of a subgroup of patients from the study by Weintraub indicating the presence/absence of success rates in different conditions. It should be noted that all of the patient groups in this study had a placebo control.

CLINICAL ASPECTS OF ELECTROMEDICINE

The main types of pain (acute and chronic; Russo, 2001) can be categorized as nociceptive and neuropathic pain (Conti et al., 2003), respectively. The nerve fibers (Aδ and C) respond to noxious chemical, mechanical, and thermal stimuli; they are known as nociceptors, and the pain perceived by nociceptors is known as nociceptive pain (Basford, 2001). In acute pain, pain results from trauma, or injury within a very short period, for example, pain resulting from a needle prick or a hot surface. The severity of acute pain directly correlates to the severity of injury. Normal individuals have protective reflexes to prevent injury in acute pain. Management of acute pain normally focuses on treating the underlying cause (such as an injury). In the case of chronic/neuropathic pain, the level of tissue damage does not correlate with the pain; instead, the pain impulses are transmitted continuously even in the absence of tissue damage or injury. Chronic pain is influenced by the way the brain processes the pain signals.

Factors such as emotions and thoughts play an important role in chronic pain (Turk, 2004). Because determining the exact cause of chronic pain is very difficult, its management is also equally challenging. Many modes of treatment including deep relaxation techniques, biofeedback, meditation, and electrotherapy are being used and investigated currently to treat chronic pain.

The mechanism involved in nociceptive pain (Russo, 2001) starts once the noxious stimuli, for example, injury to the skin, has occurred. The nociceptors (Aδ and C nerve fibers) pick up the signal, and afferent impulses are relayed to the CNS. The primary afferents synapse in the dorsal horn onto second-order neurons in the substantia gelatinosa of the spinal cord. This is followed by either a synapse via a third-order neuron to the somatosensory cortex or via second-order neurons to the thalamus by the contralateral spinothalamic tract of the spinal cord. Some fibers from the spinothalamic tract travel to the pons and midbrain to synapse on nuclear complexes such as nucleus raphe magnus and the nucleus raphe gigantocellularis (both areas are involved in descending regulation of second-order neurons). Finally, endorphins such as serotonin and epinephrine inhibit noxious stimuli and the continued firing of second-order neurons.

In neuropathic/chronic pain (Russo, 2001), the primary lesion results in transmission of afferent impulses to the peripheral and central nervous systems. This is followed by "memory of pain," which leads to neuroplasticity of the spinal cord and chronic pain, which may later persist in the absence of noxious stimuli. The anterior cingulate gyrus is related to the emotional component of pain, and the posterior cingulated gyrus is related to the localization of pain (localization of pain is said to be very precise for skin, more difficult for deep tissues such as joints and muscles, and very poor for viscera such as the abdominal viscera).

Until recently, there was no theory to describe the pain mechanism, but in 1965, Melzack and Wall proposed the gate control theory, which proposes a gating mechanism of closing and opening of ion channels in the spinal cord in response to stimulation of large-diameter fibers (touch) and smaller-diameter fibers (pain). This theory makes sense in the need for survival, as it is important to detect and respond to pain in preference to other less urgent signals. The gate control theory is said to be the clinical basis for the use of TENS in clinical medicine (Kirsch & Lerner, 1990; Merkel, Gustein, & Malviya, 1999; Sluka & Walsh, 2003).

TRANSCUTANEOUS ELECTRICAL NERVE STIMULATION

DEFINITIONS

1. Some define TENS as the application of electrical stimulation to the skin for pain control (according to the American Physical Therapy Association; Sluka & Walsh, 2003)
2. Others believe that technically any device that delivers electrical currents across the intact surface of the skin is TENS.

The different types of TENS include conventional TENS (produces segmental analgesia), which activates large-diameter Aβ-fibers without activating small-diameter Aδ- and C-fibers or muscle efferents; acupuncture-like TENS (AL-TENS), which activates small-diameter fibers (Aδ or group III) arising from muscle (ergoreceptors) by the induction of phasic muscle twitches; and finally, intense TENS, in which small-diameter Aδ cutaneous afferents are activated by delivering TENS over peripheral nerves arising from the site of pain. AL-TENS and intense TENS produce extrasegmental analgesia through ergoreceptor activity and activity in small-diameter cutaneous afferents, respectively. Conventional TENS and intense TENS can also produce peripheral blockade of afferent information in the fiber type they activate.

PRACTICAL CONSIDERATIONS

To test the practical effectiveness of a TENS device, reporting by patients about the sensation produced by the TENS device is the easiest means of assessing the type of fiber that is active (Kirsch & Lerner, 1990). Testing and experimenting with a variety of current amplitudes, frequencies, and durations to produce the appropriate outcome is the best way to assess the effectiveness of a TENS device.

Many clinicians prescribe TENS devices to their patients without showing them how to use them. An important consideration is that first-time users of TENS need to try and modulate/regulate the appropriate frequency, amplitude, and other characteristics of the device before they experience relief from pain. To implement the TENS treatment in the presence of an experienced clinician would be the best approach to use the device for the first time. Once the patient is comfortable with the appropriate electrical parameters, the clinician can set the device to those values so that there is relief of pain every time the patient uses the device.

Electrode Placement: Electrode placement in TENS therapy can be both along nerve roots or trigger points (a specific point or area which if stimulated by pressure or touch or will induce a painful response) and along dermatomes of respective nerves (Kirsch & Lerner, 1990). The clinician is the appropriate person to evaluate the best position for electrode placement initially. Once the patient has experienced pain relief, one can confidently assume that the position for placement of the electrodes has worked in favor of the patient (Figure 82.1). Prescribing a TENS device blindly without ascertaining the appropriate clinical parameters is one of the main reasons for

FIGURE 82.1 Electrotherapy device with electrodes in place. Courtesy of Healthonics' MedRelief™.

failure of TENS therapy. Other parameters such as current amplitude, frequency, and pulse repetition rate have to be adjusted as well to obtain satisfactory clinical performance of the TENS device.

Energy Source: TENS devices work with currents in the milliampere range. Sources of power include alkaline batteries and nickel cadmium batteries. The drawback of external sources of power such as batteries is the power decay, and the need for frequent replacement of batteries (Kirsch & Lerner, 1990).

Electrodes: The electrodes used in TENS have evolved over the years. Initial treatment with TENS used electrodes with a gel. The main drawbacks were uneven conductivity, minor skin burns at high currents, and messiness because of the gel. Currently, disposable self-adhesive electrodes are used, which also prevent the possibility of acquiring transmitted diseases. Disposable electrodes have become the norm in most TENS devices currently available (Kirsch & Lerner, 1990).

EFFECT OF TENS FREQUENCY, INTENSITY, AND STIMULATION SITE PARAMETERS ON PAIN THRESHOLDS IN HUMANS

In a study by Chesterton, Foster, Wright, Baxter, and Barlas (2003), the effects of varying TENS frequency, intensity, and stimulation sites were evaluated in an experimental model of pain. The study was carried out in a cohort consisting of 240 volunteers, who were randomized to one of six experimental TENS groups and a sham TENS or control. Approximately, 30 subjects were assigned to each TENS group. Two TENS frequencies (110 Hz or 4 Hz) and two intensities (the highest tolerable level) at a fixed pulse duration (200 µs) were applied for 30 minutes. The sites of application were relative to the

measurement site (segmental, extrasegmental, or a combination of these). The conclusion derived was that the high-frequency and high-intensity segmental and combined stimulation groups showed rapid onset along with significant hypoalgesic effects; the study also stated that clinical applications of these parameter combinations need to be further investigated.

In a different study by Cramp, McCullough, Lowe, and Walsh (2002), the effect of TENS intensity on local and distal cutaneous blood flow and skin temperature was determined. The aim of the study was to determine how cutaneous blood flow and skin temperature interact with the sympathetic nervous system. The study concluded that low-frequency TENS on cutaneous blood flow is dependent on whether stimulation is applied at intensity above or below the motor threshold. It also found that increase in cutaneous blood flow was local in nature and did not occur because of the depression of the sympathetic nervous system. Some typical features of TENS devices are listed below:

1. Pulse amplitude: 1 to 50 mA
2. Pulse duration: 10 to 1000 µs
3. Pulse frequency: 1 to 250 p.p.s.
4. Additional features such as batteries, timer, and number of channels

CLINICAL APPLICATIONS OF TENS

Many common clinical conditions can be treated with the use of TENS. TENS has been shown to produce both analgesic and non-analgesic effects. Some of the analgesic effects produced by TENS are used to treat postoperative pain; labor pain; dental and orofacial pain; musculoskeletal pain; low back pain; neuralgias, such as trigeminal neuralgia; angina pectoris; arthritis; and pain resulting from bone fractures. The non-analgesic effects of TENS include its use for treating nausea associated with morning sickness, travel sickness, and chemotherapy and also to improve blood circulation to enhance the speed of wound healing. It is also used to treat symptoms associated with peripheral neuropathy in diabetes.

PULSE WAVEFORMS AND PULSE PATTERNS IN TENS

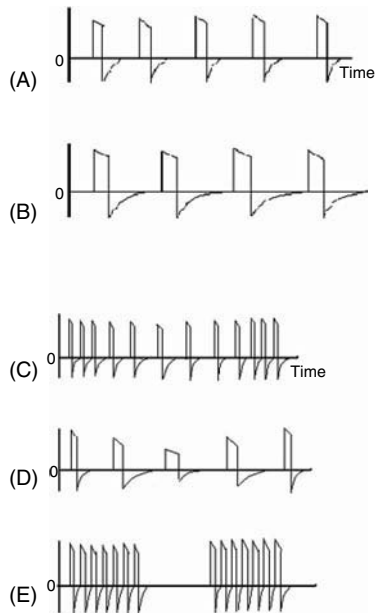
Different TENS units use different forms of pulse waveforms. Broadly, they can be classified as either monophasic (a single phase) or biphasic (two phases) waveforms. Schematics of the different pulse waveforms in TENS are shown in Figure 82.2 and Figure 82.3. Pulse patterns in TENS include continuous, burst, modulated (amplitude, frequency, and duration modulated), and random frequency modes (Figure 82.3).
FIGURE 82.2 Pulse waveforms in TENS.


FIGURE 82.3 (A) Pattern of electrical pulses. (B) Normal mode of continuous train of pulse. (C) Pulse duration mode with automatic modulation of pulse duration. (D) Frequency modulation with automatic increase and decrease in the repetition rate. (E) Strength duration modulation with automatic reductions of pulse duration followed by increases in pulse amplitude accompanied by decreases in pulse duration.

MECHANISM OF ACTION OF TENS

A brief description of the mechanism of action of the different types of TENS is presented in the following section. The mechanism of the action of TENS includes antidromic collision, which states that when tissue damage occurs, afferent impulses arise. Conversely, as TENS is applied, it induces nerve impulses, which travel away from the CNS. Both these nerve impulses meet to collide with and extinguish pain. Conventional TENS is said to follow this mechanism of action. The second type involves segmental mechanisms, in which the activity of second-order nociceptive neurons in the dorsal horn of the spinal cord is inhibited by the activity generated in the Aβ-fibers. The second mechanism is also observed in conventional TENS. Finally, the other mechanism involves extraseg-

mental routes, seen in small-diameter afferents, which form the descending pathways of pain inhibition, such as the periaqueductal gray area of the brain (physiologically involved in rage reactions, bladder responses, and pain), the nucleus raphe magnus (involved in nociception), and the nucleus raphe gigantocellularis (involved in muscle atonia during REM sleep). Figure 82.4 and Figure 82.5 show examples of TENS units.

MICROCURRENT ELECTRICAL THERAPY

Microcurrent electrical therapy (Kirsch & Lerner, 1990) (MET) uses low-frequency (0.5 to 100 Hz), microampere currents ranging from 10 to 600 μA. It produces very low and subtle currents barely perceived by the person being treated. It is used by health care professionals to accelerate the healing process and also to treat such conditions as anxiety, depression, and insomnia. According to Kirsch (Kirsch & Lerner, 1990), use of a low frequency, preferably 0.5 Hz, is suitable for most treatments. If not, a higher setting may be needed. Kirsch goes on to state that patients should be given at least three treatments to evaluate their response to microcurrent electrical therapy, as the effects are thought to be cumulative. For a thorough understanding of the workings of a MET device and the treatment

schedules required, a patient must review a MET device manual or consult his or her physician prior to undergoing any such treatments, as every individual's pain intensity threshold level is different.

MEDICAL USES OF ELECTROMEDICINE

TENS in the Treatment of Chronic Back Pain

Chronic back pain is seen usually in elderly individuals because of osteoarthritis of the intervertebral joints (Grant et al., 1999; Turk, 2004). The treatment of chronic back pain using nonsteroidal anti-inflammatory drugs has the drawback of systemic side effects (Grant et al., 1999). TENS is one of the most frequently used modalities of pain relief among nonconventional modes of treating chronic pain conditions (Grant et al., 1999). In a recent study, Grant et al. (1999) investigated the effectiveness of acupuncture and TENS to treat chronic low back pain in elderly patients. The study included 60 patients aged 60 or over who had had back pain for at least 6 months. In this investigation, the effectiveness of acupuncture was well established and demonstrated as safe. The authors concluded that both acupuncture and TENS work by different neurophysiological mechanisms; both are effective treatments for chronic back pain in the elderly and safe to administer.

Pauza et al. (2004) conducted a randomized, placebo-controlled trial of intradiscal electrothermal therapy (IDET) for treating discogenic low back pain. The study was carried out in 64 patients, in whom both IDET and placebos were used. Within 1 hour after treatment with IDET, when patients were asked about the particular treatment they believed in, 78% believed they had the active treatment, 5% believed they had the sham (placebo), and 16% were unable to determine the kind of treatment. Conversely, in those patients who received the sham treatment, 74% believed that they received active treatment, 7% assumed that they received the sham (placebo), and 14% were unable to determine the nature of the treatment. Because the cohort varied in the patients' psychological domains, in the severity of disability, and in the performance of the operator in discography, the results may not be entirely attributable to any one clinical procedure (the actual IDET or the placebo). Thus, further studies are needed to evaluate the best response.

TENS and Postoperative Pain

Postoperative pain management is one of the important aspects of providing patient relief (Benedetti et al., 1997; Bjordal, Johnson, & Ljunggreen, 2003; Rakel & Frantz, 2003). Usually various medications often containing narcotics are used to control postoperative pain. However, they often have some adverse effects such as respiratory depression, nausea, vomiting (Benedetti et al., 1997), and hypersensitivity reactions. In studies involving TENS to relieve pain after postoperative surgical procedures on the abdomen (Rakel & Frantz, 2003), thoracic surgical procedures (Benedetti et al., 1997), total knee arthroplasty (Breit & Wall, 2004), and a host of other postoperative procedures, it has been shown that TENS is an effective mode of pain management postoperatively (Benedetti et al., 1997; Bjordal et al., 2003; Rakel & Frantz, 2003). In a study by Benedetti et al. (1997) involving 324 patients who underwent different types of thoracic surgical procedures, it was shown that TENS is useful to control postoperative pain when it is mild to moderate. However, this study indicated that TENS may not be beneficial to control severe pain. The study group/patient cohort was divided into three treatment groups: TENS, placebo TENS, and control, and the effectiveness of TENS was assessed starting from the beginning of treatment to the request for further analgesia and total medication intake during the first 12 hours after operation. As mentioned previously, TENS was not an effective alternative to treat severe pain conditions (for example, after posterolateral thoracotomy). The study also concluded that TENS could be used as an adjunct to systemic medications when the pain is mild to moderate and that systemic opioid and non-opioid analgesics are the treatment of choice for severe postoperative pain conditions.

Bjordal et al. (2003) investigated if the consumption of analgesics to reduce pain was reduced after the use of TENS. They conclude that if TENS is administered with a strong, subnoxious intensity at an adequate frequency in the area of the surgical wound, the consumption of analgesics for postoperative pain can be significantly reduced (Bjordal et al., 2003). In a study by Rakel and Frantz (2003), the effectiveness of episodic TENS supplementing pharmacologic analgesia on pain with movement and at rest after surgery of the abdomen was evaluated. They also examined the use of TENS during walking and vital capacity maneuvers, and the effect it had on these activities. They concluded that TENS decreased pain significantly during walking and deep breathing maneuvers. They also showed that TENS significantly improved the distance and speed of the walk postoperatively, when it was used along with analgesics.

TENS in Dentistry

TENS has been used in dentistry (Curcio, Tackney, & Bergwerger, 1987; Harvey & Elliott, 1995; Hochman, 1988; Malamed & Joseph, 1987; Meechan, Gowans, & Welbury, 1998; Oztas, Olmez, & Yel, 1997; teDuits, Goepferd, Donly, Pinkham, & Jakobsen, 1993). The alleviation of pain is of prime importance for a successful dental procedure. It has been shown that patients with orofacial pain have a fear of severe pain and anxiety-

related distress, when compared with matched controls (McNeil et al., 2001). This is also correlated to dental fear, but not with other general psychological symptomology (Hoshiyama & Kakigi, 2000). The use of local anesthetics is mandatory practice in most dental settings. However, the use of local anesthetics has various drawbacks, which are mentioned later. To improve pain management during a dental procedure and for a successful treatment outcome, the use of electronic dental anesthesia (EDA) or TENS in dentistry is discussed as a possible clinical application for pain management (Curcio et al., 1987; Harvey & Elliott, 1995; Hochman, 1988; Malamed & Joseph, 1987; Meechan et al., 1998; Oztas et al., 1997; teDuits, et al., 1993). Successful pain management has been achieved over the years during tooth preparation by the dentist using local anesthetics. The goal of using local anesthetics during tooth cavity preparation is to minimize pain for the patient and enhance patient cooperation. This also reduces the chair-side time for the dentist to perform the procedure, as both the dentist and patient are free from unwanted interruptions. The main drawbacks of local anesthetics are the use of a syringe to deliver the drug, making it an invasive procedure, allergic reactions to the anesthetic in some people, needle phobia, and prolonged effect of anesthesia for a longer than required period. Pediatric dentists are especially opposed to the use of a syringe as the sight of a needle can aggravate a child's behavior and attitude toward the dental procedure (Harvey & Elliott, 1995; Hochman, 1988). Moreover, despite warnings by the dentist about the lack of sensation in the numbed area after administration of the local anesthetic, many patients inflict self-injury by biting their lips as they lack sensation.

TENS or EDA can be an effective alternative to conventional means of pain relief. EDA eliminates the need for drug delivery via a syringe; it also eliminates the anesthetic effect once the EDA unit is turned off. In a study by Oztas et al. (1997), in pediatric patients undergoing regular tooth cavity preparations, 56% of patients preferred EDA to conventional local anesthetics administered using a syringe. In a similar study by teDuits et al. (1993), 78% of patients preferred EDA to conventional local anesthetics. According to Harvey and Elliott (1995) for a particular kind of cavity preparation in pediatric patients, a success rate of 100% was observed with TENS. The above findings show promise in the use of EDA to obtain analgesia. Other important uses of electromedicine in dentistry are the use of TENS in the treatment of painful orofacial conditions, such as trigeminal neuralgia, atypical facial pain, and musculoskeletal pain of the craniofacial region.

According to many published reports, cognitive processes (such as psychological factors, attribution of patients, and their attitudes toward pain, depression, and worry) play an important role in the successful treatment of pain in a patient (Turk, 2004). When the body is affected due to injury, it results in disability and lack of function. As a consequence, the patient is in a psychologically negative state of mind to respond to treatment options or physical activity to alleviate the pain symptoms. In a clinical scenario, when a patient expresses pain when examined, the clinician often prescribes medication based on the intensity of pain (stronger and different combinations of one or more pain relievers for more painful conditions). The psychological and cognitive aspects of the patients are often not fully considered (Turk, 2004). This warrants further research into understanding more about the mechanisms involved in pain processes with placebo-controlled studies, taking into account factors such as cognitive processes in the pain response and psychological counseling prior to initiating treatment for pain for a better outcome.

Pain management has become an integral part of managing a clinical condition to obtain better patient relief. To manage pain, many clinicians still rely on systemic medications. The interaction between systemic medications and electrotherapy devices is important in understanding if there is a connection between drugs and electrotherapy devices.

TENS in Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) affects the wrist region. Compression of the median nerve in the carpal tunnel is thought to lead to this condition. A randomized, double-blind, placebo-controlled, crossover trial study by Naeser, Hahn, Lieberman, and Branco (2002) demonstrated that treatment with a combination of low-level laser therapy along with microampere TENS was found to be effective in treating CTS pain. A finite element model of the wrist anatomy was developed to predict the distribution of current in the nerves during diagnosis, and the possibility of therapeutic procedures involving electromagnetic excitation was investigated. Nerve conduction studies, evoked potentials, and electromyography have and are being investigated for this condition. Further studies should be conducted to determine the efficacy of conservative treatment in combination with other treatment modalities to obtain results that are more predictable.

Miscellaneous

A number of other medical uses of electromedicine have been investigated (Grace, Revell, & Brookes, 1998; Robinson & Mackler, 1995; Saha, 1984; Scott & King, 1994). Electrical stimulation has been used successfully in controlling edema. It is thought that electrical stimulation increases venous or lymphatic drainage in the absence of or inability to perform voluntary exercise. A different medical use of electrical stimulation is to aid tissue/wound healing. This is based on the tissue polarity present after injury, known as the "current of injury." The theory states

that wounds have a positive potential initially with respect to the surrounding tissue, and this positive polarity triggers the onset of the healing or repair process. It is thought that the maintenance of positive polarity favors wound healing. Other medical uses of electrical stimulation include bone growth in non-union and malunion of fractures (Nelson, Brighton, Ryaby, Simon, Nielsen, Lorich et al., 2003; Robinson & Mackler, 1995; Saha, 1984; Scott & King, 1994). Animal experiments have proved the osteogenic potential of electrical stimulation (Saha, 1984; Scott & King, 1994). It has been demonstrated in long bones of chick embryos that when an electromagnetic field of a certain pulse shape is administered, an increase in the length, weight, and mechanical strength is observed (Grace et al., 1998; Saha, Pal, Reddy, & Albright, 1982a, b). Similarly, when fibroblast cells are exposed to a pulsed electromagnetic field (PEMF) for a period of 7 days and their growth rate compared with a control group, there was an increase of growth in the test group by 15% on the first day to 100% on the fourth day. However, the growth increase dropped to 21% on the seventh day (Saha, 1984). Grace et al. (1998) demonstrated the beneficial effects of PEMFs in the healing time of fractures in animal models. It was shown that PEMFs enhance early vascular reaction and suppress pannus proliferation, along with early chondrogenesis, and bone formation. However, the same study also suggests that prolonged use of PEMFs may have a deleterious effect by enhancing chondrogenesis beyond a point observed in normal repair, thereby delaying normal subsurface trabeculation.

Scott and King (1994) carried out a double-blind trial of electrical capacitive coupling to treat nonunion of long bones in 23 patients. Of 21 patients who completed the study, 10 patients were actively managed and 11 were managed with the placebo unit. Of the 10 patients who had been managed actively, all 10 showed healing of the nonunion, but there was no evidence of healing seen in the 11 patients being treated with the placebo unit. Further studies need to be carried out to ascertain the optimum parameters of electrical stimulation in fracture healing.

In addition to the uses mentioned above, one can consider the following forms of medical treatments and diagnoses as various forms of electrotherapy. Cardiac defibrillators are life-saving devices, which deliver jolts of electricity to stimulate a stopped heart and help it start beating again. Invasive devices, such as artificial cardiac pacemakers, deliver jolts of electricity to the heart muscle to help it retain its normal rhythm. Other forms of electrotherapy include electric shock therapy to treat mental illness, schizophrenia, depression, and anxiety and brain pacemakers to treat patients with epilepsy (George et al., 2000; Maniker, Liu, Marks, Moser, & Kalnin, 2000). A recent development in the treatment of epilepsy is the introduction of the vagal nerve stimulator (George et al., 2000; Maniker et al., 2000; Morris, Mueller et al., 1999), a device

that is implanted in the neck over the left vagus nerve and sends small currents to regulate the electrical activity of the brain in patients with epilepsy. Although it has been shown to be effective in a significant percentage of patients, the placement is very technique sensitive. Other medical uses of electromedicine include electrotrichogeneis, i.e., the stimulation of hair growth by the positive influence of an electrostatic field on the hair follicle, which is being investigated as a possible treatment option for baldness. Electromedicine can also be used in patients with dysmenorrheal (Angelis, Perrone, Santoro, Nofroni, & Zichella, 2003) and hysteroscopy (used in the diagnosis of endouterine diseases; Angelis et al., 2003) and to treat postural instability after stroke (Perennou et al., 2001), as well as sciatica (Ghoname et al., 1999) and arthritic pain (Sluka, Bailey, Bogush, Olson, & Ricketts, 1998). Electrotherapy is also used to treat muscular atrophy in sports injuries and postsurgical conditions. The electromedicine treatment modalities mentioned are not described in detail here.

PHARMACOLOGICAL AGENTS, TENS, AND PAIN MANAGEMENT

Pain is a clinical symptom, presenting with different intensities and types. A good clinician will judge the symptom of pain as well as the type of treatment to manage the pain, depending on factors such as patients' acceptance of the medication (if drugs are the choice of treatment), age, and comorbid factors. Currently, most acute forms of pain are treated with systemic medications. But, chronic pain usually requires administration of a drug for long periods. This is sometimes accompanied by the added drawback of side effects involving systemic medications, such as gastrointestinal discomfort, hypersensitivity reactions, drug allergies, and a host of other undesirable systemic effects. These adverse effects of systemic medications suggest the need for adjunctive pain management techniques. Narcotics are often used in postoperative pain management with or without other conventional drugs (Benedetti et al., 1997; Fields, 1988). However, narcotics and opioids are associated with undesirable side effects such as addiction, respiratory depression, sedation, and tolerance (McQuay, 1997). There have been numerous studies indicating the effectiveness of TENS in such situations in overcoming these untoward effects (Bjordal et al., 2003; Grant et al., 1999; Rakel & Frantz, 2003). Although the effectiveness of TENS is limited in controlling severe postoperative pain and the use of pharmacological agents such as narcotics is justified in these situations, it has been shown that TENS can prove an effective alternative in controlling mild to moderate acute postoperative pain (Bjordal et al., 2003; Grant et al., 1999; Rakel & Frantz, 2003).

Electrotherapy can offer pain relief in some of these conditions, but according to a significant number of cli-

nicians, it is also indicated for specific chronic conditions, and in specific patients (Koke et al., 2004). In a study by Tomasso et al. (2003), high-frequency TENS was shown to be effective in inhibiting nociceptive responses induced by CO_2 laser stimulation in humans. However, a lack of evidence showing the effectiveness of a combination of these treatments (pharmacological agents, TENS, and placebos) indicates a need for further studies to ascertain their respective roles. Investigations, which include placebos, electrotherapy devices, pharmacological agents, and their interactions with one another, have to be carried out to ascertain the efficacy of either one or a combination of these treatments for pain. Clinical trials indicating if pharmacological agents and electrotherapy treatments will negate the effects of each other or if there is synergism between these treatment types are desirable. It will also be beneficial to ascertain the mechanisms involved in each of these treatments, to achieve the wider acceptance of these treatments.

BENEFITS AND DRAWBACKS OF ELECTROMEDICINE

Electromedicine offers many advantages over conventional therapy for pain management involving systemic drugs and surgery (Kirsch & Lerner, 1990; Turk, 2004). The main advantages are cost-effectiveness, safety of the device as the currents used are of a very low intensity, few or no side effects from the treatment, easy acceptance by most patients, and the immediate relief of acute pain. Electrotherapy also has the ability to treat a wide range of clinical pain conditions (including many chronic pain conditions such as low back pain and other musculoskeletal pain), osteoarthritis, acute postoperative pain, and labor pain (Turk, 2004). Electrotherapy is noninvasive in the broad sense, and no drug interactions of the device have been reported according to current published data. The gradual acceptance by many insurance companies that electrotherapy devices, such as TENS, are reimbursable makes it more affordable to most patients.

Rechargeable batteries used in electrotherapy devices can be unreliable in that they have peaks in their discharge rate, leading to linear power decay. Some forms of electrotherapy, such as cardiac pacemakers and brain pacemakers (vagal nerve stimulators) (George et al., 2000; Maniker et al., 2000), are technique sensitive and invasive in their approach to treating cardiac abnormalities and epilepsy, respectively. Although manufacturers claim the safety of electrotherapy devices and their lack of interaction with other electrical devices such as cardiac pacemakers (Pyatt, Trenbath, Chester, & Connelly, 2002), it is desirable to conduct further investigations to ascertain if there is any interaction between these devices. In very

young patients (infants), pain management using electrotherapy devices has not been investigated. Other contraindications include pregnancy, patients with demand-type pacemakers. Care also should be taken not to place the TENS unit on the head and neck (Kirsch & Lerner, 1990). Although conducting these studies on the very young can be difficult, the main reason being the difficulty of recording the feedback from these patients, it is desirable to know what effects these forms of electrical therapies have on this age group before one prescribes such a device. The role of placebos in studies involving TENS needs to be investigated further (Turk, 2004). Lack of placebo-controlled studies, variations in placement of electrodes in patients, and variations in parameters such as frequency, intensity, and pulse duration between studies have contributed to the lack of conclusive data on the effectiveness of various TENS in the treatment of patients experiencing pain (Turk, 2004).

CONCLUSION

Electromedicine has been used as a treatment modality for more than a century. The introduction of low currents to the body has shown beneficial effects on pain, wound healing, and neurological response related to depression, anxiety, mental illness, etc. Electromedicine has benefited medical science by providing an effective alternative to conventional forms of treatment with its effects often outweighing its few drawbacks. Although a number of studies demonstrating the effectiveness of TENS, as well as other forms of electrotherapy, have been published, it still needs to be further investigated by conducting double-blind controlled clinical trials. The effect of placebos and TENS has been investigated and some studies have shown that placebos may prove equally beneficial as TENS in many situations. This warrants further investigations into the role of placebos and TENS for pain relief in order to obtain a better understanding of their mechanisms. Similarly, other electromedicine devices, their use in various treatments, and their mechanisms of action need to be examined further to form a firm scientific basis validating the use of electromedicine as a mode of choice for treating patients with pain.

Electric Nerve Blocks

James W. Woessner, MD, PhD

INTRODUCTION

Those who have been shocked by lightning, an electric fence, or a household socket know that numbness occurs in the shocked body part(s), resulting from interruption of pain and sensory signals to the brain. That nerve blocks can be done with electricity is scientifically established. Performing nerve blocks with electricity is well enough accepted that two medical dictionaries describe nerve blocks as follows:

> *Gould's* (Gennaro et al. 1984): "nerve block. The interruption of the passage of impulses through a nerve, as by chemical, mechanical, or *electrical* [italic added] means."

> *Taber's* (Thomas, 1997): "nerve block. The induction of regional anesthesia by preventing sensory nerve impulses from reaching the central nervous system. This is usually done on a temporary basis, by using chemical or *electrical* [italics added] means."

These definitions, which accept electricity as an analgesic agent, make the concept and reality of nerve blocks being achieved scientifically accepted.

Electric nerve blocks (ENBs) involve introduction of an alternating electric current (AC) into the patient's body to interrupt the nerve impulses along pathways so that the perception of pain is decreased beyond the time of the actual treatment itself. Use of ENBs is not thought to conflict with currently accepted treatments for any part of the body, in a purely medical sense. ENBs are useful supplemental tools for patients who have pain.

NERVE BLOCKS IN GENERAL

Nerve blocks generally involve the introduction of an anesthetic agent to interrupt nerve impulses (Gordy et al., 2002). Nerve blocks provide analgesia and anesthesia. This entire volume explores the full range of therapies for the management of pain; analgesia provided by nerve blocks produced with electricity is the focus of this chapter.

THE ORIGIN OF NERVE BLOCKS FOR PAIN

Nerve blocks were originally done mechanically to facilitate local surgical procedures. Local and general anesthesia as part of surgical procedures became more sophisticated over time (Brown & Fink, 1998). It was noted that little or no pain was perceived after providing nerve blocks. Consequently, physicians began to use nerve blocks for better pain control. In both anesthetic and analgesic applications, the resultant pain relief provided a window of opportunity for the surgical procedure and for healing, respectively.

Because most nerve blocks were done with chemicals, most practitioners usually thought of chemical injections in connection with nerve blocks. Because anesthesia usually included analgesia, nerve blocks were subsequently used to promote pain control in situations where general anesthesia was considered unnecessary or undesirable.

"THE BODY ELECTRIC" (BECKER & SELDEN, 1985)

During the 20th century, electrical devices became generally accepted in medicine, initially for diagnostics. Most

are familiar with electrocardiography (ECG), electroen-cephalography (EEG), and electromyography (EMG), including surface EMG (sEMG), and nerve conduction velocity (NCV) studies. Electrooculography, electroretin-ography, electronystography, electrocochleography, skin galvanics, and various evoked potentials are more special-ized, although less well-known electrodiagnostic proce-dures (Northrup, 2001).

Many have been clinically treated with electricity. Defibrillation, used in emergency situations to reestablish cardiac activity when fibrillation occurs, involves the pas-sage of an electrical current through the chest. Lower back pain often responds to transcutaneous electrical nerve stimulation (TENS) therapy and other electrotherapeutic techniques as part of overall treatment program. Electro-convulsive therapy (ECT) for depression, spinal cord stim-ulators (SCS)/dorsal column stimulators (DCS) for chronic pain control, bone growth stimulators after ortho-pedic surgery, neuromuscular stimulation for disuse atro-phy, and a number of other electrotherapies are a few examples of the currently used electrical techniques in modern medicine. TENS devices, as designated by the FDA, also include high-voltage galvanic stimulators (HVGS), neuromuscular electrical stimulators (NMES), interference stimulators, and various transcranial stimula-tors (e.g., the Alpha-Stim® devices and the Liss Transcra-nial/Body Stimulator®). Most of these electrical devices have been approved by the FDA as safe and efficacious and are allowed for use. Other electromedical treatments include:

- Thalamic stimulation
- Electroacupuncture
- Auricular acupuncture

While generally safe, these electrical procedures require a precise understanding of the patient's overall medical condition for best results and to avoid possible undesirable side effects. As with anything in medicine, ENBs have a specific medical indication and are *not* "cure-all" procedures. Most of the side effects are directly related to local changes to blood flow, probably occurring with the blocking of pain nerve impulses with electricity because efferent C-fibers to local arterioles are also blocked.

ANESTHESIA OR ANALGESIA

Leak (1992) nicely differentiated the creation of numb-ness, i.e., anesthesia, and the interruption of pain signals, i.e., pain nerve block or analgesia. As stated, anesthesia usually includes analgesia, but not the other way around. When doing nerve blocks for pain, anesthesia can mark-edly interfere with normal sensory function and, therefore, put the patient in unnecessary danger.

Surgery has been done by blocking sensory nerve impulses with electricity (Hardy et al., 1961). Electroan-esthesia and electroanalgesia have been used in Europe (Gadsby, 1998) and in the United States (Racz et al., 1992). If the electrodes are properly placed to perform nerve blocks, the clinical effects are not due to only electrical stimulation that would "stimulate" sensation and/or pain. FDA-accepted electrical devices used for ENBs do not provide enough current energy to cause frank anesthesia.

BACKGROUND

Using electricity for medical treatments occurred in ancient times (Rossi, 2003). Thousands of years ago ancient cultures used electricity-producing animals (elec-tric eels and rays) to administer electricity to sick citizens (including those in pain) as medical treatments. Electrical machines were popular with American doctors for thera-peutic purposes until 1907, when a campaign was initiated suggesting that the use of electricity as a medical treatment was quackery. Negative publicity resulted in most prac-ticing physicians discontinuing the further use of electric-ity in their practices. There still remains some sense of illegitimacy about ENBs even into the 21st century.

ELECTROTHERAPY

Electrotherapy used in some way to treat pain is fre-quently mentioned in books on electrotherapy (Kahn, 2000; Kitchen, 2002; Nelson et al., 1999; Robinson & Synder-Mackler, 1995; Simpson, 2003). Mechanisms for relieving pain are suggested, but nerve blocks are seldom mentioned directly. The best reason for pain relief from electrical stimulation, separate from ENBs, is the release of endorphins as pain modulators, and increased circula-tion and its relationship to muscle relaxation (Kitchen, 2002), explaining the residual pain relief that occurs fol-lowing ENBs.

Interestingly, most patients in pain seldom mention any lasting effect from traditional TENS units or electrostim-ulation (E Stim) treatments. Interferential and HVGS units often provide longer-lasting relief. This pain relief makes sense in the context of this chapter because the carrier frequency of interferential therapy is 4,000 Hz (cycles per second, or cps), which may result in neuron blockade. The high energy produced by the HVGS units potentially crosses the nerve cell membrane to activate cyclic adenos-ine monophosphate (cAMP); in other words, penetrance occurs via high energy rather than via high frequency.

EVIDENCE FOR NERVE BLOCKS WITH ELECTRICITY

Most physiology textbooks provide a basic description of the electrophysiology of human cells and tissues. Charman (2002) provides a short review of the "electrical properties of cells and tissues." Becker and Seldon (1985) has provided significant scientific evidence that the body is truly an electrical organism. ENBs involve the use of electricity in medicine (Kane & Taub, 1975), and the term itself was probably first used by Dr. Jenkner in his 1995 book, *Electric Pain Control* (Jenkner, 1995).

Schwartz (1998) provided a theoretical basis for ENBs. Schwartz (1998) and Hans Jurgens (1999) presented plausible mechanisms by which nerve blocks and curative phenomena could occur via electric currents applied to the human body. Clinical experience based on these theories suggested that nerve blocks do occur with electricity (Woessner, 2002b).

Stimulatory frequencies, the frequencies below the refractory frequency of the nerve (the maximum frequency that stimulates a nerve to fire), are basically employed for electrotherapeutic techniques (Hans Jurgens, 1999). Electrotherapeutic treatments are usually much below 500 Hz (cps) (Kitchen, 2002).

De Domenico (1982) and Goats (1990) suggested that interferential therapy provides a "physiological block of nociceptive fibres." This description is largely due to the carrier frequencies (approximately 4,000 Hz), which result in greater tissue penetration, rather than just the tomographic effect of these synchronized, but offset carrier frequencies, which produce the "beat" or interferential frequencies (10 to 150 Hz). Multifacilatory frequencies described by Hans Jurgens (1999), the frequencies above the refractory frequency of the nerve (usually 4,000 to 20,000 Hz), are obviously not functioning via nerve stimulation because the target nerve can fire only once at frequencies less than the refractory frequency (which can be thought of as being around 1,000 Hz).

The frequencies used for ENBs likely carry the electrical signal and energy inside of the nerve cells and likely stimulate the cAMP (Brighton & Towensend, 1986; Knedlitscheck et al., 1994) because of the lower impedance at these frequencies (Schwartz, 1998). At sufficient levels, electrical energy has an intraneuronal effect on cAMP activity; cAMP is an intracellular second messenger, which merely passes on "permission" for the cell to do something. Knedlitschek et al. (1994) actually showed that intracellular cAMP is depleted after being subjected to 4,000 Hz of electrical energy at adequate voltage.

cAMP is utilized and decreased in absolute amounts as it relays the message to open the voltage-gated channels and start other metabolic activity to the intracellular organelles (Wilson-Pauwels et al., 1997). These later phenomena can be described as direct normalization of the cell function, which directly reverses sensitized pain feedback circuits and possibly promotes healing. As whole books are written entirely on the role of cAMP (Rasmussen, 1981), suffice it to say that ENB procedures are hypothesized to "shock" voltage-gated channels open and stimulate metabolic pathways to normalize pain nerve function.

Simply stated, AC frequencies greater than the rate a nerve can fire, i.e., greater than 1,000 Hz, specifically, in this case 20,000 Hz, have been shown by Knedlitscheck et al. (1994) to stimulate utilization of cAMP. In fact, Kilgore and Bhadra (2004) have shown that nerve block via depolarization does occur at 2,000 to 20,000 Hz. Wali and Brain (1990) showed more sustained blockade. Wyss (1967, 1976) clearly showed that depolarization is sustained with the application of these currents, specifically 4,000 Hz. The author's clinical experience, as shown in the table and histograms below, strongly suggests the analgesic, likely via nerve block, is indeed achieved with electricity (Woessner, 2002a).

Especially for electric and chemical nerve blocks that are thought to block sympathetic fibers, thermal gradients comparing side to side can be helpful to document the effectiveness of the block of these fibers, because blocking the efferent sympathetic C-fibers to the small arterioles results in distally increased circulation, therefore, increased skin temperature. However, temperature changes (e.g., increased temperature on the blocked side) are not a direct measure of afferent pain nerve function. With greater blood flow, we expect decreased edema and temperature increase.

Whether these phenomena occur or not may provide evidence that a proper nerve block has been achieved, but the basic purpose of these ENB procedures is to relieve pain temporarily or even permanently. With decreased pain, functional improvement is expected. Clinically, these positive results are seen (Woessner, 2002a). Providing "proof" is time-consuming and is often requested by the payers, yet the change in perceived pain and the duration of that change are most important for the patient.

The author has performed about 4,000 ENBs. The results of more than 3,500 ENB procedures are shown in Table 83.1 and Figure 83.1. The percent of pain relief as indicated by the patients' verbal response scores (VRS) was noted just before and after the procedure (Table 83.1).

The determination of patients' perception of pain after the electrodes were removed likely represents the pain relief effect. The duration of relief is more a reflection of the inverse severity of the causative pathology resulting in nociceptive rather than neuropathic pain and may explain the lack of any relief in a few cases.

Only a few patients get complete, immediate, and permanent relief of pain in one treatment. Over half of the patients achieve a successful outcome (defined as maintained improved function and satisfying, to the patient, level of perceived decreased pain) during a course of 5 to 15

% Pain Improvement	No. of Treatments	Percent In Category
Less than 0	24	1%
Exactly 0	298	8%
1 to 24%	426	12%
25 to 49%	590	17%
50 to 74%	791	22%
75 to 100%	1379	40%
Total	3508	100%
FIGURE 83.1 Of 3,508s ENB procedures done in the author's clinic on more than 300 patients from 1996 to 1998, clear reduction in pain perception well after the electrodes were removed, i.e., 25% improvement or better, occurred in 91% of the treatments, among which 40% perceived no pain at all after the treatment. (From J. Woessner, 2002, *Practical Pain Management, 2*(2), 19–26. Reproduced with permission.)

treatments. Individual variations occur with some short-term relief occurring in more than 80% of these cases and 20% obtaining complete immediate relief. The average duration of pain relief is from 1 to 3 days. Some obtain only a few hours of relief; the occasional subject who is essentially cured in one or more treatments may have purely neuropathic pain. Recurrence of pain depends on actual pathology, patient activities, and concomitant treatments. A successful course of treatment usually shows gradual improvement. Fewer than 2% of patients had worsened pain and discomfort because of toxic substance release.

ENB VERSUS E. STIM: WHAT ARE THE DIFFERENCES?

The term *electrotherapy* is avoided in this chapter. Electrotherapy uses stimulatory frequencies below the maximum firing rate of the pain nerves and is based on mechanisms for providing pain relief, but does not block or

ENB	E. Stim
64XXX	97XXX

interrupt pain signals along the two types of pain nerves per se, except possibly if we focus on the carrier frequencies (4,000 ± 100 Hz) in interference therapy, rather than on the beat (interference) frequency (Kitchen, 2002; Palmer & Martin, 2002) (Table 83.2).

ELECTRIC (ENB) VERSUS CHEMICAL NERVE BLOCK (CNB)

There are some general nerve block concepts that require elucidation (Table 83.3).

The main difference is that local or regional analgesic chemicals close the voltage-gated channels so that pain nerves remain in a hyperpolarized state. With ENBs, synthesis of available information suggests that intracellular cAMP is stimulated to hold the voltage-gated channels open; a normal polarized state cannot be achieved and, therefore, the nerve cannot be stimulated to fire.

MECHANISM OF ENB ACTION

As for ENB frequencies, the author has mostly used frequencies between 4,000 and 20,000 Hz. No set terminology is applied to these frequencies, although Wyss (1967) did call them "middle frequencies." In this frequency range, nerves, particularly pain nerves, are not expected to repeatedly fire because they cannot achieve a firing potential, which is called sustained depolarization (Wyss, 1976). As indicated above, these frequencies do stimulate cAMP (Knedlitscheck, et al., 1994), which in turn opens voltage-gated channels in the pain nerves (Wilson-Pau-

TABLE 83.3
Evaluative Similarities and Differences of ENBs Compared with Chemical NBs

	ENB	CNB
Invasiveness	Yes[a]	Yes[b]
Site of action	Voltage gated channels	Voltage gated channels
Locational specificity	Target nerve	Target nerve

Patient perceptions	Try and see	Ultimate, short of surgery
Consent necessity	Yes	Yes
Effective[d]	50–90%	50–90%
Curative[e]	Yes	Yes
Cost	High	Very high

[a] Just as high voltage currents and lightning.

[b] Just as microneedles and high pressure streams.

[c] Decides dose and target nerve.

[d] Very difficult to define. Author's general impression is similar; in both cases, depends more on the pain cause and the nociceptive pathology; neither is a cure-all.

[e] Both are basically cover-up procedures that should be part of a comprehensive treatment plan.

wels et al., 1997). These two mechanisms, hyperpolarization by chemicals and sustained depolarizataion by middle frequency currents, seem to explain the prolonged pain relief that occurs in most cases of chemical and electric nerve blocks. When prolonged relief does not occur, the pain stimulator, nociceptive or neuropathic, is overwhelming the nerve block action, whether induced chemically or electrically. If Waxman et al. (2001) are correct, the site of action is at the sodium voltage-gated channels. The curative action must then in part be downregulation of the increased number and density of the sodium channels.

The 8- to 20-minute time of onset is also similar between chemical and electric nerve blocks. The C-fibers are affected earlier than A-delta fibers and recover more slowly (Hadzic & Vloka, 2004). Myelin is less conductive than nerve tissue, explaining the greater effect of both local anesthetics and electricity on smaller and less myelinated pain nerve function.

ENBs treat pain, not necessarily the underlying pathology, unless the main problem is neuropathic. Nerve blocks are designed to provide a "window of opportunity" for the body to heal itself and/or for therapy or surgery benefits to be realized.

APPLICABLE NEUROANATOMY

The identified and recognized nerve can reasonably be affected in two ways, suggesting two different ways to approach electrode placement. An ENB can be achieved by treating across the nerve or along the nerve. The pain practitioner must know the anatomic course of the nerve and its distal distribution to correctly place the electrodes to fulfill regulatory and treatment needs, especially when dealing with a predominant A-delta fiber pain problem.

Theoretically, it is best to include the broad distal distribution of pain nerve endings, particularly of the A-delta fibers; these distributions also include unmyelinated free nerve endings in traditionally mapped nerve distributions (supported by Fischer, 2002). Even so, the distal distribution of sympathetic C-fiber free nerve endings are not well documented, but may be consistent with sclerotomal pain patterns that do not completely follow dermatomal patterns. Diagnosing the location of the pathology is difficult and may be better understood by considering one of the variable pain referral patterns discussed by Woessner (2003); specific electrode placement should be varied accordingly.

RELEVANT NEUROPHYSIOLOGY

The time from initiation of a nerve impulse until the time the nerve is ready to fire again is the refractory time of that nerve. If that time is 1/1000 of a second for A-delta (and 1/500 of a second for C-fibers) that nerve can fire no more than 1,000 times per second (and 500 times per second, respectively) (Ganong, 2001).

If a typical TENS unit is applied to that nerve at 100 cps, that nerve will be stimulated to fire and allowed to rest 90% of the time for the A-delta fibers. If this 100 cps

alternating current is applied to a pain nerve, then stimulation would be expected to make the pain worse, not block the pain signal. Other mechanisms of pain relief are not precluded (Kitchen, 2002).

DIAGNOSTIC CONSIDERATIONS

While sensory nerve testing may support the C-fiber and A-delta fiber pain manifested by complex regional pain syndrome (CRPS I), reflex sympathetic dystrophy, and CRPS II (causalgia), these diagnoses are basically deduced from the patient's history, physical examination, and clinical observations (Woessner, 2002b). The burning pain, characteristic of these sympathetically maintained pain syndromes, comes from the C-fibers that coat the nerve trunks and other tissue planes while the sharp, lacinating pain comes from the A-delta fibers.

TREATMENT CONSIDERATIONS

Electromedical treatments often make more sense clinically than do chemical nerve blocks, especially when it is difficult to locate the pathology or when the pathology is widespread (e.g., up and down the length of the involved nerve). ENBs are potentially the best treatment, if the pathology is believed to be neuropathic in nature.

Treating neuropathic pain with ENBs is logical in many pain conditions, remembering that ENBs are not "cure-alls" and must be incorporated into a comprehensive treatment plan. It is potentially easier to proceed in advanced cases because most other treatments often do not work and/or are too medically risky. ENBs should be incorporated earlier to improve outcomes.

When other therapies fail, electromedical treatments are potentially worthwhile and carry lower risk for patients. If the electromedical treatments work, then certain diagnoses are likely supported, and the treatment plan and ultimate prognosis may be better determined. When local widespread inflammation is involved, it is necessary to bathe nerves along tissue planes throughout the area of pain with electric current. However, this technique may not be successful in achieving pain relief, if it follows multiple chemical blocks in which scar tissue results, causing relative insulation. For these situations, an "electromedical Bier block," which involves bathing the whole limb with electricity of the frequencies mentioned above can be done with minimal risk.

TREATMENT INDICATIONS

Theoretically, ENBs can be used in any pain condition, but should be more curative in neuropathic pain conditions. Because most pain conditions have both nociceptive and neuropathic components, treatment decisions to use ENBs are complex, change over time, and may be different among individual patients. While ENBs may help in predominantly central pain conditions, the mechanism of action is not neuron blockade. In pure nociceptive conditions, any relief achieved should be more temporary. In the author's experience (Woessner, 2002b), myofascial pain is not neuropathic; any pain relief from ENBs is likely to be short lived.

Pure neuropathic conditions, without maintaining pathology, may be corrected/cured in one or a few ENB treatments; in other words, neuron blockade is achieved via cAMP opening the voltage-gated channels, and cure is also achieved by the cAMP as a second messenger, which promotes normalizations of pain nerve cellular function.

In addition, with restrictions mandated by the FDA for relative safety, ENBs will work better for localized peripheral conditions. For example, local, single-level radiculitis (irritation without obvious mass pathology) and mononeuropathies are the ideal candidates for ENBs. Fibromyalgia and diabetic pain are more difficult and relief is more likely temporary because the disease is so widespread that the current density is diluted.

An obvious treatment strategy would be to do multiple serial treatments on different parts of the body or use multiple machines; the former would be very time-consuming, and the latter is logistically complex and the cost would not likely be justified by adequate reimbursement.

THE ENB PROCEDURE

With neuroanatomical knowledge, many nerves may be blocked. Relevant for both chemical and electric nerve blocks, whether done across or along the nerve, is that the impulses from the populations of pain nerve endings are blocked. See Woessner (2002a) for a specific example of how an electric sciatic nerve block can be done.

Whether blocking across the nerve or along the nerve, a relatively small electrode is usually placed where a needle for a regional chemical nerve block would be inserted. A relatively larger electrode is placed either directly across the body part through which the target nerve transits or along the target nerve distribution either distally or proximally.

The full details of performing ENB procedures are beyond the scope of this chapter, but discussion of electrical frequency and machines that are capable of producing electric nerve blocks are presented below. Practitioners doing ENBs must be able to

- Diagnose neuropathology
- Develop a treatment plan with the patient that may include ENBs
- Use appropriate equipment
- Correctly place the electrodes
- Document what was done, including pre- and post-treatment pain intensity scores
- Provide supplemental medical advice and care

Surface Landmarks

Palpating the surface anatomy and visualizing underlying structures are essential for optimizing electrode placement. Accommodation is needed for underlying low conducting tissue and electric current pathway elongations. Accomplishing this first step requires more than just a passing knowledge of anatomy.

Small (Targeting) Electrode Placement

The relatively small (2 to 3 cm in diameter) targeting electrode should be a small to medium self-adhesive, sponge and/or vasopneumatic device. It should be placed approximately where the practitioner would insert a needle for a chemical nerve block of the same nerve. Accommodations must be made for the visualized pathway of the electric current.

For nerve root blocks, there are two possible electrode placement patterns. One placement pattern of the target electrode is on the skin surface directly above the nerve root in the area, where a needle would be inserted for a chemical injection. The other placement pattern of the target electrode is across the midline directly above the contralateral nerve root.

For predominantly C-fiber pathology, the practitioner chooses to place ipsilaterally the small electrode superior to the most distal sympathetic ganglion for the lower extremities and inferior to the stellate ganglion (over the T2 sympathetic ganglion) for upper extremity problems. Placement for thoracic pain is straightforward as long as the practitioner visualizes the path of least impedance combined with the shortest distance; scatter occurs as the electric current crosses tissue planes/interfaces along predominantly water pathways.

Large (Dispersal) Electrode Placement

The relatively large (3 to 5 cm in diameter dispersal) electrode should be a medium to large self-adhesive, sponge and/or vasopneumatic device. It should be placed either across the target nerve or distally along that nerve's distribution. It is better to follow the dermatomal distributions in predominant A-delta fiber neuropathology. For predominantly C-fiber pathology, the practitioner chooses to place the large electrode down the involved extremity, possibly even into a container of water or other ionic fluid in which the distal extremity is immersed. Placement for thoracic pain is straightforward as long as the practitioner visualizes the path of least impedance combined with the shortest distance; scatter occurs as the electric current crosses tissue planes/interfaces.

Each Treatment

The practitioner sets the intensity to tolerance during the first 30 seconds of the treatment. Turning the intensity up during the treatment may result in damage to the insensate (from the nerve block itself) skin. The ideal treatment lasts for 20 minutes and uses a frequency of approximately 15 kHz (anywhere between 4,000 and 40,000 Hz will do). Some machines sweep across frequency ranges, and sweeping theoretically results in recruitment of wider bands of nerve fibers, causing more complete pain control.

Possible Combined Treatment

The physician, depending on the exact character and distribution of the patient's pain, may place a second set of electrodes across the area of "worst pathology." For longitudinally extensive pathology, a second set of the electrodes placed differently to cover the same distribution may be better.

Treatment Course

Daily electromedical sessions for 3 weeks usually result in clinical improvement as long as the underlying peripheral pathology is being treated and corrected at the same time. Logistics and third-party payer resistance seldom allow this intense course of treatment.

It has been found that the first five treatments, if done within a 2-week period, can result in benefits. As stated above, occasional patients seem to worsen, but most do improve. Without some benefit noted, the practitioner should move on to other treatment alternatives, or at least combine ENBs with other therapeutic methods. An average of 10 to 15 treatments, each separated by 3 days or fewer are necessary to achieve optimal or maximal benefit. Longer intervals between treatments usually make more treatments necessary.

Better results are obtained when combined with adjunctive therapy, such as nutritional support, modalities, therapeutic exercise, chiropractic manipulations, chemical injections, or psychological techniques. Frequent reassessment improves outcome because the practitioner can make adjustments in the electromedical or adjunct care. Subjective (pain scores) and functional (ROM, MMT, etc.) assessment should both be done periodically, immediately before and after the ENBs.

Precautions

While avoiding conduction through the carotid sinus is logical and appropriate, risk of cardiovascular adverse events is minimal with ENBs. The cardiac system operates at one cycle per second (normal heart rates are 60 to 100 beats per *minute*), whereas machines used generate alternating currents of at least 4,000 per *second*. Davis (1993) showed that the higher the frequency, the lower the relative risk. On the other hand, as the total electrical energy increases, the likelihood of overriding the natural frequency increases.

Because the total electrical current going through both the small and large electrodes is the same, the important variable is the current density (Schwartz, 1998). The so-called targeting electrode can be considered to concentrate electrical energy at the targeted nerve(s). Practitioners should know that the point in the circuit with the greatest current density at the skin surface is where the skin can most possibly be damaged. Using small self-adhesive electrodes, skin burns are possible, but they are rare with sponges.

CONTRAINDICATIONS FOR ENBS

- Pregnancy
- Multiple sclerosis
- Parkinson's disease
- Epilepsy
- Vascular diseases/manifest thrombosis
- Acute inflammatory process
- Bacterial infection (osteomyelitis, etc.)
- Malignancies
- Metal implants
- Arrhythmia/demand pacemaker
- Over the carotid sinus
- Across the cranium

Although these are "official" contraindications according to the FDA, full knowledge and understanding of the basic principles of ENBs may allow usage on some body locations for most of these diagnoses.

ENB MACHINES

Any electric current devices producing AC of 4,000 to 20,000 cycles per second are probably capable of producing ENBs. While some manufacturers claim that square wave machines, machines that are specifically designed for interferential treatments, are more comfortable than sine wave machines, sine wave generators seem to produce more pain relief. Via a different mechanism, high volt galvanic current (HVGC) machines appear to achieve ENBs. Jenkner (1995) based most of his conclusions in *Electric Pain Control* on a rapidly pulsing direct current theoretically similar to HVGC.

PITFALLS: CAUSES FOR FAILURE

Without visible tissue changes and improvement in the pain, there may not be a peripheral pain generator. Blockade of any nerve is more difficult to confirm because the pain pathways can be missed. These pathways may not always follow the anatomic distribution of that nerve.

Trauma of the needle used in chemical nerve blocks and the caustic effects of those chemicals cause scar tissue accumulation. If multiple chemical blocks have preceded ENBs, the resultant scar tissue around the nerve may interfere with penetration of the electric current. Scar tissue development is avoided with ENB procedures.

For the best results, the right medical diagnoses are necessary so that the specific pathology can be treated. An incorrect primary diagnosis is possible. This mistake can result in inappropriate electrode placement. If the proper diagnosis is made and results from these techniques are less than expected, the pain could be generated from two or multiple sites. If the pathology is in a different area than the treated tissue, the current density could be too low to promote the nerve block. If the sympathetic nerve damage is more distal, patients may obtain pain relief without changing the nerve pathology. If the pain generator is nearby, but in a different nerve distribution, the treatment may not work well at all and/or the pathology could be too proximal or too distal to the treated area. As it may be difficult for the patient to immobilize the involved tissue, recurrent pain might be expected. As it is not impossible for central pain to occur with changes in the neurons of the dorsal horns, in the spinal pain tracks, and/or in the brain, in subcortical pathways and in the sensory strip, centrally and sympathetically maintained pain can result from anatomic and physiologic changes in central nerve system neurons. Deafferent or central pain responds poorly if at all to peripheral procedures of any type. Finally, pain maintained by psychological mechanism may fail to respond to ENBs alone, further establishing the need for multidisciplinary care.

MEDICAL PLACE OF ENBS: EFFECTS/BENEFITS

These ENB treatments have the potential to "cure" the pain pathology. If a purely neuropathic condition exists, one may expect to "cure" the patient with ENBs. Because "cure" with ENBs has been rare, one must assume that the causative pathology is ongoing in nearly all pain conditions. In other words, it appears the ENB frequencies may reverse the neuropathology, but not the underlying ongoing cause of the neuropathology. Therefore, most practitioners suspect from experience that an individualized multidisciplinary approach is necessary to help patients with ongoing pain (Rosomoff, 2000). ENBs are only one tool that must be combined with other supplemental and synergistic techniques, and those methods must be dynamically changed and refined over the course of the pain disease; once again, there is "no magic bullet."

If kept in perspective, ENB as a medical procedure is a powerful tool for treating the pathology and pain originating from neuropathy. There is also the obvious benefit of completely avoiding the need to pass a needle through other tissue. Single or multiple injections can result in new scar tissue anywhere the injected fluid goes. Thus, ENBs avoid the development of scar tissue in and around nerves

that interferes with the effectiveness of subsequent treatments, electromedical or chemical.

CONCLUSION

ENBs can and should be included in comprehensive treatment programs for temporary pain control and normalization of neuropathic problems. Proper use of ENBs requires an understanding of neuroanatomy, neurophysiology, and the mechanism of ENB action.

Static Magnetic Therapy for Pain

Michael J. McLean, MD, and Stefan Engström, PhD

INTRODUCTION

Interest in therapeutic magnets and other complementary and alternative modalities is high in the United States currently. While advances in science and technology, e.g., the evolution of magnetic resonance imaging (MRI), are a stimulus to investigation of potential therapeutic uses of magnetic fields, other factors should be considered. Important among these is the public desire for empowerment in matters of health care. The American public spends billions on complementary health modalities to fill gaps they perceive in health care provided by conventional medicine (Eisenberg et al., 1998). By one estimate, 40% of patients with peripheral neuropathy used complementary and alternative approaches and 30% used magnets (Brunelli & Gorson, 2004). Permanent magnetic devices have become commonplace for self-treatment of ordinary aches and pains, and they are sold in stores widely without approval by the Food and Drug Administration (FDA) for specific claims. So far, because of the lack of apparent significant health risk, marketing of the devices has been allowed as long as no specific claims are made. In this chapter, we review the scientific and clinical rationale upon which expectations of therapeutic benefit are founded. The discussion includes some of the methodological problems and implications for future studies.

HISTORY OF MAGNETISM AND MEDICINE

The use of magnetic fields to treat pain is not new. Interest in the West has fluctuated over centuries but has persisted in various forms in Eastern medicine in a more sustained way. Several authors have reviewed the history of magnetism in medicine (Basford, 2001; Rosch, 2004; Vallbona & Richards, 1999; Weintraub, 2004). Our understanding of how magnets came to be used for medical purposes is spotty and, at times, not well documented. Still, one would expect to find parallels between medical applications and scientific developments regarding magnetism.

The attraction between lodestones was known by the Greek, Chinese, and other ancient civilizations perhaps as early as 800 B.C. (Magnetism Group, 2002; Serway & Jewett, 2004). Chinese references to lodestones as *tzhu shih* or "loving [kissing] stones" appeared after 300 B.C. One of the earliest known uses of magnets was for geomancy (*feng shui*) in China between 400 and 100 B.C. Some historians believe that as early as the 11th century, the magnetic needle of the compass was used in China and Egypt (Savage-Smith, 1988; Serway & Jewett, 1998). Large deposits of a naturally occurring magnetic iron oxide, Fe_3O_4, called magnetite, were located in a region of Turkey then known as Magnesia (Cullity, 1972). The Greeks produced magnets by rubbing iron with magnetite.

Application of lodestones to acupuncture points for pain relief was described in the oldest known medical text, *The Yellow Emperor's Canon of Internal Medicine,* that was published sometime between 800 and 200 B.C. Therapeutic use of lodestones also was alluded to in the ancient Hindu Vedas. Egyptian, Buddhist, and Greek physicians, including Hippocrates, employed lodestones. In the 16th century, the Swiss alchemist and physician Paracelsus began using powdered lodestone in salves to promote healing in a variety of conditions, including epilepsy. However, William Gilbert, physician to Queen Elizabeth I, pointed out that the process of grinding the lodestone into powder destroyed the magnetism. Gilbert's work, *De Magnete,* published in 1600, is considered to be the first scientific opus on magnetism (Gilbert, 1958). Gilbert per-

formed experiments with magnetite and iron magnets that produced a better understanding of the earth's magnetic field in an effort to dispel the superstition that surrounded magnetic fields. By this time it was known that all magnets have two poles which behave in a manner similar to positive and negative electric charges, i.e., like charges repel and opposite charges attract. These poles were referred to as the north and south because the north pole of a freely moving magnet was observed to rotate toward the geographic north pole of the earth. A century later, magnetic cures were introduced into England by Robert Fludd as a remedy for all diseases. Perhaps not coincidentally, the patient was placed in the "boreal position" with the head north and the feet south during the treatment.

John Mitchell in England (1750) and Charles Coulomb in France (1785) described independently the law relating forces between magnetic poles. In 1819 the Danish physicist Hans Christian Oersted discovered that electric currents produced a magnetic field. Shortly after, André Ampère deduced the quantitative relationships between a magnetic force and electric current. In the 1820s, Michael Faraday and Joseph Henry demonstrated that a changing magnetic field could also produce an electric field. Up until this point, magnets were made by rubbing iron with magnetite. The invention of the electromagnet by William Sturgeon in 1825 made possible the production of much stronger magnetic fields and permanent magnets.

Important events in the history of magnetic field therapy overlapped scientific developments, especially in the 19th century. A notorious example involved Anton Mesmer who thought that a combination of magnetic and gravitational forces he called "animal magnetism" could produce cures of neurological (e.g., epilepsy) and psychiatric conditions in his patients. Later, Mesmer determined that "cures" could be effected without exposure to magnets and he held public meetings during which he claimed cures by extending his hands over the audience. In the wake of public accusations of fraud, a royal commission of the French Academy of Sciences, including Benjamin Franklin, Anton Lavoisier, and Dr. J. I. Guillotin, investigated Mesmer's claims. The commission performed blinded experiments with strong magnets and nonmagnetic materials and found that individuals could not discern reliably to which objects they had been exposed. The commission concluded that any benefit from magnetic therapy must be the result of a placebo effect or hypnosis (see Basford, 2001).

Somehow magnetic therapy was brought to America. In 1842, Stokes and Bell published a two volume medical text, entitled *Lectures on the Theory and Practice of Physics.* In it they described experiments with magnets at Dublin's Meath Hospital. Patients were described to benefit by reduced pain and increased function. The authors argued, "That a magnet should act on the human body is

neither extraordinary nor incredible" (Stokes & Bell, 1842). Despite positive reports, the negative received much attention. Daniel Palmer was a Canadian born physician who in 1890 opened Palmer's School of Magnetic Cure in Davenport, Iowa. As in the case of Mesmer, Palmer soon discovered that his patients recovered just as quickly if he omitted the magnets and merely "laid on hands." Soon, the school of magnetic cures became Palmer's College of Chiropractic. It is fascinating that interest in the therapeutic potential of magnets was never extinguished, although it seems to have waxed and waned.

The evolution of scientific knowledge about magnetism set the stage for current magnetic research. The advent of MRI in the 1980s demonstrated that externally imposed magnetic fields can interact with human tissues. This was certainly a stimulus for those interested in magnetotherapy, but it does not prove that magnetic fields are therapeutically effective. The magnetic fields used for everyday diagnostic imaging are powerful, on the order of 1 to 5 tesla (T). In contrast, the fields generated by most static magnetic field devices used for treating pain are much smaller, in the range of a few to several hundred millitesla at the surface of the devices. Field strength at tissue targets can only be inferred from dosimetric studies and simulations. There is no question that a variety of challenges confront the investigation of static magnetic fields produced by commercially available devices. Learning how to study magnetic fields clinically is one of the principal problems investigators face. Many clinical trials emulate drug trials for similar conditions. However, it is clear that many aspects of clinical trial design must be tailored to the study of magnetic fields, as discussed below.

MAGNETISM AND MAGNETS

Magnetism and electricity are inseparable according to the Maxwell equations. Magnetic fields are everywhere. Stray magnetic fields produced by industrial electrical sources and power line frequencies constitute a health risk (Portier & Wolfe, 1998) and can be viewed as pollutants, in one sense. On the other hand, we are constantly exposed to the Earth's geomagnetic field with no known health risk. The Earth behaves like a big static magnet. Its magnetic field is weak, on the order of 20 to 65 μT (Lillie, 1999; Stacey, 1977). Yet, migrating animals with specialized detectors navigate with uncanny accuracy by sensing it (see below). Understanding how magnets interact with biological systems could lead to the development of novel therapies for pain and other conditions. However, the potential for both efficacy and adverse effects must be considered for therapeutic magnets, just as for pharmaceuticals.

The properties of magnets are described in detail in physics textbooks and specialized treatises on magnetism. The interested reader is referred to additional sources for mathematical details (e.g., see Wittig & Engström, 2003,

for a recent summary). We review some properties below to establish a basis for understanding how magnetic fields may affect biological systems.

Permanent magnets have two magnetic poles, a north pole and a south pole. Lines of magnetic flux emanate from the north pole and reenter at the south pole. Iron filings scattered on a piece of paper over a bar magnet align along the flux lines and allow us to see the orientation of the lines in the plane of the paper. The flux lines exert an external force that determines the interaction between two magnets. When the south poles or north poles of two bar magnets are pushed together, they repel each other and the flux lines visualized by the iron filings bend away from each other. If the south pole of one magnet is pushed toward the north pole of the second magnet, the two magnets pull together. They behave like a longer bar magnet.

Permanent magnets are made commercially by exposing susceptible materials to an external magnetic field, such as the magnetic field produced by passing current through a wire. Electric current in a wire produces a circular magnetic field perpendicular to the wire. A long helical winding of wire or coil, called a solenoid, produces a uniform magnetic field inside the winding, except near the ends. Outside of the coil the field is similar to a bar magnet with a north and south pole. Electromagnets can be made by inserting a soft magnetic iron core into a solenoid. The field produced by current passing through the wire magnetizes the iron core. This multiplies the field around the coil because electrons in the iron are easily organized to produce a powerful magnet.

An explanation can be found in the behavior of electrons, the fundamental units of magnetism. A spinning electron can be thought of as a submicroscopic current loop that generates a magnetic moment perpendicular to the direction of spin. In the formation of a permanent magnet, electron spins become aligned in parallel and the magnetic moments sum. In nonmagnetic materials, electrons spin in opposite directions and their individual magnetic moments cancel.

Only certain elements or materials can be made into magnets, i.e., magnetized. The characteristics of the material determine how much and how strongly it will become magnetized in response to an applied magnetic field. Some ferromagnetic materials respond more than a million times more strongly than nonmagnetic materials.

Nonmagnetic materials manifest diamagnetic, paramagnetic, or antiferromagnetic properties. Diamagnetic elements, such as silicon, have filled outer electron shells. Diamonds, organic compounds, and ionic solids (NaCl) are examples of diamagnetic materials with covalent bonds. An external magnetic field creates small magnetic dipoles that oppose the applied field in such materials. Paramagnetic elements, including some transition metals, have incomplete outer or inner shells. An externally applied magnetic field aligns the spins of unpaired electrons result-

ing in a small magnetic moment. Diamagnetic and paramagnetic effects are induced by the magnetic field, but disappear when the magnetic field is removed. Other transition metal elements, such as chromium and manganese, are antiferromagnetic because their unpaired electrons spin in opposite directions, thereby canceling their magnetic moments and resulting in nonmagnetic character.

Magnetic materials acquire permanent magnetic behavior after exposure to a magnetic field. The ferromagnetic elements (iron, cobalt, and nickel) and their alloys are important materials for industry because of their strong response to applied magnetic fields and retention of magnetism. Iron, cobalt, and nickel have unpaired d-shell electrons that are easily reorganized to have parallel spins necessary for becoming permanent magnets. Ferromagnetic materials can be classified as "hard" or "soft" depending on how easily they are demagnetized by reversal of the external magnetic field. Soft iron cores are useful in electromagnets because they are easily demagnetized by reversal of the applied field. Hard magnetic materials are difficult to demagnetize. Neodymium-iron-boron magnets have shelf lives of nearly a century without loss of magnetism unless they are heated to the point that electron spins are disordered or shocked by physical forces that fracture their structure.

Magnetic materials such as ceramics and magnetite display ferromagnetic properties. The magnetic moments of their elements or ions align antiparallel in an imposed magnetic field, but there is a net magnetic moment. In the case of magnetite, Fe_3O_4, the antiparallel alignment of the Fe^{3+} and Fe^{2+} ions results in the permanent magnetization. Magnetite is important historically because it occurred naturally and was known for its magnetic properties by ancient peoples. It has also been detected in some migratory animals and may be an important navigation tool by acting as a physical transducer for geomagnetic fields (see below).

MAGNETIC FIELD INTERACTIONS WITH BIOLOGICAL SYSTEMS

There is evidence that more than 20 species of birds (Wiltschko & Wiltschko, 1996), salamanders (Deutschlander et al., 1999), sea turtles (Lohman & Lohman, 1996), monarch butterflies (Etheredge et al., 1999), and fin whales (Walker et al., 1997) navigate by using the Earth's weak geomagnetic field as a compass. Understanding how animals detect and decode geomagnetic information could reveal mechanisms that are useful for treating pain and other conditions. Diverse effects of static and time-varying magnetic fields on genetic, biochemical, and biophysical properties of cells have been reported in the scientific literature. This work has not yet proved the basis for therapeutic utility of magnetic fields, but it suggests that

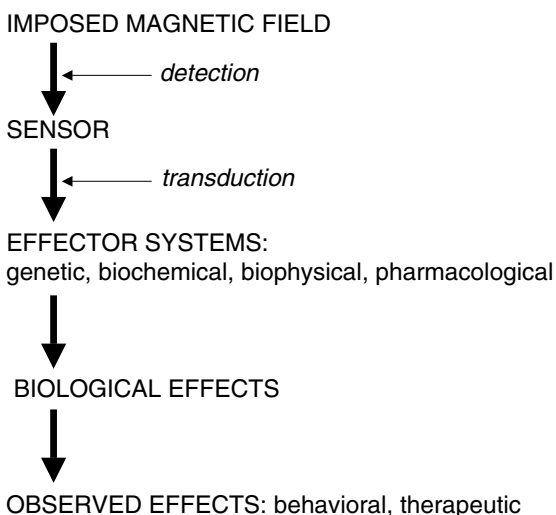

FIGURE 84.1 Cascade of how an applied magnetic field might affect biological systems.

the problem can be approached from the molecular direction, in addition to observing intact systems.

Most, if not all, commercially available permanent therapeutic magnets generate much stronger magnetic fields at their surfaces than the geomagnetic field. Strong magnetic fields may not be enough to produce useful biological effects, however. The geometry of the field in relation to the biological target may be important. Or, temporal and spatial variation in the field may be as, or more, important than field strength. This means that it is important to know what characteristic(s), or metric, of magnetic fields can be sensed. The process by which an externally applied magnetic field leads to a biological result can be conceived to involve a series of elements, perhaps something like the cascade in Figure 84.1. First, there must be a sensor(s) to detect the field. Next, a transduction mechanism(s) must couple detection to an effector system or systems. This produces biological effects. In the present context, the concept of "magnetotherapy" demands that an applied magnetic field can in some way interact with the nociceptive process to relieve "pain." Clinicians and scientists are trained to observe the behavioral and therapeutic effects of the intervention. Herein lies a conceptual framework for studying magnetic fields from bench to bedside. This is not unlikely the process of developing pharmaceutical agents, but many details about magnetic fields remain to be discovered.

BIOLOGICAL MAGNETIC FIELD DETECTORS: IS THERE SUCH A THING AS A "MAGNETOCEPTOR"?

The conceptually simplest way to detect a magnetic field is with another magnet, as described above for the interaction between two dipole magnets. Some birds have a type of magnetite in specialized receptor cells in their beaks (Hanzlik et al., 2000). But, the presence of magnetic material in animal tissues does not reveal how sensing the field is transduced. Magnetotaxis may be the result of physical attraction between an external magnetic field and magnetite in bacteria, like some physical tractor beam (Blakemore, 1975). In the absence of magnetic material, the dipole moment of unpaired electrons or dipoles within diamagnetic cell components, such as enzymes or ion channels, might be targets. In these cases, the external magnetic field can be viewed as inducing a weak magnetic field in certain cell structures and then interacting with the induced field. Altering biological dipoles intrinsic to proteins could be coupled directly to function, e.g., by modulating enzyme activity. For example, two different static magnetic fields increased calcium-calmodulin dependent myosin phosphorylation in a cell free system to different degrees (Engström et al., 2002; Markov & Pilla, 1997). Altering calcium binding to calmodulin could provide control of amplification of the phosphorylation step. Removal of the magnetic field would be expected to result in return to the baseline level of activity because diamagnetic substances do not store magnetic energy permanently. Both magnetic flux density (the number of magnetic flux lines per unit area) and field gradients (changes of field strength with distance) were implicated in these results. Thus, the sensor, or magnetoceptor, may not be very different from a pharmacological receptor, in which the agonist binding site is a peptide sequence gating an ion channel or coupled to a G protein. The "agonist" for the magnetoceptor is distinctly different, however, and operates from a distance in the form of non-ionizing radiation instead of a ligand binding to a receptor. Also, the magnetoceptor may respond to one or more characteristics of the imposed magnetic field. Put a different way, different components of an external magnetic field may modulate the magnetoceptor, suggesting that magnetic fields might be designed to have specific influences on target tissues.

Current understanding of magnetoceptors is far from complete, including the sensitivity of the sensors and what they sense. It seems that an interdisciplinary effort will be necessary to resolve problems at this interface between physics and biology.

PHYSICAL TRANSDUCTION MECHANISMS

A number of mechanisms have been proposed to explain how imposed magnetic fields interact with biological magnetoceptors and have been critically reviewed (Adair, 2000; Binhi & Savin, 2003; Engström, 2004; Liboff & Jenrow, 2002; Matthes et al., 2004; Zhadin, 2001). An important constraint is that the interaction does not ionize or heat the target tissue. Explanations for the effects of static magnetic fields generating flux densities in the

micro- to low millitesla range are the most controversial. Some potential mechanisms include the following:

1. **Magnetic induction of electric fields and currents:** Movement of charged substances in a magnetic field induces an electric field perpendicular to the direction of motion and the applied field. Induced electric fields and currents can alter voltage-sensitive neuronal activity and ion transport. This mechanism requires strong fields or high-frequency temporal variation. Transcranial magnetic stimulation with pulsed tesla-level fields induces electric fields that directly excite the cerebral cortex (Barker et al., 1987; Epstein et al., 1990; Hallett & Cohen, 1989; Hufnagel et al., 1990; Ogiue-Ikeda et al., 2003; Ziemann et al., 1998). One would imagine that response to weak fields on the order of the Earth's geomagnetic field or to roughly 100-fold stronger fields produced by commercially available therapeutic magnets would require very sensitive magnetoceptors and/or an amplification step. Such features have not been demonstrated in experimental cell or animal models of pain.

2. **Magnetomechanical** (torque on magnetic dipole moment): An external magnetic field imposes a rotational force, or torque, that tends to rotate dipoles in the direction of alignment with the field. This could be an important effect because dipole orientation is randomized by thermal noise in cells. This mechanism can only work under anisotropic conditions or if the target material has intrinsic magnetization, as in the case of magnetite. Microtubules are relatively large (5 μm) anisotropic targets and could respond to tesla-level fields (Bras et al., 1998).

3. **Magnetophoresis** (force on magnetic dipole moment): A static gradient magnetic field (spatially inhomogeneous) exerts a translational force on a magnetic dipole. This may be relevant for tesla-level fields generated by MRI machines. Magnetophoresis of anisotropically diamagnetic materials is the only proposed mechanism for gradient-specific effects, but it may or may not provide an explanation of the experimental evidence at the millitesla level of exposures. Some experimental evidence supports a role for millitesla magnetic fields with steep gradients (change in field strength with distance) in the reversible blockade of action potentials of cultured sensory ganglion cells (Cavopol et al., 1995; McLean et al., 1995). Experiments on the rate of myosin phosphorylation *in vitro* suggest that a combination of

field and gradient are required to explain the increased enzyme activity (Engström et al., 2002). This experimental system was cell free, so effects here did not rely on cell structures, such as phospholipid bilayers or ion channels embedded in the membrane. Other static and alternating fields increased phosphorylation in this assay (Markov & Pilla, 1997), suggesting that multiple field metrics may achieve similar biological effects.

4. **Anisotropic diamagnetism:** A static magnetic field will apply a torque on an anisotropic diamagnetic material because the orientations parallel and perpendicular to the imposed field become differentially magnetized. Some feel that this mechanism requires strong fields and large, elongated targets. For example, a 5-μm-long microtubule is estimated to be completely aligned by a magnetic field in the 10 T range (Jackson, 1975). This mechanism may account also for magnetic field effects on lipid bilayers (Braganza et al., 1984; Gaffney & McConnell, 1974; Helfrich, 1973; Maret & Dransfield, 1977; Tenforde & Liburdy, 1988), subsequent intracellular calcium release (Braganza et al., 1984; Helfrich, 1973), and how mitotic structures are affected by large fields resulting in abnormal embryonic development (Denegre et al., 1998; Gaffney & McConnell, 1974; Tenforde & Liburdy, 1988; Valles, 2002).

5a. **Biogenic magnetite:** Some bacteria contain biogenic magnetite (Blakemore, 1975). A chain of magnetosomes provides a large enough magnetic moment that the whole organism orients and swims along geomagnetic flux lines (magnetotaxes). Several groups have calculated that magnetite-based magnetoreception should be sensitive to very small variations in the geomagnetic field (Del Moral & Azanza, 1992; Kirschvink et al., 1992). Magnetite is present in a variety of animal models and a credible mechanism to explain physiological effects (Beason & Semm, 1996; Brassart et al., 1999; Duetschlander et al., 1999; Phillips et al., 2002). Magnetite-based magnetoception has been mapped in animals with electrophysiology and techniques of neuropathology (Diebel et al., 2000; Vainshtein et al., 2002).

5b. **Single domain crystals:** Single domain crystals can only be magnetized along one axis and the crystal maintains the magnetization. There are suggestions that such crystals form the basic functional components of higher magnetosensitive animals. Pulse remagnetization experiments provide good reasons to believe that

permanent ferromagnets are involved in the physical transduction (Beason et al., 1997; Lohmann & Johnsen, 2000). Physical models utilizing single domain crystals have been reviewed (Kirschvink et al., 1992; Phillips et al., 2002).

5c. **Superparamagnetic magnetite:** Superparamagnetic magnetite grains are too small to be permanently magnetized, but they do respond to an externally applied field. Clusters (1 to 3 μm in diameter) of superparamagnetic nanocrystals (2 to 5 nm in diameter) have been reported in the upper beak of homing pigeons (Hanzlik et al., 2000; Winklhofer et al., 2001). Single-domain features were ruled out in these studies.

6. **Magnetic resonance:** An unhydrated ion in static field at a strength matching the geomagnetic field resonates at about 60 Hz (Adair, 1998; Edmonds, 1993; Lednev et al., 1996). This and related quantum interference mechanisms are not relevant explanations for static magnetic field effects (Adair, 1992; Binghy, 1997; Prato et al., 1996).

7. **Free radical recombination rates:** Spin-correlated free radical pairs may be a target for static magnetic fields (Grissom, 1995). A spin-correlated radical pair may recombine and prevent the formation of reaction products under certain conditions that are enhanced by magnetic fields in the millitesla to tesla range (Grissom, 1995; Salikhov et al., 1984; Steiner & Ulrich, 1989). Effects of microtesla static and time-varying fields are also predicted under conditions that limit the diffusion rate of the radical pair favoring recombination (Brocklehurst & McLauchlan, 1996; Harkin & Grissom, 1995; Till et al., 1998; Timmel et al., 1998). The free radical mechanism has been proposed as the foundation for magnetically aided animal homing and navigation (Cintolesi et al., 2003; Deutschlander et al., 1999; Eichwald & Walleczek, 1998).

In addition to the transduction mechanisms discussed above, certain cofactors may enhance the probability of biological effects of micro- to millitesla magnetic fields.

1. **Geomagnetic fields:** Nociceptive behavior in snails and rats has been extensively studied as a model of animal response to low-frequency magnetic fields (Ossenkopp et al., 1984; Prato et al., 2000, 2003). Shielding out the geomagnetic field has been reported to affect mouse behavior in similar studies (Choleris et al., 2002; Prato et al., 2004). This suggests that the geomagnetic field has physiological effects on mammals.

2. **Light:** Light also appears to determine the effects of magnetic fields (Prato et al., 1997). In avian and reptile magnetic navigation it has been shown that wavelength specific effects occur (Valles, 2002) and that the light dependence is closely linked to the magnetic field detection (Deutschlander et al., 1999). In salamanders a model has been proposed in which two separate and antagonistic magnetic field sensitive systems are activated by short-wavelength light (<450 nm) and long-wavelength light (>500 nm), respectively (Brassart et al., 1999). Thermonociceptive responses in snails are reduced by magnetic fields only in the presence of light (Prato et al., 1996, 1998, 1999). It is not clear at this point whether light influences magnetic field detection or physical transduction.

3. **State dependence:** Many reported effects of static and ELF (extremely low frequency, <100 Hz) magnetic fields have not been robustly reproducible even in the course of attempts at replication. Differences between strains of animals, batches of serum, and cell lines have been considered as possible confounders (Anderson et al., 2000; Del Seppia et al., 2000; Löscher, 2001; Ritz et al., 2002). State- or activation-dependent factors have been examined theoretically in a model of free radical responses in enzyme systems (Eichwald & Walleczek, 2003). Experimentally, it has been observed that Na-K-ATPase activity may increase or decrease depending on its activation state (Blank & Soo, 1996).

4. **Structured water:** There are controversial reports that static magnetic fields in the low millitesla range can alter the structure of water making microdomains more homogeneous, for example, Novikov and Zhadin (1994), Zhadin et al. (1998), Del Guidice (2002), Goldsworthy et al. (1999), Hazlewood (2003). The consequences of this in biological systems are not clear, but the amount of oxygen in solution can be changed by magnetic fields (Sakurai et al., 2000). Also, exposure of colloids and ionic solutions to magnetic fields with flux densities in the range of 50 to 500 mT produced prolonged effects on zeta potential and diffusivity (Hagigashitani et al., 1995; Holysz et al., 2003; Oshitani et al., 1999). Descaling effects of magnetically treated water also indicate an effect on ionization (Baker & Judd, 1996; Coey & Cass, 2000). Altering the aqueous environment of the cytoplasm could lead to changes in enzy-

matic activity, intracellular signaling, and structural proteins.

EVIDENCE FROM CELL AND ANIMAL MODELS SUPPORTING CLINICAL UTILITY OF THERAPEUTIC MAGNETIC DEVICES IN THE TREATMENT OF PAIN

Nociception depends on activation of neural pathways. This leads to the expectation that magnetic field detection and transduction mechanisms relevant to analgesic effects should modulate neural function and decrease hyperexcitability. This could occur at many levels: biophysical properties of neural membranes; pharmacological properties of neurotransmitter receptors; intracellular signaling mechanisms; biochemical processes, i.e., related to energy metabolism; and gene expression. Effects of magnetic fields on any or all of these processes could result in a variety of outcomes, depending on the nature of the magnetic field and the state of neuronal activity. Potential outcomes include neural dysfunction, neuronal damage, neuroprotection against toxins, and normalization of function. As in the case of pharmaceutical development, it is necessary to test magnetic fields in cell and animal models for a number of reasons: (1) The demonstration of robust effects in disease-specific models provides a rationale for proceeding with clinical trials. (2) Potentially, disease-specific animal models can detect adverse effects of drugs and magnetic fields, determine the useful range of concentrations or field strengths, and predict levels that might result in organ toxicity. (3) Elucidation of specific mechanisms of magnetic field interactions with isolated cells or cell components is crucial for establishing the fundamental basis for expecting clinically useful effects, differentiating the mechanisms of action of magnetic fields from those of other therapeutic modalities, including drugs. (4) Understanding the mechanisms of interaction with biological systems could lead to improvements in the design of therapeutic magnetic fields.

Unfortunately, there is little basic science information about magnetic field effects in models of nociception and even less about biophysical transduction mechanisms. As reported below, most clinical trials of therapeutic magnets employ commercially available devices that have not undergone laboratory testing, and fields produced by the devices have not been characterized meaningfully. In the absence of demonstrable analgesic effects in laboratory and clinical studies, the design of placebo-controlled trials is arbitrary and may not be capable of testing the efficacy of the applied field.

Although basic research is sorely needed, there is some information that may serve as an example of what might be accomplished with more investigation and more investigators: Effects on action potentials of sensory neu-

rons could lead to nociceptive effects. Our group at Vanderbilt has examined effects of static magnetic fields produced by a square array of four magnets of alternating polarity. This device has been used in pilot studies to be described below. Gradient magnetic fields produced by this device reversibly blocked action potentials of cultured mouse dorsal root ganglion cells in a time-dependent manner without effects on resting membrane potential (Cavopol et al., 1995; McLean et al., 1991, 1995) or passive membrane properties (McLean et al., unpublished). Subtle effects of strong uniform static magnetic fields on calcium currents (Rosen, 1996) under patch clamp conditions have also been reported, but reports of effects on sodium currents have been inconsistent (Rosen, 2003; Schwartz, 1979). The effect on action potentials was reported to take several minutes, suggesting that a biochemical effect (e.g., on phosphorylation state of sodium channels that determines availability for voltage-dependent activation) had occurred, rather than a biophysical one. Exposure to gradient fields produced by the static magnetic device diminished the swelling of cultured mouse spinal cord neurons during subsequent superfusion with the excitotoxin kainic acid (McLean et al., 2003, unpublished). Gradient regions of the magnetic field produced by an electromagnetic device with a similar alternating four-polar design significantly decreased neuronal death induced by kainic acid to roughly the same extent as the kainite antagonist CNQX (McLean et al., in preparation) and decreased sound-induced clonic and tonic hindlimb extensor seizures in genetically susceptible mice (McLean et al., 2003). Pretreatment with the magnetic field potentiated the effect of phenytoin, a well-known antiepileptic drug. The ED50 for phenytoin was shifted about fivefold to the left. Multiple regions of the same electromagnetic device reduced clonic seizures induced in wild type mice by intracerebroventricular injection of the excitatory amino acid N-methyl-D-aspartate. The effect of combined treatment with phenytoin was close to additive in this seizure model (McLean et al., in preparation).

Together, these data suggest that gradient and other regions of the specific device tested may diminish neuronal excitability and neurotoxicity. Importantly, treatment with the magnetic field may enhance efficacy of drugs used to treat epilepsy and pain, namely, antiepileptic drugs. These data form a rational basis for undertaking clinical trials with the devices studied, and some of the results of some trials are presented below. These data also suggest a way in which magnetic field therapy might be brought into clinical practice, namely, in combination with drugs with which the fields could interact to result in improved outcomes and/or reduced drug load.

Alternating fields also have been shown to have analgesic effects in snails (Prato et al., 2003) and rats (Radzievsky et al., 2001), but the devices used in those studies have not been used in clinical trials against pain. Further

discussion of time-varying fields is beyond the scope of this chapter. Interested readers are referred to additional sources (e.g., McLean et al., 2003; Rosch & Markov, 2004).

OPTIMIZING ELEMENTS OF CLINICAL TRIALS DESIGN FOR THE STUDY OF THERAPEUTIC MAGNETIC DEVICES

No static magnetic field-generating devices have been accepted for therapeutic use in mainstream Western medicine despite widespread public interest. Currently, no such devices are approved by the U.S. FDA with a specific indication for the treatment of nociceptive or neuropathic pain. Nevertheless, magnetic devices are sold throughout the United States as wellness aids. Sales are seemingly tolerated by the FDA as long as no specific claims are made, probably because these devices represent no significant risk to the populace. If serious or life-threatening adverse effects were associated with the use of such devices, the enforcement powers of the FDA would undoubtedly be brought to bear to sanction sales.

In this permissive yet watchful atmosphere, there has been a growing interest among researchers in potential therapeutic applications of magnetic fields. Acceptance of new treatments in the medical community requires support by rigorous clinical trials. A critical review such as this one is intended to reveal the state of knowledge about therapeutic magnetic devices and both the strengths and weaknesses of investigative approaches. However, this task is complicated by the fact that regulatory criteria for the approval of therapeutic magnetic devices are not yet defined. In this section, we review elements of clinical study design specifically for therapeutic magnetic devices. A snapshot of current approaches also may be instructive about how to study magnetic field effects on biological systems. The weight of evidence and existence of well-established methods of study undoubtedly contribute to the wide acceptance of the pharmaceutical model in current clinical practice. There is a relative paucity of published studies of static magnetic field-generating devices. Methods for studying these devices are less well established and basically adapted from drug studies under the rubric of "scientific method."

These factors could contribute to a reluctance to accept magnetic treatment devices into widespread clinical practice and can only be overcome by rigorous testing with criteria acceptable to the medical community. Implicitly, there is a breakpoint at which there will be sufficient evidence to be convincing and clinical acceptance will ensue, or magnetic therapies will once again fall into oblivion until another effort is made to evaluate them with different approaches. An attempt is made in this chapter to determine the status of magnetic therapies relative to this hypothetical breakpoint.

In this section, we consider the study of observable effects of magnetic fields in the context of clinical trial design. We focus on permanent magnetic devices because so many such devices are sold throughout the United States and have been used in several controlled trials reported in the peer-reviewed literature. Studying therapeutic uses of focally applied permanent magnetic devices is in many ways different from the study of pharmaceuticals that are dissolved in the entire body. The former must act by local mechanisms, even though distant effects may result. The latter may interact with multiple targets in the nociceptive pathway at multiple levels of the nervous system by virtue of widespread distribution. Despite differences, the development of pharmaceutical agents serves as a model framework of how magnetic devices might become accepted into widespread clinical use.

Pharmaceutical development begins with the discovery of disease-related therapeutic efficacy in animal models and potential mechanisms of action in cell and animal studies using a variety of techniques. Cellular and animal effects of magnetic fields relevant to pain were presented in the previous section. The preclinical studies serve to establish a rationale for proceeding to clinical trials and a potential mechanism(s) underlying expectations of efficacy. This is followed by initial trials (Phase I) in humans to establish pharmacokinetic properties for dose optimization and minimization of adverse effects, and to determine a first approximation of safety. In Phase II, small numbers of patients with the condition for which an indication for use of the drug will be sought receive the investigational compound in initial tests of efficacy. Dose-ranging studies also begin at this stage to determine the range of doses to be used in pivotal trials and, when feasible, the maximally tolerable dose. In Phase III, large, randomized, multicenter trials are conducted. These studies serve as the pivotal trials upon which regulatory considerations are based.

Study designs for different classes of drugs have been validated and certain designs seem to be preferred by regulatory agencies, although novel features may be included. In this way, study design evolves but the playing field changes each time a drug is approved on the basis of a novel design. In the case of therapeutic static magnetic field devices, the first FDA approval will set the bar.

To a large extent, trial design determines the outcome. Study design must be optimized to reveal therapeutic benefits. This could not be truer than for evaluation of magnetic devices. Static magnetic field-generating devices have local effects in the vicinity of points to which they are applied. In this regard magnetic field-generating devices differ fundamentally from pharmaceutical agents that are systemically distributed and may have effects at multiple locations along nociceptive pathways due to multiple mechanisms of action. Only through a deliberate design process can the signal-to-noise ratio be optimized

in favor of detecting treatment effects. Adoption of study designs used to evaluate drugs or other devices runs the risk of incorporating variability that can result in the failure of trials with static magnetic field-generating devices. In fact, outcomes from such studies may be "false negatives." Similarly, overly specific design features may result in outcomes that limit applicability of a device. And, studies with small numbers of subjects may result in both "false positive" and "false negative" outcomes. In the absence of guidance from studies of an approved device, this means that confidence in outcomes results from cumulative experience from a large number of studies. In the case of static magnetic field-generating devices, the few available studies have been conducted with a variety of devices and some studies have been negative, limiting corroboration and confidence.

Ideally, the condition under study should be constant and the composition of the study groups should be uniform to facilitate detection of treatment-related effects. These conditions are virtually impossible to achieve. In reality, pain varies from day to day and hour to hour and can be influenced by many factors including activity level, emotion, sleep efficiency, and other illnesses. Inclusion and exclusion criteria are designed to approximate these conditions. Variability in pain intensity makes a pain study a noisy situation in which large treatment effects are most successful. It is necessary to increase the signal-to-noise level in order to detect smaller treatment effects. This can be accomplished to some degree by attempts at reducing inter- and intraindividual reporting of pain intensity. Measurement of treatment related changes in mild pain (1 to 3 on a 10 point scale) is not very reliable (Chapman et al., 1985). Successful studies of pharmaceuticals have used pain intensity of 4 (out of 10) or greater as an inclusion criterion (Backonja et al., 1998; Dworkin et al., 2003; Rice et al. 2001; Rowbotham et al., 1998). Typically, a baseline (prerandomization) period is included to be sure that study subjects meet criteria for inclusion in the study. An adequate baseline period is essential to ensure that the primary outcome measure is stable enough to study. In general this means that the pain is sufficiently intense and constant so that repeated assessments with validated outcome measures will reliably detect treatment effects (pain reduction). Whenever ethical, a placebo is used to compare with the effects of the drug under study. Alternatively, an active control (such as another pharmaceutical or device) may be used as a comparator. Qualified patients are randomized to receive either the investigational treatment or placebo in the so-called parallel-group design. In studies of crossover design, subjects receive both treatments, but the order in which the treatments are given is randomized. Both designs have strengths and weaknesses. Most studies are masked, or blinded, meaning that either the patient (single-blind) or both the patient and the investigators (double-blind) are unaware of which treatment is being administered.

Variability of pain and the focal application of a therapeutic magnetic field with shallow depth of penetration into the pain producing body tissues are two major factors limiting success in clinical trials. As a result, every aspect of study design should be carefully crafted to reduce the impact of variability and optimize chances of seeing therapeutically relevant benefits of the magnetic field.

UNIQUE FEATURES OF THERAPEUTIC MAGNETIC DEVICES: LOCALIZATION AND TISSUE PENETRATION

Studies of the use of magnetic devices to treat pain differ significantly from studies of analgesic medications. Pharmacological therapies result from dissolving compounds throughout the body where they can interact with multiple tissues at the pain-generating site as well as along neural pathways involved in the localization and perception of pain. Magnetic treatment devices, on the other hand, are usually placed in close proximity to the pain generator identified by where the patient places a hand or finger.

Elements of the pain-generating tissue structures may lie near the surface of the skin or several centimeters below the skin. To date, there are no implanted static magnetic treatment devices, so the devices must be placed at some distance from the target. To have any chance of therapeutic benefit, the magnetic field must envelop the different components of the pain-generating tissues (e.g., nerve, muscle, or bone). The placement, strength, and configuration of the magnets and the spatial variation of the magnetic field determine the depth of penetration into tissue. Thus, not all magnets and not all magnetic fields should be expected to have therapeutic benefits, just as all pains cannot be expected to respond to aspirin or other nonsteroidal anti-inflammatory compounds. Also, effective pharmacological therapies depend on dose to determine the degree of pain relief. In the case of magnetic fields that decrease as the inverse cube of the distance (to a magnetic dipole), the dose characteristic is determined by the depth of the pain generators in tissue and the time of exposure.

The dearth of data from large, well-designed, placebo-controlled trials makes it difficult to understand the meaning of both positive and negative reports at this time. Reports in the medical literature have revealed mixed benefits. For example, devices with the same basic design produced by the same company were reported to be effective against painful diabetic neuropathy (Weintraub, 1999) and ineffective against a variety of back pains (Collacott et al., 2000). The difference can be explained by differences in study design to a large extent. In contrast, results with devices with different designs showed statistical superiority to placebos in the treatment of low back pain (Holcomb et al., 1991) and painful trigger points of post-polio syndrome (Vallbona et al., 1997).

At the heart of understanding the discrepancies lies the problem of learning how to study magnetic devices. Nonsteroidal medications do not treat all pains effectively, and magnetic devices should not be expected to be panaceas. Finding appropriate conditions is the first step toward the design of discriminating studies. A seemingly obvious point is that a device should have demonstrable efficacy and a justification for clinical studies founded in basic scientific research before launching a large-scale clinical study. Experience from open study of a device is a must in order to create a successful study protocol. Even if the goal is exact replication of another finding, it is imperative to familiarize oneself with the application of therapeutic magnets and the inherent problems before undertaking a masked study.

SAFETY

Although magnetic treatment devices of many designs, sizes, and shapes are marketed in the United States, there is little evidence relating to their safety or efficacy. There has been no assessment of long-term risk of exposure to focally applied magnetic devices. Large fields that are encountered in industrial settings may have long-term and short-term health risks. In a review by Repacholi and Greenebaum (1999), a statement is made that there is no known health risk of static magnetic fields less than 3 T (a typical field strength in MRI). This is much greater than the flux densities produced by commercially available therapeutic magnets. Also, the area of the body to which these devices are attached is small and the percentage of time that the devices are worn is low in many studies. These factors limit exposure to the magnetic field and could ultimately reduce the risk of serious adverse events.

The absence of reports cannot be taken as proof of safety. In one of our studies, a patient inadvertently placed a magnetic device over a pacemaker and this resulted in a cardiac arrhythmia and brief loss of consciousness. This could be a potentially life-threatening adverse effect and led to modifications of inclusion/exclusion criteria for future studies. Effects of magnetic fields on human fetal development are unknown. For this reason, pregnant women may be excluded from the studies and women who become pregnant during the studies may be discontinued. A potential mitigating factor is that the magnetic device(s) may be placed on the body at significant distances from the fetus.

STUDY POPULATION

The proper selection of subject population is a crucial aspect of study design. Ideally, it would seem that naïve patients, i.e., those who have never been exposed to treatment with magnetic devices and do not know what to expect, would be the best candidates for formal studies.

Expectations produce biases that may affect assessment of pain in the course of repeated assessments during the study. The combination of variables may be sufficient to obscure efficacy that would otherwise be detectable. However, many potential candidates may have used therapeutic magnets already or have enough knowledge about them (e.g., through the experience of others) to have an opinion. Practically speaking, this may mean that candidates should not have used therapeutic magnets for a prolonged interval prior to entry into a clinical trial.

The symptoms or disorder to be studied should be strictly defined. Homogeneity of symptoms is one way of reducing variability.

Ulterior motives such as litigation and disability issues may also affect the ability of the patient to report changes of pain accurately during a blinded study. Careful design of the inclusion and exclusion criteria and a meaningful baseline period may eliminate concern about these factors by eliminating individuals with highly variable pain or pain outside the range acceptable for entry.

Concomitant medications are a major consideration. Many candidates for clinical trials of therapeutic magnets have chronic pain. They may be taking and have taken multiple medications. Narcotic use may be a confounder (Holcomb et al., 2003). Acute withdrawal of nonsteroidal medications may also worsen pain to a degree that responds relatively poorly to placement of magnetic devices. This and rescue medications commonly used in protocols to test novel nonsteroidal medications may unfavorably increase variability and diminish treatment effects.

A balance must be found for the appropriate set of inclusion/exclusion criteria to use for the study. Confounders must be avoided, but inclusion/exclusion criteria can also be so restrictive that it becomes impossible to recruit the necessary number of subjects. A partial list of criteria to consider for a pain study includes baseline pain level not too low or too high (Montgomery, 1999), symptoms for inclusion should be carefully defined, age group, possible confounding medical conditions, previous surgery for the condition, bodyweight if field penetration is an issue, medication use, neurological and psychiatric disorders that limit the ability of the candidates to notice and describe symptomatic changes, unstable medical conditions, patients with unresolved litigation, and pregnancy.

MASKING AND THE USE OF PLACEBOS

The design and selection of placebo devices is one of the most significant problems in studying magnetic devices. Modern scientific method demands the use of an ineffective (placebo) device in one treatment arm to compare with the active device or pharmaceutical in another group (see Harrington, 1997).

Nonmagnetic placebos may be appropriate controls for testing the benefit of brief application of magnetic

devices if subjects are observed closely by study person-nel, e.g., in the clinic environment or on a clinical research unit. Placebos must be identical in appearance and weight to the active device. This concern is particularly important in a study employing a crossover design that entails treat-ment with an active device and the placebo in any order. For the blind to be protected the individual must be observed closely and/or the devices must be covered by a pad that prevents detection of the magnetic field produced by the active device. The blind may be easily broken in studies that last for days or weeks in the absence of close observation. Once the study subject determines that he or she has the inactive device, the validity of the study is irreparably impaired.

The use of magnetic placebos means that the devices produce magnetic fields. The subject may detect this by bringing it in contact with ferromagnetic materials. Thus, they are led to believe that they are receiving a magnetic treatment. However, such a device for clinical trials must have been proved in the laboratory and in pilot validation studies to have no detectable treatment benefit. A trial that employs a magnetic comparator with any efficacy is auto-matically not placebo controlled. Instead, it becomes a head-to-head comparative trial, roughly the equivalent of a dose-controlled drug trial. Ideally, the placebo will have lesser field strength, an altered spatial distribution of the magnetic field, and a shallower tissue penetration. These devices are potentially useful for longer studies in which the patient visits the study personnel only intermittently.

CHOOSING DEVICES APPROPRIATE FOR THE STUDY OF A GIVEN CONDITION

The "golden rule" is that effective regions of the field produced by a therapeutic magnetic device must envelop pain generators or transducers in order to observe signif-icant treatment benefit. Inherent to this concept is a need, if not a requirement, to formulate a scientific basis for expecting efficacy and to demonstrate efficacy in a pilot study of the treatment of a specific disorder. It seems likely that devices may have to be designed specifically for dif-ferent types of conditions. One criterion in selecting an appropriate device for study is the depth of pain generators below the skin surface. Pain generators involved in painful diabetic neuropathy are likely to be intradermal (see stud-ies by Weintraub below), whereas those involved in low back pain are likely to lie up to several centimeters below the skin surface. Also, one must consider whether the pain is acute (e.g., osteoarthritic) or neuropathic (e.g., pain with trigeminal neuralgia or diabetic neuropathy). The mag-netic field produced by the treatment device must reach the pain generators in a way that leads to beneficial alter-ations of nociceptive mechanisms in each case. It would seem that treatment of such disparate conditions may require different magnetic fields.

POSITIONING THE DEVICES

Magnetic devices are essentially "point-and-shoot" devices. Limited area of coverage makes positioning crit-ical. If the effective portions of the field fail to envelop structures involved in pain generation, there is no chance of therapeutic benefit, and in fact, the study design is incapable of testing efficacy of the magnetic devices.

Migratory pain such as the trigger point pain of fibro-myalgia may be treated effectively initially when the devices are placed right over punctate trigger points. How-ever, this makes fibromyalgia particularly difficult to study longitudinally because the syndrome is characterized by the abrupt appearance of pain at different locations over time.

The size of the magnetic device is important. It is possible to cover large areas of skin with a single device or to apply multiple devices in the vicinity of painful or tender tissues. In the latter case, interactions between the magnetic fields of two devices could either increase or decrease therapeutic benefit.

Attachment of devices to the skin presents other prob-lems. Potential for irritation to the skin as a result of application with various types of tapes or adhesives neces-sitates good skin care. Removal of the tape, cleansing with alcohol and soap, and rubbing with vitamin oil tend to reduce irritation. An adhesive spray such as Tegaderm® may avoid irritation produced by loosely fitting devices. Use of hypoallergenic tapes is helpful. A trial-and-error method may be necessary to determine which tape is the least irritating for a given individual.

Devices in fitments, or elastic appurtenances, are a potential confounder because of splinting of joints or the spine, for example. Fitments do allow application of devices to moving parts of the body. Even with appropriate control arms, the magnitude of benefit produced by the fitments could outweigh small treatment effects of mag-netic devices. Because proximity to the skin generally is crucial because of the field's rapid decline with distance from the magnet, it is important that a fitment does not have excessive padding between the device and the skin.

CONTROLLING VARIABILITY

Pain varies from hour to hour and day to day and percep-tion of pain can fluctuate in ways that alter the weight of pain scores. Variation with time of day occurs in the case of morning stiffness, which is worse on rising. Changes in activity level can influence the efficacy of treatment devices. Increased disease activity can worsen pain, as in rheumatoid arthritis. Acute illness, anxiety, or depression, or sleep deprivation may also augment pain. Patients fre-quently use medications to sleep, and in some cases tri-cyclic antidepressants. These drugs may have analgesic and adverse effects that can confound the assessment of pain. The investigator must decide whether to slowly taper

and discontinue these medications prior to the study to achieve a monotherapy situation during the trial or to optimize the therapies and then keep the drug dose constant for the study. It is difficult to ask patients not to change their activity levels, but a measure of activity could be an outcome measure.

INSTRUMENTS OF MEASURE

Linear visual analogue scales are validated for pain studies, but have significant well-documented limitations (Chapman et al., 1985). Basically, the patient marks along a 10-cm line the intensity of his or her pain between no pain at the left and worst pain imaginable at the right limit of the line. This provides a quantitative assessment of the subjective impression of pain intensity. The limitation stems in large part from the fact that pain is a multidimensional experience that is probed incompletely by the use of linear scales. A particularly important limitation is the insensitivity of repeated measurements with a visual analogue scale to detect reductions in pain (Chapman et al., 1985). One way of circumventing this issue is the use of multiple primary and secondary outcome measures. Internally consistent treatment effects increase confidence that the outcome is biologically meaningful. Studies of pain must be designed to reduce the impact of interindividual variability or must be powered by sufficient numbers of patients to demonstrate a statistically significant therapeutic benefit.

One way of managing variability encountered with the use of linear scale is the use of "average pain over 24 hours," a form of mental averaging on the part of the patient, instead of "pain now" as the primary outcome measure. Typically, therapeutic studies with pharmacological agents involve up to 100 patients per arm in order to demonstrate therapeutic significance in the range of $p = 0.001$ to 0.05 (Backonja et al., 1998; Dworkin et al., 2003; Rice et al., 2001; Rowbotham et al., 1998). Perhaps the best index of success is that the patient chooses to continue using it after completion of the study.

In some instances, validated scales are available for use in the study of specific conditions. For example, the WOMAC scales (Western Ontario and McMasters Pain Inventory; Bellamy, 1995; Bellamy et al., 1988) have been validated for studies of pain treatment in patients with arthritis of the knee and hip. This instrument contains 27 visual analogue scales to measure different aspects of pain (five subscales), activity, and quality of life (22 subscales). The virtue of the WOMAC is that there are multiple assessments for pain and other functions. This has the advantage of looking at the pain from a number of different ways. It may also be instructive to examine pain diaries for information about subjective response to pain. In other cases, the scales have not been validated and pilot studies would be necessary to validate the instruments of measure.

The primary and secondary outcome measures should be determined in the context of claims desired for the device.

Assessments by study personnel on an intermittent basis may vary in their timing in relation to activity. A period of rest in the office, perhaps an hour or more, may allow the reversal of the activity dependent discomfort.

STATISTICS

Pilot studies are needed to assess potential effect size and calculate the number of subjects necessary to detect statistically significant differences in treatment effects between groups (power analysis) in pivotal trials. The larger the effect, the smaller the number of subjects needed. A variety of statistical methods are described in the pain literature.

ANALYSIS OF PUBLISHED CLINICAL TRIALS OF STATIC MAGNETIC DEVICES FOR THE TREATMENT OF PAIN

This section is a review of results of some controlled clinical trials published in the peer-reviewed literature. The presentation is chronological in order to give an impression of the evolution of trial design over time. A variety of devices have been studied. The result is that there are not multiple trials of a single device to give a clear impression of the robustness of effects. The studies will be analyzed as if by a referee. The intention of this mode of critique is to learn how to design clinical trials with a high likelihood of success. In the end, only devices with proven efficacy in preclinical studies and open clinical trials should be studied in placebo-controlled trials.

CHRONIC NECK AND SHOULDER PAIN (HONG ET AL., 1982)

Hong et al. (1982) were motivated by earlier subjective reports of pain-relief (Hansen, 1938; Nakagawa, 1976) to study further the effects of wearing a magnetic necklace on neck and shoulder pain. The study included 101 volunteers with and without pain and employed electrophysiological measurements. Subjects were assigned to one of four groups in a double-blind fashion: subjects with pain wearing a magnetic necklace, subjects with pain wearing a nonmagnetic necklace, subjects without pain wearing a magnetic necklace, and subjects without pain wearing a nonmagnetic necklace. The magnetic necklaces contained an average of nine cylindrical magnets, 8 mm long and 2.2 mm in diameter, interspersed at regular distance along a brass linked chain. The chain length was adjusted to each individual's neck size so that the magnets stayed in contact with the skin. The flux density of the magnets was 130 mT at the surface and zero at a distance of 9 mm. All subjects wore a necklace constantly for 3 weeks. Elec-

trodiagnostic studies (threshold voltage for activation of the supraspinatus muscle and ulnar proximal conduction time) were performed at baseline and weekly until the end of the study. Subjects in all four groups experienced a statistically significant reduction of intensity and frequency of discomfort assessed by a numerical scale of 0 to 4. There were no significant differences in subjective scores among the four groups. At the end of the study, proximal conduction time was significantly reduced (i.e., conduction velocity was faster) in subjects without pain, but not in those with pain, who wore the magnetic necklaces. No other significant differences in electrophysiological parameters were detected.

Comments

1. Study outcome negative: This study showed a significant reduction of discomfort by the placebo device (nonmagnetic necklaces) and no significant difference in reduction by the active device (magnetic necklaces).

2. Magnets of unproven efficacy: No evidence is cited to indicate that the magnets used were able to alter nerve conduction in controlled circumstances, and dosimetry required to alter nerve function had not been determined.

3. Positioning of the magnets: While magnets were held against the skin by adjusting necklace length, rotation of the necklace was possible so that magnets could have been more than 9 mm from C7–8 roots activated in testing the ulnar nerve and from the nerve to the supraspinatus muscle in the posterior cervical triangle for substantial amount of time, even during electrophysiological testing.

4. In appropriate outcome measures: The electrophysiological assays used here test predominantly large diameter, low-threshold, thickly myelinated mechanoceptive fibers with fast conduction velocities. Activity of small diameter, high-threshold, unmyelinated, nociceptive fibers may not be detected with these techniques. For this reason, the methods do not seem to provide appropriate parameters to correlate with subjective reporting of pain.

5. Questionable significance of effect: The significant increase in ulnar conduction velocity (reduced conduction time) should in the group without pain who wore the magnetic necklaces have resulted from technical factors and is not consistent with the lack of effect in the group with pain who wore magnetic necklaces.

6. Cohort size: The number of subjects is small by current standards for regulatory studies and there

was no preliminary study with a demonstrated effect upon which to base a power analysis.

7. Security of the blind: Overall, the study methods may not detect factors relevant to nociception and there was no significant change in pain assessed with an unverified verbal reporting assay. This was a trial of an unproven device, and the results are uninformative. Such a study cannot be generalized to the level of deciding whether therapeutic use of static (permanent) magnetic devices are useful for the treatment of pain.

Mechanical Low Back and Knee Pain (Holcomb et al., 1991)

This paper reports the results of a randomized, double-blind, double crossover, placebo-controlled pilot study to determine effects of a device, developed by trial and error in a clinical practice setting, on mechanical low back and knee pain. The study design was vetted with FDA personnel prior to performance of the study. The order of exposure to the experimental device and a nonmagnetic placebo was randomized. The study was conducted at two sites. In all, 54 subjects aged 25 to 86 years were randomized; 40 were treated for back pain, 14 for knee pain, and 4 for both. They were admitted to a clinical research unit for two 24 hours sessions separated by at least a week (washout period). The devices (Magna Bloc™) under study consisted of four neodymium-iron-boron magnets (200 mT over the pole) with alternating polarity in a square array and encased in a hypoallergenic plastic case. The placebo devices were nonmagnetic, but otherwise identical in appearance. The devices were 3.5 cm in diameter and weighed 30 g each. They were attached to the skin with tape in different patterns specifically for knee or back pain. The devices were masked and handled over a wooden table to protect the blind. During each session, the subjects with mechanical low back pain had seven devices (active or placebo) taped at least one diameter apart over the lumbosacral region and sacrum; patients with knee pain had four devices taped in a diamond pattern around the patella. The devices were covered with a thick, firm foam pad to protect the blind. The principal outcome measure was reduction of pain from baseline. Pain intensity was assessed with a 10-cm linear visual analogue scale and a 10-point verbal response score. Assessments were made by research personnel before devices were placed and at 1, 3, and 24 hours after placement. No devices were worn during the washout period. Medication use was recorded in patient logs.

Average pretreatment pain was about 5.3 cm in both of the treatment group. Pain was reduced significantly more by treatment with the magnetic device for 24 hours than by treatment with placebos ($P < 0.03$). Back pain

improved slightly more than knee pain, but the small number of patients makes comparison difficult. There was no evidence of carryover effects. Less medication was administered during the magnetic than placebo treatment, but the difference did not reach statistical significance. Masking was judged to be preserved throughout by both subjects and research staff.

Comments

This was considered a pilot study from conception. Therefore, it was designed to test the ability of the study methods to detect therapeutic effects of specific magnetic devices. Even though the outcome showed superiority of the magnetic device over placebo, the design raises several issues:

1. Subjects: The number of subjects was small compared with numbers in regulatory studies of pharmaceuticals.

2. Painful condition: Characteristics of the pain (e.g., burning, aching, shooting) are not described or differentiated. Pain due to muscle spasm is not distinguished from osteoarthritic changes in deep bony structures. Subjects had either one of two painful regions. A definitive study would likely involve a more homogeneous study population.

3. Devices: Flux density of the magnets was given, but no dosimetric details were reported. Importantly, the design of the magnetic devices had been optimized by patient-reported benefit. Even though there was no laboratory evidence to support effectiveness or mechanisms, there were clinical reasons to believe that the devices to be tested might be effective. Subsequent to the study, certain regions of the magnetic field produced by arrays of four magnets with alternating polarity, similar to the arrangement in the devices used in this study, were shown to block electrically stimulated action potential firing in cultured sensory neurons (McLean et al., 1991).

4. Device placement: Multiple devices were applied in different patterns for back and knee pain. In one sense, this suggests broad applicability of such devices. In another sense, interpretation of results combining data from the two treatment groups is complicated.

5. Study design: A crossover design was used. No carryover effect was detected, but parallel groups studies are the vogue for regulatory studies of pharmaceuticals.

6. Duration of the blind: The 24-hour treatment sessions are brief compared with most painful

conditions. Implications of these data for the treatment of chronic pain are not determined.

7. Masking: A nonmagnetic placebo was used. In a longer study this might jeopardize intactness of the blind. In the in-patient setting, procedures to protect the blind, including the covering pad and direct observation by research staff, could be implemented. Compliance with such methods outside a controlled unit might be difficult to ensure.

8. Data presentation and statistics: Absolute values of pain scores are not presented for all observation periods. Results are presented as differences between magnetic and placebo treatment periods. Thus, the magnitude of the treatment effect is difficult to determine. Overall pain relief during treatments with magnets was 20 to 34% better than placebo and the difference was statistically significant. One could question the biological significance of treatment effects of this magnitude, however. Beecher (1955) compared morphine injection with saline. He found that the placebo effect was greatest in the immediate postoperative period: 52% of patients had pain relief after morphine subcutaneously, 40% of patients had pain relief after placebo injection. Placebo accounted for 77% of the pain relief thus making morphine 23% more effective than placebo. Since morphine is considered to be a gold standard of pain relief, one might boldly say that pain relief by some magnetic fields approaches that of morphine. Overall, this pilot study supports further investigation of the device tested. Study design could be improved along the lines of this discussion for additional trials.

TRIGGER POINT PAIN IN PATIENTS WITH POSTPOLIO SYNDROME (VALLBONA ET AL., 1997)

Limited success has been achieved with a variety of modalities, including anti-inflammatory medications, in the treatment of postpolio syndrome. This fact and the documented utilization of static and time-varying electromagnetic fields in orthopedic conditions led the authors to test the effects of magnetic treatment devices for trigger point pain in patients with postpolio syndrome. In the study, 50 patients, predominantly female, who were not more than 1.5 times their ideal bodyweight, were randomized to treatment with a nonmagnetic placebo device or a commercially available magnetic device (Bioflex). Patients had had significant muscular and/or arthritic pain for at least 3 weeks and a trigger point or circumscribed painful region on palpation. Only one site that was tender to palpation with a blunt object 1 cm in diameter was

treated per patient, even if other painful sites were present. There was no significant difference in the location of the painful points in the two treatment groups, although the most commonly affected site (33% of the placebo group and 41% of the magnetic device group) was the sacroiliac joint. The size of the treatment device varied depending on the area involved. The flux density at the surface of discs 40 mm in diameter and 1.5 mm thick and strips 175 × 50 × 1.5 mm was 50 mT. At the surface of discs 90 mm in diameter and 1.5 mm thick and 83 × 53 × 1.5 mm pads, the flux density was 30 mT. The design of all four active devices consisted of concentrically arranged rings of alternating magnetic polarity. The nonmagnetic placebos were identical size and shape. Pain was assessed with a validated 10 point (1 to 10) scale prior to and 45 minutes after placement of the treatment devices.

Trigger point pain improved in 22 of 29 subjects in the group treated with active magnetic devices and in 4 of 21 of the group treated with placebos. Baseline pain scores were ~9.6/10 (magnet group) and ~9.5/10 (placebo group), i.e., in the severe range. After 45 minutes, pain scores were ~4.4/10 (~54% reduction) in the group that wore magnetic devices and ~8.4/10 (~12% reduction) in the group that wore placebos. The difference was highly significant ($p < 0.0001$).

Comments

1. The outcome was highly significant in favor of the magnetic treatment device. Although detailed dosimetry was not available, flux density at the skin surface was in the range of 30 to 50 mT and was spatially inhomogeneous due to the alternating polarity of the magnetic rings. The sacroiliac joint and muscle trigger points would be expected to be fairly superficial and only separated from the devices by the thickness of the skin and subcutaneous fat. Thus, a field in the millitesla range could be expected to reach the treated points of tenderness. The rationale for selecting the Bioflex magnets is not clear. Spatial inhomogeneity and regions of steep field gradients are features of alternating quadripolar arrays that reversibly blocked action potentials in cultured neurons (McLean et al., 1991, 1995). Also, alternating quadripolar arrays (plane of device contacting skin) with gradient fields with higher flux densities (1 mT at depth of 2.5 cm; see McLean et al., 2003) were used in clinical studies (Holcomb et al., 1991).

2. Different treatment devices of different magnetic strength were used, but there was no significant difference in the numbers of devices between groups.

3. Patient selection: Patients less than 1.5 times their ideal bodyweight were selected so that the field produced by the treatment devices had a chance of exposing the target tissues.

4. Duration of the blind: The exposure period was 45 minutes. This is very short compared with duration of chronic pains with or without exacerbation. It is not clear that success in the course of brief treatment of trigger points can be extended to other types of more persistent pain, although additional trials appear to be justified.

MUSCLE PAIN AND RECOVERY AFTER INTENSE EXERCISE (BORSA & LIGGETT, 1998)

Borsa and Liggett (1998) included 45 normal individuals in a single-blind, placebo-controlled study to test the effects of commercially available magnets on pain due to isometric muscle contraction. The justification for studying magnetic devices was written and anecdotal claims of benefit of the devices tested against muscle soreness. The magnets provided by the manufacturer had a flux density of 70 mT at the surface, measured 8 × 5 cm and were 3 mm thick (Nikken, Inc., Los Angeles, CA). Placebos were nonmagnetic and identical in appearance. Subjects were randomized to treatment with nothing, the magnetic devices, or the nonmagnetic placebos. The treatment devices were secured over the midbelly of the biceps muscle with elastic tape. Devices were worn constantly. Outcome measures included pain perception measured by a 10 cm visual analogue scale, pain-free range of motion measured with a goniometer, or static force production measured with an isokinetic testing device. Data were obtained before treatment and 24, 48, and 72 hours after treatment.

There were no statistically (ANOVA) significant differences among the three groups in any of the parameters tested.

Comments

1. Although there was no difference among groups, the outcome is uninformative in the absence of a testable effect; i.e., there were no pilot data showing benefit from the magnetic devices.

2. Unpublished data cited by the authors suggested that the magnets used act by membrane hyperpolarization. The data had not been published in a peer-reviewed journal and seem to have been literature from the company.

3. The magnet pads covered roughly the middle third of the belly of the biceps muscle and there was no dosimetric information upon which to base expectation about exposing of pain-sensitive structures to the magnetic field. Characterization of the field is missing. It may be that

the type of field generated by the tested devices is ineffective for the pain studied. However, this does not prove that the devices might not be effective for another type of pain or that magnetic fields in general are ineffective in the treatment of pain.

Pain and Healing After Liposuction (Man et al., 1999)

Improvements in would healing would be useful in plastic surgery and other areas of medical practice. Based on increased healing and wound tensile strength in animal models, the authors tested effects of commercially available ceramic magnets on pain (assessed with visual analog scales), edema (on a scale of 0 to 10 compared with adjacent untreated areas), and discoloration (on a scale of 0 to 10) at sites of suction lipectomy. A variety of areas were suctioned in different patients. Identical magnetic patches and nonmagnetic placebos were provided by the manufacturer (Tectonic, Magnetherapy Inc., North Palm Beach, FL). Sizes (from 5 × 15 cm to 20 × 30 cm) and shape (square and rectangular) varied. Flux density varied from 15 to 40 mT. The negative pole faced the skin. In the study, 10 patients were randomly assigned to receive magnets and 10 received placebos. Patches were attached to the skin with compressive bandages immediately after surgery and for 14 days postoperatively. Wounds were inspected on days 1, 2, 3, 4, 7, and 14.

Pain, edema, and discoloration were significantly improved in the group that received magnetic devices compared with placebos.

Comments

1. The reported benefits were detectable in a small cohort, suggesting a large treatment effect.
2. The impact of variability in the areas suctioned and the devices used to treat (with respect to field strength and geometry) on study outcome was not considered.
3. Other than the visual analogue scales used to assess pain intensity, the instruments of measure were subjective and not validated in previous large studies. Intactness of the blind was not assessed.
4. Based on experimental data in the literature, increased blood flow was considered to be a possible mechanism for the therapeutic effects seen here. Mechanistic properties of the devices used here have not been identified by basic research.
5. Further studies of postoperative wound healing have not appeared in the literature, but seem to be justified.

Fibromyalgia (Colbert et al., 1999)

Fibromyalgia is a chronic disorder characterized by fluctuating and migratory musculoskeletal symptoms, disturbed sleep, and fatigue. Prevalence is about 2% in the general population and 3.4% among women (Wolfe et al., 1995). Fibromyalgia was the second most common symptom among veterans of the first Gulf War (The Iowa Persian Gulf Study Group, 1997). Fewer than half of patients with fibromyalgia receive significant improvement with pharmaceuticals (tricyclic antidepressants, benzodiazepines, anti-inflammatory drugs, and other central nervous system active compounds) while adverse effects occur in 98% of the medicated (Carette et al., 1994). Nonpharmacological therapies have been shown to provide significant benefit to those who can continue the effort. A non-peer-reviewed study in Japan indicated benefits of using permanent magnetic mattress pads to treat a variety of musculoskeletal disorders (Shimodaira, 1990). This stimulated the authors to investigate potential benefit of magnetic mattress pads for fibromyalgia sufferers.

In the study, 30 women with a diagnosis of fibromyalgia for at least 2 years and chronic pain met inclusion criteria for the study. Age averaged 48 to 51 years and weight averaged 152 to 178 lb (significantly less in the experimental group). Of the women, 25 completed the 4-month study. There were no serious adverse effects. Subjects were randomly assigned in double-blind manner to groups that slept on magnetic or nonmagnetic pads. Subjects were asked not to determine which type of pad they received. The density of the foam covering the magnets helped to protect the blind by preventing detection of magnetism with light ferromagnetic objects, e.g., paperclips.

The pads were provided by Magnetherapy, Inc., directly to individual subjects and the code was kept by the manufacturer until all data had been collected. Each magnetic pad contained 270 ceramic magnets (2 × 4.5 × 1 cm) embedded 4 cm apart in a 4-cm-thick foam sheet. The negative poles of all magnets faced toward the subject. The flux density at the surface of the magnets was about 110 mT. This field strength was estimated to deliver 20 to 60 mT to the skin at different points along the body.

A total of eight variables were studied, and 10-cm visual analogue scales were marked weekly for pain, sleep interference, fatigue, tiredness on awakening, and global sense of well-being. The physical function scale from the Fibromyalgia Impact Questionnaire, total myalgic score (dolorimetry at standard anatomical sites), and a body pain distribution drawing were also completed. On Wednesdays of each week visual analogue scales were mailed to the principal investigator after completion by the subjects. This approach was adopted to try to minimize day-to-day fluctuations in symptoms, especially by avoiding assessments on the weekend when stress is lowest. A diary of adverse effects was also kept.

In the group that slept on the magnetic pads, statistically significant reductions from baseline were reported with respect to pain, fatigue, total myalgic score, functional scales, sleep, and pain distribution drawings. In the group that slept on nonmagnetic pads, only tiredness on awakening decreased significantly from baseline.

Comments

1. In the absence of preclinical data, the basis for expecting exposure of the skin to magnetic fields of the flux density studied here to improve symptoms of fibromyalgia is not established.
2. Statistical comparisons between the two treatment groups were not calculated. We used data tabulated in the paper to perform *t*-tests between pain scores at end point. The difference between treatments was not statistically significant.

PAINFUL DIABETIC NEUROPATHY (WEINTRAUB, 1999)

Limited efficacy of pharmacological therapies justified testing magnetic therapy for painful distal symmetric polyneuropathy associated with diabetes. Efficacy in treating painful neuropathy in patients with diabetes was compared with 10 patients with a variety of nondiabetic conditions as etiologies of their neuropathies. All patients were examined by a neurologist and underwent electrophysiological studies to characterize their neuropathies prior to randomization. Patients were randomized to treatment with commercially available permanent static magnetic insoles (Magstep, Nikken) or nonmagnetic placebo insoles provided by the manufacturer. The elastic polymer contained ferromagnetic particles that were magnetized in a multipolar triangular pattern with alternating polarity from one triangle to the next. Steep gradients existed between triangles. Flux density at the surface was 47.5 mT maximally and fell to zero within 4 cm. Patients were instructed to wear the devices constantly for 4 months. The study was conducted in four phases: In phase I (1 month), patients wore a magnetic insole in one shoe and a nonmagnetic placebo insole in the other shoe. In phase II (1 month), the insoles were switched. In phase III and IV (total 8 weeks), patients received two magnetic insoles. Pain was recorded twice daily in diaries using a five-point categorical scale. A 30-day composite score was computed to moderate effects of fluctuations in pain that occur with diabetic neuropathy. The primary instrument of measure was comparison of composite scores pre- and post-treatment.

A total of 24 subjects were enrolled. Of these, eight withdrew in the first 6 weeks of the study. Reasons for withdrawal included: four diabetics, two of whom could not tolerate the insoles and two because of excessive pain; two because of infected toes; one for adminstrative rea-

sons; and one without diabetes who could not tolerate the insoles. A significant reduction of pain and burning occurred in those with diabetes compared with those without diabetes, but only in the last 2 months when patients wore two active insoles. No changes occurred in the first two phases when a single active device was worn on one foot then the other.

Comments

1. Patients with diverse painful neuropathic disorders were compared with a more homogeneous group of patients with diabetes.
2. The pain scale used was not a validated scale. Nonetheless, the baseline intensities for patients with diabetes were in the mild to moderate range where repeated measures with visual analogue scales have proved unreliable for detecting treatment effects in the course of repeated measures. In a successful placebo-controlled trial of gabapentin to treat painful diabetic neuropathy, the inclusion criterion for pain intensity was ≥ 4 cm on an 11-point Likert scale during a 1 week baseline prior to randomization. Group average baseline pains were in the range of 6.5 on an 11-point Likert scale, averaging moderate-to-severe on this validated linear scale.
3. The reason for benefit by patients with diabetes during the wearing of two magnetic insoles, compared with a single magnetic insole on one foot then the other, is not clear. One possibility is that the blind was broken, as acknowledged by the author. Analysis was done only on data from patients who completed the study. That is, this is not an intent-to-treat analysis.
4. The reduction of diabetic pain in the late phases of the study encouraged the author to perform a second study with parallel group design (see below).

CHRONIC LOW BACK PAIN (COLLACOTT ET AL., 2000)

Citing profitability of sales of devices consisting of permanent magnets for the treatment of pain based on little evidence from controlled trials, the authors at a Veterans Administration Hospital tested a commercially available device commonly used for back pain. Of 24 veterans with chronic low back pain, 22 entered the study when asked to participate; 2 did not complete the study because of time conflicts. In all 20 subjects, mean age 60 years old, completed the study; 11 of the 20 completers were disabled. There were no serious adverse events. The subjects had a variety of diagnoses that involved intervertebral discs and facet joints. Diagnoses included spondylosis,

herniated nucleus pulposus, radiculopathy, spinal stenosis, spondylolisthesis, history of laminectomy, ankylosing spondylitis, and fibromyalgia. None of the patients had neurological deficits according to examiners. Subjects were asked not to alter medications during the study.

This study entailed a randomized, double-blind, placebo-controlled crossover design. The primary outcome measure was change in pain from baseline using the 10-cm visual analogue scale. The McGill pain questionnaire and range of motion of the lumbosacral spine (measured with inclinometers) were secondary outcome measures. The study consisted of 1 week with magnetic devices and 1 week wearing sham devices with a 1 week washout period between the treatments. Subjects wore the treatment devices for 6 hours a day on Monday, Wednesday, and Friday of each treatment week.

The devices used were flexible, trapezoidal in shape ($19 \times 11.5 \times 14$ cm and 2 mm thick) and had flux densities of 28 to 33 mT at the surface. Shams (placebos) were identical to the active devices in appearance, but were demagnetized and had no detectable magnetic field. The ferromagnetic particles in the rubber matrix were magnetized in a triangular pattern with opposite polarity of adjacent triangles, thereby producing steep field gradients. The manufacturer was not named. An abdominal binder was used to hold the treatment devices in place.

There were no statistically significant differences in visual analogue scale pain intensity measurements, range of motion, or McGill pain scale scores between treatments.

Comments

1. This study may not be an adequate test of efficacy of the experimental device because of design issues.
2. The diversity of pain etiologies suggests that the pain generators may be diverse and neither amenable to treatment with a standardized device producing a generic magnetic field nor amenable to scoring with a single linear scale. Some of the pains seem to be bony in origin (e.g., ankylosis and spondylolisthesis) while others are neuropathic (e.g., radiculopathy). Homogeneity of the study cohort is important for reducing variability, in effect improving the signal-to-noise ratio. For example, studies of efficacy of pharmaceuticals in the treatment of osteoarthritis use very strict criteria for inclusion to homogenize the study group. Also, specifically validated instruments of measure (e.g., the WOMAC) take into account functional and psychosocial aspects of the pain experience in addition to pain intensity.

3. There was no laboratory evidence of efficacy to provide a rationale for this pilot study.
4. The treatment devices were worn intermittently and for relatively short periods of time on treatment days. The basis for this is not given.
5. Order effects were not examined, i.e., sham/placebo first vs. magnetic device first, and the possibility of carryover effects was not analyzed.
6. Subjects were asked to indicate current pain levels on the visual analogue scale. In studies showing pharmaceuticals to be superior to placebo for the treatment of neuropathic pains, subjects have been instructed to mark on the visual analogue scale a pain intensity level that represents average pain over the previous 24 hours. Averaging pain in this manner reduces hour-to-hour and day-to-day variability in pain intensity.
7. Intactness of the blind is questionable. The only procedure for protecting the blind was instructing subjects not to manipulate the devices.
8. The conclusion of this study cannot be generalized to include other magnetic devices.

Fibromyalgia (Alfano et al., 2001)

Fibromyalgia is a common disorder affecting about 2% of the general population (Goldenberg, 1999). The pathophysiology is not completely understood, but there is evidence of dysfunction of nociception, the hypothalamo-pituitary-aderenal axis, and the sympathetic nervous system (see Weigent et al., 1998). Also, abnormalities of muscle microvasculature may result in chronic hypoxia and cramping (see Olsen & Park, 1998). In the absence of uniformly effective treatments, many patients with this disorder seek complementary and alternative therapies. This led the authors to study the effects of magnetic mattress pads on pain associated with fibromyalgia.

Subjects were randomized in a double-blind manner to two different groups that slept for 6 months on commercially available mattress pads from two manufacturers. The pads were used according to the instructions of the manufacturers. Magnetic flux densities were measured with a gauss meter. Ceramic magnets ($2.54 \times 5.08 \times 0.95$ cm) with flux densities of 395 mT at the surface were embedded 2.54 cm apart in pad A (MagnetiCo, Inc., Calgary, Canada); this group had 37 subjects. The negative poles of all magnets were oriented toward the subject (unipolar devices). The pad was placed between the box springs and the mattress (typically 15 to 25 cm thick). At the surface of the mattress, the magnetic flux density was –0.35 to –0.64 mT; 15 cm (6 inches) above the mattress the flux density was –0.25 to 0.43 mT. In pad B (Nikken, Inc., Irvine, CA), ceramic magnets (1.8 cm diameter; 0.3 cm thickness) with flux densities of 75 mT at the surface were embedded 12.5 cm apart with the negative poles of

all magnets facing the subject (unipolar devices). This pad was placed on top of the subjects' mattresses. Flux densities measured +0.45 to –55.8 mT at the surface of the pad; +0.09 to –3.3 mT, 2 cm above the pad; +0.03 to –0.3 mT, 5 cm above the pad; and –0.03 to –0.1 mT, 15 cm above the pad. This group had 33 subjects. Two other groups (sham pad A, 17 subjects; sham pad B, 15 subjects) slept on nonmagnetic shams identical in appearance to each of the magnetic pads. A fifth group of 17 subjects continued their usual treatments and did not sleep on mattress pads. Overall, 94 of 111 randomized subjects (8 were excluded from a total of 119 enrolled because of incorrect randomization; 17 withdrew for various administrative reasons or unrelated medical problems) completed the study. There were no serious adverse effects.

Changes in pain intensity on an 11-point scale (Item 14 of the Fibromyalgia Impact Questionnaire), functional status (based on scales in the Fibromyalgia Impact Questionnaire), the number of tender points at defined locations (assessed by dolorimetry), and tender point pain intensity scores on an 11-point scale were considered to be the primary outcome measures.

A significant difference in pain intensity ratings among treatment groups was observed ($p < 0.03$, ANOVA) and the reduction in the group sleeping on pad A was significant at 6 months. A reduction in the number of tender points was detected at 3 months. Nonsignificant improvements in other measures occurred also.

Comments

1. Statistics for group-to-group comparisons are not given. Thus, it is difficult to interpret the meaning of differences between groups detected by analysis of variance. Using data tabulated in the paper to perform two-tailed t-tests, we found that pain in the group using pad A was reduced significantly from the baseline score ($p < 0.047$). The difference between end point and baseline pain intensity ratings was not significant for pad B ($p > 0.05$).

2. The use of the two pads could provide information about time- and field strength-dependence of effects.

Pain Associated with Rheumatoid Arthritis of the Knee (Segal et al., 2001)

Rheumatoid arthritis is an immune-mediated inflammatory disorder of joints that results in pain and debility. Pharmacological management is often costly and associated with significant adverse effects that limit drug utility. Continuous exposure to a static magnetic field reduced experimental synovitis (Weinberger et al., 1996) and may inhibit development of canine osteoarthritis (Rogachefsky

et al., 2004). Square arrays of four permanent magnets of alternating polarity produced static magnetic fields with regions of steep gradients. Exposure of cultured sensory neurons to these fields reversibly blocked action potential firing (Cavopol et al., 1995; McLean et al., 1991, 1995). Such actions could reduce inflammation and nociception in joints affected by rheumatoid arthritis. These findings led the authors to study effects of steep gradient magnetic fields on knee pain in patients with rheumatoid arthritis. Commercially available devices that produce the desired field architecture and penetrated at least 2 inches into tissue were used for the study (Magna Bloc; see Holcomb et al., 2003).

For the study, 64 patients were recruited from three American and three Japanese clinics associated with academic institutions. They were randomly assigned to treatment with Magna Bloc devices or with magnetic control devices identical in weight and appearance. The Magna Bloc devices consisted of four neodymium-iron-boron magnets in a square array with alternating polarity and covered by a hypoallergenic plastic case. The magnetic flux density over each pole was about 190 mT and field gradients ranged from 0.1 to 40 T/m. The magnetic control devices contained a 0.5-mm steel disc nearest the skin surface of the device. This was topped by a single neodymium-iron-boron magnet and three aluminum blanks. The magnetic field was unipolar with a flux density of 72 mT at the surface of the device facing the skin. The magnetic control devices were used to protect the blind. Four devices were taped around the patella in a diamond-shaped pattern. Subjects were instructed to wear the devices continually. Pain was assessed in the clinic with the 10-cm visual analogue scale before and at 1 hour, 1 day, and 1 week after placement of the devices. Subjects kept pain diaries in which they recorded pain intensity on 10-cm lines upon awakening and going to bed. The primary outcome measure was reduction of pain at 1 week (end point) from baseline intensity as measured by the visual analogue scale. Secondary outcomes measures included a global assessment of disease activity (GADA, completed by rheumatologist and patient) by placing a mark along a 10-cm line marked no disease activity at one end and greatest possible activity at the other, the modified health assessment questionnaire (MHAQ) to assess difficulty with activities of daily living, and the subjects' assessment of outcome. Laboratory tests were ordered to assess disease activity; the Westergren sedimentation rate did not change in the course of the study.

Baseline pains averaged 63/100 mm in the Magna Bloc group ($n = 38$) and 61/100 in the control device group ($n = 26$). Pain intensity declined significantly at one week in both treatment groups compared with baseline values ($p < 0.0001$). The decrease in the MAG-4A group (~40%) was greater than that in the control device group (~26% decrease). The difference in pain reduction between the

two groups was not statistically significant ($p < 0.23$). The rheumatologists' GADA scores showed greater improvement in the MAG-4A group, but the difference between groups was not significant ($p < 0.18$). The subjects reported a significant difference in the GADA at 1 week versus baseline ($p < 0.01$). Subjects' assessment also revealed significantly more individuals rating outcome as better or much better in the MAG-4A group than in the control device group (68% vs. 27%; $p < 0.001$). Differences in the MHAQ were not statistically significant, but difficulty with activities of daily living decreased in the MAG-4A groups and increased in the control device group.

Comments

1. The magnetic control devices were an attempt to protect the blind. The control devices had not been compared with nonmagnetic placebos in a validation trial. Therefore, it is not possible to determine the size of the placebo effect or the treatment effect of the device. The lack of significant difference in pain intensity ratings between treatments emphasizes a need for studies to design an ineffective magnetic placebo and validate it in separate studies before inclusion in a large clinical trial.

2. The 40% reduction of pain by the MAG-4A device compares with 30 to 40% reduction of neuropathic pain in recent trials of anticonvulsant drugs.

3. In view of the variability of pain in rheumatoid arthritis, larger treatment groups may be necessary to resolve significant treatment effects. A power analysis based on the data from this study would be helpful for designing future studies.

4. The duration of the blind may have been too short to observe significant differences between treatments.

5. The magnetic field produced by the MAG-4A array had effects in animal and cell models, providing a rationale for clinical trials.

6. Positive outcomes in secondary outcome measures, particularly in assessments by subjects, encourage additional trials of magnetic treatment devices for pain of rheumatoid arthritis.

PHYSICAL FUNCTION IN PATIENTS WITH CHRONIC KNEE PAIN (HINMAN ET AL., 2002)

In general, relatively weak static magnetic fields have been used in clinical trials. As a result, it is not clear whether the field strength or geometry that penetrates to the pain generator in tissue is sufficient to produce meaningful benefit. The authors used magnets with industrial ratings of about 1 T to test the hypothesis that wearing strong magnets would improve function in patients with chronic knee pain. A pilot study showing significant improvement of knee pain with magnetic therapy (see Holcomb et al., 1991) was cited as a basis for selecting knee pain as a therapeutic target.

In the study, 47 subjects with chronic knee pain due to previous injury or osteoarthritis were randomly assigned to treatment for 2 weeks with magnets or nonmagnetic placebos in self-adherent elastic bandages. One subject dropped out because of medical complications and data of three individuals were incomplete and not included in the analysis.

Four cylindrical neodymium-iron-boron magnets (13 mm in diameter, 3.2 mm thick; Relieve Pain Today, Marietta, GA) were embedded in 7.6-cm square pads with an adhesive surface. Negative north-seeking poles faced the skin. Flux densities of individual magnets ranged from 40 to 56 mT in the center to 140 to 180 mT at the edge. The distance between poles was not given. Placebos were nonmagnetic. Devices were worn on one knee (the knee with most pain, if both were painful).

The primary outcome measures were the 5 pain scales and 17 functional scales of the WOMAC and the time for a 50-foot walk. The WOMAC is a highly validated instrument for evaluating treatments for osteoarthritis of the knee and hip. Subjects recorded the time they wore the treatment devices in a log. Subjects were asked not to place the devices on metal surfaces or otherwise try to determine whether the devices were magnetic. Overall compliance with this request was high, but two individuals in the magnet group inadvertently broke the blind. Pain (sum of 5 WOMAC visual analogue scale ratings) decreased from a mean of 19.4 to 7.4 (~62%) in the group with magnets and from 19.6 to 16.1 (~18%) in the placebo group. The difference was statistically significant ($p < 0.002$). Mean values for physical function (sum of 17 WOMAC visual analogue scale ratings; higher scores indicate more difficulty with activity) improved in the magnet group from 27.4 to 13.2 (~52%) and from 24.7 to 22.6 (~9%) in the placebo group. The difference between groups was statistically significant ($p < 0.001$). Magnet wearers also improved significantly more in the 50-foot walk test than placebo wearers ($p < 0.04$).

Comments

1. A hallmark of this study is the use of the widely used and validated instrument of measure, the WOMAC index. Osteoarthritic knee pain is a clinical condition for which the index was validated. The WOMAC is widely used in clinical trials of pharmaceutical agents for osteoarthritis.

2. The blind was compromised to some degree by the use of nonmagnetic placebos.

3. It would be interesting to know if such significant benefits of unipolar magnets could be sustained over longer study periods of typical regulatory studies.

PAINFUL DIABETIC NEUROPATHY (WEINTRAUB ET AL., 2003)

Pilot studies indicated relief of pain associated with diabetic neuropathy by magnetic insoles (see Weintraub, 1999). These results led to the design of this large, multicenter, parallel group, double-blind, placebo-controlled trial. The trial involved 375 subjects with diabetes (insulin- and non-insulin dependent) at 48 sites in 27 states in the United States. Patients had electrophysiologically characterized distal symmetric sensorimotor polyneuropathy. The associated neuropathic pain was chronic, moderate to severe in intensity (>5/10 cm on the visual analogue scale) and refractory to medications. They were asked to record pain and quality of life scores daily for 4 months. They agreed to wear the devices 24 hours a day. No new analgesic drugs were allowed during the study, but medication could be continued at a constant or reduced dose.

The study was funded by manufacturers of magnets (NuMagnetics and Nikken) without influencing study design, performance, or data analysis. The protocol was approved but not funded after review by the National Institutes of Health.

The commercially available magnetic insoles (Magsteps; Nikken Inc.) consisted of a flexible rubber matrix impregnated with strontium ferrite and magnetized in a triangular pattern such that polarity of adjacent triangles alternated. Magnetic flux density at the center of the triangles was ±45 mT. The flux density 13 mm from the surface was 0.13 mT; it was 0 mT at 20 mm. Flux density at the target area is not known. Placebo insoles were not magnetized and were identical in appearance to the magnetic insoles.

The primary outcome measures were visual analogue ratings of numbness, tingling, and burning. Other outcome measures included sleep interference tests, serial electrophysiological testing, and adverse effects.

Enrollment totaled 375 patients. Neither the investigators nor the patients knew the types of devices. Of 199 individuals randomized to magnetic treatment, a total of 58 (29%) were excluded from analysis: 25 were lost to follow-up; 15 dropped out because of allodynia that made wearing the devices intolerable; 6 had complications of their diabetes; and 12 were excluded because of missing data. Of 176 individuals randomized to placebo treatment, 58 (33%) were excluded from analysis: 27 were lost to follow-up; 13 dropped out because of allodynia; 4 had complications; and 14 were excluded because of missing data.

Analysis of results in the subset of patients who completed the 4-month study were as follows: Burning pain decreased by 12% from a baseline mean pain intensity of 5.1 cm on the 10-cm visual analogue scale compared with a 3% decrease from a baseline mean of 5.3 cm. This difference between treatments was marginally statistically significant after 3 and 4 months of treatment ($p < 0.05$ at 4 months). Numbness, tingling, and exercise-induced foot pain also decreased slightly compared with placebo ($p < 0.05$). Sleep interference scores decreased about 30% in both groups, and the difference between groups was not significant. A subset of patients with severe exercise-induced foot pain at baseline (≥ 7 cm on a 10-cm visual analogue scale) experienced substantial relief of symptoms over time (41% decrease in pain in the magnetic treatment group vs. 21% in the placebo group; $p < 0.01$). Burning and tingling pain were not significantly different in this group. In the group with severe foot pain, 50% of those treated with magnetic insoles had at least a 30% improvement, compared with 25% in the placebo treatment group ($p < 0.05$ for difference between groups). Glycemic control and neurophysiological parameters did not change significantly during the study.

Comments

This study is notable for the extent to which it mimics the design of large pivotal trials of pharmaceuticals for FDA approval. Of special interest are the large patient cohorts, careful characterization of the study population, and appropriate statistical comparisons. This study bears careful examination.

1. This is the largest trial involving magnetic treatment devices published to date. It is useful to examine the present study in detail in comparison to the standard set by regulatory studies of pharmaceuticals.
2. The analysis is not an intent-to-treat analysis. Data of about a third of the subjects were excluded from analysis in both groups for a variety of reasons. As such, the analysis was performed on a subset of patients who completed the 4-month trial. In some pain studies, the last value of data recorded for patients who exit before completion is carried forward as a method of including all randomized subjects who received treatment in the data analysis.
3. As discussed by the authors, magnetic treatment effects in the group that completed the study were small, although statistically significant in comparison with placebo. The effects increased after the second month, suggesting time-dependent improvement. Subjects with moderate baseline pain intensity may not have

responded significantly to treatment, thereby diluting the aggregate effect amplitude. The distribution of baseline pain scores in this study is not given, so the extent to which this factor limited treatment effects cannot be determined. Linear scales such as the visual analogue scale are not as sensitive for detecting treatment-induced changes with repeated measures when baseline pain is in the mild range (1 to 3/10 cm). Other neuropathic pain studies have excluded subjects with pain intensity below 4/10 cm to avoid this limitation of the visual analogue scale.

4. These details raise the issue of clinical/biological significance of the effects. The group with severe pain represented about one third of each treatment group (49/133 in the magnetic treatment group; 35/111 in the placebo treatment group). Patients with severe pain improved more with magnetic insole therapy, as did patients with severe pain in trials of gabapentin treatment for pain associated with diabetic neuropathy (Backonja et al., 1998) and posttherapeutic neuralgia (Rowbotham et al., 1998). The amplitude of treatment effects needed for improvement to be considered meaningful has been studied (Farrar et al., 2000, 2003). Analogous to the 50% responder rates in antiepileptic drug trials, the percentage of patients experiencing >30% reduction of pain has been validated as a measure of meaningful improvement in studies of neuropathic pain (Farrar et al., 2003). The ">30% responder test" was included in the analysis of data from the group of patients in the present study with severe pain. The statistical significance of the difference between groups was marginal ($p < 0.05$). Presumably, some, if not all, of the subjects who dropped out due to allodynia had severe baseline pain. Exclusion of their data may have biased the analysis and led to overestimation of significance. Reanalysis after inclusion of data from this group by the method of last-observation-carried-forward (Mallinckrodt et al., 2003) could address this. The impression is created that pain reduction in the other two thirds of patients in the magnetic treatment group who did not have severe pain was not meaningful. These considerations suggest that only patients with severe pain might be selected for a future study.

5. Significant reduction of pain in the gabapentin trials was supported by significant improvement in sleep, physician and subjects' global impressions of change, quality of life measures in the

SF-36 quality of life questionnaire, and scales of the profile of mood states. Internal consistency of benefits among these measures ascribes a dimension of meaningful clinical impact to the reduction in visual analogue scale scores. These instruments of measure were not included in the present study. Foot pain with exercise and sleep interference were analyzed as surrogates for quality of life measures. Subjective measures of improvement are commonly used and validated for trials of treatments of some disorders (see Pain Associated with Rheumatoid Arthritis of the Knee, above).

6. The placebo effect would be expected to wane with time. In the present study, the placebo effect persisted and was still increasing slowly in some measures at 4 months. Similarly, the placebo effect persisted in other studies of pharmacological treatments for neuropathic pain, such as the gabapentin trials. Factors accounting for this persistence have not been definitively identified. Routine interaction with study personnel and regimented treatments (increased compliance with medications) could contribute. Minimization or elimination of the placebo effect would increase the signal-to-noise ratio and favor detection of treatment effects with drugs or magnets. Thus, it would be desirable to learn how to avoid persistence of the placebo effect, a generic problem in studies of neuropathic pain.

Plantar Heel Pain (Winemiller et al., 2003)

A previous study with some methodological limitations found magnetic insoles to be no more effective than nonmagnetic insoles in the treatment of plantar heel pain (Caselli et al., 1997). In this study, treatment with magnetic insoles was examined in subjects with plantar fasciitis. A randomized, double-blind, placebo-controlled, parallel group design was employed. The duration of the blind was 8 weeks, during which subjects kept daily pain diaries.

Of 198 subjects evaluated, 101 met inclusion criteria and were randomized. The principal inclusion criteria were (1) at least 30 days of foot pain, (2) intensity greater than 3/10 on the visual analogue scale (mean baseline pain about 6.7-6.9/10 by visual analogue scale), and (3) specific tenderness on palpation. The pain under study was called plantar heel pain or plantar fasciitis, but the inclusion criteria regarding pain were complex and included: (1) maximal tenderness on palpation of the medial plantar fascia and medial calcaneus; (2) shooting, sharp, or localized pain in the plantar region of the foot; (3) pain exacerbated by standing or walking; and (4) pain on arising in the morning. In the study, 44 individuals were assigned

to treatment with nonmagnetic insoles; 56 of 57 were randomized to treatment with magnetic insoles (1 refused to use the insoles); 3 in the nonmagnetic insole group and 2 in the magnetic insole group did not answer questionnaires and were lost to follow-up. Data from all randomized subjects was analyzed (intent-to-treat).

The study was funded through an educational grant from Spenco Medical Corporation, Waco, Texas, the manufacturer of the insoles used in the study. The magnetic insoles contained a magnetic foil with concentric circles of alternating polarity under the proximal arch support. Flux density at the surface of the insole was 245 mT. The placebo insoles contained nonmagnetized foil, but were otherwise identical. Subjects picked a pair of insoles out of a box in which magnetic and nonmagnetic pairs were intermixed in nearly equal numbers that exceeded the number of subjects. Subjects were instructed to wear the devices at least 4 hours per day, 4 days per week for 8 weeks. Subjects signed a written agreement not to attempt to break the blind.

Data were collected by questionnaires at baseline, 4 weeks, and 8 weeks. Primary outcome measures were pain intensity ratings using the 10-cm visual analogue scale and categorical response to treatment on a 5-point Likert scale. Other measures assessed interference with employment and pleasure using the 10-cm visual analogue scale and identification of adverse events. Daily diary entries recorded time of wearing the devices and pain intensity ratings. No serious adverse events were reported and no subjects exited early because of adverse effects.

Subjects treated with magnetic and nonmagnetic insoles reported reduction of morning foot pain intensity and decreased interference with work at 8 weeks compared with baseline. Differences between groups were not significant.

Comments

1. Interindividual variability in description of the pain is not provided. Also, a reproduction of the insole with exact placement of the magnetic foil is not given. One potential reason for failure is that the field produced by the foil did not reach the tenderest plantar regions, especially the heel. No evidence of efficacy in a model system is referenced as a rationale for studying this device in the manner described.

2. Components of the complex pain were not assessed separately.

3. The blind was deemed to be intact because only about half (not different from chance) of the individuals in each treatment group correctly guessed which device they had. Also, individuals subscribed to an honor system that they would not try to assess the nature of the insoles which they received randomly.

4. An objective measure such as time required to walk 50 feet or videotapes of gait for assessment of improvement might have provided a different perspective. Observations by study personnel, e.g., reexamination of the feet to compare pain components with baseline, were not included. Only subjective measures by the subjects in the form of questionnaires were assessed. This precludes checking for internal consistency between instruments of measure. Also, patients may tend to base their pain intensity assessments on residual pain components, rather than the component(s) that resolved, thereby preventing detection of improvement in one or more components of the pain.

5. Morning pain intensity decreased on average about 42 to 43% in both treatment groups in the course of 8 weeks. This was not significant statistically. Either the placebo effect was large or one or more components of the plantar heel pain tended to resolve over time, or both. Including earlier data collection points, e.g., at 24 hours and 1 week, might have afforded assessment of efficacy and magnitude of the placebo effect before spontaneous resolution of pain.

6. Roughly three quarters of individuals in each group had used insoles before. Stratification by experience with insoles was not examined. Enrollment of larger numbers of individuals naïve to the use of insoles may have been difficult due to the long duration of preexisting pain (mean of 120 months in the group with nonmagnetic insoles; 86 months with magnetic insoles). It is not clear how many had used magnetic insoles previously, thereby creating a bias of expectations. There is some evidence of bias in the collected data. Irrespective of treatment group, individuals who believed in the efficacy of magnets had significantly lower morning pain intensity scores at 8 weeks than those who did not believe. The percentage of "believers" in the two groups is not given. The absence of significant differences between groups argues against the importance of such bias as a determinant of outcomes.

CONCLUSIONS

Studies of magnetic devices must be carefully tested and designed to optimize the likelihood of determining significant benefit. Careful attention to every aspect of study design is necessary in the testing of magnetic

devices. As shown above in the spirit of a reviewer for a journal or for the FDA, there are shortcomings in the design, execution, and analysis of clinical studies involving therapeutic magnets. However, it is also clear that the quality of studies is improving (Table 84.1). The results of well-performed studies are likely to be of greater interest to the general medical community because of confidence in the methods. The question remains about a breakpoint at which therapeutic magnets become acceptable to the medical community at large. FDA approval of devices for specific indications will undoubtedly move this moment forward. Also, there is much basic scientific work to be done, not only to demonstrate robust effects but also to elucidate physical transduction mechanisms and provide a rational basis for expecting therapeutic benefits.

Many intangibles will determine the fate of magnetism in medicine, among them the number of interested researchers, the number of well-performed positive studies, and the availability of adequate funding to support research. The cost of bringing a new drug to market is estimated at $500,000,000. Financial resources of this magnitude are found only in pharmaceutical companies and federally funded programs. Currently, companies that market therapeutic magnetic devices, content to profit from sales of magnets as wellness aids, supply little money to support research. Perhaps there is a perception that the potential risk of failing in clinical trials is commercially unacceptable compared with whatever increase in profitability might accrue from regulatory approval. Support from federally programs, such as the National Centers for Complementary and Alternative Medicine, for research involving proprietary devices is helpful but complicated by potential conflicts of interest of manufacturers. Industrial funding of large pivotal trials has been uncommon until recent years. Attracting funding and establishing high-quality research programs that can compete for funding with programs employing conventional approaches remain significant challenges for researchers interested in magnetic therapies.

Focal treatment with therapeutic magnetics is a double-edged sword. One would expect fewer side effects, but the chance of showing therapeutic benefit is made more difficult by local application of devices. The clinical trials mentioned above revealed no significant adverse effects of magnetic fields in the millitesla range. This is encouraging, but chronic intermittent effects of using skin-attached magnetic devices have not been evaluated. Further study is needed to reveal the true magnitude of treatment benefits and to clarify the apparent freedom from adverse effects encountered in the use of therapeutic magnets in the peer-reviewed literature.

TABLE 84.1
Controlled Studies of Efficacy of Static Magnet Field-Producing Devices in the Treatment of Diverse Pains

Study	Type of Pain	Study Design	No. Enrolled	Magnetic Device[a]	Placebo Device[b]	Duration of Masked Period	Security of Masking[c]	Instrument(s) of Measure	Outcome	Adverse Events
Holcomb et al., 1991	Mechanical low back and knee pain (pilot study)	R, DM, PBO, XO	54 (41, low back; 13 with OA of the knee)	Magna Bloc, 7 devices over low back, 4 over knee	Nonmagnetic devices	Two 24-h periods, 1 week apart, continuous wearing	Intact per physician and patient "Intactness of Blind" forms	VAS (10 cm line)	Magnetic devices superior to PBO ($p < 0.03$)	Discomfort due to pad designed to protect blind
Vallbona et al., 1997	Trigger point pain, postpolio syndrome (pilot study)	R, M, PBO, PG	50	Bioflex, discs and pads of two different strength = 4 devices	Nonmagnetic discs and pads	45 min, continuous wearing	Assumed to be intact, patients under observation in waiting room	McGill Pain Questionnaire	Magnetic devices superior to PBO ($p < 0.0001$)	Not reported
Borsa & Liggett, 1998	Exercise-induced biceps pain and microinjury	R, SB, PBO, PG	45	Nikken, 5 cm × 8 cm × 3 mm pad	Nonmagnetic pads	72 h post-exercise, continuous wearing	Not reported	VAS (10 cm line), range of motion, arm girth, force production	No significant differences reported	Not reported
Weintraub, 1999	Painful diabetic and nondiabetic neuropathy, burning and numbness/ tingling assessed, both feet treated	R, XO with PBO (1 month on each foot), then 2 months with two active devices	10 with diabetes, 9 other	Nikken Magstep insoles	Nonmagnetic insole	4-month study period, continuous wearing	Dubious with nonmagnetic PBO	Nonvalidated 5-point pain intensity scale ($0 =$ none, $4 =$ worst)	No change during PBO treatments; significance reported vs. nondiabetics ($p < 0.02$)	Devices intolerable due to pain ($N = 2$); withdrawals due to surgery for persistent infection ($N = 2$)
Colbert et al., 1999	Fibromyalgia	R, DM, PBO, PG	30 of 35 women screened entered, 25 completers	Magnetherapy, Inc, magnetic mattress pad	Nonmagnetic mattress pad	4-month study period, sleeping on pads nightly	Honor system; not objectively assessed	VAS for global well-being, sleep, pain, fatigue; Total myalgic score; pain distribution drawings; Fibromyalgia Impact Questionnaire	Significant decreases in most outcome measures in both groups from baseline; difference between groups not significant	None
Collacott et al., 2000	Chronic low back, multiple pathologies (pilot study)	R, DM, PBO, XO	20	Nikken[d] back pad (trapezoid, 19 × 11.5 × 14 cm, 2 mm thick	Nonmagnetic pads	Two 1 week periods, 1 week apart; devices on 6 h per day, 3 days per week	Not reported; dubious with nonmagnetic PBO	VAS, McGill Pain Questionnaire, range of motion testing	No significant differences reported	None
Alfano et al., 2001	Fibromyalgia	R, DM, PBO, PG	119 enrolled; 94 completers, 13 dropouts, 8 incorrect randomizations, 4 did not complete the assessment at 6 months	Magnetic mattress pads from two sources (MagnetiCo, Inc and Nikken, Inc.)	Nonmagnetic versions of both active pads	6 months	Subjects blinded to treatment group assignments; not objectively assessed	Pain intensity ratings (11 point scale); Fibromyalgia Impact Questionnaire; tender point count and pain intensity	No significant differences between treatment groups	No magnet-related AEs; no difference in incidence between groups

TABLE 84.1 (Continued)
Controlled Studies of Efficacy of Static Magnet Field-Producing Devices in the Treatment of Diverse Pains

Study	Type of Pain	Study Design	No. Enrolled	Magnetic Device[a]	Placebo Device[b]	Duration of Masked Period	Security of Masking[c]	Instrument(s) of Measure	Outcome	Adverse Events
Segal et al., 2001	Pain associated with rheumatoid arthritis of the knee	R, DM, PG, AC, MC	64, intent-to-treat	Magna Bloc, 4 devices in diamond pattern around knee	4 magnetic control devices of different design in diamond pattern around knee	1 week	Intact based on preservation of positioning of devices and all devices were magnetic	Physicians' assessments at time 0, 1 h, 1 day, 1 week; patient diaries; VAS for pain intensity; subject and rheumatologist GADA; MHAQ; subjects assessment of treatment outcome	No significant difference between groups with respect to pain reduction; Magna Bloc superior to other magnetic device by S-GADA ($p < 0.01$) and subjects assessment of treatment outcome at 1 week ($p < 0.001$)	No serious AEs
Hinman et al., 2002	Chronic pain associated with degenerative disease of one or both knees	R, DM, PBO, PG	43 (18 randomized to magnetic devices; 25 to placebo), completer analysis	4 unipolar magnetic discs in self-adherent bandage (Relieve Pain Today brand)	Nonmagnetic discs	2 weeks	Two subjects accidentally broke blind, identified magnetic devices	WOMAC	Magnetic devices superior to placebo with respect to self-treated pain ($p < 0.001$), function ($p < 0.002$), and gait speed ($p < 0.04$)	None reported
Weintraub et al., 2003	Moderately to severely painful diabetic neuropathy	R, DM, PBO, PG, MC	258 per protocol (48 sites)	Magsteps[d] magnetic insoles (Nikken, Inc.)	Nonmagnetic insoles	4 months after 2-week baseline	Intact per physician and patient by questionnaire	Daily VAS for numbness, tingling, and burning; sleep interference scores	Magnetic devices reduced pain more than PBO ($p < 0.05$; $p < 0.01$ for severe pain); sleep not significantly different	29% (magnets) and 33% (PBO) dropouts for administrative reasons, allodynia, and nonstudy-related complications
Winemiller et al., 2003	Plantar heel pain (plantar fasciitis)	R, DM, PBO, PG	101 randomized, completer analysis	Active Comfort magnetic insoles (Spenco Medical Corp.)	Nonmagnetic insoles	8 weeks	Honor system; about half in each group guessed treatment (not different from chance)	Reported average daily foot pain (VAS); morning foot pain; categorical response of change from baseline; impact on employment and pleasure	No significant differences between groups	No serious AEs reported

Abbreviations: AC = active control; AE = adverse effect; DM = double-masked; MC = multicenter; OA = osteoarthritis; PBO = placebo or placebo-controlled; PG = parallel group; R = randomized; SM = single-mask ed; VAS = visual analogue scale; XO = crossover.

[a] See text for description of device design. All devices tested were commercially available.
[b] Placebos were identical in appearance to the magnetic devices used in the respective study. In some cases, nonmagnetic placebos were provided by the manufacturer.
[c] Interpretations/comments by authors of this review.
[d] Not specifically stated in published paper. Assumed from description in methods and inferred by communication with one of the authors.

Recurrent and Chronic Pediatric Pain

Paola M. Conte, PhD, and Gary A. Walco, PhD

INTRODUCTION

Chronic pain is a frequent complaint in childhood and adolescence and is estimated to affect 15 to 20% of children (Goodman & McGrath, 1991). In addition to the suffering this brings, there are significant physical, socioemotional, and financial consequences related to pain and disability for both children and families. Literature on the long-term effects of pain in early childhood raises interesting questions about permanent changes in pain processing and increased sensitization to noxious stimuli that may persist years into the future (Fitzgerald & Howard, 2003). The interface between pain, mood disorders, and broader social and emotional adjustment seems obvious, yet few studies have systematically examined these effects in children (Bursch, Walco, & Zeltzer, 1998). The relationship between pain experiences and chronic pain in childhood and clinical pain problems in adulthood is an area discussed from a theoretical standpoint, but little has been done empirically (Campo et al., 2001; Walco, 2004; Walco & Harkins, 1999). There is a great deal of literature on the fiscal impact of chronic pain in adults (Turk, 2002), and one can only speculate on the financial impact of lost wages and decreases in productivity from work missed to care for a child in pain. Perquin et al. (2000) found that 25% of a sample of children and adolescents aged 0 to 18 years had chronic pain (defined as continuous or recurrent pain for more than 3 months), of whom 57% consulted a physician and 39% used medication for the pain, clearly adding to costs of medical care. In sum, chronic and recurrent pain in children is hardly a trivial concern that children will merely outgrow (McGrath & Finley, 1999).

Recurrent and chronic pain syndromes in children may be categorized into major types, based principally on the character of the pain and its presumed etiology (McGrath, 1999): pain associated with chronic illness (e.g., juvenile rheumatoid arthritis, cancer, sickle cell disease), pain resulting from trauma (e.g., complex regional pain syndrome, phantom limb pain), chronic nonspecific pain (e.g., musculoskeletal pain, dysmenorrhea), recurrent pain (migraine headache, recurrent abdominal pain), and pain related to mental health (e.g., psychogenic pain disorder, somatization disorder). Although conceptually these categories may be distinct, in practice there may be significant blurring and thus strategies for assessment and intervention are not always so clear (McGrath & Finley, 1999).

EPIDEMIOLOGY OF RECURRENT AND CHRONIC PAIN IN CHILDREN

Studies on the prevalence of chronic pediatric pain suffer from numerous methodological limitations such as varying definitions of recurrent and chronic pain, sampling techniques, and methods of data collection (Goodman & McGrath, 1991). As a result, estimates of prevalence reflect orders of magnitude in variance, a finding that transcends virtually all categories of pain defined above.

PAIN ASSOCIATED WITH CHRONIC ILLNESS

Musculoskeletal pain related to inflammatory process is a major source of pain in children. Estimates of the prevalence of juvenile rheumatoid arthritis vary from 56 to 460 cases per 100,000 children under the age of 16 years. Within that group, there are no systematic data regarding the prevalence of ongoing or recurrent pain, but available clinical data indicate that untreated pain is a significant

problem and has a substantial impact on adaptive functioning (Lovell & Walco, 1989; Schanberg et al., 2003).

In a similar vein, it is estimated that there will be 9,200 new cases of childhood cancer in the United States each year (American Cancer Society, 2004). Available data indicate that approximately 62% of those children experience pain as a first symptom of their disease (Miser et al., 1987b), but this pain dissipates fairly quickly after the initiation of antineoplastic treatment. Iatrogenic pain associated with cancer treatment arises in about 25 to 54% of cases and principally includes oral pain from mucositis and joint pain associated with chemotherapeutic agents, such as vincristine (Miser et al., 1987a). Procedure-related pain, which is more focused on acute distress, presents difficulties for over half of children treated and may have implications for later difficulties in coping with recurrent and chronic pain (Conte & Walco, in press). Recent data also indicate that long-term survivors of childhood cancer may be faced with various pain problems months to years after completing treatment (Crom et al., 1999).

Recurrent episodes of intense acute pain associated with vaso-occlusion are a major challenge for children and adolescents with sickle cell disease. Common presentations include pain in any part of the body, as well as acute hand–foot syndrome, acute joint inflammation, acute chest syndrome, splenic sequestration, intrahepatic sickling, abdominal pain, and priapism, as well as the more chronic conditions of avascular necrosis and neuropathic pain (American Pain Society, 1999). Recent diary data indicate that these problems are quite common, as patients between the ages of 6 and 21 years required analgesic medication on 88% of the days and 76% of the nights (Dampier et al., 2002).

Pain Associated With Trauma

Perhaps the most common pain problem associated with trauma among children and adolescents is complex regional pain syndrome (CRPS), type 1 (formerly known as reflex sympathetic dystrophy). Although the exact incidence of CRPS in children is not known, it is being recognized with increasing frequency (Wilder, 2003). Among adolescents, it is far more common in females than males (estimated 6:1 ratio) and more common in lower than upper extremities (5:1). In one clinical series, it was reported that CRPS is most likely to occur in highly stressed adolescents, often involved in individual competitive sports (Wilder et al., 1992).

Chronic Nonspecific Pain

Epidemiological studies indicate that many children and adolescents experience significant episodes of chronic, nonspecific pain at least once in their lifetime. Included are knee pain (up to 18.5%), back pain (7.6 to 34%), and dysmenor-

rhea (from as low as 5% up to 79%, with 51% of girls describing pain as moderate to severe; McGrath, 1999).

Although one might debate the specific category into which it might belong, juvenile fibromyalgia syndrome represents another entity of rather diffuse, nonspecific pain. Many of the features of this syndrome parallel those found in adults, but very few systematic studies of epidemiology in children are available. Mikkelsson et al. (1997) studied almost 2,000 Finnish children between the ages of 9 and 12 and found a prevalence rate of 1.25%. This age range is quite restricted, however, and it would seem to occur with even more frequency in older teens. The majority of patients are female, with estimates as high as almost 94% (Yunus & Masi, 1985). The prevalence of juvenile fibromyalgia forms approximately 7% of new referrals to pediatric rheumatology clinics (Siegel, Janeway, & Baum, 1998).

Recurrent Pain Syndromes

Perhaps the inadequacy of diagnostic criteria is reflected best when discussing the prevalence of certain recurrent pain syndromes. For migraine headaches, estimates range from as low as 1.4% overall to as high as 28% in older adolescents (Split & Neuman, 1999). The estimated prevalence of recurrent abdominal pain was 10 to 15% of school-age children in one study (Liebman, 1978), but has been reported as high as 32% when focused on single episodes in a 1-year period (Abu-Arefeh & Russell, 1995). Recurrent limb pain, not specifically focused in the joints, ranges from as low as 4.2% to as high as 33.6% of children, depending on definitions and inclusion criteria of the study (McGrath, 1999).

NO THANKS RENÉ DESCARTES: INTEGRATED MODELS OF CHRONIC PAIN AND DISABILITY

Chronic pain is not acute pain that continues on for some arbitrarily defined period of time. Even when acute pain recurs, the first episode may hardly be considered essentially the same as the *n*th occurrence. Acute pain typically signals a specific nociceptive event and is self-limited. Chronic or recurrent pain in children is the result of an integration of biological processes, psychological factors, and sociocultural contexts, all of which must be considered within a developmental framework.

With chronicity there are qualitative, and not simply quantitative, shifts in the severity, characteristics, and regularity of pain. Ongoing pain can result in sensitization of the peripheral and central nervous systems to produce neurophysiological, neurochemical, and neuroanatomical changes (Woolf & Salter, 2000). In addition, the extent of disability related to chronic pain may vary from none to severe, and the system may be maintained independent of tissue damage (American Pain Society, 2001).

A comprehensive review of the development of pain pathways and the impact of untreated pain is beyond the scope of this chapter. In summary, it has been demonstrated that by 24 weeks gestation the nerve pathways necessary for transmission and perception of pain are established. Recent findings have shown that the failure to provide adequate analgesia for pain can result in "rewiring" nerve pathways responsible for pain transmission in the dorsal horn of the spinal cord and can result in increased pain perception in the future (Coggeshall, Jennings, & Fitzgerald, 1996; Craig et al., 1993; Fitzgerald, 1999; Fitzgerald, Shaw, & MacIntosh, 1998; Porter, Grunau, & Anand, 1999). A possible clinical implication of such changes comes from a study that showed a relationship between analgesia for newborn circumcision and longer-term behavioral changes in response to the pain of routine immunizations 3 to 4 months later (Taddio et al., 1997). Another study found that premature infants who experienced repeated invasive procedures continued to display adverse behavior at the age of 18 months (Grunau et al., 1994). Studies such as these may begin to elucidate the relationship between acute pain experiences and later difficulties with chronic pain, but much more needs to be done to define specific changes, related mechanisms, and durability.

Developmental studies, as well as recent data on chronic pain mechanisms in adults, make it clear that what used to be considered "psychological" or "supratentorial" factors related to pain have some identifiable neurophysiological bases (Zeltzer, Bursch, & Walco, 1997). To view pain as purely physiologically based ("real" pain) versus pain that is strictly psychogenic in nature ("it is all in the patient's head") is virtually nonsensical and such mind–body dualism must be avoided if we wish to make progress in this field. Such dichotomization may also lead clinicians to pursue unnecessary or inappropriate diagnostic procedures and invasive interventions that ultimately are not helpful and may in fact be harmful (Zeltzer et al., 1997).

ASSESSMENT OF RECURRENT AND CHRONIC PAIN

An evaluation of chronic pain should include assessment of biological, psychological, and sociocultural factors in a developmental context (Bursch et al., 1998). The evaluation should begin with the history of the current problem, including description of the pain, detailing the sensory nature, intensity, quality, location, duration, variability, predictability, exacerbating and alleviating factors, and impact of pain on daily life (e.g., sleeping, eating, school, social and physical activities, family and peer interactions). A detailed account of the history, evaluation, and treatment of the pain problem in terms of onset and

development should be obtained. Information should be gathered on the level of distress for the child and family, which can be attributed to the pain and the impact of the pain on cognitive functioning, anxiety, depression, and feelings of hopelessness. Information should be solicited on the child's and family's perceptions of the cause of the current pain problem, history of any past pain problems and how they resolved, and a family history regarding significant illness and or pain problems (Zeltzer et al., 1997). Additionally, a pediatric history should include a history of surgeries and hospitalizations; birth and early childhood history; developmental milestones; social history including school, social life, and activities; and family medical and social history.

In general, the physical examination should include appearance, posture, gait, and emotional and cognitive state. Vital signs should include height weight, blood pressure, heart rate, respiratory rate, and temperature. A brief neurological examination should be included, as well as trigger points and areas of sensitivity to light touch. One should evaluate responses to stimulation of painful sites and be vigilant to pain behaviors, such as compensatory posturing, guarding, rubbing, and moaning. The consistency of such pain behaviors should be observed, as well as the relationship between pain behaviors, pain reports, parental pain reports, and various environmental stimuli. The precise methods of all aspects of the history, pain assessment, and physical examination depend on the presenting issue and characteristics of the child, including developmental status (Bursch et al., 1998).

In contrast to simple assessments of acute pain, the evaluation of recurrent or chronic pain should also include a good deal on contextual factors. Consider the following issues and questions:

1. What is the relationship between the nature and severity of the pathophysiology underlying pain and the child's pain experience?
2. What is the nature of the development of experimental indices, such as pain threshold, pain tolerance, and pain responsiveness, and how do those relate to clinical pain experiences?
3. What is the relationship between physiological maturation and pain, especially around critical periods in development, such as infancy and puberty?
4. What role does gender play in pain, to what degree are those factors genetically based versus environmental, and how do gender-related factors interact with other developmental processes?
