25 Reproductive Aspects of Epilepsy Treatment

Torbjörn Tomson

Karolinska University Hospital, Stockholm, Sweden

While reproductive health is regarded as one of the most important health issues for women with epilepsy, surveys in different countries have repeatedly revealed marked deficiencies in the provision of health care and advice on this issue. Only a minority of women with epilepsy who plan to have children have any pre-pregnancy counselling and knowledge among health-care providers about the reproductive health of women with epilepsy is often inadequate. To be worthwhile, counselling should ideally be provided long before pregnancy in order to allow for adequate treatment measures which reduce risks. Reproduction may be more complicated for people with epilepsy for a number of reasons related to epilepsy and to its treatment. Although most women with epilepsy will be able to give birth to perfectly normal children, a number of questions are raised when they consider becoming pregnant, and these need to be addressed early in the pregnancy planning.

Fertility may be altered, and the efficacy of steroid oral contraceptives may be reduced by certain antiepileptic drugs (AEDs). Epilepsy might affect the outcome of pregnancy and there may be increased risks of obstetric complications. Seizure control may change during pregnancy and treatment may need to be adjusted because of altered pharmacokinetics of AEDs. Fetal risks associated with uncontrolled seizures during pregnancy need to be weighed against the teratogenic effects and other potential developmental toxicity of AEDs. The possibility for a woman on AEDs to nurse her child also needs to be discussed.

Fertility

Studies indicate lower fertility rates among men and women with epilepsy than in the general population [1]. There are many possible causes for reduced fertility rates among people with epilepsy. Social isolation and stigmatization may contribute, which also explain why marriage rates are reported to be lower. Women may also refrain from pregnancy because of fears of deterioration in their epilepsy or risks to the fetus incurred by seizures or the drug treatment. The lesion causing epilepsy and the epileptic activity as such may also induce endocrine dysfunction that could affect fertility. Some studies, however, suggest that concurrent disabilities and co-morbidities (e.g. learning disabilities or cerebral palsy) could be the major cause [2,3]. Fertility rates among people with epilepsy were essentially normal in two population-based studies from Iceland and Finland when people with such severe co-morbidities were excluded [2,3]. Treatment with AEDs has also been considered to contribute to lower fertility and other reproductive dysfunction.

Reproductive dysfunction

Reproductive dysfunction and endocrine disorders are common among both men and women with epilepsy. In men, this will manifest itself as loss of libido, reduced potency and infertility; in women, by menstrual dysfunction, hirsutism and infertility. In some studies, between 40% and 70% of men with epilepsy report decreased potency and hyposexuality, but this apparently high figure needs to be related to the proportion among control populations [4]. Rättyä *et al.* [5] evaluated sexual function, including libido, potency, satisfaction with erection and orgasm, in men, 18–50 years of age, under treatment with an AED in monotherapy. Of these, 77% were considered to have a normal sexual function compared with 88% among healthy age-matched control subjects. Menstrual disorders are more common among women with epilepsy, occurring in one-third compared with 12–14% in the general population [6].

Whether reproductive dysfunction is related to the underlying epilepsy is still controversial, but it has been suggested that epileptiform discharges may promote the development of reproductive endocrine disorders by disruption of normal temporo-limbic modulation of hypothalamopituitary function [6]. This hypothesis is supported by observations of lower testosterone levels in men with temporal as compared with extratemporal foci and that successful temporal lobe epilepsy surgery may lead to a normalization of low preoperative serum androgen concentrations [7].

Treatment with AEDs can also contribute to reproductive dysfunction. Enzyme-inducing drugs such as carbamazepine, phenytoin and phenobarbital may increase the concentration of sex hormone-binding globulin (SHBG) and reduce the unbound, biologically active concentrations of testosterone [8]. In a cross-sectional study, monotherapy with carbamazepine was associated with decreased serum androgen levels and high SHBG concentrations in men with predominantly partial seizures. Oxcarbazepine treatment in doses of at least 900 mg/day was associated with similar endocrine effects. In contrast, serum androgen levels were increased in 12 out of 21 men treated with valproic acid for generalized or partial seizures [5].

Infertility in men may also be related to impaired spermatogenesis or sperm function. Poor sperm motility was noted in epileptic patients with long-term AED treatment and *in vitro* studies

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

suggest a direct effect of phenytoin, carbamazepine and valproic acid on sperm membrane function [9]. A cross-sectional small study of men with epilepsy suggested that all investigated drugs, carbamazepine, oxcarbazepine and valproic acid, were associated with an increase in abnormal sperm morphology [9], although the clinical relevance of these findings remains to be shown.

The discussion on reproductive endocrine disorders in women with epilepsy has focused on polycystic ovaries (PCO) and polycystic ovarian syndrome (PCOS). PCO, which is normally a diagnosis made on ultrasound examination and which may be asymptomatic, is a common condition with an estimated prevalence of about 20% in the general population. PCOS has been defined as ovulatory dysfunction with clinical evidence of hyperandrogenism and/or hyperandrogenaemia in the absence of identifiable adrenal or pituitary pathology, although criteria vary between researchers. PCOS is a syndrome with multiple aetiologies and a prevalence ranging from about 4% up to 18% in the general female population, depending on the criteria and the population studied and probably higher, 10–20%, in women with epilepsy [6]. Genetic as well as environmental factors can contribute to the development of this syndrome.

Cross-sectional studies from Finland, Norway, the Netherlands and the UK have indicated that polycystic ovaries and hyperandrogenism, and PCOS are related to the drug treatment and specifically to treatment with valproic acid [8]. In these studies 30–40% of patients treated with valproic acid had polycystic ovaries and hyperandrogenism, compared with 5–15% among those taking carbamazepine or lamotrigine. However, two studies from other epilepsy populations found no difference between women taking valproic acid and carbamazepine in this respect [10,11]. A randomized open-label study compared the development of PCOS after 12 months on valproic acid and lamotrigine [12]. Hyperandrogenism and ovulatory dysfunction was found in 44% of those randomized to valproic acid compared with 23% of those on lamotrigine if treatment was initiated before 26 years of age, whereas the rates were similar (24% versus 22%) if treatment was started above 26 years.

In many patients, reproductive endocrine dysfunction appears to be reversible on withdrawal of or change in AED treatment. A switch from valproic acid to lamotrigine in women with polycystic ovaries and hyperandrogenism whilst on valproic acid was associated with normalization [8], and so was withdrawal of valproic acid in a large proportion of patients in a 5-year follow-up study [13]. Taken together, these observations confirm that valproic acid can indeed induce polycystic ovaries and hyperandrogenism, although the role may not be as important as reported in the initial cross-sectional studies from Finland.

Withdrawal of carbamazepine in seizure-free male and female patients has also been associated with normalization (increase) of serum testosterone and free androgen index [14].

Two cross-sectional studies assessed endocrine function in a younger female population with epilepsy [15,16]. A cohort of 77 girls, 8–18 years of age, under treatment with valproic acid (n = 40), carbamazepine (n = 19) or oxcarbazepine (n = 18) were compared with 49 healthy age-matched controls. No difference was observed in linear growth and sexual maturation [15]. When 41 girls on valproic acid were compared with 54 healthy controls, hyperandrogenism was observed more frequently among the valproic acid-exposed girls, but the incidence of polycystic ovaries or menstrual disturbances was not increased [16]. A long-term follow-up of these cohorts revealed normal endocrine function in those that had come off medication but an increased prevalence of endocrine disorders including PCOS among those remaining on AEDs into adulthood [13].

Choice of antiepileptic drug

Given the partly conflicting data concerning the association between valproic acid and reproductive dysfunction, and the excellent effectiveness of this drug, particularly in idiopathic generalized epilepsies, valproic acid is still a reasonable first choice in young women with these types of epilepsy, unless they can be assumed to become pregnant while on treatment (see below). However, based on the intriguing observations discussed above, the patients should be monitored closely. If adverse effects such as considerable weight gain or menstrual disturbances occur, a change in drug therapy should be considered. The potential role of AEDs always needs to be considered in women and men with epilepsy with reproductive dysfunction, and in such cases it may be necessary to reassess the choice of treatment [17].

Birth control

Contraception in women with epilepsy is complicated by the bidirectional pharmacokinetic interactions between AEDs and steroid oral contraceptives. Enzyme-inducing AEDs may reduce the effectiveness of oral contraceptives by inducing the metabolism of the oestrogen and progestagen components, and possibly also by increasing the hepatic synthesis of SHBG, thus decreasing the unbound, active concentration of progestagen. This may lead to contraceptive failure and an increased frequency of unplanned pregnancies [18]. AEDs with and without known inducing effects on oral contraceptives are listed in Table 25.1.

Depot injections of medroxyprogesterone, hormone-releasing intrauterine systems and other intrauterine contraceptive devices seem to be unaffected by enzyme inducers and could be good alternatives for some women [18].

If this is not an alternative, patients treated with enzyme-inducing AEDs are often recommended oral contraceptives with an oestrogen content of at least 50 μg. Whether this dose is sufficient, however, is uncertain. Others, therefore, recommend either the use of a combined oral contraceptive with a progestin dose well above the dose needed to inhibit ovulation, or continuous use of combined contraceptive pills without a pill-free interval [19]. Where available, tricycling is another alternative. These are combined oral contraceptives given continuously for three sets of 21 days followed by 7 days' pause.

Estradiol-containing oral contraceptives, on the other hand, induce the elimination of lamotrigine. Lamotrigine serum concentrations decline by approximately 50% when such contraceptives are introduced. This can lead to breakthrough seizures unless the lamotrigine dose is adjusted. These changes occur rapidly and hence lamotrigine levels rise during the pill-free week if sequential pills are used [20]. This may induce toxic symptoms. Preliminary data suggest that estradiol may have a similar effect on serum concentrations of valproic acid. Pure progestagen-containing pills

Table 25.1 Pharmacokinetic interactions between steroid oral contraceptives and antiepileptic drugs.

Drugs which increase the clearance of oral contraceptives	Drugs which do not affect the clearance of oral contraceptives	Drugs in which the clearance is induced by estradiol-containing oral contraceptives
Carbamazepine	Benzodiazepines	Lamotrigine
Felbamate	Gabapentin	Valproic acid
Lamotrigine[a]	Levetiracetam	
Oxcarbazepine	Pregabalin	
Phenobarbital	Tiagabine	
Phenytoin	Valproic acid	
Topiramate (at dosages >200 mg/day)	Vigabatrin	
	Zonisamide	

[a] Lamotrigine does not affect estradiol concentrations but has a modest effect (18% reduction in plasma concentration) on the norgestrel component of the combined oral contraceptive.

do not seem to affect lamotrigine serum concentrations, and concomitant use of valproic acid appears to block the estradiol-induced effects on lamotrigine kinetics [21].

Women need to be informed about these clinically relevant bidirectional interactions. Enzyme-inducing properties should be taken into account when choosing an AED for a woman on oral contraceptives. Given the choice of two drugs similar in all other important respects it is reasonable to select a drug known not to interact with oral contraceptives. The possibility of using complementary or alternative contraceptive methods should also be discussed, and it should be stressed that the effectiveness of many contraceptive methods other than the intrauterine device may actually be lower than that of an oral contraceptive taken together with enzyme-inducing drugs. Women on lamotrigine who are started on estradiol-containing pills should have their dosage increased guided by drug level monitoring, and pills are best avoided.

Pregnancy in women with epilepsy

In the treatment of epilepsy during pregnancy, maternal and fetal risks associated with uncontrolled seizures need to be weighed against the increased risk of adverse outcomes in the offspring due to maternal use of AEDs.

Effects of maternal seizures on the fetus

Epileptic seizures in a pregnant woman may have adverse effects on the fetus, in addition to risks for the woman. With respect to the risks to the fetus, effects of generalized tonic–clonic seizures are probably different from effects of other types of seizures [22]. Tonic–clonic seizures are associated with transient lactic acidosis, which is likely to be transferred to the fetus. Prolonged decrease in fetal heart rate, which is a common response to acidosis, has been reported after maternal tonic–clonic seizures. Furthermore, generalized tonic–clonic seizures induce alterations in blood pressure and blood flow, but it is presently not known to what extent this affects uterine blood flow and thus the fetus. Seizure-related maternal abdominal trauma could also, theoretically, cause injury to the fetus or placental abruption. Despite these effects, intrauterine fetal death as a result of a single seizure appears to be rare and only a few such reports have been published. In contrast, prolonged seizure activity, such as status epilepticus, may be a serious threat to the fetus as well as to the woman. In an early review, fetal death was reported in about 50% of cases with status epilepticus during pregnancy, and in 30% of the mothers [23]. This is in contrast to the results of a recent large prospective study, which reported only one case of intrauterine death and no maternal mortality among 36 women with status epilepticus (12 of whom were convulsive) [24]. According to most prospective studies, seizures during early pregnancy are not associated with an increased risk of birth defects. However, occasional reports have indicated an increased risk for cognitive dysfunction in the offspring of women who have had more than five convulsive seizures during pregnancy [25], although conclusive evidence for a causative role of the seizures is lacking.

Other types of seizures are in general unlikely to affect the fetus when they occur during pregnancy unless they lead to a secondarily generalized tonic–clonic seizure. However, they may cause some risks if the seizure results in injury or trauma.

Generalized tonic–clonic seizures during labour can cause fetal asphyxia. Partial seizures that impair consciousness may also impose risks since the mother's ability to co-operate during the delivery is lost. In such situations, Caesarean delivery should be considered.

In conclusion, our knowledge concerning fetal risks associated with maternal seizures is based on case reports rather than systematic studies and we lack quantitative risk estimates. Nevertheless, there is a general consensus among physicians that in particular generalized tonic–clonic seizures should be avoided during pregnancy for the sake of the well-being of the fetus as well as the mother.

Seizure control during pregnancy and delivery

The largest prospective study of seizure control in pregnancy to date reported that 59% of 1736 women remained seizure free throughout pregnancy [24]. Earlier studies, mainly from specialized epilepsy centres, indicated that approximately one-third of women with epilepsy will experience an increase in seizures during pregnancy [26]. Prospective studies of fewer selected women with epilepsy suggest that the proportion of women who deteriorate is smaller [22]. Some of the observed changes in seizure frequency are likely to be explained by the normal spontaneous fluctuations in seizure occurrence, but it appears that some periods of pregnancy are associated with a significant increase in seizures. A generalized tonic–clonic seizure occurs during labour in about 1–2% and within 24 h after delivery in another 1–2% [22]. Taking all seizure types together, roughly 5% of women with epilepsy will experience seizures during labour, delivery or immediately thereafter.

Status epilepticus occurs in less than 1% of all pregnancies of women with epilepsy and does not seem to occur more frequently during pregnancy than in other periods of life.

Most studies report that patients with a satisfactory seizure control before pregnancy are less likely to deteriorate than patients with uncontrolled epilepsy [27]. There are observations

suggesting that those women who fail to have prepregnancy counselling are most at risk of deterioration during pregnancy. This agrees with several reports indicating that poor compliance with the drug treatment, often due to fear of the teratogenic effects, is a major cause of loss of seizure control during pregnancy.

Some women may experience onset of a seizure disorder during pregnancy, and they should be investigated according to the same general principles as non-pregnant patients with new-onset epilepsy, although there are some causes of seizures that need to be considered more specifically. If seizures occur for the first time during the last 20 weeks of pregnancy, eclampsia needs to be excluded. Stroke and cerebral venous thrombosis also occur at a higher frequency during pregnancy. The general principles for initiation and choice of AED treatment also apply for women in pregnancy, although treatment is often withheld during the first trimester unless the risk is high for recurrent tonic–clonic seizures.

Pharmacokinetics of antiepileptic drugs during pregnancy

The pharmacokinetics of many drugs undergoes significant changes during pregnancy, which may have consequences for maternal seizure control as well as for fetal drug exposure [28]. At constant drug dosages, serum levels of most of the older AEDs tend to decrease during pregnancy, and return to prepregnant levels within the first month or two after delivery. This appears to be due mainly to a decrease in drug binding to plasma proteins and/or an increase in drug metabolism and elimination. A decrease in protein binding will result in lower total drug levels but leave unchanged the unbound, active concentration of the drug.

By the end of pregnancy, total and unbound concentrations of phenobarbital decline by up to 50% [28]. Total concentrations of carbamazepine decline to a lesser extent and the changes in unbound concentrations are insignificant [28]. Marked decreases in total phenytoin concentrations to about 40% of prepregnancy levels have been reported [28], whereas free concentration decreased to a much lesser extent. For valproic acid, no significant changes were noted in unbound concentrations despite a fairly marked decrease in total concentrations [28]. Hence, for highly protein-bound drugs such as valproic acid and phenytoin, total plasma concentrations may be misleading during pregnancy, underestimating the pharmacological effects of the drugs.

The most pronounced changes have been reported with lamotrigine. In some patients, serum concentrations may decline in late pregnancy to 30% of prepregnancy levels with normalization within a few days post partum [28]. Such alterations in serum concentrations have frequently been associated with deterioration in seizure control [29]. Preliminary data suggest a similar decline in serum concentrations of the active moiety of oxcarbazepine [28] and a fall in serum concentrations of levetiracetam of up to 50% has also been reported [30].

The figures quoted above represent average changes for groups of patients, while the effect of pregnancy varies between individuals. The decline in plasma concentration may be insignificant in some patients and pronounced in others, prompting dosage adjustments to maintain seizure control. Monitoring drug levels is therefore recommended during pregnancy. For highly protein-bound AEDs such as valproic acid and phenytoin, unbound drug levels should ideally be measured. A single drug level is of limited value since the optimal concentration is individual. When pregnancy is planned in advance, it is therefore advisable to obtain serum drug concentrations before pregnancy, when seizure control is optimal, in order to establish a baseline to be used for comparison purposes.

Obstetric complications during pregnancy and delivery

The literature on rates of obstetric complications in pregnant women with epilepsy is somewhat conflicting. Earlier studies suggest that induction of labour and instrumental deliveries are more frequent in women with epilepsy. This may be a consequence of fear of seizures and unfamiliarity with epilepsy among obstetricians rather than a reflection of an increased rate of obstetric complications. More recent studies suggest that, with modern management, there is no significant increase in common obstetric complications among women with well-controlled epilepsy [22,31,32]. However, a Caesarean section might be needed if frequent seizures greatly impair co-operation in the forthcoming labour and delivery or if a generalized tonic–clonic seizure occurs during labour [22]. For these reasons, pregnant women with epilepsy should be counselled by obstetricians who are familiar with epilepsy-related problems and delivery should take place in well-equipped obstetric units.

Developmental toxicity of antiepileptic drugs

The first reports of adverse effects of AEDs on the fetus were published in the 1960s. Since then, all of the major old-generation AEDs, such as phenobarbital, phenytoin, valproic acid and carbamazepine, have been shown to be teratogenic. Adverse effects reported in exposed infants include major congenital malformations, minor anomalies and dysmorphism, growth retardation and impaired postnatal cognitive development. Although the pathogenesis is likely to be multifactorial, including genetic predisposition, socioeconomic circumstances, seizures and epilepsy, the available data strongly suggest that AEDs are the major cause of the increased risks.

Major congenital malformations

A large number of retrospective and prospective cohort studies have confirmed an increased frequency of major malformations in offspring of women treated with AEDs. The prevalence of major congenital malformations has ranged from 4% to 10%, corresponding to a two- to fourfold increase compared with the expected [22,33,34]. Differences in treatment strategy, study populations, controls and criteria for malformations can account for the variation in outcome [34]. Some studies have included untreated women with epilepsy as additional controls. In general, such studies have not found an increased malformation rate among children of mothers with untreated epilepsy [35], suggesting that the increased risk for major malformations in the offspring of women taking AEDs is due to the drug therapy rather than the epilepsy.

Although all major older generation AEDs have been shown to be teratogenic, it is not until recently that sufficiently large studies have been carried out to compare different AEDs with respect to their teratogenic potential. The prevalence of major malforma-

Table 25.2 Malformation rates (%) in infants exposed *in utero* to antiepileptic drugs in monotherapy recently reported from pregnancy registries (*n* = offspring with malformations).

tions in some recent large studies are summarized for the most frequently used drugs in Table 25.2 [36–43]. Malformation rates in association with exposure to a specific AED as monotherapy vary between studies, which could be explained by differences in methodology. However, the prevalence of malformations among children exposed to carbamazepine is consistently fairly low (2.2–4.0%). This observation indicates that with monotherapy and modern management the risks might not be as greatly increased as previously thought. Second, it appears that malformation rates are higher in association with valproic acid than with carbamazepine, and that the risk of major malformations with lamotrigine is similar to that of carbamazepine. Unfortunately, the numbers of pregnant women on other newer generation drugs are still too small to allow a meaningful analysis. Even within-study comparisons of malformation rates need to be interpreted with caution considering the possible effects of confounding factors in these observational studies. Even larger studies are needed to analyse the contribution of seizure control, type of epilepsy, family history of birth defects, and so on.

The drug dosage also needs to be considered in any comparison. A dose–effect relationship has been demonstrated for valproic acid, with significantly higher risks for birth defects with doses exceeding 800–1000 mg/day [22,27,33,37]. One recent study also reported a positive dose–response for malformations with lamotrigine exposure. Doses above 200 mg/day were associated with higher risks [38]. This, however, was not confirmed in the manufacturer's own lamotrigine pregnancy registry [39]. Polytherapy has consistently been associated with a higher risk for major congenital malformations than monotherapy [22,33].

Pregnancy registries have generally compared overall malformation rates, but the pattern of birth defects differs between drugs [22]. Orofacial clefts, congenital heart defects and distal digital defects are more common in children exposed to phenytoin and barbiturates. Valproic acid exposure has been associated with an increased risk of neural tube defects, reported to occur in 1–2% of exposed infants. Valproic acid has also been associated with skeletal abnormalities including radial aplasia. A risk of neural tube defects of 0.5–1% has also been reported after carbamazepine exposure. Carbamazepine is also associated with an increased risk of congenital heart defects and, recently, lamotrigine was reported to be associated with a significant increase in the risk of oral clefts [42].

Minor anomalies and fetal antiepileptic drug syndromes

Minor anomalies are structural variations that are visible at birth but without medical, surgical or cosmetic importance. Such anomalies are common in normal unexposed infants but have been reported to occur more frequently in infants of mothers treated for epilepsy during pregnancy. Combinations of several anomalies are less frequent and can form a pattern, or a dysmorphic syndrome, which may indicate a more severe underlying dysfunction. Facial features such as hypertelorism, depressed nasal bridge, low-set ears, micrognathia and distal digital hypoplasia, sometimes in combination with growth retardation and developmental delay, were first reported in association with exposure to phenytoin. Subsequently, however, similar patterns have been associated with exposure to carbamazepine. Valproic acid exposure has been claimed to cause a somewhat different dysmorphic syndrome characterized by thin arched eyebrows, broad

nasal ridge, short anteverted nose and thin upper lip [44]. However, there is a considerable overlap in the various dysmorphisms and their drug specificity has been questioned [45]. A more general term of fetal or prenatal AED syndrome has therefore been suggested. In addition, the pathogenesis is still somewhat controversial, and Gaily *et al.* [46] attributed most of the minor anomalies to genetic factors rather than drug exposure. Finally, it should be emphasized that minor anomalies are much more difficult to assess objectively than major malformations, and that the incidence of minor anomalies in exposed infants varies markedly between studies.

Growth retardation

Reduced birth weight, body length and head circumference in the offspring of women treated with phenytoin was reported as early as the 1970s. Reductions in body dimensions, in particular head circumference, have been confirmed in several subsequent studies of larger cohorts [47,48]. Most studies report a more pronounced effect in infants exposed to polytherapy. However, the association with specific AEDs in monotherapy varies. Some investigators found an association with phenobarbital and primidone, whereas others report carbamazepine to be more strongly associated with a small head circumference. In a more recent publication, Wide *et al.* [49] studied body dimensions in infants exposed to AEDs *in utero* in a Swedish population over a period of 25 years comparing data with those of the general population. There was a clear trend towards normalization of the head circumference over the time period in parallel with a shift from polytherapy towards monotherapy despite an increasing use of carbamazepine.

Postnatal cognitive development

One of the most important issues is whether exposure to AEDs *in utero* could adversely affect postnatal cognitive development. Long-term follow-up studies of large cohorts of exposed individuals are necessary in order to address this issue. Such studies are difficult to perform and also complicated to interpret since environmental factors become more important with increasing age of the child. A Cochrane review concluded that the majority of earlier studies are of limited quality and that there is little evidence about which drugs carry more risks than others to the development of children exposed [50]. A few studies have been published since then, and indicate that exposure to valproic acid might be associated with specific adverse cognitive effects [25,51,52]. A retrospective study from the UK found significantly lower verbal intelligence quotient (IQ) in 41 children exposed to valproic acid than in unexposed and in children exposed to carbamazepine ($n = 52$) or phenytoin ($n = 21$) [25]. Multiple regression analysis identified exposure to valproic acid, five or more tonic–clonic seizures in pregnancy and low maternal IQ to be associated with lower verbal IQ also after adjustment for confounding factors. Doses above 800 mg/day were associated with lower verbal IQ than were lower doses. These important signals need to be confirmed or refuted in prospective studies. Two small prospective population-based studies from Finland found similar trends for lower verbal IQ in children exposed *in utero* to valproic acid, although the studies were too small (13 children exposed to valproic acid monotherapy in each) to demonstrate statistically significant associations [51,52].

Hence, adequately powered prospective studies are urgently needed to assess long-term cognitive effects of exposure to valproic acid and other AEDs.

Sensitive periods

Sensitive periods in embryonic development with reference to some of the more important major malformations associated with AEDs are summarized in Table 25.3. Obviously, adverse effects of this type occur early, often before the woman is aware that she is pregnant. In contrast, drugs may affect growth and cognitive development throughout pregnancy.

Breastfeeding

Most drugs pass from maternal plasma to breast milk and are transferred to the nursed infant. In general, the amounts thus transferred are much smaller than those transferred via the placenta during pregnancy. The amount that the infant will be exposed to through breastfeeding depends on the maternal plasma concentration, the extent of transfer to breast milk and the amount of milk intake by the infant. Drug exposure of the suckling infant is also dependent on the infant's absorption, distribution, metabolism and elimination of the drug. In particular, metabolism and excretion may be markedly different in the infant compared with children and adults and also vary with the drug in question. Relevant pharmacokinetic information is summarized in Table 25.4 [30,53,54].

Table 25.3 Gestation periods sensitive to specific congenital malformations.

Malformation	Approximate sensitive period (gestational weeks)
Neural tube defects	3–4
Congenital heart defects	4–8
Orofacial clefts	6–10

Table 25.4 Antiepileptic drugs in breast milk and in the breast-fed infant.

Antiepileptic drug	Milk–maternal plasma concentration ratio	Infant–maternal plasma concentration (%)
Carbamazepine	0.1–0.3	10–20
Clobazam	0.1–0.4	
Ethosuximide	0.8–1.0	40–60
Felbamate	?	
Gabapentin	0.7–1.3	4–12
Lamotrigine	0.4–0.8	25–50
Levetiracetam	0.8–1.3	<20
Oxcarbazepine[a]	0.5–0.8	7–12%
Phenobarbital	0.3–0.5	50–100
Phenytoin	0.1–0.6	<10
Pregabalin	?	
Tiagabine	?	
Topiramate	0.7–1.1	9–17
Valproic acid	0–01–0.1	<5
Zonisamide	0.9	

[a] Refers to the active mono-hydroxy metabolite of oxcarbazepine.

For carbamazepine, gabapentin, levetiracetam, oxcarbazepine, topiramate and valproic acid, only small amounts are transferred and serum levels in suckling infants are generally so low that pharmacological effects are unlikely to occur. For ethosuximide and lamotrigine, infant serum concentrations may occasionally reach levels at which pharmacological effects can be seen. However, so far there is no clear evidence for the occurrence of adverse effects in nursed infants. Phenobarbital, and phenobarbital as a metabolite of primidone, can accumulate in the suckling infant, and sedation and poor suckling have been reported. Similarly, sedation may occur due to exposure to benzodiazepines such as diazepam, clonazepam and possibly clobazam if taken chronically by the nursing mother. However, such adverse effects do not occur in all nursed infants.

The benefits of breastfeeding in general are unquestionable. These must be weighed against the possible risks to the infant induced by drug exposure. Taking this into account, women with epilepsy should, in general, be encouraged to nurse their infants, and the risk for adverse effects due to drug exposure through breast milk is, in most cases, negligible.

Women who nurse while taking phenobarbital, primidone, benzodiazepines and perhaps also ethosuximide and lamotrigine should be encouraged to monitor their infant for side-effects such as sedation or poor suckling, rather than being advised not to nurse. If suspicion of pharmacological effects arises, this could be confirmed or rejected by measuring serum drug levels in the infant.

Folate supplementation

Low folate intake has been associated with an increased risk of congenital malformations, in particular neural tube defects, in animal studies and in humans. In a randomized study of more than 7000 Hungarian women planning pregnancy, supplementation with 0.8 mg folic acid reduced the risk of neural tube defects significantly [55], demonstrating the effectiveness of folate for prevention of first occurrence of neural tube defects. A randomized British study [56] assessed the effect of folic acid supplementation on the risk of recurrence of neural tube defects in high-risk pregnancies. More than 1000 pregnancies were included and 4.0 mg/day folate reduced the recurrence risk by 72%. Periconceptional intake of 0.4 mg of folic acid daily has also been shown to reduce the risk of neural tube defects in a public health campaign in China [57]. Unfortunately, no randomized study has specifically assessed the effectiveness of folic acid supplementation in women with epilepsy. In fact, such patients were excluded from the study in the UK [56].

In the absence of data specific for women with epilepsy, recommendations have to be drawn from studies based on the general population. In general, women of child-bearing potential are recommended a daily intake of 0.4 mg folic acid, and the most practical way of achieving that is as a daily supplementation. It is reasonable to suggest this also to all women with epilepsy. A higher dose of 4 mg/day is recommended for secondary prevention to women with a previous history of giving birth to a child with neural tube defects or with a family history of such malformations. However, as AED use is associated with an increased risk of neural tube defects and other malformations, many guidelines recommend that all women under treatment with such drugs should take up to 5 mg of folate per day from before conception and throughout the first trimester [22,58]. However, it is essential to inform the patient that it is uncertain whether folate supplementation will reduce this risk induced by AEDs [59], and pregnancy monitoring with prenatal diagnosis should be offered in the same way whether or not high-dose folate is prescribed.

Vitamin K supplementation and neonatal haemorrhage

Vitamin K deficiency can cause early neonatal haemorrhage, and neonates of mothers treated with enzyme-inducing AEDs during pregnancy may have an increased risk. Decreased levels of vitamin K-dependent clotting factors are found in the cord blood of newborns of women taking enzyme-inducing AEDs, and supplementation with 10 mg/day of vitamin K orally for the last month of pregnancy has been shown to normalize these levels. It remains to be shown that prenatal oral vitamin K supplementation also reduces the risk of neonatal haemorrhage. Hey [60] studied prospectively cord blood prothrombin time in 137 babies born to women on phenobarbital, phenytoin or carbamazepine. Only 14 of the babies had prolonged prothrombin time and none an overt bleeding tendency. The abnormality was corrected within 2 h by 1 mg of parenteral vitamin K. Based on these observations, Hey concluded that evidence is lacking for a particular early form of neonatal haemorrhage related to use of anticonvulsants, and that oral vitamin K supplementation during late pregnancy is unjustified, where intramuscular injections of vitamin K to the newborn are routine. This notion is further supported by two more recent controlled studies that failed to find an increased risk of neonatal haemorrhage related to the use of enzyme-inducing AEDs [61,62].

Preconception counselling

Several surveys have revealed that women with epilepsy often receive insufficient and even inaccurate information concerning issues related to reproductive function. Clinical practical guidelines for the care of women with epilepsy of child-bearing age have been published in many countries [58]. Unfortunately, many important questions are still unanswered, and many of the recommendations build on rather weak evidence, from observational studies rather than randomized trials. This is reflected in the slight differences found in the different guidelines. Nevertheless, they provide useful tools and need to be brought to the attention of health-care providers and utilized in their counselling of women with epilepsy. An optimal management of pregnancy depends largely on considerations that have to be made, and measures that have to be taken, before conception. Prepregnancy counselling is therefore essential, and it is an important challenge to change the present situation whereby such counselling seems to be offered to only a minority of women with epilepsy. Preconceptional counselling should cover the issues listed below.

- Contraception and fertility. The bidirectional interaction between hormonal contraceptives and AEDs should be discussed when relevant. The possibility that drug treatment may induce endocrine dysfunction affecting fertility should also be addressed.

- Genetic counselling with respect to the risk of giving birth to a child who will develop epilepsy and with respect to birth defects.
- Risks associated with seizures during pregnancy, and information that such risks to the fetus probably outweigh the risks incurred by an optimized treatment with AEDs.
- Risks of adverse effects of AEDs to the fetus, including a two- to fourfold increase in the incidence of major malformations.
- The option of prenatal diagnosis of birth defects, including possibilities and risks with the different methods.
- General principles of AED use in pregnancy, and the importance of optimizing seizure control and making any major change in drug therapy before pregnancy. The importance of medication compliance during pregnancy and the risks associated with abrupt withdrawal need to be underlined.
- Recommendations concerning folate supplementation, including information on the lack of evidence for its effectiveness in preventing birth defects related to AED exposure.
- Risk of seizures at delivery and the recommendation that delivery should take place in well-equipped obstetric units.
- Risk for deterioration in seizure control due to sleep deprivation after delivery.
- Feasibility of breastfeeding.

In conclusion, although there are specific risks and problems associated with pregnancy in women with epilepsy, counselling should focus on the feasibility of reducing risks and on the fact that more than 90% of women with epilepsy can look forward to an uneventful pregnancy and to giving birth to a normal and healthy child.

Some of the issues discussed above (e.g. genetic counselling and the risk for deterioration in seizure control due to sleep deprivation) are also relevant for men with epilepsy who are considering having children, although this is often completely neglected.

Table 25.5 Optimizing treatment of epilepsy in pregnancy.

Women seeking advice before *becoming pregnant*
All attempts at major changes in drug treatment should be accomplished and adequately assessed before conception
Confirm diagnosis of active epilepsy and reassess need for treatment with antiepileptic drugs
For women in remission, gradual withdrawal of antiepileptic drugs may be considered if the risk of recurrence is low and the woman is aware of the risks and potential consequences
For women who need treatment, select the appropriate drug for the patient's seizures or epilepsy syndrome but avoid valproic acid if possible
Aim at monotherapy and try out the lowest effective dosage of the appropriate drug
Document the patient's optimal drug concentration before pregnancy. Measure unbound concentrations of phenytoin and valproic acid
Prescribe folate at 4–5 mg/day from before conception
During pregnancy
Offer prenatal diagnosis
Monitor the patient clinically and with serum drug concentrations each trimester, more frequently in patients with poor seizure control or if lamotrigine is used
Adjust dosage in case of generalized tonic–clonic seizures
In sensitive patients a dose adjustment may be justified in response to a significant drop in active drug concentrations also in the absence of seizures
Stress the importance of compliance with prescribed treatment
Monitor drug concentrations closely after delivery and re-adjust dosage if increased during pregnancy

Management during pregnancy

Antiepileptic drug treatment during pregnancy

The optimal management of a woman with epilepsy during pregnancy relies on a close collaboration, with exchange of information between the physician responsible for epilepsy care and the obstetrician (Table 25.5). Treatment with AEDs should be optimized before conception, with the objective to use monotherapy at the lowest effective dosage. Select the AED that is most likely to control seizures (i.e. the appropriate first-line drug for seizure type and epilepsy syndrome). However, accumulating data suggest that valproic acid should be avoided if other equally effective treatment options are available. There is, at present, no simple answer to what the suitable alternative could be for women with idiopathic generalized epilepsies (e.g. juvenile myoclonic epilepsy). Lamotrigine has a reasonable documentation concerning pregnancy outcomes, but the pronounced pharmacokinetic alterations during pregnancy can result in breakthrough seizures. Levetiracetam may be less problematic in this respect, but data on pregnancy outcomes on the other hand are limited. Although as yet we have no signals of major increase in fetal risks with levetiracetam, the data are insufficient to allow firm conclusions. Some prefer carbamazepine. This drug is likely to be effective against generalized tonic–clonic seizures, which is the most important for fetal safety. However, carbamazepine could aggravate myoclonic seizures. Although such seizures are of limited importance during pregnancy, poorly controlled myoclonic seizures can be a major problem after birth when the mother has a newborn infant to care for. Irrespective of which of the alternatives is considered, it is necessary to allow sufficient time before conception to assess its effectiveness.

Treatment should aim at complete control of, in particular, generalized tonic–clonic seizures. Other seizure types are probably less hazardous but may, in some patients, signal an increased risk also for tonic–clonic seizures. Complex partial seizures may also compromise maternal co-operation at delivery.

An attempt to withdraw treatment should be considered in women who plan pregnancy and who have been seizure free for 2 years or more. However, this needs to be assessed individually based on the estimated risk of recurrence and potential consequences thereof. In the case of polytherapy, conversion to monotherapy should be considered, and an attempt to titrate the lowest effective dosage be made. All such major changes should ideally be completed several months before conception to allow a reasonable observation period before pregnancy. It may be useful to document the optimal serum drug level before pregnancy to facilitate interpretation of serum concentration measurements during pregnancy.

Conversion from polytherapy to monotherapy, or changes between AEDs, for the purpose of reducing teratogenic risks,

should not be attempted during pregnancy. At this stage of pregnancy the potential gain is minor compared with the risks associated with such procedures.

The treatment should be monitored more closely during pregnancy than otherwise. This, too, needs to be tailored to the individual but in most cases an assessment each trimester, with a last visit at week 34–36, will suffice. This should include clinical evaluation and drug level monitoring where appropriate. Where phenytoin and valproic acid are used, monitoring the unbound levels is preferred. More frequent drug level monitoring may be justified with lamotrigine and possibly also oxcarbazepine. A decrease in serum levels of AEDs alone does not automatically justify an increase in dosage, but in particular for lamotrigine, declining plasma concentrations have been linked to deterioration in seizure control [29]. The overall clinical state should be assessed and the individual patient's optimal drug concentration and sensitivity to changes in drug levels documented before pregnancy should be taken into account. If a dosage increment was made during pregnancy, serum drug levels should be monitored during the first weeks after delivery, since a dose reduction may be necessary.

Prenatal diagnosis

Women on antiepileptic drugs should be offered the possibility of prenatal testing if elective termination of pregnancy is acceptable. A malformation-directed ultrasound investigation at 16–20 weeks of gestation has a high sensitivity and specificity in the detection of major malformations, including more than 90% of neural tube defects, and a high proportion of cardiac malformations, skeletal defects and orofacial clefts [63]. An ultrasound examination is often offered also at week 33–34 for assessment of intrauterine growth retardation.

Vitamin supplementation

Women with epilepsy considering pregnancy should be prescribed 4–5 mg folate/day, but also informed about the lack of evidence for its efficacy.

Labour and delivery

In general, labour and delivery do not imply any particular obstetric measures. However, delivery should take place in a well-equipped obstetric unit in view of the increased risk of seizures during labour and delivery and the increased risk of neonatal death.

Emergency Caesarean delivery is indicated during labour when seizures induce fetal asphyxia or cause poor maternal co-operation. Intravenous benzodiazepines to the mother are also indicated in such cases.

Puerperium

Stress and sleep deprivation in the puerperium may sometimes adversely affect seizure control. Furthermore, the new responsibilities of the care of the newborn may necessitate special considerations and precautions at home. It is recommended that the mother with epilepsy is given extra support from her partner or others during the first weeks at home, in particular if she is sensitive to sleep deprivation, when seizures are likely to occur. In order to minimize risks to the infant, care for the child, including breastfeeding, is best carried out on the floor, and another person should supervise bathing of the newborn.

Implications for the treatment of women of child-bearing age

The rate of unplanned pregnancies in the general population is high and the first contact with health-care providers is frequently late. These factors are as true for women with epilepsy as they are for anyone else. Therefore, issues related to management during pregnancy will have implications for the treatment of women of child-bearing potential with epilepsy in general. Furthermore, the potential adverse effects of epilepsy and drug therapy on reproductive function, pharmacokinetic interactions with oral contraceptives, as well as developmental toxicity of AEDs, need to be included in the overall risk–benefit equation, which should be the basis for decisions on when and how to treat epilepsy in young women. Thus, it is sometimes reasonable to withhold treatment in new-onset seizures if the indication is weak or ambiguous. If treatment is indicated, it is particularly important in this patient group to aim at monotherapy with the lowest effective dosage. When treatment is initiated in a woman of child-bearing potential, information must be given concerning drug effects on oral contraceptives, when appropriate, as well as potential adverse effects on endocrine reproductive function and implications in relation to pregnancy. The benefits of planning pregnancy should be emphasized. Because of the high rate of unplanned pregnancies, supplementation with folic acid (0.4 mg/day) is reasonable in all women of child-bearing potential who take AEDs. Counselling needs to be iterated at regular intervals. It is also important to inform, at an appropriate age, those women who had onset of their epilepsy as young girls but continue on AEDs beyond puberty.

Based on the considerations above, it is essential to identify young women with epilepsy who are likely to be able to withdraw their treatment without seizure recurrence, and to support them in attempts to taper treatment before they consider pregnancy. Likewise, suitable candidates for epilepsy surgery have the prospect of becoming seizure free, eventually without medication, after a successful operation. Hence, it is of particular value to avoid unnecessary delay in assessment for epilepsy surgery in women of child-bearing potential.

Potential adverse effects on reproductive function should be considered, together with all other relevant properties, when selecting an AED for a woman with epilepsy. The most important property of an AED is its effectiveness in preventing seizures, and for women of child-bearing potential the best choice is the drug that is most appropriate for the seizure type or syndrome. However, the patient should be closely monitored for possible adverse effects on reproductive endocrine function and the treatment reassessed should such side-effects occur. It should also be remembered that drug preferences are likely to change as we gain more information on adverse effects on endocrine function from randomized clinical trials and comparative data on teratogenic effects of different antiepileptic drugs from pregnancy registries.

26 Epilepsy Counselling

Anthony Linklater, Doreen Patsika and Susan Usiskin
National Hospital for Neurology and Neurosurgery, London, UK

Introduction

The management of epilepsy presents challenges to clinicians that go beyond the medical aspects of the condition. Some people require assistance in coming to terms with the diagnosis, which can be stigmatizing and associated with psychological problems, reduced social standing and employment difficulties [1]. Some people may feel excluded from society [2]. Most people with the condition, their families and their carers require information about many aspects of epilepsy.

Patient-centred approach

There is a growing awareness of the importance of providing relevant information to people with long-term chronic conditions such as epilepsy. This has been demonstrated in changes in the way that health services are delivered. There is a shift towards a more patient-centred approach, which aims to establish people living with long-term conditions as experts in their particular condition and to empower them to become involved in a collaborative approach to its management [3]. This is demonstrated, for example, in relation to concordance with medication. In the past, people were viewed as compliant with treatment or non-compliant according to the degree to which they followed instructions about how to take their medication. Now, the process of concordance switches the focus from whether the medication is taken and instead focuses on a shared approach to the decision-making process [4].

Whilst some people wish to leave decisions about their treatment to clinicians, many require to be involved in these decisions [5], and initiatives such as concordance require that information is shared in a meaningful way.

Information provision

A review of the literature around the information and counselling needs of people with epilepsy found that people with epilepsy want information on general epilepsy issues, diagnosis and treatment options, medication and adverse effects, seizures and seizure control, prevention of injury, psychological issues, benefits, driving and insurance, employment, prognosis, lifestyle and social issues. People with epilepsy were also found to have counselling needs in relation to anxiety and depression and expressed a need for emotional support [6].

Accessibility of information

Providing information that is relevant and accessible to an individual at any given time is a challenge. Any information aimed at people with epilepsy needs to be accessible and relevant to all people with the condition, including those from disadvantaged backgrounds such as:

- people from various ethnic groups, especially those whose first language is not that of the country in which they reside;
- people with learning disabilities; and
- people with poor literacy skills.

People from these disadvantaged backgrounds are less likely to be able to find relevant information independently. Written information may need to be made available in a variety of languages to suit the local population and to be pitched at an appropriate level using symbols and pictures where appropriate.

How is information given?

Adequate time is needed to provide the full range of information required. In the clinic setting, longer consultations may be required, which can be difficult to achieve in practice. The utilization of specialist epilepsy nurses can help meet the need for longer consultations to encourage dialogue and open discussion of pertinent issues as well as to review clinical issues. The time invested in longer consultations can save time and reduce costs in the longer term by preventing misunderstandings which lead to poorer outcome. Specialist epilepsy nurses also are able to offer continuity of care, which may be important to individuals, allowing for a rapport to be established and trust to be developed [7].

Most people with chronic epilepsy under the care of a neurologist are reviewed at regular intervals as outpatients. Problems can arise between appointments and a telephone advice line, often manned by specialist nurses, is an excellent way of providing assistance. Table 26.1 shows the reasons why people access this type of service within our practice at the National Hospital for Neurology and Neurosurgery. Ninety per cent of the calls received by our service are resolved by the specialist nurses. Consultant neurologist advice is sought for the remaining 10% of calls. Where necessary, changes to treatment can be instigated or outpatient appointments can be brought forward if necessary as a result of calls. Table 26.2 shows the outcomes of calls to our service. Such helplines can be accessed not only by patients but also by their family, carers, GPs, community nurses, hospital

Caller	Frequency (%)
Patient	65
Family member/carer	25
GP	5
Others, e.g. community nurses, social workers, hospital doctors	5

doctors, social workers and others. Table 26.3 shows the breakdown of callers to our service.

Types of information

Information can be given in a variety of formats. Verbal information, given either face to face or via the telephone, has the advantages that understanding can be checked and uncertainty can be quickly clarified, and it can be personalized to an individual's needs. The major problem with verbal information provision is the lack of retention. Techniques to improve retention include the simplification of information by using shorter words and shorter sentences and the repetition of information. Communication can be impaired by anxiety or stress. Verbal information can be reinforced with written information, increasing understanding and improving adherence [8]. Written information can be kept for reference purposes and shared with family or carers.

People with all long-term conditions, including epilepsy, use the internet as a source of information [9]. The internet has much useful information about epilepsy, but quality varies and people should be guided to reputable and reliable sources. In the UK, the NHS maintains a database of information about a variety of medical conditions, including epilepsy, on its website, and some voluntary sector organizations also provide information, much of which can be downloaded via the internet as well as helplines where people can obtain information and advice. People without access to the internet can be supported to obtain information from clinics or other sources such as libraries or voluntary sector organizations in the form of information leaflets, books and DVDs.

Usefulness of information

Counselling at the time of diagnosis

At the point of diagnosis, information is needed about all aspects of the condition but it is neither possible nor desirable to cover all points immediately. The provision of information should be viewed as an ongoing process, with a dialogue established between the clinician and the person with epilepsy. The use of information checklists can be helpful to prompt discussion and to identify what the person with epilepsy would like to know about the condition, as well as keeping a record of what has previously been discussed. Repetition of key points in subsequent reviews with clinicians may help with the retention of information.

Adjustment to a diagnosis of epilepsy is a gradual process for many and can be difficult. Feelings of bereavement may be experienced during the early stages following diagnosis. Grieving for lost hopes and expectations leads to social withdrawal, depression and loss of self-esteem [10]. These problems can stem from a feeling of a loss of control, and this feeling of powerlessness may be coupled with a low mood, which may develop into a reactive depression. Depressive illness may require the assistance of mental health services. Those who are receptive to regular support through counselling benefit from the opportunity to voice fears and emotions openly. The ability to share concerns and fears and to work on difficulties may be sufficient for many and enable the necessary adjustment.

Denial, poor adherence and abuse of alcohol or recreational drugs can compound adjustment difficulties. Problematic adherence to therapy can indicate denial of the diagnosis. It can be helpful in this situation to encourage the weighing up of the detrimental impact on quality of life of a certain course of action against an alternative. Ongoing support may help prevent problems recurring and also identify other difficulties at an early stage.

Issues around taking medication regularly

Once a diagnosis has been established and a decision taken to start treatment with AEDs, information is needed about medication. This includes information about the name of the drug, the dosing schedule and possible adverse effects. People with epilepsy will need to know what to do if adverse effects occur or what to do if their seizure control does not improve with the medication. They will also need to understand at an early stage that AEDs must be taken regularly in order to derive maximal benefit [11].

If medication is not being taken as agreed, the reasons should be explored. For example, people with epilepsy may have problems with memory [12] and may simply forget to take their medication. Sometimes people may not take their medication because they experience adverse effects, and some women may stop taking their medication because they are planning pregnancy and want to avoid the teratogenic effects of AEDs. Some may become complacent if seizures are controlled. Poor adherence with antiepileptic medication is also associated with a poor understanding of the condition [13].

A concordant approach to treatment decisions may be helpful at improving adherence. Open, two-way communication between individuals and clinicians about medicines leads to better adherence, improved satisfaction with care received and greater knowledge of the condition and its treatment [14].

Sometimes, a person can regularly forget to take his/her medication. Establishing the extent of the problem can be difficult. Pill boxes are a cheap and effective prompt in this situation.

Other methods of improving adherence are use of mobile phone alarms to provide reminders, enlisting the support of family members to check that medication has been taken and leaving medication in places where it will be seen during a person's usual routine, such as with a toothbrush or kettle. The carrying of extra medication can be helpful to avoid omitting doses.

Safety and risk considerations

Any individual with epilepsy should be aware of the risks of seizures. The degree of risk depends on the nature and frequency and timing of seizures. The degree of risk acceptable to an individual is a personal choice. Some people with epilepsy have identified precipitants for their seizures and will require advice regarding avoidance of these precipitants. Precipitants vary from individual to individual, but common precipitants include febrile illness, sleep deprivation, psychological stress and excessive alcohol.

People with epilepsy will require advice about situations which can be dangerous if seizures occur. Some are obvious but others are less so. People should be encouraged to perform a mental risk assessment for any activity they are considering.

Safety in the home

Safety advice for the home environment should be tailored to suit each individual's circumstances. Questions to consider include: Does the person live alone? Do they have family support? What are the risks in the event of having a seizure? Is the accommodation accessible by stairs and, if so, is this appropriate and safe? Will a move to more suitable housing be necessary or can the present home be adapted in some way? Are children or other dependants in a vulnerable position if seizures occur? [15]. Referral to occupational therapy may be appropriate and allow for an assessment of the home environment to be made.

A significant danger in the home is the risk of drowning during a seizure whilst bathing. This is an important and preventable cause of death in people with epilepsy [16]. Showering or supervised bathing should be encouraged.

Risks associated with cooking can be reduced by using the back plates on the stove and turning pot and pan handles to the side to reduce the likelihood of being inadvertently knocked during a seizure. Microwave cooking is thought to be safer than cooking on the hob as cooking vessels will be contained, which reduces the risk of scalds and burns, and the timer means it will switch off even if left unattended. Use of sealed containers to carry hot food can also be helpful. A kettle should be filled with the minimum amount of water necessary.

Leisure activities

Many people spend leisure time engaging in activities that may be hazardous if a seizure occurred at that time. Activities such as rock climbing and pot-holing carry obvious risks, and even cycling or swimming can be potentially dangerous if seizures occur. Using a cycling helmet, wearing protective clothing and using designated cycling lanes may reduce some of the risk of cycling. For swimming, it might be advisable for people with epilepsy to limit swimming to pools with clear water, a lifeguard presence and some additional supervision, although the degree and type of supervision will depend on individual factors.

Even when taking precautions it is not possible to remove all risk, and the amount of risk which is acceptable is an individual decision. However, it is important that an individual has made the personal risk assessment with full awareness and understanding of the nature of the risk and has considered ways of reducing any potential risk.

Addressing the risk of death

The possibility of dying as a consequence of epilepsy is a topic that needs to be discussed sensitively. People with epilepsy have a mortality rate which is two to three times higher than that of the general population [17]. Death can occur as a result of a serious seizure-related injury, status epilepticus or sudden unexpected death in epilepsy (SUDEP). Risk can be reduced by measures such as the use of alarms to alert family members to seizures at night. Knowledge of the risk of death in a seizure can improve the adherence to medication, the avoidance of seizure precipitants such as late nights or alcohol, and more risk-averse behaviour.

First aid for seizures

The occurrence of seizures can be distressing and frightening to onlookers, and family and carers should know what to do if a seizure occurs and when to seek medical attention. There is a general lack of awareness about epilepsy among the public, and inappropriate actions taken during seizures can endanger the individual [18]. Information should therefore be given to family and carers about how to manage each type of seizure and the circumstances in which urgent medical assistance should be sought.

Some individuals require the administration of rescue medication to terminate seizures and to prevent the occurrence of status epilepticus. It is good practice in this situation to provide a written plan outlining what medication should be given, how it should be given and what to do if the rescue medication is ineffective. For people with epilepsy living in care homes, the provision of a detailed written plan is of more importance due to staff turnover, and new staff will need clear, concise information that is not open to misinterpretation. Some families and carers will

require training in the administration of rescue medications such as rectal diazepam or buccal midazolam.

Anxiety, social difficulties and overprotection

It has been suggested that there is 'an innate prejudice against epilepsy' rooted in the fear that the person with the condition is always liable to sudden, unpredictable and dramatic losses of motor control or to 'going berserk', something that 'normal' people fear happening to themselves [19]. This fear of going out of control at any time of day or night may be extremely difficult to accept, whether seizures are frequent or not.

The unpredictability of seizures is a particular problem. This may lead to debilitating anxiety. The biggest concerns are around loss of dignity, social isolation and low self-esteem. The involvement of a counsellor with whom they have regular contact presents a forum for patients with epilepsy to examine and discuss these issues.

A natural reaction of family members is to try to protect the person with epilepsy. Setting the boundaries of risk can be difficult, and 'overprotection' is a common reaction. It may in part be the result of feelings of grief or guilt [2]. Overprotection can be harmful to the person with epilepsy and to the family. It may inhibit social life and the forming of independent relationships. It may hinder the development of self-image and a practical attitude towards seizures and risk. It encourages dependency and inhibits psychological coping.

A counsellor should work with the family to overcome issues of overprotection. This can include the setting of realistic educational or employment goals. It can be helpful to meet family members involved in the daily life of the person with epilepsy and to identify areas of specific difficulty. It is important, where possible, to encourage the person with epilepsy to deal with problems rather than to provide protection from them. Encouragement from the counsellor and family will be important if this is to be achieved. 'Learned helplessness' is a common reaction to overprotection and results in a failure to meet potential and unnecessary levels of social withdrawal. Where this has endured to adulthood, it becomes increasingly difficult to reverse and can result in irritability, anger and manipulation, and a situation where the primary disability is the maladaptive illness behaviour.

Employment issues

Employment difficulties are common [1], with economic consequences and adverse effects on self-esteem and mood.

When choosing work, some jobs (e.g. front-line service in the armed services, working on scaffolding, and working as a pilot, etc.) are closed to people with epilepsy. However, there are many types of work that can be undertaken. Considerations for appropriate types of work include the type and frequency of seizures, the presence of a warning and the impact on others in the workplace.

For people in employment who develop epilepsy, the onset of their seizures can signal the end of their career (for instance as a public service vehicle driver). In this situation, people need accurate information about their specific circumstances. People should be encouraged to discuss the implications of the epilepsy with their employer as it may be possible for an alternative job to be found within the same organization. However, it should be recognized that personal identity may be strongly bound up with work, as may financial status, social companionship and sense of purpose.

Communication between employer and employee may be problematic, especially where the employee does not divulge their epilepsy. Fear of having a seizure at work is often reported, and indeed some even report feeling stressed on the journey into work, particularly if they have not disclosed their epilepsy. There is legislation in many countries, such as the Disability Discrimination Act in the UK, which protects people with epilepsy from being discriminated against on the grounds of their epilepsy, although this can be difficult to enforce in practice. However, it can be helpful to inform people of any such legislation to ensure that they know their rights and so that they can seek assistance from the law if necessary.

For people with epilepsy who are unable to find employment or who are unable to continue with their present job, help with interview technique and advice on how to introduce the subject of their seizures can be needed. Assistance from disability employment advisors can also be helpful in assisting people towards appropriate employment or voluntary work where appropriate.

A long period of unemployment should be viewed, where possible, as an opportunity to increase skills through further training and to address difficulties in specific areas.

Women's issues

Women with epilepsy have specific issues around contraception and pregnancy. Information about these issues should be given in advance of the time that the woman becomes sexually active.

Women with epilepsy need to know that some AEDs can impair the efficacy of the combined oral contraceptive pill by inducing hepatic enzymes which speed up the metabolism of the oestrogen component of the pill, putting them at risk of unwanted pregnancy. Women taking enzyme-inducing antiepileptic drugs (AEDs) should be informed of the need to seek specialist family planning advice to achieve effective contraception. Even with appropriate advice, there is a higher risk of contraceptive failure and additional or alternative forms of contraception may be advisable.

Fertility

Epilepsy is associated with reduced fertility [20]. There are various possible social and biological reasons why this may be so. The medication can be a factor, and sodium valproate, for instance, may be associated with polycystic ovary syndrome [21]. Given the issues of fertility, women with epilepsy may wish to consider pregnancy at an earlier age than they would otherwise choose to maximize the chances of conception.

Menstruation and epilepsy

About one in three women with epilepsy experiences clustering of seizures around the time of menstruation [22]. Accurate documentation of seizures with details of the menstrual cycle will help

identify catamenial exacerbations which may have treatment implications.

Pregnancy

There are a number of different issues regarding pregnancy which should be addressed in counselling. The most pressing are the teratogenic effects of maternal drug ingestion on the fetus and the effect of pregnancy on seizure control and the effect of seizures on the fetus. These issues require detailed counselling. Whilst most women with epilepsy will have a normal pregnancy and delivery with no negative effect on their epilepsy and over a 90% chance of a healthy baby, pregnancies in women with epilepsy are considered high risk and require careful management by both neurological and obstetric services [23]. Women with epilepsy should be regularly reminded that their epilepsy should be reviewed by a specialist before they attempt to become pregnant to optimize therapy. Women contemplating pregnancy are advised to take high-dose folic acid until at least the end of the first trimester as this may be protective against neural tube defects. Some women may wish to discuss temporarily discontinuing their AEDs during the first trimester to minimize any risk to their baby. This is possible in some cases, but the advantage of a drug-free period should be balanced against the risk of deterioration in seizure control.

There are various voluntary registers around the world collecting data on the outcome of pregnancies in women taking AEDs, such as the UK's Epilepsy and Pregnancy Register [24], and pregnant women with epilepsy should be encouraged to participate in these registers.

When preparing for the birth of their baby, women should be advised of the importance of continuing to take their AEDs throughout labour to reduce the risk of seizures during labour or in the first 24 h following delivery. Often the labour partner can be entrusted with the job of ensuring this.

Care of the baby

Breastfeeding is generally considered acceptable for women taking AEDs [25], and mothers with epilepsy should be encouraged to choose the feeding method that suits them best.

If a parent with a young baby has seizures, there is a risk to the infant of harm resulting from seizures if, for example, the infant is dropped as a result of a seizure. Parents with young children will therefore need to be advised on safe handling, bathing and feeding. This is particularly important during the immediate postpartum period, as the risk of seizures may be increased as there may be a worsening in seizure control in the context of sleep deprivation, which is common around this time. Parents can be encouraged to reduce risk by changing babies at ground level or not bathing the baby whilst they are unaccompanied by another responsible adult.

Presurgical assessment and support

An increasing number of people with epilepsy who do not achieve seizure control with AEDs are now undergoing resective surgery for the treatment of epilepsy of focal origin [26]. Prior to any surgery, a number of investigations need to be undertaken over weeks or months to establish whether surgery is a suitable therapy. This can be a difficult and stressful time. Counselling is crucial to maintain psychological well-being during the presurgical assessment phase and as a preparation for surgery.

During the presurgical assessment, people are usually hospitalized for some of the investigations. This gives an opportunity for the clinician to discuss key issues without the normal time constraints of outpatient clinics. This is important as prospective surgical candidates need to understand the full ramifications of surgery. It is important, for example, to emphasize the need to continue with AEDs, initially at least, after any surgery. The opportunity to express feelings about the potential future surgery needs to be given, hopes in regard to outcome explored and an assessment made as to how realistic are the goals. The odds of success and the risk of complications of surgery will help individuals come to a rational decision about their suitability for surgery.

Sexual dysfunction

Hyposexuality has been attributed to both epilepsy and AED use. This particular issue is more widely reported in those with temporal lobe epilepsy [27]. Women may find it less difficult to talk about sexual dysfunction than men. Sexual dysfunction can cause considerable emotional turmoil and difficulties within relationships. The frank discussion of such difficulties is often very helpful.

Conclusion

Every person with epilepsy should be assisted towards a good understanding of their epilepsy and its impact throughout their lives. An effective programme of information provision can only have beneficial implications for people with epilepsy, allowing informed decision-making in many aspects of life and enabling appropriate treatment goals. The provision of relevant, good-quality information will also help people to combat the stigma associated with the condition and assist in coping with the condition [28].

Counselling can also be helpful to support people through the psychological difficulties experienced as a consequence of their epilepsy. The need for ongoing support varies and whilst some people may benefit from regular counselling sessions over several months, others may require sessions over a period of years.

The need for the provision of information, advice and psychological support continues throughout the lives of people with epilepsy. Whilst epilepsy may not be an easy condition to live with, providing these services at times when people with the condition really need them will bring relief, optimize outcomes, assist seizure control and facilitate coping with all that a diagnosis of epilepsy brings.

27 Genetic Counselling in Epilepsy

Federico Zara
Gaslini Institute, Genoa, Italy

Introduction

There have been striking recent advances in the study of the genetics of epilepsy. These carry the promise of elucidating the aetiology of many different epileptic phenotypes, currently considered cryptogenic, in the near future. Although much work towards this goal still lies ahead, current knowledge provides important clues to the pathogenesis and mode of inheritance of various epileptic syndromes. The implementation of this new genetic information in clinical practice has become an important issue in epileptology. Central to this is the process commonly referred to as genetic counselling. The American Society of Human Genetics has defined genetic counselling as a 'communication process dealing with human problems associated with the occurrence, or risk of recurrence, of a genetic disorder in a family' [1].

Genetic counselling aims to help patients and families to:

- comprehend medical data, the diagnosis, the probable course of the disease and the treatment available;
- understand how hereditary factors contribute to the disorder and to appreciate the risk of occurrence of the disorder in specific relatives; and
- choose the appropriate course of action in view of their risks, taking into account the goals and personal morality of the person being counselled.

Genetic counselling therefore involves a diagnostic task, risk assessment and a communicative process.

The pedigree as a diagnostic tool

Accurate genetic counselling is based on reliable diagnoses, and the first principal task for the clinician is to reach as firm a diagnosis as possible.

As familial recurrence is the distinctive feature of most hereditary disorders, the first step towards an accurate diagnosis is a review of the patient's family history. This involves the drawing up of a family tree, which is a powerful tool that can provide the clinician with essential clinical and biological information and which constitutes a permanent and concise record that can be widely interpreted. Pedigrees are drawn by using a universally accepted language that includes the use of symbols indicating sex, disease status and relationships (Fig. 27.1). The pedigree may be used (1) to decide on testing strategies, (2) to distinguish between genetic and non-genetic aetiology, (3) to establish the pattern of inheritance and to calculate risks and (4) to decide on medical screening for unaffected individuals.

The collection of family data should include basic clinical details from both sides of the family for three or four generations. It is advisable to personally examine family members who may be affected or at risk. In doing so, unexpected findings often emerge from relatives with an apparently negative history. A clear diagnosis can be difficult to establish in family members who are deceased. However, detailed information can be obtained by interviewing close relatives, and the exclusion of specific disorders is often possible. Home visits should be considered in selected cases. When collecting family data, it is also important to enquire about consanguinity as a clue to autosomal recessive inheritance. The ethnic and geographical origins of family members should also be carefully investigated in order to detect hidden consanguinity. Unacknowledged paternity (e.g. adoption) should be considered in puzzling situations, as this may exert a confounding effect on segregation of the disease.

Genetic testing is a definitive tool for establishing the diagnosis of an inherited disorder. A genetic test is defined as a laboratory analysis aimed at detecting the alteration of a gene, chromosomal abnormality and DNA variation associated with a genetic disorder. Genetic tests can focus on the analysis of the DNA structure (chromosomes or specific DNA segments) or of gene products (e.g. biochemical assays). Although genetic tests are attractive diagnostic tools, they should be used carefully. Indeed, population screening is recommended for very few genetic disorders, and genetic tests should usually be performed on the basis of precise clinical indications. Moreover, for many genetic disorders, genetic tests have not yet been developed and the accurate analysis of clinical data is the only means of establishing a diagnosis.

Risk assessment

Once a hereditary disorder has been diagnosed, it is possible to estimate any family member's risk of developing the disease. However, as the genetics of many hereditary disorders have not yet been discovered nor appropriate tests devised, the risk of recurrence can often not be calculated exactly and, for many hereditary disorders, will be estimated on the basis of probability. Risk assessment depends on the information available, which is often not complete.

Empirical risks are based on observed data collected through epidemiological studies; these usually provide an acceptable approximation and are widely used for several poorly understood genetic conditions. Population-based estimates are, however, strongly influenced by worldwide variability in incidence and aetiology and may not, therefore, be applicable to all populations.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

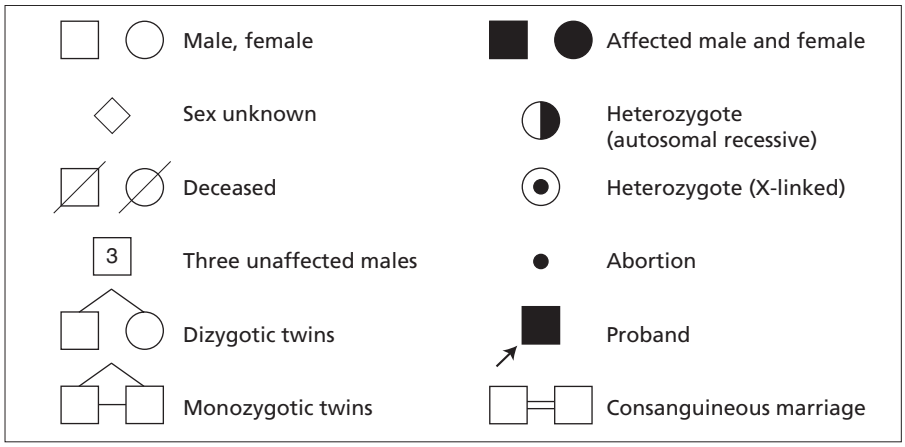

Fig. 27.1 Most common symbols used for drawing a pedigree.

Moreover, empirical risks are frequently revised as new phenotype definitions and more accurate genotype–phenotype correlations become available.

By contrast, genetic risks are defined when the mode of inheritance of the disease is known. To date, such risks may be calculated for disorders that are caused by mutations in a single gene and segregate throughout populations according to mendelian laws. Family members may be classified into clear-cut categories: (1) no risk (i.e. offspring of healthy siblings in autosomal dominant disorders); (2) low risk (i.e. offspring of a potential carrier of autosomal recessive disease); and (3) high risk (i.e. offspring of individuals affected by an autosomal dominant disorder).

Genetic testing

Genetic tests are analyses of human DNA, RNA, chromosomes, proteins or metabolites carried out to detect disease-related genotypes, mutations, karyotypes or molecular phenotypes for clinical purposes. Genetic tests are unique in the sense that they carry information about the biological identity of either the individual or his family ancestors and offsprings. The primary focus of genetic testing is to provide information that contributes to an improvement of health through the prevention or management of disease and illness. Clinical purposes include establishing a clinical diagnosis or prognosis, identifying carriers, predicting risk of disease. Thus, genetic testing should be placed within a specific clinical context, and a variety of conditions must be in place to ensure that the use is appropriate: specialized personnel to perform the test and interpret the results for patients and their families; genetic counselling before and after the test; and follow-up interventions to treat affected patients. Genetic testing may have a beneficial impact on diagnosis, prognosis and treatment. Some patients might be relieved or comforted to have a genetic explanation for their seizures or those of their family members. On the other hand, genetic testing also has potential harmful effects. Genetic information in epilepsy can contribute to psychological distress, discrimination in social life, health insurance and employment [2,3]. To evaluate the utility of a specific test the following parameters should be considered:

- Analytical validity – the ability of the test to appropriately identify a positive sample (sensitivity) and to identify a negative sample (specificity). The analytical validity of a test should be discussed with the laboratory staff before referring the patient.
- Clinical validity – the capability of the test to predict the present or future affection status of the person under investigation.
- Clinical utility – the potential impact of the test on the clinical management of the patient (e.g. surgical interventions, therapeutic approach).
- Ethical, legal and social implications – the potential consequences of the test on stigmatization and discrimination. These, as well as privacy and confidentiality issues, need to be carefully evaluated, particularly when testing should be extended to other family members in order to assess risk.

Clinical genetic tests can be classified into five broad categories, detailed below.

Diagnostic tests

These tests aim to confirm a clinical diagnosis or resolve a differential diagnosis in a affected individual or fetus. Diagnostic tests may:

- save the patient from undergoing other diagnostic procedures which may include risky and/or costly measures;
- direct clinical management, including therapy;
- be of psychological significance even in the absence of a specific therapy; and
- help to manage non-medical but individually important life-spanning aspects.

Carrier identification tests

These tests aim to identify heterozygous carriers in families with a positive history of a recessive genetic disorder or in populations showing a high prevalence of a recessive disease in the context of a community programme. Carrier identification tests may:

- assist individuals in planning future pregnancies; and
- assist, by subsequent counselling, in lowering the disease prevalence in a specific population.

Predictive tests

These tests aim to predict the future health status of a unaffected individual. Predictive tests may be applied to a person showing an elevated risk of developing a disease because of a relevant

family history. These tests are typically used in late-onset disorders. However, predictive tests can applied to the general population as a part of newborn screening. Predictive tests may:

- direct clinical management if a therapy is available to prevent the onset of the disease;
- be of psychological significance even in the absence of a specific therapy; and
- assist individuals in planning future pregnancies.

Susceptibility tests

These tests aim to identify genetic factors increasing the risk of developing a multifactorial disease. In epilepsy, as in many other areas of medicine, the predictive value of these tests is limited and their clinical utility depends on the availability of effective measures that may prevent the disease or its major complications. Susceptibility tests may:

- direct preventing measures in at-risk individuals.

Pharmacogenetics tests

Pharmacogenetics tests are intended to identify genetic factors predicting the response to medicines. Pharmacogenetics tests will enable better prediction of likely outcomes and thus influence the benefit-to-risk ratio of a medicine for patients. Pharmacogenetics tests may:

- predict the efficacy of a specific drug; and
- predict the risk of idiosyncratic reactions of specific drugs and direct therapeutic strategies.

The clinical utility of a genetic test strongly depend on the way testing is integrated into genetic counselling. There are three stages:

1. pre-test genetic counselling;
2. genetic analysis; and
3. post-test genetic counselling.

Pre-test genetic counselling

Pre-test genetic counselling is aimed at:

- gathering pedigree information and identifying necessary clinical documentation;
- making or verifying the diagnosis by history-taking, physical examination and use of information obtained before or during the consultation;
- providing information about the condition which may include its cause, pattern of inheritance, course, complications, outcome and treatment options;
- estimating risk for the counsellee where applicable;
- discussing the medical, emotional and social implications for the individual and family; and
- presenting options, including genetic testing and reproductive options, and assisting with informed decision-making in a non-judgemental/non-coercive manner. The choice of a genetic test should be discussed with the client/family. This includes the nature of the sample required, the appropriateness of the test, the information the test is seeking, the limitations of the test, and the possible implications of the result.

Genetic analysis

Genetic tests may be carried out by using different methodological approaches:

- direct identification of mutations on DNA or retrotranscribed RNA;
- analysis of DNA polymorphisms linked to the disease gene (linkage analysis);
- expression analysis of RNA and protein products; and
- analysis of gene function (i.e. measurement of enzymatic activity or metabolites). Functional tests are included among genetic tests only when the functional abnormalities are unambiguously linked to a specific genetic trait.

Post-test genetic counselling

Post-test genetic counselling is aimed at:

- conveying test results;
- referring to other health professionals as needed;
- considering, and discussing with the counsellee, implications for third parties (i.e. relatives);
- providing education material and/or appropriate references; and
- offering contact with community-based support groups or persons.

Genetic counselling is not just a communication process aimed at informing patients of the risk of recurrence in specific relatives. It should also support patients in taking decisions (e.g. on reproduction) in accordance with their view of life. To this end, genetic counselling should help the patient to understand medical data and clarify any misconceptions.

Diagnosing a specific genetic disorder often implies the involvement of many family members who have been unaware of being at risk. Whether to contact members of extended families should be carefully discussed with patients and, if this is deemed necessary, an 'ad hoc' strategy should be planned.

The evolution of genetic counselling into a process that involves an entire family requires extreme caution. A central principle of genetic counselling is that a non-directive attitude should be adopted. Non-directiveness implies that patients are fully aware of the genetic risks and their consequences and are therefore able to make their own decisions. A totally neutral approach to genetic counselling cannot realistically be achieved; nevertheless, it must be emphasized that counsellors should not aim to provide solutions to critical questions concerning patients' lives.

Mode of inheritance of genetic disorders

It has long been known that many phenotypic characteristics of living beings are transmitted according to Mendel's laws. In Mendel's model, genetic factors segregate from parents to offspring as independent and unaltered units, and phenotypes result from the interaction of variants (alleles) of these discrete units according to hierarchical relationships (dominant versus recessive).

Mendel developed his model of the transmission of phenotypic traits just by observing peas in a garden. This discovery provides a valid basis for the understanding genetic inheritance. However, it has been subsequently realized that mendelian laws are simplified, and that the segregation of phenotypes in humans is more complicated. We now know that Mendel's units (genes) lie along

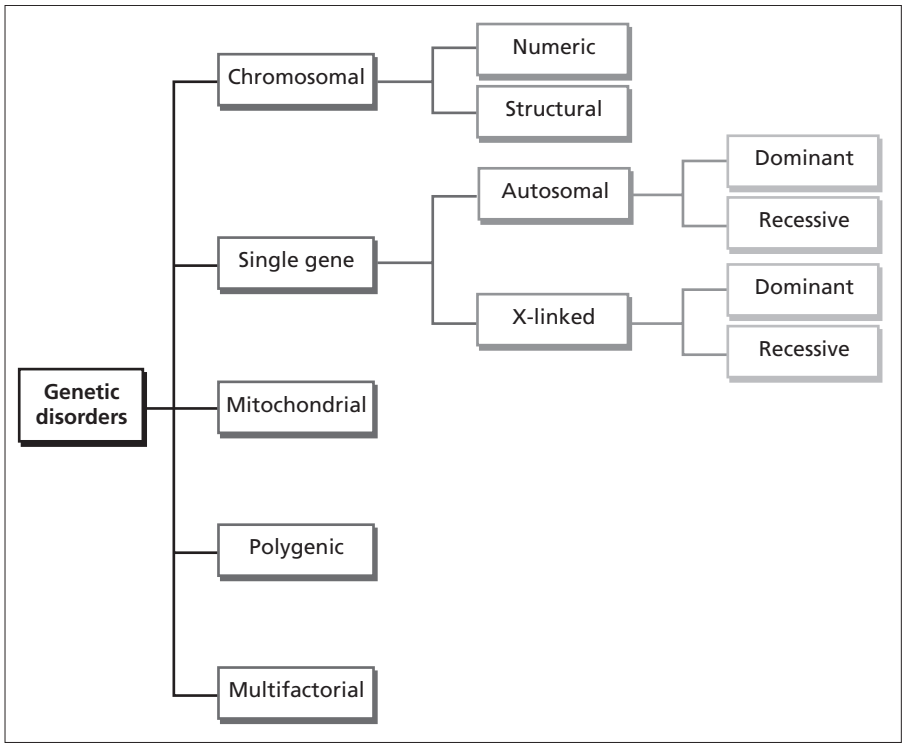

Fig. 27.2 Classification of genetic disorders.

chromosomes in close proximity and that DNA is transmitted in segments containing tens to hundreds of genes. Genes are not, therefore, always independently transmitted. We also have learned that genes sometimes undergo mutations during transmission (i.e. *de novo* mutations and dynamic mutations due to trinucleotide repeat expansions) instead of being maintained unaltered. Moreover, most molecular pathways and cellular functions are regulated by very complex systems that may involve hundreds of genes. Thus, most cellular, physiological and clinical phenotypes frequently result from the interaction of several genes and not from single genes. The presence of genes on the X chromosome and maternally inherited mitochondrial DNA add further complications to the analysis of the transmission of clinical phenotypes.

In accordance with the above considerations, we may class inheritance patterns as: (1) chromosomal inheritance; (2) single-gene mendelian inheritance; (3) X-linked inheritance; (4) mitochondrial inheritance; (5) complex inheritance (Fig. 27.2). Moreover, it should be stressed that a genetic disorder is not always a transmitted condition. Although several cellular mechanisms strive to maintain DNA structure and sequence unaltered during the cell cycle, mutations and chromosomal anomalies can take place during gametogenesis (so-called *de novo* mutations). When *de novo* mutations occur, clinical phenotypes manifest as sporadic events in families with an unremarkable history, and in these families no inherited risk is found. *De novo* mutations usually result in severe phenotypes and represent a persisting reserve of otherwise selectively eliminated conditions.

Chromosomal inheritance

The correct segregation of genes through meiotic division is a critical step for the survival of a species. In humans, this function is carried out by 23 pairs of chromosomes (22 autosomal pairs and two sex chromosomes), each harbouring tens to thousands of genes. In chromosomal disorders, chromosome segments are missing from or added to the normal set, leading to the absence or duplication of various genes and to composite phenotypes. The most common clinical signs of chromosomal disorders are dysmorphic features and mental retardation, resulting from an unbalanced dosage of different genes. The severity of the phenotype may, however, vary according to the type and number of genes involved.

Most chromosomal disorders are associated with chromosomal abnormalities occurring *de novo* and thus the occurrence of the clinical phenotype is a sporadic manifestation. More rarely, chromosomal disorders (e.g. balanced translocations) arise from healthy carriers of balanced and phenotypically silent rearrangements. The presence of multiple miscarriages and/or mental retardation in a family may be suggestive of such parental rearrangements. The recurrence risk mainly depends on the type and size of the rearrangement, the chromosome involved and the sex of the carrier (the father being at increased risk) (Table 27.1).

Mendelian inheritance

Mendelian inheritance applies when mutations in a single autosomal gene are sufficient to determine a clinical phenotype. According to the type of genes and mutations implicated, we find autosomal recessive (AR) disorders, in which both copies of the disease gene have to be mutated in order to express a phenotype, and autosomal dominant (AD) disorders, in which a single copy of the gene is mutated.

- Autosomal recessive disorders are characterized by healthy carriers who are heterozygous for a mutated allele and affected individuals who have inherited two mutated alleles from carriers. Affected individuals may be homozygous, or what is termed

Table 27.1 Risk for relatives of proband for different disease modes of inheritance.

Inheritance	Risk to family members of a proband			
	Parents	Siblings	Offspring	Other family members
Chromosomal	Relative risks depend upon specific chromosomal rearrangement			
Autosomal recessive (AR)	Obligate heterozygotes Heterozygotes are asymptomatic	*At conception:* 25% chance of inheriting both disease alleles and being affected 50% chance of inheriting one disease-causing allele and being a carrier 25% chance of inheriting both normal alleles and being unaffected *Normal sibs:* 2 out of 3 chance of being a carrier	>99% heterozygotes (healthy carriers) Very rarely homozygous (affected) (only if husband/wife is heterozygous or affected) [frequency heterozygous in the general population × 0.5 (risk of transmitting the disease allele)] + [frequency homozygous in the general population × 1 (100% risk of transmitting a disease allele)]	Maternal and paternal relatives are at risk of being carriers
Autosomal dominant (AD)	One parent of the proband has the same disease-causing allele as the proband; that parent may or may not have symptoms depending on the penetrance of the disease allele	50% risk of inheriting the disease allele 50% risk of developing the disease for fully penetrant genes <50% risk of developing the disease for incomplete penetrant disease alleles (0.5 × penetrance rate). A proportion of sibs [0.5 × (1 – penetrance rate)] may carry the disease allele without expressing the phenotype	50% risk of inheriting the disease allele 50% risk of developing the disease for fully penetrant disease alleles <50% risk of developing the disease for incomplete penetrant disease alleles (0.5 × penetrance rate). A proportion of offspring [0.5 × (1 – penetrance rate)] may carry the disease allele without expressing the phenotype	
X-linked recessive	Mothers are obligate carriers. Mild symptoms of the disease may manifest	Males: 50% chance of inheriting the disease allele and of being affected Females: 50% change of being carriers with no or mild symptoms, 50% chance of not inheriting the disease allele and being normal	All daughters will be carriers Sons will not inherit the mutant allele, will not have the disease and will not pass it on to their offspring	Maternal aunts and their offspring may be at risk of being carriers or affected depending upon their gender
Mitochondrial	mtDNA deletions generally occur *de novo* and thus cause sporadic disease with no significant risk to other family members mtDNA point mutations and duplications may be transmitted through the maternal line The mother of a proband usually has the mtDNA mutation and may or may not have symptoms The father of a proband is not at risk of having the disease-causing mtDNA mutation	The risk to the sibs depends upon the genetic status of the mother. If the mother has the mtDNA mutation, all sibs are at risk of inheriting it	A male does not transmit the mtDNA mutation to his offspring A female harbouring a mtDNA mutation may transmit a variable amount of mutant mtDNA to her offspring, resulting in considerable clinical variability amongst sibs within the same nuclear family	The proband's grandmother and her descendants are at risk
Complex	Empirical risks should be deduced from disease-specific epidemiological studies			

mtDNA, mitochondrial DNA.

compound heterozygous, when each allele contains a different mutation. Autosomal recessive inheritance usually manifests as a sporadic event within pedigrees in which carriers are phenotypically normal. At conception, the sibs of probands have a 25% chance of inheriting both disease-causing alleles and being affected, a 50% chance of inheriting one disease-causing allele and being a carrier, and a 25% chance of inheriting both normal alleles and being unaffected. The normal sibs of a proband have a 2 out of 3 chance of being a carrier. The offspring of a proband are all obligate heterozygotes (Table 27.1). Consanguinity may significantly increase the risk of an autosomal recessive disorder being expressed, since a single ancestral mutation could be transmitted along both paternal and maternal lineages (Fig. 27.3).

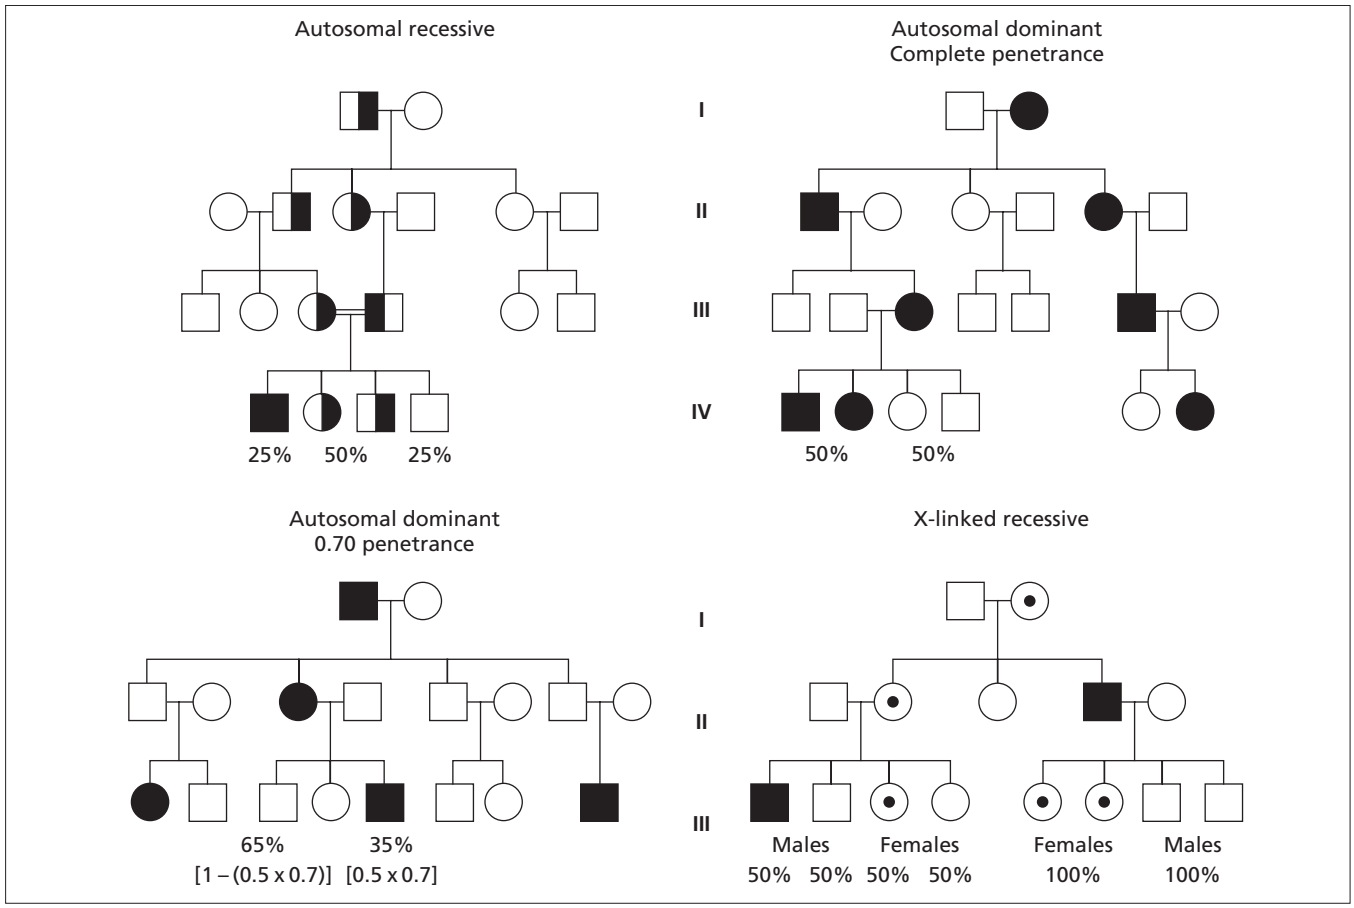

Fig. 27.3 Pedigrees showing different single-gene patterns of inheritance and relative risks for offspring.

- Autosomal dominant disorders are characterized by vertical transmission of the disease through generations. Affected individuals present a 50% risk of transmitting the phenotype to their offspring (Table 27.1). Autosomal dominant inheritance is typically recognized in large multigenerational pedigrees showing a high density of affected cases (Fig. 27.3).

By definition, single-gene mendelian disorders are homogenous traits; transmission of the disease is defined by Mendel's laws and phenotypes usually show little variability among affected individuals.

However, it is well known that several disorders classified as mendelian – mostly in the autosomal dominant category – show a certain degree of variability in expression of clinical features. This can be the result of *incomplete penetrance*, in which a proportion of individuals carrying the mutation(s) do not manifest the phenotype. The onset of clinical symptoms and variation in the severity of the phenotype also occur (Fig. 27.3). Recent advances in genetic research have revealed that the variability in expressivity found in some single-gene mendelian traits is definitively influenced by other genes. Since the phenotype is mostly determined by mutations in a single gene, we may define these traits as major-gene disorders. For the sake of simplicity, these are included in the single-gene disorder category, as the pattern of inheritance (so-called oligogenic inheritance) overlaps to a great extent with mendelian inheritance.

X-linked inheritance

When mutations occur in genes lying on the X chromosome, a peculiar mode of inheritance is found because of the difference in gene dosage between males and females. X-linked mutations are usually transmitted from heterozygous healthy females (carriers) to 50% of their offspring. Male offspring will develop the disease, since they lack the second normal copy of the gene (hemizygosity), whereas females will be the healthy carriers. A distinctive feature of X-linked inheritance is the absence of male-to-male transmission of the disease (since the Y chromosome is always transmitted). Since the disease is transmitted by normal carriers, we may define most X-linked disorders as recessive traits (Table 27.1 and Fig. 27.3).

It should, however, be stressed that use of the recessive–dominant dichotomy should be cautious, as female carriers can show a variable phenotype, with usually mild abnormalities, that is the expression of the random inactivation of one X chromosome. This phenomenon (also called lionization) occurs in a female in whom one X chromosome (either the maternally or paternally derived X) is randomly inactivated in early embryonic cells and this inactivation is carried forward by all cells descended from these cells. This is an epigenetic change, in other words an inheritable change in gene function without a change in the sequence of the DNA. X inactivation can occur in males with

syndromes (e.g. Klinefelter's) who have more than one X chromosome. Moreover, some X-linked genes show a clear dominant effect and heterozygous females express the full phenotype. Furthermore, in rare X-linked dominant syndromes, hemizygosity is lethal in males.

It is noteworthy that the counterpart of X-linked inheritance does not exist in practice, since no genes responsible for serious diseases are known to be mapped on chromosome Y. For those rare disease genes that are mapped on both sex chromosomes (within the so-called pseudoautosomal regions), the pattern of inheritance is typically mendelian.

Mitochondrial inheritance

In human cells about 1% of the DNA is contained within mitochondria as small circular genomes. The mitochondrial DNA (mtDNA) of each individual is derived from maternal mitochondria (in humans, sperm does not contribute to the initial set of mitochondria) and to replicate independently from nuclear DNA.

Mitochondrial DNA harbours 37 genes encoding for transfer RNA (tRNA) and proteins that are involved in mitochondrial function. Mitochondrial genes undergo a variety of mutations, leading to disorders that typically affect the central nervous system, heart, skeletal muscle, endocrine glands and kidneys; transmission is always from females, no transmission being observed from males (Table 27.1). Because of the maternal origin of mtDNA, a peculiar inheritance pattern is found (Fig. 27.4).

A further distinctive feature of these disorders is phenotypic variability in both the severity and progression of disease and the age of onset. Furthermore, individuals with no clinical manifestations may transmit the disease. The clinical heterogeneity is because the proportion of mutated mtDNA varies in different cells; in some cells, all mitochondria carry the mutated mtDNA (homoplasmy), while in others only a fraction of mtDNA is mutated (heteroplasmy). Thus, the variable expression of the disease is strongly influenced by the amount and the tissue distribution of mutated mtDNA. The proportion of offspring possibly affected is therefore variable and cannot be determined by any rule.

Since several genes involved in mitochondrial function are localized in nuclear DNA, it should be emphasized that mitochondrial inheritance does not apply to all mitochondrial disorders.

Complex inheritance

Most common disorders show a complex aetiology that includes multiple genetic and environmental factors. In these disorders, a single gene is not sufficient to cause the disease by itself, but increases the risk (i.e. carries genetic *susceptibility*). The disease may develop when other genes (polygenic disorders) or environmental factors (multifactorial disorders) are superimposed on a genetic predisposition. As a result, these conditions may show a familial tendency but do not fit into a clear inheritance pattern (Fig. 27.4).

Distinctive epidemiological features of genetically complex disorders are (1) increased clinical concordance among monozygotic twins; (2) increased risk for close relatives of affected individuals, rapidly decreasing for more distant relatives; and (3) pedigrees showing a sparse aggregation of affected cases. Recurrence risks are usually based on empirical data, indicating the risk for relatives of affected individuals as a function of the degree of relationship and of the presence of multiple affected cases in family (Table 27.1). For many complex disorders, large and dense pedigrees do occur, showing that a subset of occasional families carry rare genetic variants which have a major effect. Recognizing these mendelian subsets is crucial to identifying high-risk individuals.

Genetic counselling in epilepsy: approaching a heterogeneous disorder

Epilepsy is a very heterogeneous disorder, which is manifested in a variety of clinical signs and which has multiple causes. Generally speaking, humans may have a seizure or develop epilepsy as a result of acquired and/or genetic causes.

In the *symptomatic epilepsies*, the seizures are caused by neurological damage. These conditions are commonly acquired during postnatal life, and causes include head injury, cerebrovascular disease, central nervous system infections and brain tumours or degenerative disorders. There are, therefore, few influenced by the genetic background, although the genetic make-up can affect an individual's susceptibility to developing epilepsy; for instance,

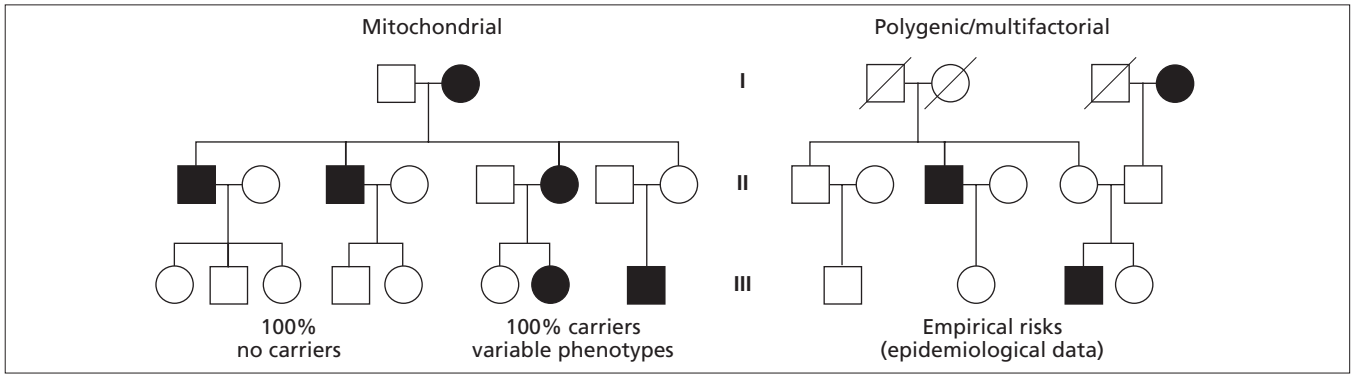

Fig. 27.4 Pedigrees showing complex patterns of inheritance.

the rate of post-traumatic epilepsy after head injury has been found to be greater in patients with a family history of epilepsy. In rare cases, symptomatic epilepsy may arise from structural brain lesions or altered metabolic states that are associated with specific inherited disorders (e.g. tuberous sclerosis, neuronal ceroid lipofuscinoses).

By contrast, individuals with *idiopathic epilepsies* suffer recurrent unprovoked seizures without any detectable neurological or metabolic abnormality. Epidemiological studies have shown that genetic factors strongly contribute to the aetiology of idiopathic epilepsies [4]. The mode of inheritance of idiopathic epilepsy is, however, highly variable and includes mendelian, polygenic and multifactorial traits. In recent decades, a great effort has been made to narrow down phenotypes in the idiopathic epilepsies according to clinical details such as age of onset, type of seizures and EEG findings. Epileptic syndromes have been defined according to unique clusters of signs and symptoms, and then grouped into extended classifications [5,6]. On this basis, epidemiological studies have been undertaken in an attempt to provide empirical estimates of recurrence risks for each phenotypic trait. In epilepsy, most of the available data for genetic counselling are derived from this exhaustive workup. Although many patients do not fit any proposed phenotypic class, and clinical classification may have little aetiological value, it is important to approach the current classification as a diagnostic scheme on which empirical risks for recurrence have been calculated. Thus, by definition, relatives of probands affected by idiopathic generalized epilepsy show an increased risk of developing generalized epilepsy. By contrast, relatives of individuals showing temporal lobe epilepsy with hippocampal sclerosis are not considered to be at increased risk.

The classification of some genetically determined forms of epilepsy is likely to undergo extensive reappraisal, with significant implications for clinical diagnosis and genetic counselling. Dissecting the complex aetiology of different forms of epilepsy will have considerable impact on genetic counselling by providing reliable genetic tests for diagnosis and more accurate estimation of risks. A further issue, which is critical in relation to genetic counselling, is the clinical variability observed for many epileptic traits. Thus, although it is often possible to estimate a recurrence risk for a specific disorder, it may be impossible to estimate severity of the disease. Whilst this question may be of little significance when clinical variability encompasses a benign spectrum, it becomes very important in conditions in which severe phenotypes occur. A deeper knowledge of the aetiological factors involved in such disorders and the development of appropriate tests are crucial to addressing this issue.

Idiopathic epilepsies

In epilepsy, the term idiopathic refers to clinical conditions in which seizures manifest as unique symptoms in the absence of structural brain lesions or other neurological dysfunctions. Most of these conditions cause generalized epilepsy, although several focal forms of epilepsy are now also recognized to be genetically determined [7]. A distinctive feature of most idiopathic forms is the age dependency of clinical manifestations. Seizures and EEG abnormalities are observed in a specific age window, usually within the first two decades of life, as a result of a complex interaction between brain maturation and inherited factors. The inheritance pattern of idiopathic epilepsy is heterogeneous; the most common forms show a complex mode of inheritance, indicating the involvement of several genes and environmental factors, whilst other phenotypes are inherited as single- or major-gene traits. The age dependency of idiopathic forms of epilepsy can complicate diagnosis in adults and make the recognition of mendelian patterns of inheritance difficult; and the incidence of single- or major-gene traits in the general population is probably underestimated. In view of the above considerations, idiopathic epilepsies can be subdivided into mendelian, complex and sporadic forms.

Mendelian epilepsies

Seven syndromes have so far been identified as having mendelian inheritance: benign familial neonatal seizures (BFNS), benign familial infantile–neonatal seizures (BFNIS), benign familial infantile seizures (BFIS), generalized epilepsy with febrile seizures plus ($GEFS^+$) syndrome, autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE), autosomal dominant partial epilepsy with auditory features (ADPEAF) and benign adult familial myoclonic epilepsy (BAFME) (Table 27.2). These phenotypes have been clearly characterized at the clinical level and are consistently recognized worldwide. In addition, several epilepsies with mendelian inheritance have been reported in single families, and additional studies will be necessary to assess whether these traits have importance in the general population.

Benign familial neonatal seizures

Seizures are the most frequent neurological events in newborns. In most cases, seizures are the result of an acute severe metabolic or structural cerebral disturbance. A small number of neonatal seizures, however, show no obvious precipitating factors and have a benign prognosis and a family history; some of these cases are defined as BFNS. Distinctive clinical features of BFNS include the occurrence of brief focal or generalized seizures with an onset between 2 and 4 days of life, and which spontaneously remit within a few weeks. Seizures usually start with a tonic posture, ocular signs (staring, blinking or gaze deviation) and apnoea and progress to clonic movements and motor automatism [8]. The ictal EEG usually shows a characteristic sequence of bilateral flattening for 1–5 s, followed by bilateral discharges of slow waves and spikes lasting 1–2 min. The cortical spread may vary between left and right among seizures, resulting in asymmetric motor signs. BFNS was originally classified as a generalized epilepsy but it has been recently included among the partial epilepsies [6]. However, in view of the immaturity of the neonatal brain, such a rigid classification is inappropriate. Seizures are usually controlled by phenobarbital; phenytoin and valproate are occasionally used in non-responsive patients. Psychomotor development is normal, although about 10–15% of patients will develop febrile or non-febrile seizures later in childhood or adolescence [9]. The pattern of inheritance is typically autosomal dominant with high penetrance (around 85%), indicating involvement of a single gene. Mutations in the voltage-gated potassium channel α-subunit genes *KCNQ2* and *KCNQ3* have been identified as responsible for BFNS, and several mutations which result in either

Table 27.2 Mendelian epilepsies.

Disease	Age at onset	Suggestive clinical and EEG features	Mode of inheritance	Gene(s)
Benign familial neonatal seizures	2–4 days	Tonic posture, ocular signs, apnoea evolving into clonic movements and motor automatisms. Ictal EEG: bilateral flattening of the EEG followed by bilateral discharge of slow waves and spikes	AD, 0.85 penetrance	*KCNQ2*, *KCNQ3*
Benign familial neonatal–infantile seizures	2 days to 6 months	Focal seizures originating from posterior regions with secondary generalization and prominent motor manifestations	AD, high penetrance	*SCN2A*
Benign familial infantile seizures	4–7 months	Seizures usually in clusters: psychomotor arrest, slow deviation of the head and eyes, diffuse tonic contraction, cyanosis and limb jerks. Ictal EEG: fast activity in occipitoparietal areas and secondary generalization	AD, high penetrance	Unknown
Generalized epilepsy and febrile seizures plus (GEFS$^+$) syndrome	1–9 years (mean 1.5)	Very frequent febrile seizures lasting beyond 6 years and/or followed by generalized tonic–clonic seizures. Occasional recurrence of afebrile generalized myoclonic, absence and atonic seizures	AD, 0.80 penetrance	*SCN1A*, *SCN1B*, *GABRG2*
Autosomal dominant partial epilepsy with auditory features	8–50 years (mean 20)	Focal seizures mostly with secondary generalization, auditory auras, seizures triggered by noise	AD, 0.70 penetrance	*LG1*
Autosomal dominant nocturnal frontal lobe epilepsy	1–55 years (mean 14)	Nocturnal motor seizures: moans, extension and abduction of arms, axial rocking, grabbing, oral automatisms, aura. Ictal EEG: fast bifrontal rhythm	AD, 0.80 penetrance	*CHRNA4*, *CHRNB2*
Benign familial adult myoclonic epilepsy	18–45 (mean 30)	Tremulous finger movements and/or myoclonus of the extremities and rare generalized tonic–clonic seizures. Photic sensitivity. Enhanced long-loop C-reflex. Ictal EEG: generalized spikes or poly-spikes and slow-wave complexes	A, high penetrance	Unknown

AD, autosomal dominant.

a truncated or altered protein have so far been described [10,11].

Genetic testing for BFNS includes the mutational screening of *KCNQ2* and *KCNQ3* by using genomic DNA from patients. This is costly and should be undertaken only when the clinical diagnosis is highly suggestive. Familial clustering of neonatal seizures constitutes a distinctive marker of the syndrome, although it may be not easily recognized because of the absence of clinical and EEG signs in adult individuals. For genetic counselling, the risk estimate is typical of any autosomal dominant single-gene disorder with high penetrance, with a 50% risk of transmission for offspring or siblings of affected individuals.

Benign familial neonatal–infantile seizures

Benign familial neonatal–infantile seizures were originally described by Kaplan and Lacey as an autosomal dominant epileptic trait characterized by clusters of seizures developing between 2 days and 3.5 months and spontaneously remitting after the first year of life and with a benign outcome [12]. This phenotype was under-recognized for a long time and only recently has the genetic aetiology of this disorder been dissected and its phenotypic spectrum further delineated [13]. BFNIS is characterized by focal seizures usually originating from posterior regions with secondary generalization and prominent motor manifestations as described for BNFS and BFIS. Seizures onset between 2–3 days and 6 months, usually around the ages of 2–3 months. The diagnosis of BFNIS should be considered when seizures start before the age of 6 months, particularly if a combination of neonatal and early-infantile seizures is found in the family. Genetic studies have revealed that BFNIS is due to mutations affecting *SCN2A*, the gene encoding the α_2-subunit of the neuronal voltage-gated sodium channel [13–15]. The expression of mutant channels in cultured hippocampal neurons has revealed that these mutations increase both subthreshold and action Na^+ currents causing hyperexcitability [16]. So far, only a few families with BFNIS have been reported. However, all have *SCN2A* mutations and BFNIS is a benign age-related trait. The mutational screening of *SCN2A* has limited utility in the clinical management; however, it may be attempted to obtain the confirmation of the diagnosis in highly suggestive families.

Benign familial infantile seizures

Benign familial infantile seizures were described in 1992 as an autosomal dominant disorder characterized by partial seizures occurring between 4 and 7 months and spontaneously remitting at about 18 months, and with a benign outcome [17]. Seizures are brief (usually less than 1 min), occur mainly in clusters of 4 to 10 per day and last for a period of 2–4 days. Isolated seizures may sporadically precede clusters. Clinically, seizures are highly stereotyped among patients, and include psychomotor arrest,

slow deviation of the head and eyes to one side, diffuse tonic contraction, cyanosis and limb jerks starting unilaterally and evolving into synchronous or asynchronous bilateral manifestations. Depending on the seizure, the head and eyes may be turned to either the right or left side. Ictal EEGs show a fast activity originating in the occipitoparietal areas of one hemisphere and then spreading over the entire brain and increasing in amplitude. Phenobarbital therapy is usually effective and brings seizures under control within 2 days. Interictal EEG and psychomotor development are normal and no increased risk of developing febrile or non-febrile seizures is observed in later life.

The mode of inheritance of BFIS is typically autosomal dominant, although occasionally the disease is transmitted from apparently healthy individuals. It is not clear whether this is due to incomplete penetrance or difficulties in collecting a reliable history from adult individuals.

Non-familial cases with idiopathic seizures with onset within the first year of age, spontaneously remitting and showing overlapping clinical features with BFIS, have been described [18]. Clinical dissection of benign infantile seizures has been attempted in order to identify any phenotypic variants that may underlie the observed difference in inheritance pattern. In some (but not all) sporadic cases, EEG recordings have demonstrated a temporal lobe onset, suggesting a different pathogenesis.

Extensive family studies led to the localization of two different BFIS genes on chromosomes 19q and 2q. Genetic heterogeneity is further emphasized by families in which the disease is not linked to either 19q or 2q, thus suggesting the presence of at least a third BFIS gene [19–21]. The complexity of the BFIS syndrome is, moreover, highlighted by recent reports of familial cases of infantile seizures and paroxysmal choreathetosis (ISCA syndrome) [22]. In ISCA, typical epileptic manifestations of BFIS are associated with involuntary movements that occur spontaneously (dystonic type) or are induced by movement (kinesiogenic type), exertion or anxiety. In familial ISCA, both choreathetosis and seizures show reduced penetrance and thus the disorder may manifest as an epileptic, choreoathetotic or combined phenotype. Whether BFIS and ISCA constitute different clinical manifestations of the same genetic defects is currently unclear. Both ISCA and BFIS have been linked to chromosome 16p in some families, suggesting a genetic overlap between these two syndromes [23]. The identification of *SCN2A* mutations on chromosome 2q24 in BFNIS syndrome and in some families with typical BFIS [13,24] confirmed that these syndromes show a significant genetic and clinical overlap. Due to the rare occurrence of *SCN2A* mutations in BFIS, the screening of this gene is usually negative and should not be routinely requested.

Generalized epilepsy with febrile seizures plus syndrome

The GEFS$^+$ syndrome was originally described in Australia and has since been reported worldwide in many families. The epilepsy is inherited as an autosomal dominant trait [25]. Clinical features include febrile seizures and various forms of other seizures, mostly generalized, but more recently non-febrile focal seizures have been also recognized to occur (and for this reason, it has been suggested that the syndrome be renamed genetic epilepsy with febrile seizures plus. The febrile seizures last beyond 6 years of age (hence the term febrile seizures plus) and are frequently followed by generalized non-febrile seizures of various types, such as myoclonic, absence and atonic seizures. In GEFS$^+$ families, however, about 40% of affected individuals show typical febrile seizures without further seizures, reflecting variable expression.

The pattern of transmission is typically autosomal dominant and a single major gene is thought to determine the phenotype. Incomplete penetrance and variable expression of the disease suggest that minor alleles might influence the phenotype. So far, three major genes have been associated with the GEFS$^+$ syndrome: voltage-gated sodium channel subunits α_1 and β_1 genes (*SCN1A* and *SCN1B*, respectively) [26,27] and the $GABA_A$ receptor subunit γ gene (*GABRG2*) [28]. GEFS$^+$ can be difficult to distinguish from febrile seizures or common forms of idiopathic generalized epilepsy if the familial clustering is missed. The occurrence of febrile seizures plus is an important diagnostic clue. Genetic counselling should take into account the variability of the disease, which may manifest with severe (i.e. myoclonic astatic epilepsy) or mild phenotypes [29]. Incomplete penetrance (about 80%) lowers the risk for relatives of probands compared with fully penetrant traits.

The fact that the GEFS$^+$ genes so far identified account for only about 20% of the GEFS$^+$ phenotypes indicates that other genes are involved. The screening of GEFS$^+$ genes is a costly task and should be undertaken only to confirm diagnosis when febrile plus seizures are consistently found in different family members.

Autosomal dominant nocturnal frontal lobe epilepsy

Frequently misdiagnosed as sleep disorder, ADNFLE is characterized by clusters of brief nocturnal motor seizures that begin at different ages – usually in childhood – and may persist throughout adult life [30]. Seizures are brief – usually 30–40 s – and occur in clusters of up to 20 attacks during light sleep. Clinical manifestations include moans, extension and abduction of arms, axial rocking, grabbing at people or objects and oral automatisms. Individuals may experience an aura associated with tonic and hyperkinetic motor activity. The ictal EEG shows generalized high-voltage slow and sharp activity, followed by fast bifrontal rhythm and then by a burst of poly-spikes and slow waves with sudden cessation. Intrafamilial variability in the severity of symptoms is frequently observed. Interictal and psychomotor development are normal. Carbamazepine is usually effective in controlling seizures.

Autosomal dominant nocturnal frontal lobe epilepsy is an inherited autosomal dominant condition with 80% penetrance. Seizures may be difficult to detect in family members, and nocturnal motor manifestations are frequently misdiagnosed as sleep disorders such as nightmares, hysteria and paroxysmal dystonia. Clinical heterogeneity further complicates clinical diagnosis. The presence of non-familial cases suggests a composite aetiology for nocturnal frontal lobe epilepsy. Mutations in the neuronal acetylcholine receptor α_4- and β_2-subunit genes (*CHRNA4* and *CHRNB2*) have been identified in ADNFLE patients [31,32]. More recently, mutations of the gene encoding the α_2-subunit of the acetylcholine receptor – *CHRNA2* – have been identified in a single family with autosomal dominant

inheritance, confirming the highly heterogeneous genetic aetiology of this phenotype [33]. Analysis of ADNFLE genes demonstrated a *de novo* mutation in only one of several patients affected by non-familial nocturnal frontal lobe epilepsy, thus suggesting that other factors are involved in sporadic nocturnal frontal lobe epilepsy [34].

In ADNFLE, as in all mendelian forms of epilepsy, genetic counselling should first focus on clinical diagnosis and the recognition of familial clustering. The screening of *CHRNA4* and *CHRNB2* may then be attempted when the transmission pattern supports autosomal dominant inheritance. *CHRNA6* mutations have been identified in only a single family so far and the screening of this gene should not be attempted for diagnostic purposes. Likewise, current data do not suggest extending the test to sporadic cases.

Autosomal dominant partial epilepsy with auditory features

Autosomal dominant partial epilepsy with auditory features is a syndrome which has been recently delineated by Ottman and colleagues [35,36], and is now recognized to have a worldwide occurrence. The distinctive clinical features are autosomal dominant mode of inheritance with incomplete penetrance, an onset of seizures spanning childhood and adulthood but usually in adolescence, the occurrence of rare focal seizures mostly with secondary generalization, the absence of structural brain abnormalities and a benign evolution. The clinical hallmark of this phenotype is the auditory aura occurring during focal seizures and suggesting a lateral temporal seizures onset. Different types of auras such as visual or aphasic may also occur, which confirm the localization to the lateral temporal lobe [and thus the alternative name of autosomal dominant lateral temporal lobe epilepsy (ADLTE) has been suggested [37]]. The interictal EEG is not usually contributory, although in some patients mild temporal EEG abnormalities occur. In addition, the seizures may be triggered by sudden external stimuli, in particular noise [38]. Genetic studies led to the identification of mutation in leucine-rich glioma-inactivated 1 (*LGI1*), a gene originally described to be deleted in gliomas [39]. *LGI1* mutations are almost invariably associated with familial forms of this condition, and only a single *de novo* mutation has been identified in a sporadic case affected by idiopathic partial epilepsy with auditory features [40]. In addition, the analysis of mutations in this gene in patients with common forms of temporal lobe epilepsy has been consistently negative, indicating that *LGI1* mutations are specific for ADPEAF and are not a common genetic factor for temporal lobe epilepsy [41]. Mutations may lead to premature protein truncation or single amino acid changes, and no genotype–phenotype correlations have so far become apparent. The biological function of *LGI1* has been extensively investigated in recent years, but to date no clear-cut picture has emerged. A first study established that *LGI1* was a novel subunit of the voltage-gated potassium (K_v) channel subunit $K_{v1.1}$ and suggested that *LGI1* mutations induce changes in the inactivation gating of presynaptic A-type channels [42]. Another study showed that LGI1 is a secreted protein that enhances AMPA receptor-mediated synaptic transmission through the binding of ADAM22, a transmembrane protein that when mutated itself causes seizure [43]. The presence of two different isoforms, one secreted and the other retained within the cell, may underlie the complex biological function of LGI; however, further studies will be necessary to clarify the role of *LGI1* in epileptogenesis [44]. As was observed in other mendelian epilepsies, a consistent proportion of families (about 50%) fulfilling the clinical criteria of ADPEAF do not show *LGI1* mutations [45]. The screening of *LGI1* is recommended in suggestive families for diagnosis confirmation. The prognostic value of the test is limited because of the variable clinical expressivity of *LGI1* mutations.

Benign familial adult myoclonic epilepsy

Benign familial adult myoclonic epilepsy (BFAME) is a rare phenotype characterized by tremulous finger movements and/or myoclonus of the extremities and rare generalized tonic–clonic seizures [46]. Myoclonus is easily precipitated by photic stimuli and sporadically by insomnia and fatigue. Peculiar electrophysiological findings are generalized spikes or poly-spikes and slow-wave complexes in the EEG, enlarged cortical components of somatosensory-evoked potential and enhanced long-loop C-reflex. No neurological degeneration, dementia or ataxia are found in BFAME patients, as have been observed for other mendelian idiopathic forms of epilepsy. Myoclonic jerks and tremulous finger movements typically begin around between adolescence and the third decade of life. Generalized tonic–clonic seizures manifest later with a sporadic occurrence [47]. This late age at onset is a distinctive sign of BFAME. Clonazepam or sodium valproate is usually effective in treating the disorder, though the tremulous finger movements may not disappear with therapy.

Family studies indicate that BFAME is an autosomal dominant trait showing high/complete penetrance and genetic heterogeneity. A BFAME gene has been localized on chromosome 8q24 [48,49] and chromosome 2p11.1–q12.2 [50,51]; since the mutant genes have not yet been identified, no genetic tests are available other than linkage analysis of chromosome 8q and 2p loci on informative extended pedigrees. The accurate analysis of clinical and electroclinical findings and the pattern of inheritance can yield critical clues to establishing a diagnosis and providing genetic counselling.

Despite considerable clinical and electroclinical diversity, the mendelian idiopathic forms of epilepsy so far described share important genetic features:

- Mendelian idiopathic forms segregate with autosomal dominant inheritance.
- Different genes are involved in the same phenotype, thus indicating genetic heterogeneity.
- Sporadic cases of mendelian forms are occasionally found, the significance of which is not fully understood. Possible explanations include failure to recognize familial clustering, *de novo* mutations arising from non-carrier individuals and inadequate differential diagnosis from other epileptic conditions.
- Genetic tests for mendelian idiopathic forms of epilepsy are not yet available or are very costly (e.g. mutational screening of different genes).

In light of the above considerations, genetic counselling in cases of mendelian epilepsy should rely on careful analysis of clinical signs in patients and family members and on recognition of a clear pattern of transmission. When available, genetic testing may be

undertaken to confirm the diagnosis and to better estimate recurrence risks in relatives of affected individuals.

Complex epilepsies

In human genetics, the term 'complex' refers to conditions arising from multiple concomitant factors of either genetic (polygenic inheritance) or genetic and environmental origin (multifactorial inheritance). In mendelian disorders, the mode of inheritance may be easily deduced from the analysis of transmission patterns within pedigrees. In complex disorders, segregation of the disease does not fit a precise pattern and more exhaustive epidemiological studies are needed in order to define the mode of inheritance. In genetic epidemiology, important indexes are defined in terms of the clinical concordance of monozygotic (MZ) twins and the risk of recurrence for different degree relatives of affected individuals. The first index indicates the heritability of a disorder; the second indicates the complexity of the genetic component. The higher the concordance rate among MZ twins, the stronger the contribution of genetic factors to the disorder. The higher the risk for relatives of probands, the fewer the genetic factors involved. Many forms of epilepsy show a complex inheritance, and epidemiological data are the only available tools for genetic counselling.

Idiopathic generalized epilepsies

The term idiopathic generalized epilepsies (IGEs) covers the most common forms of idiopathic epilepsy and includes childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE), juvenile myoclonic epilepsy (JME) and epilepsy with generalized tonic–clonic seizures only (EGTCS), as defined by the 1989 International Classification of Epileptic Syndromes and further modifications [5,6].

Several epidemiological studies have been conducted in recent decades in order to dissect the genetic aetiology of IGE. Although different methodological approaches have been adopted, results agree on a concordance rate of about 70–80% in MZ twins, increasing up to 90% when epileptiform EEG changes are considered [52–54], and a risk of developing IGE for first-degree relatives of probands of about 5–15% (compared with a cumulative incidence of about 0.5% in the general population) [55,56]. The recurrence risk for first-degree relatives is significantly lower in IGE than in single-gene disorders; when second-degree or more distant relatives are considered, the risk is close to that of the general population.

When considered together, the high concordance rate in MZ twins and the rapid decrease in risks for more distant relatives indicate a strong but complex genetic aetiology [57]. The involvement of multiple interacting susceptibility genes would result in low familial clustering and the absence of a recognizable pattern of inheritance. On the other hand, large and dense pedigrees are rarely found and suggest mendelian inheritance for a subset of IGE cases (Table 27.3).

The Rochester study has drawn up various clinical parameters in order to further refine recurrence risks for relatives of affected individuals [55,56].

- *Risk for siblings*. When all forms of epilepsy are considered, the risk of developing epilepsy for a sibling of a proband is about 4%. This increases to 6% when the IGE subgroup is considered and to 8% if photosensitivity is found in the proband or if a parent has epilepsy. The risk of developing generalized epilepsy for a sibling rises to 12% when a parent also shows generalized EEG abnormalities and to 15% when the sibling shows a generalized EEG trait.
- *Risk for offspring*. For all forms of epilepsy, the risk of recurrence for offspring of affected individuals is about 4–6%. A striking difference is seen between the offspring of affected females (8.7%) and those of affected males (2.5%) but it is not yet understood why. If the IGE subgroup is considered, the risk for offspring increases to about 9%.

Interestingly, if EEG abnormalities are considered, a recurrence rate of about 25–30% is found for specific traits (e.g. generalized spike–wave 3 Hz or generalized poly-spike EEGs) in first-degree relatives of probands [58,59]. Clinical variability among family members provides further epidemiological evidence. A study of 74 families with at least three members affected by IGE showed that only 25% of the families were concordant for a specific IGE syndrome, whereas 75% of families segregated at least two IGE

Table 27.3 Complex epilepsies.

Disease	Mode of inheritance and empiric risks for first-degree relatives	Rare mendelian subsets	Mode of inheritance	Gene(s)
Idiopathic generalized epilepsies (childhood absence epilepsy, juvenile absence epilepsy, juvenile myoclonic epilepsy, epilepsy with generalized tonic–clonic seizures only)	Polygenic/multifactorial Risk for first-degree relatives: Seizures 5–15% Generalized spike-wave EEG trait 20–30%	Juvenile myoclonic epilepsy Childhood absence epilepsy with tonic–clonic seizures	AD (penetrance 0.7) AD (penetrance 0.8)	*EFHC1*, *GABRA1* *GABRB3*
Rolandic epilepsy	Polygenic/multifactorial Risk for first-degree relatives: Seizures: 10% Centrotemporal spikes: 20–30%	Rolandic epilepsy and speech dyspraxia Rolandic epilepsy and exercise-induced dystonia and writer's cramp	AD AR	 Unknown
Temporal lobe epilepsy	Sporadic conditions: no increased risk for relatives	Familial partial lobe epilepsy with variable foci Familial mesial temporal lobe epilepsy	AD AD (low penetrance)	Unknown Unknown

AD, autosomal dominant; AR, autosomal recessive.

syndromes [60]. These data reinforce the hypothesis that IGE might represent a clinical continuum which is determined by a cohort of susceptibility genes.

Efforts have been made to identify both susceptibility alleles for common forms of IGE and major genes involved in rare mendelian subsets. In various studies, putative susceptibility loci have been localized [61–63]. One such susceptibility allele for JME has been localized within the *BRD2* gene on chromosome 6p [64], but the role of *BRD2* in IGE is still controversial [65]. Thus, so far, there are no well-established genetic variations associated with genetic susceptibility to IGE and no tests available to estimate the risk. Mutations in rare autosomal dominant subsets have been identified for CAE (*GABRB3*) [66] and for JME (*GABRA1* and EFHC1) [67,68].

In clinical practice, the estimation of recurrence risks for relatives of individuals affected by IGE is, in most situations, based on epidemiological data. A possible methodological approach to the estimation of risks for IGE has been proposed above. The mutations identified in a few autosomal dominant pedigrees are rare and the implementation of any genetic test in the diagnostic workup is not recommended.

Idiopathic partial epilepsies

Different forms of partial epilepsy have been described, which have a complex genetic origin (Table 27.3).

Benign childhood epilepsy with centrotemporal spikes (rolandic epilepsy)

Rolandic epilepsy is a common disorder characterized by brief, focal, hemifacial motor seizures that usually manifest during sleep and frequently evolve into generalized tonic–clonic seizures. The seizures typically begin between 3 and 13 years of age, and abate by the age of 16 years. The EEG hallmark of the syndrome is a striking age-dependent centrotemporal spike discharge. The spike discharge can occur in family members without the occurrence of seizures. The genetics of rolandic epilepsy are complex and controversial. Although the rate of clinical concordance in MZ twins has varied from 0% to 100% in different studies, it is widely accepted that genetic factors are involved in the aetiology of rolandic epilepsy [54,69,70]. A 15% risk of developing rolandic epilepsy has been reported for first-degree relatives of probands; this rises to about 30% if centrotemporal EEG abnormalities are considered [71]. In view of this, polygenic and multifactorial inheritance have each been proposed for seizures, and a pseudo-dominant mode of inheritance for rolandic discharges. So far, however, the mode of inheritance is unclear. Rolandic epilepsy has also been found to segregate in association with other neurological conditions, thus defining a few rare mendelian phenotypes such as the increasingly recognized condition named rolandic epilepsy and speech dyspraxia [72–74] or the autosomal recessive rolandic epilepsy with paroxysmal exercise-induced dystonia and writer's cramp [75].

Familial temporal lobe epilepsy

Temporal lobe epilepsy is generally considered have a lesional origin (in other words to be a symptomatic epilepsy), although it has long been recognized that some cases have a positive family history [76,77]. In recent years, different familial forms of temporal epilepsy have been described. Most of these represent rare phenotypes observed in one or few pedigrees. Autosomal dominant temporal lobe epilepsy may be found in families with the *LGI1* mutations as a part of the ADPEAF phenotype [35–38, see above]. Temporal lobe epilepsy has, furthermore, been found to segregate in a condition known as familial partial epilepsy with variable foci (FPEVF) and a gene has been mapped on chromosome 22q [78]. In addition, the description of a few families with multiple members affected by mesial temporal lobe epilepsy indicates that genetic factors may exceptionally underlie this condition [79,80]. However, no pathogenic mutations have been identified so far and genetic testing is not available for the most common forms of temporal lobe epilepsy. The recognition of rare mendelian phenotypes through the analysis of specific clinical and familial data is critical to identifying high-risk pedigrees. On the other hand, the risk of developing a temporal lobe epilepsy for offspring or siblings of probands with negative family history is not significantly increased.

Sporadic epileptic syndromes

For some epilepsies, neither hereditary nor environmental or lesional causes have unequivocally been identified. Most of these are complex and usually severe phenotypes with onset in infancy or early childhood, such as West syndrome, Lennox–Gastaut syndrome, epilepsy with myoclonic–astatic seizures, and severe myoclonic epilepsy in infancy. The identification of mutations within the neuronal sodium channel gene *SCN1A* in severe myoclonic epilepsy in infancy (SMEI) patients yielded important insight into the genetics of severe sporadic epileptic conditions [81].

Severe myoclonic epilepsy in infancy

Severe myoclonic epilepsy in infancy manifests itself within the first year of life with tonic, clonic or tonic–clonic seizures. Seizures are frequent and prolonged and are often associated with fever. Later in life, patients develop atypical absence, myoclonic, generalized tonic–clonic and partial seizures. Psychomotor development is normal at onset but development stagnation and progressive ataxia occur after the second year. Seizures are usually refractory to drug therapy [82].

Although a positive familial history of febrile seizures has been described, SMEI manifests itself as a sporadic condition [83,84]. In at least 70% of patients, SMEI is due to *de novo* mutations in the neuronal sodium channel gene *SCN1A,* which occur during gametogenesis in one of the parents. Thus, the lack of familial clustering observed in SMEI is consistent with the sporadic occurrence of *SCN1A* mutations. From this standpoint, SMEI is a genetic disorder even though it is not usually hereditary. The occurrence of SMEI in siblings has been rarely reported and is attributed to the presence of a somatic or a germline mosaicism in one of the parents [85]. Interestingly, *SCN1A* is also involved in other severe related encephalopathies [86,87] and in GEFS^{+} syndrome [26, see above]. Genotype–phenotype correlations indicate that mutations resulting in the premature truncation of the channel subunit (e.g. nonsense, frameshift) lead to severe encephalopathic phenotypes whereas mutations affecting a single amino acid (e.g. missense) lead to either severe or milder epileptic trait according to the functional consequence on channel activity [88].

In addition, about 5% of the SMEI patients show a genomic deletion affecting part of the entire *SCN1A* gene [89]. The investigation of the epileptic *SCN1A* knockout mouse revealed a selective deficit of the voltage-gated sodium current in GABAergic neurones [90]. Thus, the observed differences in severity are probably due to the different effects of mutations on *SCN1A* function: in SMEI, channel activity is heavily impaired, whereas in GEFS$^+$ a residual activity is maintained. As more than 70% of the SMEI patients have mutations in the *SCN1A* gene, the screening of *SCN1A* is a valuable diagnostic tool [88]. The test has a significant clinical utility by allowing the early diagnosis with significant impact in the management of the patients. In addition, the identification of *SCN1A* mutations may assist the parents of a proband in planning future pregnancies. Indeed, the recurrence risk for parents with a child carrying a *de novo* mutation is low, except in the rare situation in which somatic or germline mosaicism occurs that may not be detectable by routine genetic testing.

Febrile seizures

The most common precipitant of seizures is fever and 3% of the population experience febrile seizures during childhood. Although febrile illnesses are acquired, pre-existing inherited factors determining a low threshold for febrile seizures are indicated by the high rate of familial clustering.

Febrile seizures have long been observed to occur in pedigrees. In MZ twins, clinical concordance has been found to be increased by 35% to 70%, depending on ascertainment strategy [91,92]. Epidemiological studies have reported an increased risk for first-degree relatives of probands, ranging from 8% in whites to up 20% in Japanese, in comparison with rates of 3% and 7% respectively in the general populations [93,94]. The mode of inheritance is by definition multifactorial, since an acquired condition is needed to trigger seizures. By contrast, the mode of transmission of genetic susceptibility is controversial. Polygenic inheritance has been proposed as most common, whereas pseudodominant inheritance has been suggested for rare large pedigrees [95]. A clinical approach has attempted to differentiate high-risk families segregating high-penetrant genes from the general population. Whether the number of seizures occurring in patients and EEG abnormalities correlate with higher recurrence risk is controversial.

A major epidemiological finding is the 2- to 10-fold increased risk for febrile seizures probands of developing afebrile seizures later in life. On the basis of retrospective studies, it has been proposed that prolonged febrile seizures frequently observed in the history of patients with temporal lobe epilepsy may lead to mesial temporal sclerosis [96,97]. On the other hand, genetic factors underlying febrile seizures could also confer liability to epilepsy [29].

Recent studies have provided clues to the mode of inheritance of febrile seizures and their relationship with epilepsy. Genotype–phenotype correlations in GEFS$^+$ families demonstrate that about 90% of individuals carrying mutations on *SCN1A*, *SCN1B* and *GABRG2* genes show febrile seizures and about half of these develop idiopathic generalized epilepsy [26–28]. Thus, early epidemiological data indicating autosomal dominant inheritance in a subset of febrile seizures cases and a common genetic aetiology for febrile seizures and epilepsy found strong support from biological evidence. On the other hand, the lack of causative genes for pure febrile seizures provides an indirect confirmation of this genetic complexity.

Genetic counselling in febrile seizures relies on empirical epidemiological data. The recognition of occasional autosomal dominant subsets of febrile seizures (including GEFS$^+$ syndrome) that may manifest as non-specific familial clustering of febrile seizures cases should, however, lead to caution when attempting to identify high-risk subjects.

Genetic syndromes including epilepsy as an important clinical feature

A variety of genetic syndromes include epilepsy as an important component (Table 27.4). The seizure disorders in these conditions usually consist of symptomatic generalized epilepsies associated with structural brain lesions and/or metabolic abnormalities of

Table 27.4 Genetic syndromes including epilepsy as important feature.

Group	Name of disease
Neurocutaneous	Tuberous sclerosis
	Neurofibromatosis
Malformations of cortical development	Ito hypomelanosis
	Miller–Dieker syndrome
	X-linked lyssencephaly
	Subcortical band heterotopia
	Polymicrogyria
	Periventricular nodular heterotopia
Neurological	Dentatorubropallidoluysian atrophy
	Fragile X syndrome
	Angelman's syndrome
	Down syndrome (tri 21)
	Wolf–Hirschhorn (4p–)
	Ring chromosome 20
	Huntington's disease
Metabolic	Rett's syndrome
	Progressive myoclonic epilepsies (PMEs)
	Alpers' disease
	Non-ketotic hyperglycinaemia
	D-Glyceric acidaemia
	Proprionic acidaemia
	Sulphite oxidase deficiency
	Fructose 1,6-diphosphatase deficiency
	Piridoxine dependency
	Aminoacidopathies
	Urea cycle disorders
	Disorders of carbohydrate metabolism
	Disorders of biotin and folic acid metabolism
	Glucose transport protein deficiency
	Menkes' disease
	Glycogen storage disorders
	Krabbe's disease
	Fumarase deficiency
	Peroxisomal disorders
	Sanfilippo's syndrome
	Mitochondrial encephalopathy, lactic acidosis and stroke-like (MELAS) syndrome
	Pyruvate dehydrogenase deficiency
	Respiratory chain defects

genetic origin. Malformational, metabolic, neurocutaneous and tumorous disorders showing chromosomal, single-gene and complex inheritance are included. Among these, progressive myoclonus epilepsies deserve special discussion.

Progressive myoclonus epilepsies

Progressive myoclonus epilepsies (PME) are a group of disorders characterized by myoclonic seizures, tonic–clonic seizures and progressive neurological dysfunction, in particular ataxia and dementia. Myoclonus is quite severe, with bilateral synchronous or multifocal asyncronous manifestations often affecting facial and bulbar muscles in addition to limbs. Convulsive seizures and neurological decline may predominate over myoclinic manifestations in some patients. Amongst the commonest causes of PME are Unverricht–Lundborg disease, Lafora's disease, myoclonus epilepsy and ragged red fibres (MERRF), sialidoses and neuronal ceroid lipofuscinoses. Although these conditions show substantial overlapping with other progressive encephalopathies (e.g. GM2 gangliosidosis) or progressive myoclonic ataxias (e.g. spinocerebellar ataxias), the strong contribution of the epileptic manifestations to the phenotype has led PMEs to be classified into epileptic disorders [5]. Autosomal recessive inheritance is always found, except in MERRF, which is maternally transmitted through mitochondrial DNA (Table 27.5).

Unverricht–Lundborg disease

Initially described in Finland, Unverricht–Lundborg disease is a rare disorder subsequently recognized worldwide, the clinical features of which include an onset at age 8–13 with myoclonus or tonic–clonic seizures, mild progression to ataxia and dementia, and neuronal loss with no evidence of storage material [98]. Some individuals show slow disease progression and others a faster course, even within the same family, and in many patients the condition deteriorates slowly and then the disability becomes static. Improvement may be obtained with sodium valproate, whereas phenytoin is deleterious [99].

The mutation causing Unverricht–Lundborg disease affects the gene encoding cystatin B (CSTB), which is involved in the inhibition of a group of lysosomal proteases known as cathepsins [100]. The most common mutation is an expansion of an unstable dodecamer repeat in the 5′-untranslated region, which suppresses transcription. In the general population, two or three repeats usually occur, whereas up to a hundred repeats are found in patients. However, no correlation between clinical severity or age at onset and size of expansion has been observed [101]. Alleles in the range of 12–17 repeats have been found to be unstably transmitted to offspring. These alleles are not associated with clinical phenotypes and are therefore called 'premutational'. Most patients are homozygous for dodecamer expansion; point mutations are occasionally found in compound heterozygous patients.

Identification of the clinical features is the first step in diagnosing the disease. When suggestive indications are found, mutational analysis of CSTB may be attempted. Genetic testing is also a powerful tool for prenatal diagnosis and for the identification of carriers among at-risk individuals.

Lafora's disease

Lafora's disease is a rare disorder with onset between the ages of 10 and 18 years, characterized by progression to inexorable dementia and frequent occipital seizures, in addition to myoclonus and

Table 27.5 Progressive myoclonus epilepsies.

Disease		Age at onset	Suggestive clinical features	Suggestive laboratory features	Genetics	Gene(s)
Unverricht–Lundborg disease		8–13 years	Severe myoclonus, mild dementia and ataxia	None identified	AR	*CSTB*
Lafora's disease		10–18 years	Severe myoclonus, occipital seizures, inexorable dementia, Lafora bodies	Lafora bodies in skin biopsies	AR	*EPM2A* *EPM2B*
Myoclonus epilepsy and ragged red fibres (MERRF)		Variable	Deafness, optic atrophy, myopathy, myoclonus	Ragged red fibres, increased level of pyruvate and lactate (blood)	Mitochondrial	$tRNA^{lys}$
Sialidoses	Type I	8–20 years	Severe myoclonus, tonic–clonic seizures, ataxia, cherry-red spot, visual failure	Elevated urinary sialyloligosaccharides, deficiency of neuroaminidase in leucocytes and cultured skin fibroblasts	AR	*NEU*
	Type II	10–30 years	Severe myoclonus, ataxia, cherry-red spot, visual failure, dysmorphic features, hearing loss	Elevated urinary sialyloligosaccharides, deficiency of neuroaminidase and β-galactosidase in leucocytes and cultured skin fibroblasts	AR	*PPGB*
Neuronal ceroid lipofuscinoses	CLN2	2.4–4 years	Myoclonic, tonic–clonic, atonic or atypical absence seizures, psychomotor delay and ataxia, visual failure	Curvilinear, rectilinear or fingerprint lipidic inclusions in skin biopsy at electron microscopy	AR	*TPP1*
	CNL3	5–10 years	Myoclonus and tonic–clonic seizures, macular degeneration, optic atrophy, dementia		AR	*CLN3*
	CNL4	15–50 years	Generalized seizures, myoclonic jerks, extrapyramidal symptoms		AR/AD	–

AD, autosomal dominant; AR, autosomal recessive.

tonic–clonic seizures. Prognosis is poor, with death occurring 2–10 years after onset [102]. A distinctive feature of the disease is the occurrence of polyglucosan inclusions (Lafora bodies) in neurones and in various other tissues [103]. In 1998 the gene involved in Lafora's disease (*EPM2A*) was identified as the gene encoding dual-specificity phosphatase (laforin) [104], a cytoplasmic protein associated with polyribosomes and possibly involved in the translational regulation of glycogen metabolism. Microdeletions and point mutations are observed in all four exons, although R241X is found in about 40% of patients [105]. In a proportion of patients with typical Lafora's disease that varies considerably between populations, the disorder is due to mutations in a second gene with unknown function called *EPM2B* [106]. *EPM2B* mutations include point mutations as well as deletions affecting the entire gene. The pathogenic mechanisms leading to polyglucosan accumulation in Lafora bodies have not yet been clearly elucidated and alternative models have been proposed which involve up-regulation of glycogen synthase activity [107] or suppression of glycogen phosphorylation, an essential process of normally structured glycogen [108]. Clinical diagnosis is not usually difficult when the disease is fully developed. Lafora bodies detected in skin biopsies constitute a unique marker. Pathological examination, however, is laborious and may lead to either false-positive or false-negative results. Conversely, genetic testing based on mutational screening of *EPM2A* and *EPM2B* shows a very high sensitivity and has become the preferred diagnostic tool. Genetic testing is of critical importance for prenatal diagnosis and carrier identification.

Myoclonus epilepsy and ragged red fibres

Myoclonus epilepsy and ragged red fibres is a mitochondrial disorder characterized by a broad clinical spectrum and intrafamilial variability in severity and age of onset. In addition to typical PME manifestations, patients may show deafness, optic atrophy and myopathy [109]. The pathological changes and other findings such as decreased metabolism for glucose and oxygen on positron emission tomography (PET) and an increase in organic phosphate in resting muscle indicate a possible dysfunction in the mitochondrial respiratory chain. However, biochemical assays of mitochondrial respiratory enzymes may be normal and ragged red fibres absent, suggesting a complex pathogenesis [110].

Myoclonus epilepsy and ragged red fibres is inherited through the maternal line as a paradigmatic example of mitochondrial inheritance. Clinical variability is dependent on the amount of mutated mtDNA. In this perspective, MERRF may also manifest as a sporadic condition. A missense mutation (*A8344G*) affecting the $tRNA^{lys}$ and, consequently, the translation of all genes encoded by the mtDNA has been described [111].

Although increased levels of pyruvate, lactate and ragged red fibres are often found, identification of clinical signs is crucial for diagnosis. In the presence of suggestive clinical data, the analysis of *A8344G* mutations is an excellent diagnostic tool. Genetic testing may also be used to perform prenatal diagnosis and to identify at-risk individuals.

Sialidoses

The sialidoses are very rare autosomal recessive lysosomal disorders characterized by complex phenotypes subgrouped into sialidosis type I and type II.

Occurring in the second decade of life, sialidosis type I presents with cherry-red macular spots, progressive severe myoclonus, gradual visual impairment, tonic–clonic seizures and ataxia without dementia [112]. Sialidosis type II includes complex phenotypes showing additional clinical symptoms such as coarse facies, corneal clouding, mental impairment and hearing loss, and may be subdivided into juvenile and infantile forms depending on the age of onset [113].

Neuronal lipidosis and vacuolated Kupffer cells are distinctive histological findings in sialidoses. Clinical diagnosis can be confirmed by documenting elevated urinary sialylyl-oligosaccharides and a deficiency of α-*N*-acetylneuroaminidase in leucocytes and cultured skin fibroblasts [113]. In some cases of type II sialidosis – predominantly in Japanese cases of juvenile type II sialidosis – β-galactosidase deficiency is found in addition to neuroaminidase deficiency [113]. Complementation between neuroaminidase-deficient cells and combined neuroaminidase/β-galactosidase deficiency suggests different genetic aetiology and pathogenesis [114]. Thus, classification of sialidoses into type I and II has only a clinical value, whereas the definition of neuroaminidase deficiency and galactosialidosis best describes the aetiology and pathogenesis of sialidoses.

Mutations in the neuroaminidase gene (*NEU*) on chromosome 6p have been detected in neuroaminidase deficiency [115]. In galactosialidosis, mutations were found within the cathepsin A gene on chromosome 20q encoding a 32-kDa protein (PPGB, protective protein for beta-galactosidase), which is required to protect galactosidase from degradation and to promote the catalytic action of neuroaminidase [116]. Genotype–phenotype correlations in neuroaminidase deficiency indicate that type I or type II sialidosis occurs depending on the residual activity of neuroaminidase resulting from different mutations.

Biochemical assays focus on measuring the activity levels of neuroaminidase and β-galactosidase. Mutational screening of the NEU and PPGB genes is a powerful tool for confirming the clinical diagnosis in probands and can be utilized in prenatal diagnosis and carrier identification.

Neuronal ceroid lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are autosomal recessive neurodegenerative disorders characterized by accumulation of ceroid lipopigment of granular, curvilinear or fingerprint appearance in the lysosomes of various tissues. According to the age of onset and clinical variants, various NCLs have been described over the years, leading to a complex classification comprising at least seven different forms [117]. Among these, CLN2, CLN3 and CLN4 are most commonly involved in PME, whereas infantile neuronal ceroid lipofuscinosis (CLN1) does not manifest as PME. CLN5, CLN6 and CLN8 are very rare disorders restricted to specific geographical areas.

Neuronal ceroid lipofuscinosis, late infantile type (CLN2)

Late infantile NCL displays myoclonic, tonic–clonic, atonic or atypical absence seizures between 2.5 and 4 years of age. Psychomotor delay and ataxia appear a few months later, whereas visual failure develops as the disease progresses. Prognosis is very poor, in that seizures are intractable, dementia is relentless and death usually occurs by the age of 5 years [118]. The gene has been

localized on chromosome 11 and identified as encoding tripeptidyl peptidase 1 (TPP1) [119]. Although affected individuals are sometimes clustered in specific areas (e.g. Newfoundland), cases have been reported worldwide and several different mutations reported.

In the past, electron microscopy detection of typical curvilinear lipidic inclusions was used to confirm the clinical diagnosis and to reach a prenatal diagnosis in uncultured amniocytes. The recent cloning of the gene has provided a further tool for the diagnosis of late infantile NCL.

Neuronal ceroid lipofuscinosis, juvenile type or Batten's disease (CLN3)

This disease usually appears between 5 and 10 years of age, with rapid deterioration of vision and progressive dementia. Macular degeneration, optic atrophy and attenuated vessels are revealed by fundoscopy. Seizures may be minor manifestations or major symptoms involving myoclonus and tonic–clonic seizures. Although the clinical course may vary among patients, death usually occurs within about 10–12 years of onset [120]. The Batten's disease gene encodes for an integral membrane protein (CLN3) that is primarily localized in the Golgi apparatus. More than 20 different mutations have been observed so far [121]. However, a 1-kb deletion is found in 70% of disease chromosomes, suggesting a strong founder effect.

Diagnosis may be established by electron microscopy examination of curvilinear and rectilinear bodies and fingerprint profiles in skin biopsies. The presence of inclusions in heterozygous carriers is controversial. Mutational screening of *CLN3* may also be attempted for the molecular diagnosis of Batten's disease.

Neuronal ceroid lipofuscinosis, adult type (Kufs' disease)

Kufs' disease is a very rare disorder characterized by generalized seizures with onset around 30 years of age and a subsequent cerebellar syndrome presenting with myoclonic jerks and extrapyramidal symptoms. Notably, fundoscopy examination is normal and blindness is absent. Death occurs within about 10–12 years of onset [122]. The pattern of inheritance is still unclear, in that both autosomal dominant and autosomal recessive inheritance have been described [123,124]. Since the Kufs' disease gene has not yet been localized or cloned, electron microscopy examination of muscle biopsies to detect curvilinear bodies is the only diagnostic test available.

Conclusion

Epilepsy is a complex phenotype with a complex aetiology. A variety of syndromes differing in clinical and physiological manifestations, pharmacological properties and prognosis are influenced by multiple factors of acquired and genetic origin. Genetic aetiology is highly heterogeneous and autosomal dominant, autosomal recessive, polygenic, mitochondrial and multifactorial disorders are found. Genetic counselling in epilepsy therefore has to deal with a composite picture in which recurrent seizures may be the expression of individually acquired conditions and/or familial background. The genetics of several hereditary forms of epilepsy are still poorly understood and genetic counselling frequently has to rely on empirical data alone, as in the case of idiopathic generalized epilepsy, rolandic epilepsy or febrile seizures.

Table 27.6 Genetic testing in epilepsy.

Disorder	Gene(s)	Diagnostic validity	Clinical utility
Benign familial neonatal seizures	*KCNQ2* *KCNQ3*	High in correct clinical context	Limited – *KCNQ2/KCNQ3* mutational analysis does not alter management or prognostic implications
Benign familial neonatal–infantile seizures	*SCN2A*	High in correct clinical context	Limited – *SCN2A* mutational analysis does not alter management or prognostic implications
Generalized epilepsy with febrile seizures plus	*SCN1A, SCN1B, GABRG2*	High in correct clinical context	No – variable expressivity of mutations. Mutation does not inform about prognosis or treatment
Severe myoclonic epilepsy of infancy (SMEI)	*SCN1A*	High in correct clinical context	Yes – early optimization of antiepileptic therapy. Implications for genetic counselling
Autosomal dominant nocturnal frontal lobe epilepsy	*CHRNA4, CHRNB2, CHRNA2*	High in correct clinical context	Yes – establish aetiology, no need of follow-up imaging. Implications for genetic counselling
Autosomal dominant partial epilepsy with auditory features	*LGI1*	High in correct clinical context	Yes – establish aetiology, no need of follow-up imaging. Implications for genetic counselling
Unverricht–Lundborg disease	*CSTB*	High	Yes – inform about prognosis and treatment. Implications for genetic counselling. Detection of at-risk individual
Lafora's disease	*EPM2A* *EPM2B*	High	Yes – inform about phenotype, prognosis and treatment. Implications for genetic counselling. Detection of at-risk individual
Myoclonus epilepsy and ragged red fibres (MERRF)	$tRNA^{lys}$	High	Yes – variable expressivity of mutations. Mutation does not inform about prognosis or treatment. Implications for genetic counselling. Detection of at-risk family members
Sialidoses	*NEU* *PPGB*	High	Yes – inform about prognosis. Implications for genetic counselling. Detection of at-risk family members
Late infantile neuronal ceroid lipofuscinoses	*TPP1*	High	Yes – inform about prognosis. Implications for genetic counselling. Detection of at-risk family members
Juvenile neuronal ceroid lipofuscinoses	*CLN3*		Yes – inform about prognosis. Implications for genetic counselling. Detection of at-risk family members

We should, however, be aware of the significant advances that have been made in recent times. The genetic mechanisms of most inherited conditions underlying severe epileptic phenotypes such as progressive myoclonus epilepsies have been successfully investigated. Genetic tests for the identification of at-risk carriers and for prenatal diagnosis are being developed and more accurate estimates of recurrence risks can be provided (Table 27.6).

In idiopathic forms of epilepsy, different genes have been linked to mendelian phenotypes, and neuronal ion channels are promising candidates for investigating pathogenetic processes. The presence of many ion-channel genes in the genome provides a promising working hypothesis for many idiopathic epileptic disorders of unknown genetic aetiology. A paradigmatic example is *SCN1A*, which was initially associated with the GEFS$^+$ phenotype and was subsequently found to be mutated in severe myoclonic epilepsy of infancy. Mendelian subsets have also played an important role in proving genetic aetiology in apparently symptomatic forms of epilepsy such as temporal lobe epilepsy.

It will probably take a long time to dissect the complex aetiology of hereditary forms of epilepsy and before clinical practice and genetic counselling gain significant benefits. There is no doubt, however, that the journey has already begun.

28 Drug Interactions

Edoardo Spina
University of Messina, Messina, Italy

Introduction

The widespread use of co-medications in current medical practice carries the risk of drug interactions. While certain drug combinations may be used advantageously, in many cases multiple drug therapy reduces the therapeutic efficacy or increases the toxicity of one or more of the administered compounds.

Drug interactions are a frequent complication in patients treated with antiepileptic drugs (AEDs) for a variety of reasons [1,2]. The AEDs are usually administered for prolonged periods, often for a lifetime, increasing the probability of co-medication. They are often prescribed in combination with other AEDs or medications used for the management of associated disorders. Approximately 70% of patients with epilepsy can be made seizure free by currently available AEDs given as monotherapy. In most of the remaining patients, better control can be achieved only with long-term AED polytherapy. All newer AEDs are given as a first prescription as add-on therapy in patients with chronic refractory partial epilepsy, so polytherapy will initially be the only option for these agents. In addition, AEDs are widely used to treat other non-epilepsy disorders such as bipolar disorder, migraine and chronic pain, further enhancing the possibility of combination therapy. Their pharmacokinetic properties also make the AEDs particularly susceptible to drug interactions. Many of the older AEDs have a narrow therapeutic index, and even a relatively small change in their plasma concentrations can easily result in loss of efficacy or signs of intoxication. Finally, some AEDs have prominent inhibitory or inducing effects on the activity of the hepatic enzymes which metabolize the majority of existing medications, while most of the old and new generation AEDs are substrates of the same enzyme systems. Compared with older agents, new AEDs appear to have clear advantages in terms of a lower potential for interaction [3–5].

The purpose of this chapter is to highlight the basic principles and mechanisms of drug interactions involving AEDs, providing necessary information to prevent or minimize their occurrence. Examples of specific clinically important interactions will be presented.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Definition and basic types of drug interactions

A drug interaction can be defined as a quantitative or qualitative modification of a drug effect caused by concomitant administration of another drug [2]. In a broad sense, the responsible agent can be not only a drug but also a dietary component, a nutritional supplement, a herb, alcohol, tobacco or an environmental agent. The consequences of a drug interaction can be either beneficial, if the interaction results in increased therapeutic efficacy or reduced risk of adverse effects, or harmful, if it leads to decreased efficacy or enhanced toxicity of one or more of the administered compounds. Drug interactions may be clinically important not only when additional drugs are co-administered, but also when one or more drugs are discontinued. When an interacting drug is removed from a multidrug regimen, interaction processes go into reverse, possibly resulting in either reduced efficacy or increased risk of undesirable effects.

There are two basic types of drug interactions: pharmacokinetic and pharmacodynamic [2]. Pharmacokinetic interactions consist of changes in the absorption, distribution, metabolism or excretion of a drug and/or its metabolite(s) after the addition of another chemical agent. These interactions are associated with a modification in plasma concentration of either the drug or its metabolite(s) and alter the concentration of the active drug at the site of action. They account for most of the interactions reported to date as they are easily detected by a change in plasma drug concentrations. Pharmacodynamic interactions occur when two drugs act at the same or inter-related receptor sites, resulting in additive, synergistic or antagonistic effects. Pharmacodynamic interactions are less well recognized and are commonly inferred to explain drug-induced modifications in clinical status that cannot be ascribed to a pharmacokinetic mechanism. While this classification is useful for didactic purposes, it should be pointed out that many interactions involve a complex sequence of events at both pharmacokinetic and pharmacodynamic levels.

Pharmacokinetic interactions

Pharmacokinetic interactions may occur at the level of drug absorption, distribution, metabolism and excretion. The vast majority of pharmacokinetic interactions with AEDs arise as a consequence of drug-induced changes in hepatic metabolism, through enzyme inhibition or induction, and less frequently from changes in plasma protein binding [6]. In recent years, however,

the increasing recognition of the role played by drug transporters, notably P-glycoprotein, in the absorption, distribution and excretion of a wide variety of drugs has raised the possibility that other mechanisms may occasionally be involved [7]. P-glycoprotein is a multidrug efflux transporter, encoded by the *MDR1* gene (or *ABCB1*), highly expressed in the intestine, brain, liver and kidney, which acts as a natural defence mechanism against several substrates by limiting their absorption from the gut and penetration to the brain and promoting their elimination in the bile and urine [7].

Absorption

Absorption is the entry of a drug into systemic circulation via the mucous membranes of the guts or the lungs, via the skin or from the site of an injection. Oral intake is by far the most common route of administration of drugs including AEDs. Clinically significant drug interactions with AEDs are rare during absorption. In this respect, co-administration of antacids containing magnesium hydroxide or aluminium hydroxide has been reported to cause a moderate decrease in the absorption of phenytoin and gabapentin, presumably by decreasing the acidity of the stomach and also by the formation of insoluble complexes, thereby resulting in diminished plasma concentrations and, possibly, reduced efficacy [2]. Another example is the impaired absorption of phenytoin when given concurrently to epileptic patients receiving continuous nasogastric feeds, an effect that has been attributed to binding of phenytoin to constituents of the feeding formulas to form insoluble, not absorbable, complexes [3].

Drug transporters, notably P-glycoprotein, play an important role in the gastrointestinal absorption of many drugs [7]. The distribution of P-glycoprotein varies substantially across the gastrointestinal tract, and its role and contribution to drug absorption differs between drugs. At present, its role in the gastrointestinal absorption of AEDs is not fully understood. Within the intestinal epithelium, P-glycoprotein is found in close proximity to cytochrome P450 enzyme (CYP) 3A4. There is evidence that P-glycoprotein and CYP3A4 are an integral part of an intestinal defence system to protect the body against xenobiotics, and can be major determinants of bioavailability of orally administered drugs. Furthermore, most but not all substrates of CYP3A4 are also substrates of P-glycoprotein and inhibitors and inducers of CYP3A4 are usually also inhibitors and inducers of P-glycoprotein [8]. This interplay between transporters and drug-metabolizing enzymes makes it difficult to define transporter-mediated drug interactions [9]. It is likely that some AED interactions currently attributed to enzyme induction are in fact mediated by reduced gastrointestinal absorption or enhanced renal elimination – an example is the interaction in healthy subjects between carbamazepine and the β_1-blocker talinolol [10]. More recently, inhibition of the intestinal transporter for valproic acid absorption has been hypothesized as one of the mechanisms to explain the pronounced fall in plasma levels of valproic acid caused by concomitant administration of carbapenem antibiotics [11].

Distribution

Once a drug enters into systemic circulation, it is distributed in interstitial and intracellular fluids. Drugs are found in plasma either bound to serum protein or free (unbound). The principal proteins involved are albumin and α_1-acid glycoprotein. Generally, acid drugs bind predominantly to albumin, but not necessarily to the same site, while basic and neutral drugs bind to various sites on α_1-acid glycoprotein in addition to albumin. Plasma protein binding interactions can be due to competition between two drugs for binding sites on plasma proteins [3]. Displacement from plasma proteins will then cause a rise in the fraction of unbound drug in plasma or tissue, thereby potentially increasing the effect of the displaced drug. If the displacing drug is withdrawn, the reverse will occur. However, such interactions are likely to be clinically significant only if two criteria are fulfilled: (1) the displaced drug must be highly protein bound (usually greater than 90%) and (2) the drug must have a low volume of distribution. In fact, if the displaced drug is not highly bound, the amount displaced (which is usually of the order of a few per cent) will make little impact on the circulating unbound concentration, and if it is widely distributed to the tissues, any increase in the free concentration will be diluted by further distribution. Important drugs which fulfil these criteria and may therefore be object drugs in protein binding displacement interactions include warfarin, phenytoin and tolbutamide. The most common displacers from protein binding sites include sulphonamides, salicylates, chloral hydrate and some of its congeners (because of their metabolite trichloracetic acid), phenylbutazone and valproic acid.

The relevance of protein binding displacement interactions has been overestimated and such interactions are usually of no clinical significance [12,13]. For highly protein-bound drugs eliminated by low-extraction hepatic metabolism, such as phenytoin, the initial displacement may result in transient increase in free (or pharmacologically active) drug concentrations. However, the increased unbound drug is metabolized by the hepatic enzymes and a new steady state may occur. This new steady state results in a higher percentage of unbound drug but a lower total drug concentration, and therefore no overall change in the unbound plasma concentrations of the displaced drug [14,15]. In this situation, the monitoring of free rather than total drug concentrations can be more clinically useful, but in practice is seldom required.

Amongst AEDs, only valproic acid, phenytoin and tiagabine are highly bound to plasma proteins and liable to be displaced from protein binding sites [1,3]. The most common of these interactions is the displacement of phenytoin by valproic acid [3,16]. The effect of valproic acid on phenytoin pharmacokinetics is complex, being a combination of a protein binding displacement and enzyme inhibition. Valproic acid displaces phenytoin from plasma proteins, increasing its unbound fraction, and inhibits phenytoin metabolism, reducing its intrinsic clearance. Total phenytoin concentrations may be reduced, unchanged or occasionally even increased, but the concentration of free phenytoin is usually increased. As a result of this interaction, in patients co-medicated with valproic acid, therapeutic and toxic effects occur at total plasma phenytoin concentrations lower than usual. Valproic acid may also displace carbamazepine from plasma binding sites, but the magnitude of this interaction is generally small and without clinical significance.

Distribution of AEDs from the blood to the brain is necessary for a successful therapeutic outcome. There is conflicting evidence that P-glycoprotein plays a role in mediating the efflux of some

AEDs including carbamazepine, phenytoin, phenobarbital, lamotrigine and felbamate across the blood–brain barrier [3]. Therefore, the overexpression of P-glycoprotein in brain tissue could theoretically limit the penetration of AEDs to their sites of action and could be a potential mechanism of pharmacoresistance in epilepsy [17]. Moreover, it is possible that AED interactions are due to competition for transport across the blood–brain barrier via P-glycoprotein mechanisms.

Metabolism

The majority of clinically relevant pharmacokinetic interactions of AEDs occur at the level of drug metabolism. Metabolic processes are necessary to convert a non-polar (lipid-soluble) drug into one or more polar (water-soluble) metabolites, facilitating their excretion in urine or bile. Although metabolism usually results in inactivation or detoxification, many drug metabolites have pharmacological activity similar to or different from that of the parent molecule, and may therefore contribute to therapeutic outcome or be responsible for toxic effects. When metabolites are active, termination of their action occurs by further biotransformation or by direct excretion of the metabolite in urine or bile. The chemical reactions involved in the biotransformation of drugs are catalysed by various enzyme systems and can be classified as either phase I (functionalization) or phase II (conjugation) biotransformation reactions, which may occur in series. Phase I reactions involve the addition of a polar functional group (e.g. a hydroxyl group) or the deletion of a non-polar alkyl group (e.g. N-demethylation) by oxidation, reduction or hydrolysis. Phase II conjugation reactions lead to the formation of a covalent linkage between the drug or the phase I metabolite and a water-soluble endogenous substrate (e.g. glucuronic acid, acetic acid, sulphate, amino acids or glutathione), usually resulting in an inactive, easily excretable compound. The liver is usually the main organ responsible for phase I and phase II reactions, but other organs such as the gastrointestinal tract, the kidney, the lungs, the brain, the blood, the skin and the placenta may also contribute to metabolism. In the hepatocyte, phase I oxidative enzymes are located almost exclusively in the smooth endoplasmic reticulum, along with the phase II enzyme, glucuronyltranferase. Other phase II enzymes responsible for conjugation reactions are found predominantly in the cytoplasm.

Major enzyme systems involved in the metabolism of antiepileptic drugs

Knowledge of the major enzyme systems involved in the biotransformation of AEDs is essential for understanding the principles and mechanisms of metabolically based drug interactions.

Cytochrome P450 system

The human cytochrome P450 (CYP) system consists of a superfamily of more than 50 haem-containing enzymes, located in the membranes of the smooth endoplasmic reticulum in the liver and in many extrahepatic tissues, that are responsible for the phase I oxidative reactions of many drugs, nutrients, environmental toxins and endogenous substances [18]. These enzymes are categorized into families and subfamilies according to similarities in their amino acid sequence, with each enzyme being designated as CYP followed by a number indicating the family, a letter indicating the subfamily, and another number denoting the specific isoform [19].

The CYP isoenzymes playing a major role in the biotransformation of therapeutic agents are CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4. Minor but clinically relevant isoforms include CYP2A6, CYP2B6, CYP2C8 and CYP2E1. Each CYP isoform is a specific gene product and possesses a characteristic but relatively broad spectrum of substrate specificity. Different CYP isoforms may display overlapping substrate specificities, that is one CYP isoenzyme can metabolize multiple substrates and most substrates can be metabolized by various CYP isoenzymes. There is a large variability in the expression and activity of these isoenzymes, which can lead to interindividual differences in drug metabolism. Such variability results from genetic, pathophysiological and environmental factors, including concomitant administration of other drugs. Mutations or polymorphisms in genes coding for CYP isoforms can result in enzyme variants with higher, lower or no activity, or occasionally the total absence of the enzyme. When a variant allele occurs in 1% or more of the population, it is referred to as genetic polymorphism [20]. The CYP polymorphisms that have the greatest clinical implications involve CYP2C9, CYP2C19 and CYP2D6. In recent years, the major CYP isoenzymes have been characterized at the molecular level and their different substrates, inhibitors and inducers have been identified (Table 28.1) [21,22]. As shown in Table 28.1, the majority of commonly used AEDs are metabolized by CYP enzymes and some of these may also act as inhibitors or inducers of one or more of these isoforms. The major CYP isoforms are described in more detail below [22–24].

CYP1A2

CYP1A2 accounts for approximately 10–15% of total hepatic CYPs and is the primary enzyme involved in the oxidative metabolism of many drugs, including theophylline, caffeine, tacrine, propranolol, mirtazapine, clozapine and olanzapine. With regard to AEDs, CYP1A2 contributes, to a minor extent, to carbamazepine metabolism. There is a wide interindividual variability in CYP1A2 activity, but the impact of genetic polymorphism on CYP1A2 metabolic capacity is controversial. The antidepressant fluvoxamine and various fluoroquinolone antibiotics (i.e. ciprofloxacin) are potent, but not selective, inhibitors of CYP1A2. The activity of CYP1A2 is induced by polycyclic aromatic hydrocarbons (including those found in charcoal-broiled foods and cigarette smoke), rifampicin, omeprazole and, possibly, by phenobarbital, phenytoin and carbamazepine.

CYP2C9

CYP2C9, the most abundant among human CYP2C isoforms, plays an important role in the oxidation of many drugs, including phenytoin, phenobarbital, S-warfarin (the active isomer of racemic warfarin), tolbutamide, losartan, fluvastatin and many non-steroidal anti-inflammatory agents such as diclofenac, ibuprofen, naproxen and piroxicam. CYP2C9 is polymorphically expressed in humans. To date, three different allelic variants that code for enzymes with different catalytic activity have been identified. The frequencies of the defective alleles CYP2C9*2 and CYP2C9*3 vary between 8% and 12% and 3% and 8% respectively among whites, but they are somewhat lower in Orientals and black

Table 28.1 Substrates, inhibitors and inducers of the major drug-metabolizing cytochrome P450 isoenzymes.

Enzymes	Substrates	Inhibitors	Inducers
CYP1A2	Antidepressants: amitriptyline, clomipramine, imipramine, fluvoxamine, mirtazepine, duloxetine Antipsychotics: haloperidol, clozapine, olanzapine Methylxanthines: theophylline, caffeine Miscellaneous: phenacetin, paracetamol, tacrine, tamoxiphen, *R*-warfarin	Ciprofloxacin Enoxacin Fluvoxamine Clarithromycin	Smoking Rifampicin Barbiturates Phenytoin Carbamazepine
CYP2C9	AEDs: phenytoin, phenobarbital, valproic acid NSAIDs: diclofenac, ibuprofen, naproxen, piroxicam, celecoxib Miscellaneous: *S*-warfarin, tolbutamide, losartan, torasemide, fluvastatin	Sulphaphenazole Amiodarone Fluconazole Miconazole Valproic acid Fluoxetine Fluvoxamine	Rifampicin Barbiturates Phenytoin Carbamazepine
CYP2C19	AEDs: phenobarbital, phenytoin, diazepam Antidepressants: amitriptyline, clomipramine, imipramine, citalopram, escitalopram Miscellaneous: diazepam, lansoprazole, omeprazole, propranolol, proguanil, *R*-warfarin	Omeprazole Ticlopidine Fluvoxamine Felbamate Topiramate (weak) Oxcarbazepine (weak)	Rifampicin Barbiturates Phenytoin Carbamazepine
CYP2D6	Antidepressants: amitriptyline, clomipramine, imipramine, desipramine, nortriptyline, fluoxetine, paroxetine, fluvoxamine, citalopram, escitalopram, venlafaxine, mirtazapine Antipsychotics: haloperidol, thioridazine, perphenazine, risperidone, clozapine, olanzapine, sertindole, aripiprazole Beta-blockers: alprenolol, bufuralol, metoprolol, propanolol, timolol Antiarrhythmics: encainide, flecainide, propafenone Miscellaneous: atomoxetine, codeine, donepezil, galantamine, phenformin, tramadol	Quinidine Thioridazine Fluoxetine Paroxetine Bupropion Duloxetine	None known
CYP3A4	AEDs: carbamazepine, ethosuximide, felbamate, tiagabine, zonisamide Antidepressants: amitriptyline, clomipramine, imipramine, sertraline, citalopram, escitalopram, venlafaxine, mirtazapine, nefazodone Antipsychotics: haloperidol, pimozide, clozapine, risperidone, quetiapine, ziprasidone, sertindole, aripiprazole Benzodiazepines: alprazolam, clonazepam, diazepam, midazolam, triazolam Calcium antagonists: diltiazem, felodipine, nifedipine, verapamil Statins: atorvastatin, lovastatin, pravastatin, simvastatin Immunosuppressants: ciclosporin, sirolimus, tacrolimus Miscellaneous: amiodarone, astemizole, cisapride, clarytromycin, donepezil, erythromycin, ethiniyestradiol, galantamine, levonorgestrel, methadone, ritonavir, quinidine, tamoxifen, terfenadine	Ketoconazole Itraconazole Erythromycin Troleandomycin Nefazodone Grapefruit juice Ritonavir	Rifampicin Barbiturates Phenytoin Carbamazepine St John's wort Glucocorticoids[a] Oxcarbazepine[a] Topiramate[a] Felbamate[a] Rufinamide[a]

Based on refs 21 and 22.
[a]Weaker or tissue-selective inducers.

Africans. Subjects carrying two mutated CYPC9*3 alleles lack almost completely CYP2C9 activity, and, therefore, are unable to metabolize important CYP2C9 substrates such as phenytoin and S-warfarin. The frequency of this genotype is 0.4% in white subjects. Inhibitors of CYP2C9 include sulphaphenazole, amiodarone, fluconazole, fluoxetine, paroxetine, ritonavir and valproic acid. The activity of CYP2C9 isoforms may be induced by administration of rifampicin, barbiturates, phenytoin and carbamazepine.

CYP2C19

CYP2C19 is involved in the biotransformation of phenobarbital, phenytoin, omeprazole, proguanil, diazepam, citalopram and tricyclic antidepressants (demethylation reactions). CYP2C19 also exhibits a clinically important genetic polymorphism. The frequency of the poor metabolizer (PM) phenotype varies from approximately 3% in whites to 12–25% in many Asian populations, while in black Africans PM frequencies vary between 4% and 7%. The defective alleles responsible for the PM phenotype are CYP2C19*2, the most common among whites and Orientals, and CYP2C19*3, found at a frequency of about 12% among Orientals, but almost absent among whites. The activity of CYP2C19 may be inhibited by omeprazole, ticlopidine, ritonavir, fluvoxamine and by the AEDs felbamate, stiripentol, topiramate and oxcarbazepine. Inducers of CYP2C19 include barbiturates, phenytoin, carbamazepine and rifampicin.

CYP2D6

CYP2D6 represents only 2% of the total P450 content in the liver. Nevertheless, CYP2D6 plays an important role in the biotransformation of a variety of drugs including many psychotropic and cardiovascular drugs. To date, however, none of the major AEDs has been found to be metabolized to a significant extent by CYP2D6. This enzyme is commonly polymorphic. CYP2D6 activity ranges from complete deficiency to ultrarapid metabolism. There are 70 known allelic variants of the *CYP2D6* gene. PMs lack CYP2D6 activity and represent approximately 3–10% of whites, but only 1–2% of Orientals. Among extensive metaboliz-

ers (EMs), the catalytic activity varies largely, and a subgroup of subjects with extremely high enzyme activity have been classified as ultrarapid metabolizers (UMs). Three major mutated alleles, CYP2D6*3, CYP2D6*4 and CYP2D6*5, account for 90–95% of the PM alleles in whites. Alleles with duplication or multiduplication of a functional *CYP2D6*2* gene are associated with an increased CYP2D6 activity: the frequency of this condition varies from 1–2% in Swedes to up to 7–10% in Spaniards and southern Italians. Potent inhibitors of CYP2D6 include quinidine, thioridazine, fluoxetine and paroxetine. In contrast to all other CYPs involved in drug metabolism, CYP2D6 does not appear to be inducible, an important consideration in predicting interactions caused by AEDs.

CYP3A4

CYP3A4 accounts for approximately 30% of total CYP in human liver and 70% in small intestine and participates in more than half of all drug oxidation in human liver. CYP3A4 plays an important role in the biotransformation of AEDs, being the primary enzyme responsible for the metabolism of carbamazepine, ethosuximide, tiagabine and zonisamide, and it is also involved in the biotransformation of felbamate. Drugs primarily metabolized by CYP3A4 include immunosuppressants (e.g. ciclosporin and tacrolimus), triazolobenzodiazepines (e.g. alprazolam, midazolam and triazolam), non-sedating antihistamines (e.g. terfenadine and astemizole), calcium antagonists (e.g. diltiazem, verapamil, nifedipine and other dihydropyridines), cholesterol-lowering drugs (e.g. simvastatin and lovastatin), antiarrhythmics (e.g. amiodarone and quinidine) and several steroids (e.g. cortisol, ethinylestradiol and levonorgestrel). CYP3A4 is also involved in the metabolism of a variety of endogenous compounds such as progesterone, estradiol, testosterone and cortisol. As previously mentioned, CYP3A4 and P-glycoprotein are both expressed in enterocytes and hepatocytes and contribute to a major extent to first-pass elimination of many drugs. Furthermore, there is a considerable overlap in substrate and inhibitor/inducer for CYP3A4 and P-glycoprotein. Although CYP3A4 drug-metabolizing activity varies more than 20-fold among individuals, it has a unimodal distribution and does not appear to be subject to genetic polymorphism. Its wide interindividual variability is caused, at least in part, by modulation of CYP3A4 activity by many environmental compounds, including dietary constituents and medications. Compounds that inhibit CYP3A4 activity include azole antimycotics (e.g. ketoconazole and itraconazole), macrolide antibiotics (e.g. erythromycin and troleandomycin), HIV protease inhibitors (e.g. ritonavir and indinavir), nefazodone and some of the furanocoumarin dimers found in grapefruit juice. The hepatic and, possibly, the intestinal CYP3A4 isoforms are induced by glucocorticoids (e.g. dexamethasone), rifampicin, phenobarbital, phenytoin, carbamazepine and St John's wort. Some newer AEDs, such as felbamate, oxcarbazepine, topiramate and rufinamide, appear to exert a selective inducing effect on CYP3A4 activity, at least in some tissues.

Other CYPs

Minor CYP isoforms include CYP2A6, CYP2B6, CYP2C8 and CYP2E1. CYP2A6 and CYP2B6 are involved in minor pathways of valproic acid elimination, CYP2C8 contributes to the metabolism of carbamazepine and CYP2E1 plays a minor role in the oxidative biotransformation of felbamate and phenobarbital.

Uridine diphosphate glucuronosyltransferases

The human uridine diphosphate-glucuronosyltransferases (UDPGTs) are a superfamily of enzymes that catalyse the glucuronidation of a large number of endobiotics (i.e. bilirubin, steroid hormones, thyroid hormones, bile acids and fat-soluble vitamins) and xenobiotics (i.e. drugs, chemical carcinogens, environmental pollutants and dietary substances) [25]. These enzymes are bound to the internal membrane and face the luminal side of the endoplasmic reticulum, mainly in the liver, but also in the kidney, intestine, skin, lung, prostate and brain. Glucuronidation, which is the most common pathway in phase II drug metabolism, transfers glucuronic acid from UDP-glucuronic acid to functional groups on hydrophobic drug molecules or their metabolites to form the corresponding glucuronides. While most substrates undergo glucuronide conjugation after phase I reactions, in some cases (i.e. morphine and valproic acid) direct conjugation proceeds without phase I functionalization of the parent compound. In most cases, glucuronidation abolishes the pharmacological activity, but active and reactive glucuronide metabolites have also been described, as in the case of morphine.

The human uridine-glucuronosyltransferase (UGT) superfamily comprises two families (UGT1 and UGT2) and three subfamilies (UGT1A, UGT2A and UGT2B) [26]. UGT amino acids have been sequenced and, as in the case of the CYP system, a nomenclature based on amino acid similarity has been developed. While few substrates are relatively selective for a specific UGT enzyme, the majority are glucuronidated by multiple UGTs, thereby making it difficult to know which is the predominant isoform responsible for the glucuronidation reaction. As shown in Table 28.2, some AEDs are substrates of UGT enzymes [22,25]. Among the isoforms of the UGT1 family, UGT1A3, UGT1A6 and UGT1A9 are involved in the glucuronidation of valproic acid, while UGT1A4 has been found to be the major isoform responsible for the N-glucuronidation of lamotrigine and retigabine. Among the isoforms of the UGT2 family, the UGT2B7 variant also appears to contribute to the glucuronidation of valproic acid. The expression of individual UGTs is subject to genetic polymorphism and their activity may be inhibited or induced by

Table 28.2 Substrates of the major UGTs.

Enzymes	Substrates
UGT1A1	Bilirubin, atorvastatin, simvastatin, buprenorphine, gemfibrozil, clofibrate
UGT1A3	Atorvastatin, simvastatin, buprenorphine, gemfibrozil, losartan, morphine, valproic acid
UGT1A4	Lamotrigine, olanzapine, retigabine
UGT1A6	Entacapone
UGT1A9	Dapsone, diclofenac, propofol, tolcapone, valproic acid
UGT2B7	Codeine, gemfibrozil, lorazepam, morphine, naloxone, naltrexone, valproic acid, zidovudine
UGT2B15	Phenytoin metabolites

Based on refs 22 and 25.

xenobiotics. In contrast to extensive documentation for CYP-mediated drug interactions, there are fewer data on interactions involving glucuronidation. It is difficult to make mechanistic interpretation of data obtained from clinical studies on UGT-mediated drug interactions. In this respect, a major limitation has been the lack of quantification of the glucuronide metabolite(s), thereby making it impossible to conclude whether there was an effect at the level of glucuronidation. Any substrate of UGT has the potential to competitively inhibit glucuronidation of other substrates metabolized by the same enzyme. Unlike the CYP system, no specific inhibitors of individual UGT isoforms have been identified.

Other drug-metabolizing enzyme systems

Other drug-metabolizing enzymes may be involved in the biotransformation of some AEDs [22,23]. Tissue hydrolases are involved in the metabolism of levetiracetam, while microsomal epoxide hydrolase is responsible for the clearance of carbamazepine-10,11-epoxide, the main and pharmacologically active metabolite of carbamazepine. Mitochondrial β-oxidation is one of the major pathways of valproic acid biotransformation. The new AED zonisamide is partially metabolized via acetylation by a phase II N-acetyltransferase.

Mechanisms of metabolic drug interactions: enzyme inhibition and enzyme induction

Drug interactions involving CYP isoforms and other drug-metabolizing enzymes may result from one of two processes: enzyme inhibition or induction.

Enzyme inhibition

Enzyme inhibition is the most common mechanism that can lead to drug interactions. A large number of compounds may inhibit the activity of drug-metabolizing enzymes, thereby temporarily blocking their activity. As a consequence of enzyme inhibition, the rate of metabolism of a particular agent is decreased, resulting in increased plasma drug concentrations and potential enhancement of its pharmacological effects. The mechanisms of enzyme inhibition can be categorized as reversible (competitive or non-competitive) or irreversible (mechanism-based inactivation) [27,28]. In reversible inhibition, the normal function of the enzyme is resumed after the inhibitor has been eliminated from the body. Conversely, the loss of enzyme activity caused by irreversible inhibition persists even after the elimination of the inhibitor, and *de novo* biosynthesis of the new enzyme is the only means by which activity can be restored.

Reversible inhibition

This type of enzyme inhibition is probably the most common and can be subdivided further into competitive and non-competitive inhibition [27].

Competitive inhibition refers to a mutually exclusive competition between two drugs (the substrate and the inhibitor) for the binding to the catalytic site of the enzyme. Competitive inhibitors can be alternative substrates of the enzyme with higher binding affinity or non-substrates with, nevertheless, high binding affinity. The binding of the inhibitor prevents the substrate from binding to the active site of the enzyme and, therefore, the substrate cannot be metabolized. The amount of enzyme inhibition depends upon the inhibitor and substrate concentration and the relative affinities of the inhibitor and substrate for the active site. This inhibition can be reversed by increasing the concentrations of the substrate. Competitive inhibition is typically a rapid and dose-dependent process [14,15]. The initial effect usually occurs within 24 h from the addition of the inhibitor, though the time to reach maximal inhibition will depend on the elimination half-lives of the affected drug and of the inhibiting agent. When the inhibitor is withdrawn, restoration of baseline (pre-interaction) conditions is also dependent on the rates of the elimination of the affected drug and of the inhibitor. Among commonly used AEDs, valproic acid is the most notable competitive inhibitor of drug metabolism [1–3].

Non-competitive inhibition involves the strong, covalent binding of the inhibitor to another site of the enzyme. Therefore, the substrate can still bind to the active site, but the basic structure of the enzyme is modified and formation of the enzyme–substrate–inhibitor complex results in loss of enzyme activity. With non-competitive inhibition, the time course of the interaction may be more complex, and a significant role may be played by the turnover (re-synthesis) rate of the enzyme.

Irreversible inhibition

This type of enzyme inhibition usually derives from the activation of a drug by CYPs into a reactive metabolic intermediate that binds tightly and irreversibly to the enzyme active site [29]. These metabolic intermediates cause a chemical modification of the haem, the protein, or both as a result of covalent binding of modified haem to protein. This process is called 'mechanism-based inhibition' or 'suicide inhibition' and may result into a severe and long-lasting inactivation. Enzymatic activity can only be restored through *de novo* protein synthesis. The covalent modification of CYP enzymes can also lead to hapten formation and can in some cases trigger an autoimmune response, resulting in toxicological consequences. Mechanism-based inactivation has been described for CYP3A4. To date, the identified clinically important mechanism-based CYP3A4 inhibitors include macrolide antibiotics (e.g. clarithromycin and erythromycin), anti-human immunodeficiency virus (HIV) agents (e.g. ritonavir and indinavir), antidepressants (e.g. fluoxetine and fluvoxamine), calcium channel blockers (e.g. verapamil and diltiazem), steroids and their modulators (e.g. gestodene and mifepristone) and several herbal and dietary components.

Enzyme induction

The activity of drug-metabolizing enzymes in the liver and/or other organs may be increased ('induced') by prolonged administration of several exogenous agents including drugs, industrial contaminants, dietary or voluptuary substances, as well as by endogenous compounds [30]. The inducing process involves predominantly CYP isoenzymes, but induction of other drug-metabolizing enzymes has also been documented. From a biological point of view, induction is an adaptive response that protects the cells from toxic xenobiotics by increasing the detoxification activity. Morphologically, enzyme induction may be associated with a proliferation of the smooth endoplasmic reticulum and hepatic hypertrophy.

Although enzyme induction has been known for almost half a century, the molecular mechanisms involved have only recently been elucidated. In most cases, enzyme induction is the consequence of an increase in gene transcription, usually mediated by intracellular receptors, resulting in an enhanced protein synthesis. However, enzyme induction may also occur through non-transcriptional mechanisms by an inducer-mediated decrease in rate of enzyme degradation or by protein stabilization. An example of the latter is the induction of CYP2E1 by alcohol and isoniazid by stabilization of the enzyme protein not involving a receptor-mediated mechanism [31]. Each inducer has specific actions on a given range of drug-metabolizing enzymes, and several mechanisms of induction are often activated to different extents by a single agent. Currently, intracellular receptors have been identified to be involved in enzyme induction including the aryl hydrocarbon receptor (AhR), the constitutive androstane receptor (CAR), the pregnane X receptor (PXR) and the glucocorticoid receptor (GR) [30,32].

Aryl hydrocarbon receptor

Polycyclic aromatic hydrocarbons, such as benzo(*a*)pyrene and 3-methylcholanthrene, are environmental contaminants formed by incomplete combustion of organic matter (i.e. cigarette smoke and charcoal-broiled beef). These agents selectively induce CYP1A1 and CYP1A2. The mechanism of this type of induction, involving the intracellular AhR, has been well characterized [30,32]. In addition to polycyclic aromatic hydrocarbons, certain constituents of cruciferous vegetables, and certain drugs such as omeprazole and rifampicin, appear to induce CYP1A enzymes by the same mechanism.

Constitutive androstane receptor

Phenobarbital is recognized as the prototype of a class of agents known to induce drug metabolism. Many other compounds – including the AEDs phenytoin, primidone and carbamazepine and the antitubercular agent rifampicin – have been shown to stimulate drug-metabolizing enzymes with an induction pattern which overlaps, at least in part, that of barbiturates. The cluster of enzymes induced by phenobarbital and related agents appears to include several CYPs, such as CYP2C subfamily members, CYP3A4, CYP2B6, possibly CYP1A2, but not CYP2D6. In addition, different UGTs and microsomal epoxide hydrolase appear to be induced by these agents. Thus, the drugs metabolized by enzymes subject to phenobarbital-type induction include a major fraction of all drugs undergoing biotransformation. The orphan receptor CAR has been identified as the molecular target and mediator of phenobarbital-type induction. However, the exact mechanisms of this type of enzyme induction remain to be elucidated. It should be pointed out that the molecular mechanism of phenobarbital-type induction may show partial overlap with that of the PXR and GR, which mediate CYP3A4 induction by rifampicin and glucocorticoids.

Pregnane X receptor

This type of induction is mediated by activation of the human PXR. PXR is expressed predominantly in the liver and, to a lesser extent, in the small intestine, and it mediates the induction of CYP3A4, CYP2B and CYP2C enzymes. This nuclear receptor can be activated by numerous structurally different drugs and xenobiotics including rifampicin and hyperforin, an active component of St John's wort.

Glucocorticoid receptor

The GR is activated by glucocorticoids, in particular dexamethasone. GR mediates the induction of a number of CYP isoforms including CYP2C9 and CYP3A4, both directly and indirectly by facilitating CAR- or PXR-mediated pathways.

Unlike enzyme inhibition, which is an almost immediate response, enzyme induction is a slow regulatory process, usually dose and time dependent [23]. The extent of induction is generally proportional to the dose of the inducing agent and, since the process usually requires synthesis of new enzymes, it occurs with some delay after the exposure to the inducing agent. In practice, the time required for induction depends on the time to reach the steady state of the inducing agent (approximately five elimination half-lives) and the rate of biosynthesis of the enzyme(s). Similarly, the time course of de-induction is also gradual and depends on the rate of degradation of the enzyme and the time required to eliminate the inducing drug. Either of these two processes could be the rate-limiting step.

Enzyme induction may have a profound impact on the pharmacokinetics of drugs metabolized by the susceptible enzyme. As a consequence of enzyme induction, the rate of metabolism of a particular agent is increased, thereby resulting in lower plasma drug concentrations and, possibly, a loss of clinical efficacy. Conversely, if the affected drug has an active metabolite, induction may lead to increased metabolite concentrations and enzyme induction may paradoxically increase pharmacological or toxicological activity. Because of the nature of time-dependent processes, enzyme induction may complicate drug dosing regimens and influence therapeutic decision-making in chronic drug therapy. Addition of any potent inducer to, or withdrawal of, a potent inducer from an existing therapy may cause pronounced changes in drug concentrations, leading to failure of drug therapy or adverse effects. The magnitude and timing of these interactions are critical to allow clinicians to adjust dosages in order to maintain therapeutic effects and prevent toxicity. Enzyme induction represents a common problem in the management of epilepsy as various AEDs, in particular phenobarbital, phenytoin and carbamazepine, possess enzyme-inducing properties [1–3].

Predictability of metabolic interactions based on *in vitro* data

The potential for metabolic drug interactions is an important aspect to consider during the development of new drugs. In the past, most drug interaction studies were performed relatively late in phase II and III clinical studies, using a strategy based on the therapeutic indices of drugs and the likelihood of their concurrent use. Since susceptibility of drug interaction is an undesirable property of a drug, such information should ideally have been obtained already in the preclinical phase. More recently, different *in vitro* methods have been developed and have become widely used as screening tools to predict potential drug interactions before a drug reaches the clinical phases of development. The *in vitro* systems

established for assessing drug metabolism and metabolic drug interactions include enzyme-based techniques, such as purified enzymes, recombinant human enzymes and human liver microsomes, and cell-based techniques, such as liver slices, immortalized cell lines and primary hepatocytes. Each method has its advantage and disadvantage, and the readers are referred to other review articles for further information on this topic [33,34].

Two complementary approaches have been developed to predict potential drug interactions *in vivo* based on *in vitro* data: (a) identification of the enzymes (CYP isoforms or other drug-metabolizing enzymes) responsible for the biotransformation of a test drug; and (b) determination of the potential of the test drug to inhibit or induce the activities of the various drug-metabolizing enzymes. The first approach allows prediction of interactions affecting the metabolism of the test compound (i.e. interactions affecting the test drug as a substrate), while the second allows prediction of any effect that the test compound may have on the metabolism of other drugs (i.e. interactions in which the test drug may act as an inducer or an inhibitor).

The test drug as a substrate (target for interactions)

To predict interactions, the individual enzyme system responsible for the biotransformation of a drug must be identified, and its relative contribution to the overall drug elimination assessed. This may be obtained by using a general *in vitro* strategy [27,33] involving assessment of (a) catalytic activity in human liver microsomes; (b) correlation of this activity with markers for known CYP isoforms; (c) catalytic activity in complementary DNA (cDNA)-based vector systems; (d) catalytic activity in purified enzymes; (e) effects of selective inhibitors; and (f) immunoinhibition with monoclonal or polyclonal antibodies against various CYP isoforms. Once the contribution of different isoenzymes to the metabolism of a given drug has been elucidated, prediction of interactions affecting the biotransformation of that drug can easily be made, based on existing knowledge of the influence that other drugs have on the activity of the same isoenzymes. Identification of CYP3A4 as the primary enzyme involved in carbamazepine biotransformation has allowed the understanding of the effects of several drugs on its plasma concentrations. In fact, most of the drug interactions with carbamazepine that have been documented in clinical practice involve CYP3A4 inhibitors or inducers [35].

The test drug as a cause of interactions affecting the metabolism of other drugs

An *in vitro* strategy similar to that previously mentioned to identify enzymes responsible for the metabolism of a given drug may also be applicable for the evaluation of drugs as potential inhibitors of specific enzyme isoforms. By the use of human liver microsomes or individual enzymes, a series of drugs and/or their metabolites can be screened relatively quickly to determine quantitatively their potency in inhibiting reactions considered to reflect specifically the activity of individual enzyme isoforms. *In vitro* assessment of inhibitory interactions is based on calculation of kinetic parameters such as the inhibitor concentration at which the reaction rate is reduced by 50% (IC_{50}) and the inhibition constant (K_i), the detailed description of which is beyond the scope of this chapter. Different *in vitro* systems, including liver slices, immortalized cell lines and primary hepatocytes, may be used to estimate the enzyme-inducing potential of a drug at preclinical level. In general, these experiments are far more complex, time-consuming and expensive [36]. Once it has been established that an AED inhibits or induces the activity of a given isoenzyme, then one can predict that the metabolism of substrates of the same isoenzyme will be correspondingly affected. A good correlation between the ability to inhibit various enzyme systems *in vitro* and the *in vivo* inhibitory interaction profile has been established for valproic acid [37–40].

While it is relatively easy to assess *in vitro* a drug interaction, the correct interpretation and extrapolation of *in vitro* data to the *in vivo* situation requires a good understanding of pharmacokinetic principles and is complicated by other factors [27,41,42] and, for instance, the extent of inhibition or induction of a given pathway, as assessed on the basis of *in vitro* data, does not necessarily imply that the total clearance of the affected substrate *in vivo* will be affected to the same extent. Factors influencing this include the degree of inhibition/induction of the affected pathway *in vivo* (which may not necessarily correspond to the *in vitro* situation, due to intervention of confounding variables), the contribution of the affected pathway to the overall elimination of the substrate, the pharmacokinetic characteristics of the substrate and its route of administration.

Clinical relevance of metabolic interactions

Information on the drug-metabolizing enzyme systems and their substrates, inhibitors and inducers may be of great value for rational prescribing and may help clinicians to anticipate and eventually avoid potential interactions. In fact, co-administration of two substrates of the same enzyme, or co-administration of a substrate with an inhibitor or an inducer, entails the possibility of a drug interaction. As shown in the previous section, not all theoretical drug interactions that are predicted from *in vitro* studies will occur *in vivo*, and, at any rate, some may not be clinically significant. Drug-related, patient-related and epidemiological factors (Table 28.3) must be taken into account when evaluating the potential occurrence and clinical significance of a metabolic drug interaction [3,23]. Taken together, these factors contribute to the large intersubject variability in the extent and magnitude of metabolic drug interactions.

Therapeutic index of the affected drug

In general, interactions affecting drugs with a narrow therapeutic index (e.g. phenytoin, anticoagulants, immunosuppressants or anti-cancer drugs) are more likely to be clinically relevant than interactions affecting drugs with a wider margin of safety.

Role of pharmacologically active metabolites

Many metabolites are biologically active and this needs to be considered when predicting the clinical consequence of a drug interaction. Another factor to be considered is whether metabolites have any enzyme-inducing or -inhibiting effects independent from those of the parent drug. For example, if a metabolite has an inhibiting effect on a given isoenzyme that is not shared by the parent drug, *in vitro* experiments designed to test the enzyme-inhibiting potential of the parent drug may fail to identify a clinically important interaction.

Table 28.3 Factors to be considered when evaluating the clinical implication of a potential metabolic drug interaction.

Drug-related factors	Therapeutic index of the substrate	Interactions affecting drugs with a narrow therapeutic index are more likely to be clinically relevant
	Dose/concentration of the substrate	Changes in plasma concentrations of the affected drug are more likely to be clinically significant if the baseline values are close to the threshold for therapeutic or toxic effects
	Extent of metabolism of the substrate through the affected enzyme (versus alternative metabolic routes)	If the affected enzyme plays a minor role in the overall metabolic elimination, inhibition will not result in an important decrease in drug clearance, while induction may cause a substantial increase
	Role of pharmacologically active metabolites	The presence of pharmacologically active metabolites may complicate the outcome of an interaction; metabolites may also act as enzyme inhibitors or inducers
	Potency of the inhibitor/inducer	A potent effect is more likely to result in an interaction involving most patients
	Dose/concentration of the inhibitor/inducer at the enzyme site	The effects of enzyme inhibitors/inducers are usually dose dependent; low concentrations at the enzyme site may not be sufficient to elicit an interaction
Patient-related factors	Genetic predisposition	Patients with a genetically determined defect of a polymorphic enzyme will not have interactions mediated by inhibition or induction of this enzyme
	Level of risk for toxicity	Elderly subjects or patients with hepatic or renal impairment are more susceptible to drug interactions
Epidemiological factors	Probability of concurrent use	A potential drug interaction is of limited clinical interest if the drugs involved are rarely prescribed in combination

Based on refs 3 and 23.

Extent of metabolism of the substrate through the affected enzyme

For interactions involving enzyme inhibition, a clinically relevant change in the plasma concentration of the affected drug may occur only if the inhibited enzyme is the major pathway of elimination. As most drugs have several metabolic pathways, the inhibition of an enzyme contributing less than 20–30% to the overall clearance of the affected drug will have a limited impact on its disposition. On the other hand, the situation may be totally different for interactions involving enzyme induction. As there is theoretically no limit to the increase in the efficiency of a given metabolic pathway when the corresponding isoenzyme(s) have been induced, enzyme induction could transform an initially minor metabolic pathway into a major contributor to the overall elimination of the drug, with a consequent important increase in its total clearance.

The different susceptibility of felbamate and topiramate to the action of inhibitors and inducers of their metabolism provide a typical example of this situation. Since CYP3A4 plays only a minor role in the metabolism of felbamate, inhibitors of this isoform would be expected to have only minimal effects on the overall clearance of this drug and, in line with this prediction, felbamate pharmacokinetics have been found not to be significantly affected by the potent CYP3A4 inhibitor erythromycin [43]. On the other hand, the total plasma clearance of felbamate is significantly increased and its plasma concentrations are significantly decreased by concomitant treatment with the CYP3A4 inducers phenytoin, phenobarbital and carbamazepine. A similar situation is observed with topiramate, a drug which, in healthy subjects, is primarily excreted unchanged in urine. Because metabolism is of minor importance in the overall clearance of topiramate, no significant changes in its plasma concentration are expected when an enzyme inhibitor is added on in patients receiving topiramate monotherapy. On the other hand, metabolic elimination possibly becomes the major determinant of topiramate disposition in patients treated with inducing drugs, and this may explain the twofold increase in the total clearance of topiramate reported during co-medication with phenytoin [44].

Genetic predisposition

In patients receiving drugs metabolized by a polymorphic enzyme, the effects of inhibitors or inducers may vary between phenotypes/genotypes. Extensive metabolizers are generally more susceptible to enzyme inhibition or induction than poor metabolizers. This has been most clearly documented for CYP2D6: interactions caused by potent inhibitors of this isoform (i.e. quinidine) are not observed in poor metabolizers, who show a genetically determined lack of functional CYP2D6 in their liver. Similarly, poor metabolizers of CYP2C19 and CYP2C9, who play a role in the metabolism of phenytoin, are not expected to be vulnerable to the inhibition of phenytoin metabolism caused by selective inhibitors of the corresponding enzymes.

Certain metabolic drug interactions are particularly complex and may be difficult to predict where enzyme induction and inhibition occur at the same time. The ability of a given compound to act as both enzyme inducer and inhibitor provides an explanation for the inconsistent and apparently contradictory nature of some drug interactions. For example, at low doses phenobarbital tends to induce the metabolism of phenytoin, probably through induction of CYP2C9 and/or CYP2C19, whereas at higher doses it may competitively inhibit phenytoin metabolism [2]. The extent of these differential interactions may vary across individuals, which may explain the unpredictable and bidirectional changes in plasma phenytoin concentration after addition or removal of phenobarbital therapy. Even more complex is the interaction between phenytoin and warfarin. When phenytoin is started in a patient stabilized on warfarin therapy, phenytoin may initially competitively inhibit the metabolism of warfarin because both phenytoin and S-warfarin are substrates for CYP2C9. After an

initial increase, the plasma concentration of S-warfarin will then decline within 1–2 weeks because of CYP2C9 induction [45]. Other complex situations may arise in patients receiving combinations of three or more drugs. In some cases, the opposite effects of an enzyme inhibitor and an enzyme inducer may cancel out reciprocally. In this respect, the clearance of lamotrigine is markedly increased by co-administration of enzyme-inducing AEDs (e.g. phenobarbital, carbamazepine and phenytoin) and inhibited by valproic acid. However, lamotrigine clearance values in triple-therapy regimens which included valproic acid and an enzyme inducer are similar to those observed in patients on lamotrigine monotherapy [23].

Antiepileptic drugs and metabolic interactions

AEDs may be involved in metabolically based drug interactions because they act as inhibitors or inducers of various drug-metabolizing systems or because they are substrates for the same enzymes. The effect of AEDs on the most common drug-metabolizing enzyme systems is reported in Table 28.4, while the elimination pathways and protein binding for AEDs are shown in Table 28.5.

Table 28.4 Effects of antiepileptic drugs (AEDs) on the most common drug-metabolizing enzyme systems.

Drug	Effect	Enzymes involved
Older AEDs		
Phenytoin	Inducer	CYP2B6, CYP2C, CYP3A UGT Epoxide hydrolase
Phenobarbital/ primidone	Inducer	CYP2B6, CYP2C, CYP3A UGT Epoxide hydrolase
Carbamazepine	Inducer	CYP2B6, CYP2C, CYP3A, CYP1A2 UGT Epoxide hydrolase
Valproic acid	Inhibitor	CYP2C9 UGT1A4, UGT2B7 Epoxide hydrolase
Ethosuximide	None	
Newer AEDs		
Felbamate	Inhibitor Inducer	CYP2C19 β-oxidation CYP3A4
Gabapentin	None	
Lamotrigine	None or weak inducer	UGT
Levetiracetam	None	
Oxcarbazepine	Inhibitor (weak) Inducer (weak)	CYP2C19 CYP3A4 UGT
Pregabalin	None	
Rufinamide	Inducer (weak)	CYP3A4
Stiripentol	Inhibitor	CYP1A2, CYP2C19, CYP3A4
Tiagabine	None	
Topiramate	Inhibitor (weak) Inducer (weak)	CYP2C19 CYP3A4 β-oxidation
Vigabatrin	None	
Zonisamide	None	

Based on [23].

Antiepileptics as inhibitors of metabolic enzymes

Valproic acid is considered to be a broad-spectrum inhibitor of various drug-metabolizing enzymes. Studies in human liver microsomes have documented that, at clinically relevant concentrations, valproic acid competitively inhibits the activity of CYP2C9, inhibits only weakly CYP2C19 and CYP3A4, and has no appreciable effect on CYP2D6 and CYP2E1 [37]. This is consistent with clinical evidence that valproic acid may significantly increase the plasma concentrations of CYP2C9 substrates including the AEDs phenytoin and phenobarbital [40]. *In vitro* studies have indicated that valproic acid may also inhibit epoxide hydrolase, which explains its ability to increase the plasma concentration of carbamazepine-10,11-epoxide in carbamazepine-treated patients, without any substantial changes in the concentration of the parent drug [38]. Valproic acid is an *in vivo* inhibitor of UGTs. At concentrations that are relevant *in vivo*, valproic acid was found to inhibit the UGT2B7-mediated glucuronidation of zidovudine, but had little or no effect on UGT1A1, UGT1A6, UGT1A9 or UGT2B15 [39]. The clinically relevant interaction between valproic acid and lamotrigine has been attributed to inhibition of UGT enzymes, notably UGT1A4 [40]. Valproic acid has been demonstrated to almost double the half-life and serum concentrations of lamotrigine and this contributes to the increased risk for skin rashes when these two drugs are co-administered. Valproic acid has also been reported to inhibit the glucuronidation of lorazepam [25].

Some of the newer AEDs may at times act as enzyme inhibitors. Topiramate has been reported to be a modest inhibitor of the activity of CYP2C19 *in vitro*, and this may account for the moderate elevation of plasma concentrations of phenytoin observed in a small subset of phenytoin-treated patients given topiramate [46]. Oxcarbazepine is also a weak inhibitor of CYP2C19, which might explain its ability, especially when used at high dosages (>1800 mg/day), to increase by up to 40% the plasma concentrations of phenytoin and, to a lesser extent, phenobarbital [2].

Felbamate is a potent and selective *in vitro* inhibitor of CYP2C19 and may increase plasma concentration of phenytoin [43,47]. Administration of felbamate to patients treated with valproic acid has been shown to significantly decrease the clearance and increase the plasma concentrations of valproic acid, presumably by inhibiting the mitochondrial β-oxidation of valproic acid [48]. Felbamate has also been reported to increase the plasma concentrations of other AEDs such as phenobarbital, clobazam, carbamazepine-10,11-epoxide (concomitantly with a reduction in plasma carbamazepine levels), but the molecular mechanisms of these interactions have not been elucidated [2]. Stiripentol, a new AED used for the treatment of severe myoclonic epilepsy in infancy, is a well-documented *in vitro* inhibitor of various CYPs, namely CYP1A2, CYP2C19 and CYP3A4 [49]. Consistent with this, stiripentol increases the plasma concentrations of a wide variety of AEDs, including phenytoin, phenobarbital, carbamazepine, valproic acid and clobazam [50].

Antiepileptics as inducers of metabolic enzymes

The first-generation AEDs carbamazepine, phenytoin, phenobarbital and primidone are broad-spectrum inducers of a variety of CYP enzymes, including CYP1A2, CYP2C9, CYP2C19 and

Table 28.5 Elimination pathways and protein binding for older and newer antiepileptic drugs (AEDs). Fraction of absorbed dose cleared by metabolic and renal elimination refers to average values described for patients on monotherapy. CYP and UGT isoforms responsible for metabolic clearance of each drug are shown in brackets (bold characters identify enzymes involved in metabolic pathways responsible for a major proportion of total drug clearance).

Drug	Proportion of drug eliminated (%) by				Protein binding (% bound)
	CYP	UGT	Other metabolism	Renal	
Older AEDs					
Carbamazepine	75 (**CYP3A4**,CYP2C8, CYP1A2)	15	Negligible	<5	75
Ethosuximide	70 (**CYP3A4**)	No	Negligible	20	0
Phenobarbital	30 (**CYP2C9**, CYP2C19, CYP2E1)	Negligible	25 (N-glucosidation)	25	50
Phenytoin	90 (**CYP2C9**, **CYP2C19**)	No	Negligible	<5	90
Valproic acid	10 (CYP2C9, CYP2A6, CYP2B6)	40 (various UGT)	35 (β-oxidation)	<5	90
Newer AEDs					
Felbamate	15 (CYP3A4, CYP2E1)	10	25 (hydrolysis)	50	30
Gabapentin	No	No	No	100	0
Lamotrigine	No	>80 (**UGT1A4**)	Negligible	10	55
Levetiracetam	No	No	30 (hydrolysis)	70	<10
Oxcarbazepine[a]	<5	60%	No	30	40
Pregabalin	No	No	No	100	0
Tiagabine	90 (**CYP3A4**)	No	Not identified	<2	96
Topiramate	<25	No	Not identified	75	15
Vigabatrin	No	No	No	100	0
Zonisamide	50 (**CYP3A4**)	Negligible	20 (acetylation)	<30	40

Based on refs 1 and 23.

[a]Data refer to the active monohydroxycarbazepine derivative (MHD). Oxcarbazepine is transformed to MHD by ketoreduction catalysed by cytosolic arylketone reductase.

CYP3A4, as well as UGTs and microsomal epoxide hydrolase [1–3]. The time-course of induction and deinduction differs between enzyme-inducing AEDs [14,15]. Induction by phenobarbital starts after approximately 1 week, with maximal effect occurring after 2–3 weeks following initiation of therapy. De-induction follows a similar time-course. With phenytoin, maximal induction or de-induction occurs approximately 1–2 weeks after initiation or removal of therapy. Carbamazepine significantly induces its own metabolism (autoinduction) and, as a result of this, its plasma clearance more than doubles during the initial weeks of therapy. Carbamazepine autoinduction should be completed within approximately 3–5 weeks. Consistent with their enzyme-inducing properties, these AEDs have been reported to increase the clearance and reduce plasma concentrations of many different compounds including other concurrently administered AEDs [1–4]. Clinically relevant interactions should be expected when enzyme-inducing AEDs are given in combination with drugs with a low therapeutic index such as oral anticoagulants, oral contraceptives, immunosuppressants or chemotherapeutic agents [1]. When active metabolites are formed, enzyme induction may result in potentiation of therapeutic and/or toxic effects. Furthermore, these AEDs may induce endogenous substrates including sexual and thyroid hormones and vitamin D [51]. As patients with epilepsy may experience a wide variety of long-term endocrine effects including sexual/reproductive disorders, bone metabolism disturbances and thyroid abnormalities, it has been suggested that this may be related, at least in part, to the use of enzyme inducers. The decreased propensity of most newer AEDs to enzyme induction makes it likely that they may have less effect on the endocrine systems.

In addition to classical enzyme-inducing AEDs, some newer agents, namely felbamate, oxcarbazepine and topiramate, may produce significant enzyme induction, though the spectrum of enzymes induced by these agents appears to be more restricted. Felbamate can induce the activity of CYP3A4, as indicated by a decrease in the plasma concentrations of CYP3A4 substrates such as carbamazepine [43,52]. Unlike carbamazepine, oxcarbazepine is not subject to autoinduction, but can selectively induce the specific isoforms of the CYP3A group involved in the metabolism of oral contraceptives and dihydropyridine calcium antagonists [53]. Oxcarbazepine may also induce UGTs, as suggested by a significant acceleration of lamotrigine clearance [54]. Topiramate is also a weak inducer of CYP3A4, because at dosages above 200 mg/day it may decrease plasma concentrations of ethinylestradiol with a risk of failure of contraception [55]. At lower dosages, topiramate does not appear to affect the metabolism of steroid contraceptives, reinforcing the important concept that enzyme induction is a dose-dependent phenomenon [56]. Recent evidence indicates that rufinamide, a new AED used as adjunctive therapy for the treatment of seizures associated with Lennox–Gastaut syndrome, can act as inducer of CYP3A4 as it can cause a reduction in plasma concentrations of oral contraceptives and triazolam [57].

Antiepileptics as substrates for metabolic enzymes

All commonly used AEDs, except gabapentin, pregabalin, levetiracetam and vigabatrin, are metabolized in the liver by CYPs or UGTs and their biotransformation can be affected by concomitant administration of drugs including other AEDs with inhibiting or inducing properties towards these enzymes.

As CYP2C9 and CYP2C19 are the major isoenzymes participating in the metabolism of phenytoin, it can be anticipated that co-administration of any drug that inhibits these two isoforms will decrease the clearance of phenytoin and increase its plasma concentrations [58]. Interactions consistent with inhibition of CYP2C9 can be caused by, for example, amiodarone, phenylbutazone, fluconazole, miconazole and valproic acid, while interactions consistent with inhibition of CYP2C19 are those caused by ticlopidine, omeprazole, felbamate and topiramate. Isoniazid non-competitively inhibits the metabolism of phenytoin, but it is not clear which CYP enzyme is involved. Other enzyme-inducing AEDs, such as phenobarbital and carbamazepine, have limited effects on plasma phenytoin concentrations as they can also inhibit its metabolism.

CYP2C9 and CYP2C19 are also the major isoforms responsible for phenobarbital biotransformation. However, since each phenobarbital metabolic pathway contributes no more than 20–30% of its total clearance, it can be expected that only broad-spectrum inhibitors could produce clinically relevant effects on phenobarbital elimination. In line with this prediction, valproic acid may cause an up to twofold increase in phenobarbital concentrations, presumably by inhibiting at the same time the CYP2C9-mediated para-hydroxylation and the UGT-mediated N-glucosidation [59]. Potent enzyme-inducing AEDs, such as carbamazepine and phenytoin, have limited effects on phenobarbital metabolism and usually do not modify its plasma concentrations.

CYP3A4 is the primary isoform responsible for carbamazepine metabolism and this information is sufficient to explain the clinically significant elevation in plasma carbamazepine concentrations associated with co-administration of different compounds known to inhibit CYP3A4 activity such as troleandomycin, erythromycin, diltiazem, verapamil, ketoconazole, fluconazole, nefazodone, fluoxetine, fluvoxamine, propoxyphene, danazol and ritonavir [35]. Induction of this isoform also explains the decrease in plasma carbamazepine levels caused by phenytoin, phenobarbital and felbamate.

The metabolism of valproic acid involves a variety of processes including direct glucuronide conjugation, mediated by UGT, mitochondrial β-oxidation and minor CYP-dependent oxidation, mainly mediated by CYP2C9 [16]. Because of the multiplicity of pathways of valproic acid metabolism, drug interactions resulting in increased plasma concentrations are complex and often multifactorial. As already reported [48], the new AED felbamate may significantly increase its plasma concentrations, presumably by inhibition of the β-oxidation pathway. On the other hand, valproate plasma concentrations are decreased in the presence of CYP2C9- and UGT-inducing drugs such as the AEDs phenytoin, phenobarbital and carbamazepine. Activation of UGT by carbapenem antibiotics is the most likely mechanism involved in the reduction of plasma levels of valproic acid during co-medication with these antibiotics [11].

CYP3A4 contributes to the metabolism of ethosuximide, felbamate, tiagabine and zonisamide, and induction of this isoform is consistent with the decrease in plasma concentrations of plasma levels of these drugs in patients treated with classical enzyme-inducing AEDs [1–3]. As oxidative metabolism is of minor importance in the overall clearance of topiramate, significant interactions resulting from inhibition are unlikely. On the other hand, metabolic elimination becomes an important determinant of topiramate clearance in patients treated with enzyme-inducing AEDs, an observation which explains the ability of the latter to decrease plasma topiramate concentration by 40–50% [44].

Lamotrigine is primarily metabolized via N-glucuronidation by UGT1A4. This enzyme is inhibited by valproic acid and induced by classical enzyme-inducing AEDs. Consistent with this, valproic acid may cause a significant increase in the plasma concentrations of lamotrigine, and, conversely, concomitant treatment with phenobarbital, phenytoin or carbamazepine results in reduced lamotrigine concentrations [1–3].

Oxcarbazepine is essentially a prodrug for the active 10-monohydroxy derivative resulting from reduction by a cytosolic reductase. This metabolite is subsequently glucuronidated and its levels are decreased in patients receiving enzyme-inducing AEDs [53].

Excretion

Excretion of AEDs is largely mediated by the kidneys. Although drug interactions at the renal level are rare, compounds that undergo extensive renal elimination in unchanged form may be susceptible to interactions affecting the excretion process, particularly when it involves active transport mechanisms or when the ionized state of the drug is highly sensitive to changes in urine pH [60]. This might particularly affect gabapentin, pregabalin, vigabatrin, levetiracetam and topiramate, which are eliminated predominantly through the kidneys, but it has not been established whether this occurs by active transport systems [6]. On the other hand, agents that cause alkalinization of urine (i.e. ammonium chloride) may increase the excretion of acidic drugs such as phenobarbital by reducing their reabsorption from the renal tubules. This effect can be exploited therapeutically in severe cases of barbiturate intoxication [6].

Pharmacodynamic interactions

Pharmacodynamic interactions take place directly at the site of action of a drug or indirectly by interfering with other physiological mechanisms [2]. They result in a modification of the pharmacological action of a drug without any change in the plasma concentration and are more difficult to identify and measure than pharmacokinetic interactions. These interactions can be additive (i.e. equal the sum of the effects of the individual drugs), synergistic (i.e. combined effects are greater than expected from the sum of individual effects) or antagonistic (i.e. combined effects are less than additive) and can be associated with beneficial effects or increased toxicity. Pharmacodynamic interactions involving AEDs have been well documented in experimental animal studies, but limited information is available on their occurrence and magnitude in humans, given the complexity of quantifying dose–response relationships in the clinical setting [61].

Combinations of AEDs can result in increased efficacy, but also a higher risk for toxic effects. The mode of action of marketed AEDs involves different mechanisms including sodium channel blockade, calcium channel blockade, inhibition of

GABAergic transmission and potentiation of glutamatergic transmission. In general, combinations of AEDs acting by different mechanisms would be expected to be more beneficial than combinations of drugs sharing the same mechanism of action [62]. Concerning potentially favourable interactions, clinical evidence does indicate that the combination of valproic acid with ethosuximide or with lamotrigine may lead to seizure control in patients refractory to the highest tolerated does of either drug given alone [1]. Conversely, there are many examples of undesirable pharmacodynamic potentiation of toxic effects that can occur when AEDs are co-administered. Association of drugs that enhance GABAergic inhibition, such as valproic acid and phenobarbital, may result in profound sedation that cannot be explained by pharmacokinetic interactions [61]. The combination of carbamazepine with lamotrigine or with oxcarbazepine has been reported to cause additive neurotoxic effects, such as dizziness, diplopia and ataxia, presumably explained by their common action in blocking voltage-dependent sodium channels [1]. Combination of AEDs may also increase the likelihood of an idiosyncratic toxic reaction. This is the case of the rare occurrence of an acute encephalopathy, characterized by a change in mental status that can evolve to stupor or coma, described in some patients given valproate in combination with other AEDs, particularly phenobarbital. Moreover, AED polypharmacy may occasionally result in seizure exacerbation and an improvement in seizure control is not uncommon when their drug load is reduced [3].

Potentially adverse pharmacodynamic interactions may also occur between AEDs and other drugs, in particular other central nervous system (CNS) agents. Concomitant administration of sedative AEDs (i.e. barbiturates and benzodiazepines) with CNS depressants such as alcohol, antihistamines, tricyclic antidepressants and phenothiazines can potentiate CNS depression, thereby impairing psychomotor and cognitive function, especially in an elderly population [61]. A number of AEDs, particularly those with mood-stabilizing properties (i.e. carbamazepine, valproic acid and lamotrigine), are increasingly used in the management of psychiatric disorders and often in combination with lithium, antidepressants or antipsychotics. There is some evidence that the combination of carbamazepine with lithium may lead to an increased incidence of neurotoxic symptoms such as confusion, drowsiness, lethargy, tremor and cerebellar signs, especially in patients with pre-existing CNS disease [63]. Although the combination of lithium and valproate is generally well tolerated and effective in treating bipolar disorder, additive adverse reactions such as weight gain, sedation, gastrointestinal complaints and tremor have been reported in some patients [63]. Concomitant administration of valproic acid with the second-generation antipsychotics clozapine or olanzapine appears to be relatively safe, although it may be associated with additive side-effects including weight gain and drowsiness [63]. On the other hand, concurrent treatment with carbamazepine and clozapine is generally contraindicated due to concerns about potential additive adverse haematological side-effects [63].

Pharmacodynamic interactions between AEDs and other drugs are poorly characterized. A well-documented case is the interaction between AEDs and non-depolarizing neuromuscular blockers (NDNMBs) [64]. Acutely administered AEDs may potentiate the neuromuscular effects of NDNMBs as a result of direct pre- and postjunctional effects. Conversely, long-term AED therapy may cause resistance to NDNMBs, due to a combination of effects such as enzyme induction and up-regulation of acetylcholine receptors. Another example is represented by combined treatment of pivmecillinam, a pivaloyl-conjugated antibiotic, and valproic acid, which has been reported to cause a hyperammonaemic encephalopathy, presumably due to reduced serum carnitine concentration, induced by the two drugs via independent and possibly additive mechanisms [65].

Drug interactions in vulnerable patient groups and special conditions

Children

Although monotherapy is the strategy of choice for the majority of paediatric patients with epilepsy, co-medication is often needed for patients with pharmacoresistant epilepsy [66]. Treatment of epilepsy in the neonate and child requires an understanding of the peculiar biochemical and pharmacological characteristics of this age range. All pharmacokinetic processes can be markedly affected by maturation and development [67]. Absorption and distribution alterations seem to be confined mostly to neonates and infants, who exhibit a delayed gastrointestinal absorption and reduced concentrations of drug-binding proteins, such as albumin and α_1-acid glycoprotein. The efficiency of elimination processes also changes markedly during development. Renal function at birth is 25–30% of adult values, increasing to 50–75% by 6 months and reaching full maturation at 2–3 years of age. The activity of drug-metabolizing enzymes, notably CYPs and UGTs, is reduced in newborns, particularly in the premature, but increases rapidly in postnatal life, and by 2–3 years of age the metabolic capacity is usually higher than in adults. However, the pattern of enzyme maturation varies between enzyme isoforms and within individuals, resulting in a large pharmacokinetic variability [67].

The combined influence of ageing and co-medication can significantly influence susceptibility to clinically important drug interactions. In this respect, concomitant treatment with valproic acid may increase the risk of lamotrigine-induced hypersensitivity. Lamotrigine is cleared by glucuronide conjugation and only minor amounts are converted by CYP enzymes to an arene oxide intermediate. In infants and children, the reduction of glucuronide conjugation and the faster rates of CYP-mediated reactions, compared with those of adults, can result in increased production of reactive metabolites, which may explain the greater susceptibility to lamotrigine-induced skin rashes in this age group [68]. The inhibition of lamotrigine glucuronidation caused by valproic acid can further increase the formation of reactive oxide intermediate through the alternative CYP-mediated pathways and, therefore, the risk of lamotrigine-induced hypersensitivity, particularly when the lamotrigine starting dose is not reduced and its titration rate slowed appropriately [69]. Another example of an idiosyncratic reaction which may occur more frequently in children on combined AED therapy is provided by the enhanced hepatotoxicity of valproic acid in young patients concurrently treated with enzyme

inducers, possibly related to accelerated formation of reactive oxidation products [69,70].

Elderly patients

Drug interactions in the elderly are usually more frequent and severe than those in younger subjects [71]. In fact, the large inter-individual variability in drug response resulting from genetic, pathophysiological and environmental factors affecting pharmacokinetics and pharmacodynamics is further amplified in the elderly because of the effect of age-related changes, co-morbid disorders and multiple therapy. As a consequence, any given dose of a drug may produce a different, and sometimes unexpected, response, adverse effects and drug interactions in elderly patients. There are various factors associated with the use of AEDs in the elderly that substantially increase the risk of clinically relevant drug interactions [72,73]. These include polypharmacy and age-related changes in pharmacokinetics and pharmacodynamics.

Polypharmacy

AEDs are frequently prescribed in the elderly due to the high prevalence of epilepsy and other AED-treatable neuropsychiatric disorders in this age group. Elderly patients on AEDs, therefore, often take many medications simultaneously, and the probability of both pharmacokinetic and pharmacodynamic drug interactions increases significantly with the number of medications a person takes. Several studies in different settings have unequivocally indicated that the number of prescriptions (and not the age) is the best predictor of adverse drug reactions [74]. Moreover, elderly patients often self-medicate with over-the-counter preparations and natural remedies (herbal products), which also increase the risk of drug interactions. In this respect, in a study in elderly nursing home residents receiving AEDs, the most commonly prescribed co-medications included CNS drugs, cardiovascular agents and anticoagulants, all of which have the potential to interact with AEDs [75].

Age-related changes in pharmacokinetics and pharmacodynamics

Ageing results in the progressive loss of cellular, organ and system functional reserves and thus in changes in pharmacokinetics and pharmacodynamics. Many age-related physiological changes are known to affect drug absorption, distribution, metabolism and excretion [76]. Moreover, medical conditions common in the elderly, such as cardiovascular, renal or gastrointestinal diseases, further alter drug disposition. While drug absorption is generally not significantly influenced by age, changes in body composition may affect drug distribution in the elderly. In particular, the decrease in total body mass with age is associated with an increase in the proportion of body fat. These alterations may lead to increased volume of distribution of lipid-soluble drugs, as the vast majority of CNS drugs are, which tend to accumulate and persist longer in the body. Older subjects may also undergo a gradual reduction in serum albumin, which may result in a decreased protein binding. However, the most relevant age-related pharmacokinetic modifications involve drug elimination, through hepatic metabolism and/or renal excretion. Hepatic metabolic capacity and renal function decline progressively with age. The decline in drug metabolism is mainly explained by changes in liver blood flow and liver mass, while it is still controversial if there is an age-dependent decrease in microsomal enzyme activity [77,78]. These age-related changes in hepatic drug metabolism are unpredictable and difficult to estimate. Changes in renal clearance are more predictable, as glomerular filtration rate decreases by approximately 10% per decade of life beginning at the age of 40 years. The reduced drug clearance may lead to higher and more variable steady-state plasma concentrations. As pharmacological effects, including the inhibitory/inducing effects on drug-metabolizing enzymes, are often concentration dependent, the likelihood of drug interactions is increased in the elderly. Published reports of pharmacokinetics of older and newer AEDs in elderly have been reviewed [67,73].

Although age-related pharmacodynamic changes may be even more important than pharmacokinetic modifications, the pharmacodynamic alterations have been less extensively investigated. Even if the pharmacokinetics of a drug are not modified, an elderly patient may require a smaller dosage because of a change in pharmacodynamic sensitivity. This can produce either a narrower therapeutic range or a shift downward in the lower and upper limits of the range. Elderly patients treated with AEDs appear to be more sensitive to the effects of centrally active drugs, even when plasma concentrations are controlled, as documented in a controlled clinical trial comparing the efficacy and safety of carbamazepine and valproic acid. Patients over 65 years of age experienced side-effects at concentrations of carbamazepine and valproic acid of 50% and 20%, respectively – lower than in younger subjects [72].

Pregnancy

The use of AEDs in women of child-bearing age requires special consideration with respect to fertility, contraception and pregnancy.

Prescription of oral contraceptives in women with epilepsy is relatively common and may be associated with clinically important drug interactions [1]. CYP3A4 is involved in the metabolism of both endogenous and exogenously administered oestrogens and progesterones. Various AEDs (i.e. carbamazepine, phenytoin, phenobarbital, primidone, felbamate, oxcarbazepine and rufinamide) stimulate the metabolism of steroidal oral contraceptives, thereby reducing the efficacy of the contraceptive pill, with the potential for unwanted pregnancy [1,57]. Topiramate might also induce the metabolism of steroid contraceptives, but only at doses >200 mg/day [55]. Other AEDs, including valproic acid, ethosuximide, lamotrigine, gabapentin, tiagabine, levetiracetam and zonisamide, do not affect the metabolism, and therefore the efficacy, of oral contraceptives. With lamotrigine, however, a reciprocal interaction has been documented, in which oral contraceptives induce the metabolism of lamotrigine and decrease its plasma concentrations by approximately 50% [1]. Therefore, women with epilepsy taking lamotrigine need to be monitored carefully for seizures when oral contraceptives are started and for signs of toxicity when they are discontinued.

Concomitant administration of different AEDs to pregnant women with epilepsy may increase the risk of congenital malformations in newborns. Results of large-scale studies, including collaborative multinational registries, have indicated that AED

monotherapy with the most commonly used AEDs is associated with a two- to threefold increase in risk of major congenital anomalies compared with the general population, and that the magnitude of risk increases with increasing number of AEDs administered during the first trimester of pregnancy [79,80]. Information on teratogenic potential of newer AEDs is still limited and it is not known if they enhance the teratogenic potential of older AEDs when prescribed in combination therapy. As the mechanism of teratogenesis may involve the production of epoxide or other toxic metabolite intermediates, it is difficult to differentiate the relative contribution of pharmacokinetic and pharmacodynamic factors in the occurrence of a teratogenic interaction.

Conclusions

Drug interactions represent a frequent complication of AED therapy. The vast majority of pharmacokinetic interactions with AEDs arise as a consequence of drug-induced changes in hepatic metabolism, through enzyme inhibition or induction, and less frequently from changes in plasma protein binding. On the other hand, limited information is available on the occurrence and clinical significance of pharmacodynamic interactions involving AEDs. Based on the available evidence, newer AEDs appear to have a more favourable drug interaction profile than older compounds.

Wherever possible, drug interactions with AEDs should be prevented by avoiding the unnecessary use of multiple drug therapy. In recent years, an improved understanding of the mechanisms involved, in particular increased knowledge of the specific enzymes responsible for the metabolism of each individual AED and the effects of these compounds on the activity of the same enzymes, has allowed a more rational approach to prediction and management of drug interactions. In most cases, adverse clinical consequences of drug interactions may be anticipated and minimized by appropriate dosage adjustments based on close evaluation of clinical effects and, possibly, plasma drug concentration monitoring.

29 Medical Treatment of Epilepsy in Situations with Limited Resources

Gretchen L. Birbeck
Michigan State University, MI, USA

Global burden and distribution of epilepsy

An estimated 40 million people worldwide suffer from epilepsy, with 85% of these individuals residing in resource-poor regions [1]. This disproportionate burden of disease is partly determined by their large populations and the age distribution of these populations, but also reflects a heavy burden of traumatic brain injury, poor antenatal services, high incidence of central nervous system (CNS) infections and the very limited capacity of developing country systems to provide basic resources including adequate nutrition, safe drinking water, and preventive and primary health-care services. The implementation of simple measures such as vaccination programmes, the training of traditional birth attendants, and enforced helmet and seatbelt laws are cost-effective approaches to preventing insult and injury to the nervous system throughout the life-course of individuals. For our purposes, 'resource-limited setting' refers not only to limited resources for *care*, but also limited resources for *survival*. Much of the material presented here is most applicable to extremely resource-limited settings, including southern Africa. A comprehensive text addressing epilepsy care globally with an emphasis upon developing regions of the world is available [2].

In extremely resource-limited settings, brain disorders are particularly common, but occur within the context of competing needs for fiscal investments into basic services. The individual in resource-limited settings is focused upon food acquisition, the provision of shelter, adequate personal safety, and the maintenance of the social relationships required for survival in such environments. The state is focused upon investments in the development of infrastructure for education, food security, transport, trade and economic development. Regional conflicts and political corruption worsen such situations drastically. As a general rule, the need for neurological health-care services either goes unrecognized or is overtly neglected.

Health systems and neurological services

Wealth largely determines health. Resources for public infrastructure, particularly to provide public health resources such as clean accessible water, are the minimal investments required in addressing the health of the citizenry. Further investments in health services for preventive and curative care are also needed to optimize the health of a population, and individuals within the region must have the personal financial resources to access care. The resources available for health and health care are largely determined by a country's wealth while the distribution of services internally can be predicted by the progressive or regressive nature of income redistribution. Given the neglected nature of neurological illness and service development in resource-poor settings, little was known regarding available services for epilepsy care in many regions until 2004, when the World Federation of Neurology (WFN) produced a comprehensive atlas that delineated the service availability for neurological care [3], followed in 2005 by a similar atlas focused upon epilepsy care resources [4]. These atlases provide a broad range of information from the number of neurologists to the availability of neuroimaging and electroencephalography in all regions of the world. The implications that the data presented in the atlases have for neurological care delivery in most resource-poor settings are profound. Resources for care available to people with epilepsy in very low-income countries (as defined by the World Bank) include a mean of 0.03 neurologists per 100 000 people. Electroencephalography and computed tomography (CT) availability is generally limited to large cities and often only to individuals with personal resources to access and pay for this service. Less than 30% of countries within the African region have magnetic resonance imaging (MRI) technology. Postgraduate training programmes in neurology are generally not available in low-income regions. Within sub-Saharan Africa, only South Africa offers such training and the median number of postgraduates per year specializing in neurology in all of Africa is only 18. The dearth of neurological expertise in such regions is unlikely to improve unless a 'reverse' brain drain occurs, with neurologists from wealthier countries immigrating to these areas, or local training programmes initially staffed by such individuals are established. Regardless, the model in the West of epilepsy care being delivered by neurologists is not a feasible model for epilepsy care provision in resource-poor settings.

In low- to middle-income countries (LMICs, as defined by the World Bank), neurological specialists are often non-existent, and physician-level care is also extremely limited. Most health care is provided by non-physician health-care workers including nurses, midwives and clinical officers. Clinical officers (COs), who receive 3 years of technical training after secondary school (i.e. high school), are the backbone of the health-care system in much of sub-Saharan Africa. To some extent, COs are similar to the 'barefoot doctors' serving regions of Asia and Latin America. While developed regions might consider such non-physician health-care workers 'physician extenders', most non-physician health-care

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

workers in resource-poor settings do not have the direct supervision of a physician. In rural regions of Zambia, clinics and even hospitals are staffed without physicians on site and the median distance to the nearest physician is 50 km [5]. Where ox-carts and bicycles are common modes of transport, such travel, particularly for ill individuals or persons with physical disabilities, is almost impossible. Decentralized epilepsy care, delivered as close to the patient as possible, offers the best chance of providing access to basic treatment for most people in the world with epilepsy.

The training curriculum of non-physician health-care workers in LMICs is generally determined by the commonest recognized health-care needs of the population to be served and the expertise of the trainers. As such, the focus is generally on basic primary health care and infectious diseases of public health import. Most training emphasizes vaccinations, maternal and child health-care services, and acute curative care delivery for common treatable conditions such as malaria, pneumonia, sexually transmitted infections and infectious diarrhoea. A 2002 survey of Zambian clinical officers and nurses found seizure to be the most common neurological problem encountered by these individuals. Yet, less than a third of respondents felt they knew how to treat acute seizures, and even fewer were comfortable managing epilepsy [6]. Although this situation probably reflects the ongoing reality in epilepsy care delivery for most resource-poor settings, small investments in health-care workers' education can change this and make basic epilepsy care services available, affordable and feasible to the masses. This has been shown in World Health Organization (WHO) demonstration projects in China and Brazil [7,8], WFN-funded programmes in Zambia and Malawi, and projects in Bamako [9], amongst others. Despite many examples that non-physician health-care workers with inexpensive medications can effectively treat many people with epilepsy at a community-based level, the *epilepsy treatment gap*, meaning the proportion of people who require treatment but are not receiving it, remains between a dismal 80% and >95% in many of the very low-income countries of the world [10].

Aetiology of epilepsy in resource-limited settings

Even in developed countries, we are unable to determine an underlying aetiology for epilepsy in at least 30% of patients assessed, so it should hardly be surprising that in resource-limited settings without recourse to neuroimaging or electroencephalography, we have limited information regarding the aetiology for epilepsy in most people with epilepsy. Furthermore, the individuals who access care and have an evaluation to assess the aetiology of their epilepsy in LIMC are a select few and hardly representative. On a population basis, however, we do have some insights as to what may be among the underlying causes of epilepsy in such regions.

Infections

Central nervous system infections from vaccine-preventable diseases, such as infection with *Haemophilus influenzae* type B, remain common in resource-poor settings. The meningitis belt of Africa has almost annual outbreaks of meningococcal infections. Delays in care seeking and delivery further worsen the neurological prognoses of such infections. Three to four million children in the world suffer from severe malaria annually, and cerebral malaria survivors are at substantial risk of subsequent epilepsy. A retrospective cohort study in Kenya found an odds ratio of 4.4 for epilepsy in cerebral malaria survivors relative to other children in the region [11]. A prospective exposure–control study in Malawi found that almost a third of paediatric cerebral malaria survivors experienced adverse neurological outcomes over 2–3 years of follow-up, with 15% of survivors experiencing unprovoked seizures during an 8–15-month follow-up period [12]. When children in resource-limited settings develop serious illnesses associated with fever, seizure and/or coma, the diagnostic evaluation may be rather limited, and empirical treatment with antibiotics and antimalarials may be given, with little documentation available for later review if, or when, the child develops a subsequent seizure disorder. Careful questioning of the parents regarding any such prior illnesses can elicit helpful data.

Parasitosis, particularly from *Taenia solium* with neurocysticercosis (NCC), is a common cause of epilepsy in Latin America and regions of Africa. Public health measures that improve the management of human waste and regulate animal husbandry practices are needed to decrease NCC rates. Until these occur, acute symptomatic care and chronic management are recommended in addition to seizure management [13]. Schistosomal eggs, usually limited to the gastrointestinal or genitourinary tracts, may occasionally end up in the CNS and produce seizures [14–16]. Some have suggested that onchocerciasis (infection with *Onchocerca volvulus*), which usually results in river blindness, may also be a cause of epilepsy [17–20], but this is still under debate. Other parasitic infections, such as trypanosomiasis, may cause acute seizures, but without treatment are generally fatal and as such will not result in a chronic epileptic condition.

Tuberculosis (TB) and human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS), two disorders tightly interlinked in resource-poor settings where the co-epidemics rage on, can also result in epilepsy related to tuberculomas, TB meningitis, HIV-related opportunistic infections, HIV encephalopathy or immune reconstitution syndrome. As antiretroviral therapy (ART) becomes increasingly available, HIV/AIDS as a chronic condition will become more common in LMICs. Studies suggest that 3–11% of people with HIV/AIDS will experience seizures [21,22]. Although no data are available regarding long-term outcomes, we can anticipate an increase in epilepsy prevalence in regions with high HIV/AIDS rates as ARTs continue to roll out.

Traumatic brain injury

The risk of traumatic brain injury (TBI) across the lifespan is greater for people residing in resource-limited settings than in those living in more developed regions for many reasons. Sports-related head injuries occur and helmet availability and use in most resource-poor regions is uncommon. Few protective measures are in place to prevent work-related head injuries from falls or faulty equipment. Bicycles and motorbikes are common modes of transportation, but road conditions are poorly suited for these vehicles. Seatbelts are not typically available in public buses or minibuses. In fact, much of the public transport in rural regions is provided by informal 'taxis', which simply load (and substantially overload!) people and their animals into the back of pick-up trucks (Plate 29.1). In regions with war or internal conflict, head injury

in combatants as well as civilians contributes to the burden of epilepsy. Where war or civil unrest prevails, violence against civilians may result in a greater number of deaths and injuries than the official 'conflict' figures.

Perinatal causes

Central nervous system injury and malformation related to intrauterine infections such as toxoplasmosis and rubella and cytomegalovirus infection remain problematic in LMICs. Frequent maternal infections with associated fevers add additional risks for poor neonatal outcomes. Inadequate access to midwifery and obstetric services also result in higher rates of labour-related hypoxic brain injuries. Improvement in child health and a decrease in under-5 mortality rates are within the United Nations' Millennium Development Goals, but most planned measures will benefit older children rather than neonates. Brain injury rates in the first year of life are unlikely to change as a result of the Millennium Development Goals [23,24].

Other

Whether a general state of physical deprivation contributes to the development of epilepsy remains unclear. The epidemiologic 'life-course' approach to disease [25,26] attempts to quantify the accumulated burden of exposures from conception forward and would offer an ideal approach to considerations of epilepsy aetiology in resource-limited and tropical settings, if data were available. The Barker hypothesis [27] suggests that chronic health conditions, including hypertension and diabetes, are more likely to occur in individuals who have parents or even grandparents who were deprived in their own life-course. Although few data are available to support quantitative analysis using the Barker hypothesis or life-course approach, it seems likely that an accumulated burden of CNS injuries or insults (at least within the individual's lifespan) can predispose to a chronic seizure disorder and that such CNS insults are probably common in resource-poor settings [28–30].

Social context of epilepsy in resource-limited settings

Having epilepsy is more than having seizures. 'Being epileptic' results in psychosocial dysfunction and suboptimal quality of life. For many people with epilepsy, the burden of 'being epileptic', its stigma and its psychosocial consequences outweigh the biomedical burden of the condition. Perhaps nowhere is this more apparent than in resource-limited settings, where epilepsy-associated stigma and its social and economic sequelae have a large impact on people with epilepsy and consequences for their entire household [31–33].

In developing regions where education levels and literacy are relatively low, local beliefs regarding the underlying causes of epilepsy incorporate religious beliefs with issues of possession, blame and witchcraft, and include substantial contagion fears [31–36]. Contagion beliefs, uncontrolled seizures and open fires spell disaster for people with epilepsy in developing regions [37]. High rates of injury and death related to burns and drowning among people with epilepsy are well recognized by epilepsy care providers in such regions. Sadly, such accidents often occur with frightened friends or family members witnessing the event. Comorbid psychiatric disorders, especially depression and anxiety, among people with epilepsy are common.

The social and economic sequelae of epilepsy-associated stigma in resource-poor regions are particularly heavy. Even in relatively developed regions, people with epilepsy suffer from such stigma, but in developed regions this stigma tends to be more felt stigma or internalized stigma, while in less-developed regions stigma is often external and accompanied by gross discrimination [38]. Limited opportunities for education, employment and marriage translate into poorer housing quality, less food security and poorer access to health-care services [32]. Poor housing quality increases exposure to open fire and open bodies of water. Economically, the entire household is disadvantaged. Children with epilepsy reside in poorer households, but are marginalized within the household in terms of access to education and food, relative to their siblings. Social vulnerability for people with epilepsy results in high rates of physical abuse within and rejection from the household. Women with epilepsy are at increased risk of experiencing sexual assault. The social and economic consequences of being a person with epilepsy in a resource-poor setting, if laden with the additional burden of epilepsy-associated stigma, may lead to a steady downward-spiralling decline in terms of social, economic and medical well-being (Fig. 29.1). These circumstances make delivering care to this population extremely challenging.

The role of the neurologist

While much of this text has been dedicated to helping the neurologist determine how to provide *optimal* care to *individuals* with epilepsy, in resource-limited settings the goal is often to determine what epilepsy services are *possible* to deliver to as large a *population* as is possible. Optimal, individualized care may simply not be an option.

Setting the groundwork

Neurologists presently working in resource-poor settings and/or planning to conduct such work should spend some time learning about the local intricacies of the health and health services system. Table 29.1 lists key information that should be obtained to assist in determining where and by whom neurological care services can be best delivered, who to train to provide such care, and what treatment options and ancillary support services can and should be offered to people seeking epilepsy care.

Diagnosis

The neurologist's approach to caring for a person with epilepsy in a resource-poor setting will be largely dictated by what resources are available for care. In terms of diagnostics, neuroimaging may not be available, may be available but at substantial out-of-pocket costs, or may be available to a limited number of publicly funded patients each month. Electroencephalography technology may not be available. Or the quality of the records and review may be so poor as to make the resource essentially obsolete. In the resource-limited setting, history-taking, from the patient as well as close family members, is the most critical and sometimes only diagnostic assessment available.

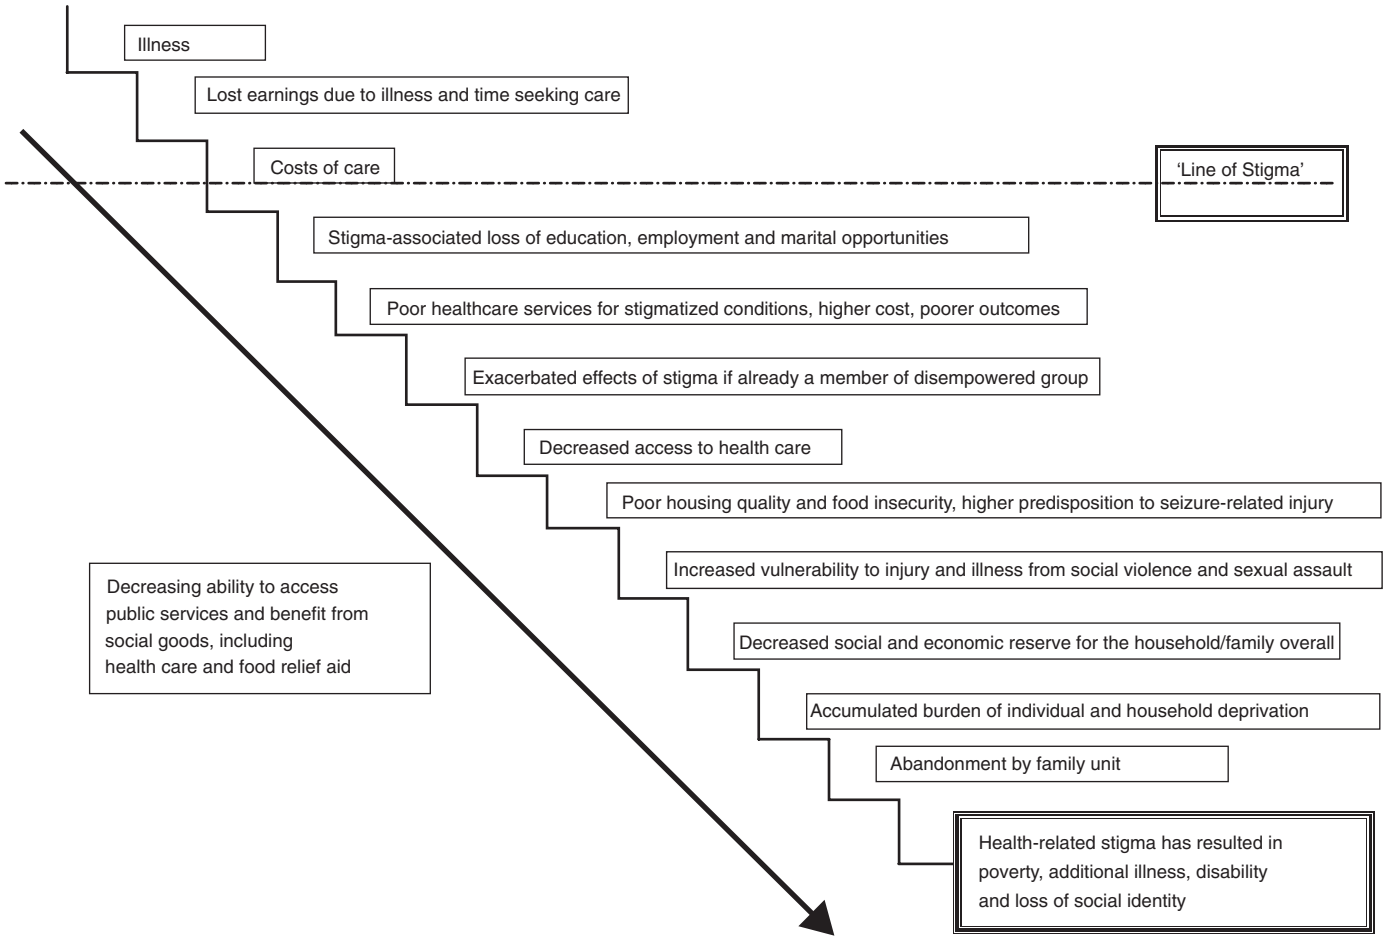

Fig. 29.1 Stigma stairs – the accumulated burden of epilepsy-related stigma.

Treatment

Many LMICs have only phenobarbital available for chronic seizure treatment, with other AEDs not provided by the health system, technically provided but only rarely in stock at local pharmacies, or available but at substantial cost to the patient, who already has a number of competing financial needs to cover his/her basic survival needs. Unless the neurologist is certain that the patient has the resources to purchase other anticonvulsant medications on a long-term basis, phenobarbital should be the initial drug of choice.

Phenobarbital

Dosing

A loading dose of 10–20 mg/kg is needed to achieve therapeutic drug levels. Where intravenous access is limited, loading can be undertaken by dividing the dose into multiple intramuscular injections. Because of its prolonged half-life, by initiating maintenance dosing, it will be more than a week before therapeutic levels are achieved. Maintenance doses of 2–6 mg/kg/day, taken daily in adults, and daily or twice daily in children, are recommended.

Advantages

Phenobarbital is generally cheap, even if purchased out of pocket. As the AED for the WHO essential drugs list, phenobarbital is usually available in government clinics and pharmacies. Dosing parameters and side-effects are more familiar to health-care personnel than other medications for chronic seizure management. Phenobarbital also offers a relatively broad spectrum of activity, being appropriate for use in patients with primary generalized as well as partial-onset seizures.

Disadvantages

Phenobarbital can cause cognitive and behavioural problems, especially in the elderly and young children.

Side-effects

In addition to cognitive and behavioural side-effects, Dupuytren's contracture, facial coarsening and folate deficiency may occur. Abrupt discontinuation of treatment (from either non-adherence or erratic drug supplies centrally) may result in withdrawal seizures, including status epilepticus. Rapid intravenous dosing and/

Table 29.1 Key questions to consider when setting the groundwork for epilepsy services development.

Health system
How is the public system funded?
How is the system organized administratively?
What are the routes and routines for referrals?
What facilities exist for care at each level in terms of primary, secondary and tertiary care centres?
How are priorities and health policies developed?
What user fees are imposed?
What is the quality of care at various levels, including laboratory support?
What diseases/conditions constitute the bulk of what health-care workers see?
What parallel systems of care are there? Private? Faith-based? Traditional?
What medications are provided free? Which others are accessible? Where? And at what cost?
Health-care workers
Who provides primary care? Inpatient care? Antenatal care? And what is their training?
What extenders are used (community health workers, trained birth attendants, etc.) and what is their training?
What neurological education, if any, have the non-physician health-care workers had?
How comfortable and competent are the health-care workers (physician and non-physician) in caring for patients with epilepsy?
Patient-level factors
What barriers to care and adherence do people with epilepsy encounter in the system?
What indirect costs are associated with care seeking and adherence?
What is the average wage? Relative to drugs and indirect costs?
What traditional beliefs regarding epilepsy are commonly held in the region?
How substantial is the burden of epilepsy-associated stigma?

or high loading doses must be avoided where ventilators for respiratory support are not available.

Interactions

Phenobarbital, and in fact all of the enzyme-inducing AEDs, may interact with antiretroviral medications used for HIV/AIDS and could potentially result in subtherapeutic levels of antiretroviral medications, specifically protease inhibitors (PIs) and non-nucleoside reverse transcriptases (NNRTIs) [39]. Phenobarbital can also decrease the efficacy of hormonal contraceptives. Rifampicin, a commonly used TB medication, may lower phenobarbital levels. Interactions with co-administered traditional medicines should be considered.

Other considerations

Decisions regarding when to initiate or discontinue AEDs require careful weighing of the burdens and benefits of the available treatment. Burdens of treatment may include drug side-effects (particularly when treatment options are limited to phenobarbital), extreme efforts required to acquire AEDs for people located in remote regions, and personal and/or family reluctance for daily medication versus occasional seizures.

Other antiepileptic drugs

Carbamazepine, valproic acid and phenytoin may also be available in resource-poor settings, but their consistent availability can be less reliable, especially in non-urban settings. Health-care workers may be less familiar with dosing and potential side-effects for these medications. Laboratory resources for AED drug levels are generally not available. Monitoring of electrolytes and liver functions may also be difficult to assess. Inappropriate use of carbamazepine in persons with unrecognized primary generalized epilepsy can be problematic. Health-care personnel unfamiliar with the zero-order kinetics of phenytoin often make unwise decisions in terms of titrations and dose changes. Several cases of carbamazepine toxicity as a result of antiretroviral medication initiation have been reported [40–42].

Other aspects of care

In addition to diagnosis and treatment, patient and family education and counselling must play a central role in clinical management of epilepsy. Patients and their families must be persuaded of the need for chronic treatment. This can be difficult in a culture of only acute curative care. Educational efforts to alleviate family members' contagion fears and enlist their support for adherence and retention are critical. Families also need to be informed as to what to do when seizures occur (e.g. the recovery position). Counselling regarding the risks to the person with epilepsy for burns, drowning and other injuries may open a dialogue that allows the family to reallocate domestic duties to decrease injury risk. Such counselling sessions can be conducted in groups to optimize the physicians' time. A trained community health worker or nurse can also undertake to lead such discussions once that have been properly educated and provided with medications to dispense.

In developed countries, neurologists provide medical care services with care tailored to the individual's needs. Where there is only one neurologist for every 5–10 million people, this model of care abandons the vast majority of people with epilepsy to care provision by local traditional healers. With such limited neurological expertise, a more effective use of the neurologists' talents is not that of a specialist care provider for a small population of patients but that of a medical educator, policy advisor and community advocate for people with epilepsy.

Medical educator

In resource-limited settings with few neurologists, the neurologist should ideally maintain a strong focus on medical education, including curriculum planning and training of medical students, non-physician health-care workers and continuing medical education for physician-level colleagues. A key limitation is the lack of training tools and educational materials for non-physician health-care workers to provide epilepsy care services independent of physician oversight. Even texts written for general physicians assume a knowledge of anatomy, physiology and pharmacology that exceeds the background education acquired by nurses and clinical officers. Some texts have been developed [43,44]. The thoughtful development of simple algorithms for epilepsy care delivery that utilize available medications in terms familiar to local clinicians can go a long way towards improving the care available for people with epilepsy. The neurologist can also train other physicians who see many people with epilepsy (e.g. internal medicine physicians), and this should substantially improve the quality of care available to people with epilepsy, particularly if these general physicians participate in medical student and postgraduate education.

Policy advisor

Ideally, if a neurologist has become familiar with the health system, health-care workers and patient population in the resource-limited setting in which he/she works, then the neurologist is uniquely positioned to offer policy-makers advice and assistance in developing protocols for care, national guidelines and selecting essential drugs to be made available within each level of care. If involvement in such activities is not spontaneously solicited, service on hospital or clinic committees and/or formal letters of interest and offer to the appropriate persons within the health sector may help foster such opportunities. Contact with embassies can be helpful by facilitating introductions to policy-makers. Often non-governmental organizations also play a substantial role in care delivery and policy development.

Community activist

Even in countries with few neurological experts, organizations affiliated with the International League Against Epilepsy (ILAE) and/or the International Bureau for Epilepsy (IBE) often thrive. The interests of people with epilepsy are also often represented by groups that advocate for the rights and care for people with disabilities. Consulting the ILAE and IBE websites or personnel can help locate support groups.

Researcher

Resources for laboratory-based research are limited in LMICs, but the environment is ideal for implementation and operations research and with some infrastructure development, clinical research (epidemiological as well as clinical trials) is possible. Acquisition of research skills appropriate for use in resource-limited settings requires thoughtful consideration. Standard fellowships and postgraduate training programmes may or may not offer the skills needed. Guidance from groups such as the World Federation of Neurology's Research Committee or the International Brain Research Organization (IBRO) is recommended.

Additional considerations

Paradoxical situations encountered in epilepsy care provision in resource-poor settings include trying to deliver medically advanced services to patients who may be living in very primitive domestic settings (in terms of, for example, housing quality) and who may hold very traditional beliefs regarding their medical condition and health in general. Traditional healers may be their health-care provider of choice [45] and dual, parallel care-seeking practices are common. Historically, traditional healers and physicians have had generally antagonistic relationships, but this is avoidable. Physicians can offer the respect due to traditional healers based upon their social role as 'healers' without endorsing the biomedical efficacy of their treatments.

Acknowledgments

I would like to thank Charles E. Culpeper Medical Scholars Fund, Doris Duke Charitable Foundation ORACTA grant, and grants NIH K23NS046086, R21NS048060 and R01NS061693-01.

30 Introduction to the Choice of Antiepileptic Drugs

Emilio Perucca
University of Pavia, Pavia, Italy

Until second-generation antiepileptic drugs started to be introduced in the early 1990s, the pharmacological management of epilepsy was relatively simple. Only a handful of drugs could be prescribed, and making a choice among them was not a major problem. Today, with about 20 different medications available, selection of an antiepileptic drug is a much more complex process. In fact, the existence of a broad pharmacological armamentarium is a mixed blessing. On one hand, since each drug differs from the others, a wide choice of medications means that physicians have unprecedented opportunities to tailor treatment choices to the characteristics of the individual [1]. On the other hand, familiarizing with the indications, contraindications, specific properties and dosing schedules of 20 different drugs is no easy task, and there are concerns that suboptimal knowledge could result in incorrect prescribing and related harmful consequences. Keeping up to date with rapidly expanding knowledge is a challenge for every practitioner, and easy availability of information in the electronic age does not necessarily imply ready access to high-quality, unbiased documentation.

In the era of evidence-based medicine, drug selection should be best guided by an assessment of the comparative benefits to risks ratios of available treatments, based on results of well-conducted, randomized double-blind trials. Unfortunately, a fully evidence-based approach to the treatment of epilepsy is hampered by the fact that the vast majority of randomized active-control trials in this area have significant methodological shortcomings, including recruitment of populations poorly defined in terms of syndromic diagnosis, insufficient sample size, suboptimal dosing regimens and bias in study design which may have favoured the sponsor's product [2–4]. Additionally, therapeutic outcome in many epilepsy syndromes has never been evaluated in controlled trials. Because of this, drug choice cannot be based solely on results of therapeutic trials, and a broader range of information must be taken into account. In fact, none of the available medications can be recommended as the treatment of choice for all patients, and rational prescribing requires a critical assessment of both the properties of each drug and the characteristics of the patient (Table 30.1). The overall objective is to select the treatment which provides the best match for the characteristics of the individual, and ensures the highest probability of achieving seizure freedom without causing undue adverse effects [5].

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

The purpose of this chapter is to highlight the main factors to be considered in choosing an antiepileptic medication, while the properties of each of the major drugs are discussed in the subsequent chapters. The rational approach to the management of adults and children with newly diagnosed seizure disorders, as well as individuals with chronic active epilepsy and other specific categories of patients, are discussed in Part 2 of this volume.

Spectrum of efficacy in relation to seizure types and epilepsy syndromes

Most randomized trials of antiepileptic drugs have been conducted in patients with partial seizures, and very few controlled studies have assessed the potential efficacy of these medications in generalized seizure types, or in specific epilepsy syndromes [3,6,7]. As a result, information on the spectrum of efficacy of individual drugs in generalized seizures derives mostly from uncontrolled studies and clinical experience, including the opinion of experts [8–10]. Despite these methodological limitations, there is clear evidence that antiepileptic drugs differ markedly in their spectrum of efficacy in various seizure types (Table 30.2).

Based on available data, drugs can be differentiated into so-called broad-spectrum agents, which are effective against partial seizures and several primary generalized seizure types, and agents whose efficacy spectrum is restricted to very few seizure types (Table 30.2) [1,8–10]. The latter include a group of drugs which are mostly useful in the treatment of focal epilepsies, the relatively selective anti-absence drug ethosuximide, and the drugs used primarily to treat infantile spasms, e.g. vigabatrin (which is also efficacious against partial seizures, but which is rarely used in this indication because safer alternatives are available), ACTH and corticosteroids. An additional drug used in a very restricted indication is stiripentol, which received conditional approval from the European Medicines Agency as adjunctive therapy to valproic acid and clobazam in patients with severe myoclonic epilepsy in infancy [11].

Among drugs classified as broad spectrum, valproic acid and benzodiazepines are the only ones for which there is evidence of protective activity against virtually all seizure types, irrespective of syndromic form [12]. However, benzodiazepines are rarely used as first-line agents for chronic treatment, and valproic acid, which is often used preferentially in the management of generalized epilepsies, is regarded as the treatment of choice only when equally effective and safer alternatives are unavailable. For many second-generation drugs which are classified as broad

Table 30.1 Factors to be considered in choosing an antiepileptic drug.

Medication-related characteristics
Spectrum of efficacy against specific seizure types and syndromes
Expected magnitude of therapeutic response in the specific seizure type (syndrome)
Approved indications. Contraindications
Adverse effect profile (including teratogenicity)
Potential for interacting with other medications
Potential impact on co-morbidities
Dose escalation requirements, and ease of use in adjusting dosage
Frequency of administration
Availability of formulations (including parenteral formulations)
Cost and reimbursability
Other (mechanisms of action, monitoring requirements, quality and amount of available information)
Patient-related characteristics
Seizure type and epilepsy syndrome
Other epilepsy-related characteristics (EEG features, aetiology)
Age
Gender (including childbearing potential)
Co-morbidities
Co-medications
Response to previously administered medications (including adverse drug reactions)
Other risk factors for adverse drug reactions (including genotype)
Psychological and social setting, including personal concerns about specific side-effects

Table 30.2 Efficacy spectrum of the main antiepileptic drugs in different seizure types.

Effective or possibly effective against most seizure types	Effective against partial and secondary generalized tonic–clonic seizures	Effective against absence seizures	Effective against infantile spasms
Valproic acid	Carbamazepine[i]	Ethosuximide[l]	Vigabatrin[m]
Phenobarbital[a]	Phenytoin[i]		ACTH[n]
Primidone[a]	Gabapentin[j]		Corticosteroids[n]
Benzodiazepines[b]	Lacosamide[k]		
Lamotrigine[c]	Oxcarbazepine[i]		
Levetiracetam[d]	Pregabalin[j]		
Rufinamide[e]	Tiagabine[i]		
Topiramate[f]			
Zonisamide[g]			
Felbamate[h]			

[a] Phenobarbital and primidone are not effective against absence seizures.

[b] Benzodiazepines occasionally exacerbate tonic seizures, particularly after intravenous use in patients with Lennox–Gastaut syndrome or West syndrome.

[c] Lamotrigine may aggravate severe myoclonic epilepsy of infancy (Dravet's syndrome), and may aggravate myoclonic seizures in other syndromes. The efficacy of lamotrigine is best documented against partial and secondary generalized tonic–clonic seizures, primary generalized tonic–clonic seizures, absence seizures and drop attacks associated with the Lennox–Gastaut syndrome.

[d] Efficacy against tonic and atonic seizures has not been documented. The efficacy of levetiracetam is best documented against partial and secondary generalized tonic–clonic seizures, primary generalized tonic–clonic seizures, and myoclonic seizures.

[e] Efficacy against absence and primary generalized tonic–clonic seizures has not been documented. The efficacy of rufinamide is best documented against partial and secondary generalized tonic–clonic seizures and drop attacks associated with the Lennox–Gastaut syndrome.

[f] Efficacy against absence seizures has not been documented. The efficacy of topiramate is best documented against partial and secondary generalized tonic–clonic seizures, primary generalized tonic–clonic seizures and drop attacks associated with the Lennox–Gastaut syndrome.

[g] Efficacy against most generalized seizures types is poorly documented. The efficacy of zonisamide is best documented against partial and secondary generalized tonic–clonic seizures.

[h] Efficacy against absence, myoclonic and primary generalized tonic–clonic seizures has not been documented. The efficacy of felbamate is best documented against partial and secondary generalized tonic–clonic seizures and drop attacks associated with the Lennox–Gastaut syndrome.

[i] Carbamazepine, phenytoin and oxcarbazepine may also be efficacious against primary generalized tonic–clonic seizures. Carbamazepine, phenytoin, oxcarbazepine and tiagabine may precipitate or aggravate absence and myoclonic seizures.

[j] Gabapentin and pregabalin may precipitate or aggravate myoclonic seizures.

[k] Tentative classification. Lacosamide has not been assessed in patients with primary generalized seizures.

[l] Ethosuximide may also be efficacious against myoclonic seizures and continuous spike–waves during sleep (CSWS).

[m] Vigabatrin is also effective against partial seizures. Vigabatrin may precipitate or aggravate myoclonic seizures.

[n] ACTH and corticosteroids may also be effective in continuous spike–waves during sleep (CSWS), particularly in Landau–Kleffner syndrome.

spectrum, adequate information on potential efficacy in less-common seizure types is not available, and there seem to be specific seizure types or syndromes which are paradoxically aggravated by some of these drugs (Table 30.2) [13,14].

Because available drugs have different spectra of efficacy in relation to seizure type, a correct classification of the seizure type(s) is the most valuable single piece of information in selecting a drug for initial treatment. All efforts should also be made to establish as early as possible a correct syndromic diagnosis. In fact, if the epilepsy syndrome has been identified, drug choice can be made more rationally by taking into account additional seizure types which might occur as part of the natural history of the disorder. For example, awareness that children with childhood absence epilepsy may develop tonic–clonic seizures later in life can be used as an argument for prescribing a medication effective against both these seizure types (e.g. valproate or lamotrigine) instead of ethosuximide, which is efficacious only against absences. The epilepsy classification also provides a useful insight into the probability of a favourable response to treatment, since for any given seizure type responsiveness to treatment may vary depending on the syndromic form; for example, myoclonic jerks associated with juvenile myoclonic epilepsy are much more easily controlled than myoclonic seizures associated with the Lennox–Gastaut syndrome. Equally important, knowledge of the epilepsy syndrome allows the best prediction of the probability of the patient's achieving spontaneous remission. This is of crucial importance in determining whether drug treatment should be given for many years and possibly indefinitely, as is usually the case in juvenile myoclonic epilepsy, or whether discontinuation of therapy is feasible following an adequate interval of freedom from seizures [15].

Correct identification of seizure type and epilepsy syndrome is also very important because some antiepileptic drugs may paradoxically precipitate or aggravate seizures in patients with certain syndromes [13,14]. The most common example is the precipita-

tion of absence seizures and myoclonic jerks by carbamazepine or oxcarbazepine in patients with juvenile myoclonic epilepsy, a syndrome which is often misdiagnosed and, therefore, incorrectly treated. Carbamazepine and oxcarbazepine may precipitate myoclonic and absence (or absence-like) seizures in other types of epilepsies, particularly in patients with bursts of generalized bilateral spike-and-wave discharges in their electroencephalogram (EEG) [13,16]. Tiagabine and vigabatrin may also induce myoclonic and absence seizures, gabapentin and pregabalin may precipitate or worsen myoclonus, barbiturates may aggravate absence seizures, and lamotrigine may aggravate severe myoclonic epilepsy in infancy [13,14]. Even status epilepticus, particularly nonconvulsive status, can be precipitated by antiepileptic drugs, particularly when an agent has been chosen which is inappropriate for a specific epilepsy syndrome [17].

Magnitude of efficacy in specific seizure types

Partial seizures

Randomized comparative long-term monotherapy trials in patients with newly diagnosed partial seizures have been conducted with carbamazepine, phenytoin, valproic acid, phenobarbital, clobazam, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, topiramate and vigabatrin. Most of these trials failed to identify major differences in seizure freedom rates among the drugs being compared [2,3,6,18]. However, suggestive evidence was provided to show that valproic acid may be less efficacious than carbamazepine in reducing the frequency of complex partial seizures [19], and that gabapentin may be less efficacious than carbamazepine or lamotrigine [20,21] and phenobarbital may be less efficacious than carbamazepine and phenytoin [22] in controlling partial seizures. Whenever differences in efficacy were found, however, these were relatively modest in magnitude. It should be understood that achievement of sustained seizure freedom is dependent not only on a drug's ability to control seizures, but also on the patient being able to tolerate the administered treatment. In a few studies where appreciable differences in seizure freedom rates were identified, these were related more to differences in tolerability (e.g. number of patients withdrawing due to adverse effects) than to efficacy per se [20,23–27].

All second-generation antiepileptic drugs were also tested in placebo-controlled adjunctive therapy trials in refractory partial epilepsy, and some differences in responder rates among the various drugs emerge when results of different trials are compared [28]. However, with few exceptions [29], there are no adjunctive therapy studies evaluating active treatments head to head, and results of different trials cannot be easily compared due to specificities of the populations being assessed and differences in dosages, titration rates and study design.

Generalized seizures

Randomized controlled trials in patients with primary generalized seizures are very scarce. This is regrettable because, unlike findings for partial seizures (where no major efficacy differences seem to exist among drugs, at least in newly diagnosed patients), for some generalized epilepsy syndromes appreciable differences in magnitude of therapeutic response seem to exist between the various drugs.

Small groups of patients with primary generalized tonic–clonic seizures have been included in some monotherapy trials designed primarily to assess drug response in patients with newly diagnosed partial seizures [3]. Additionally, placebo-controlled adjunctive therapy trials in patients with refractory primary generalized tonic–clonic seizures have been completed for lamotrigine, levetiracetam and topiramate [3,30]. Overall, the data from these studies suggest that valproic acid, carbamazepine, oxcarbazepine, phenytoin, phenobarbital, lamotrigine, levetiracetam and topiramate are all efficacious in this seizure type, although special caution is required in prescribing carbamazepine, oxcarbazepine and phenytoin in patients with syndromes potentially associated with absence and myoclonic seizures, which may be aggravated by these drugs [3]. Due to inadequate statistical power of monotherapy trials, and lack of an active control in adjunctive therapy studies, no definite conclusions on the comparative efficacy of the various drugs against primary generalized tonic–clonic seizures can be drawn from available data.

Studies in specific epilepsy syndromes are of special interest, but these have been mostly uncontrolled. A retrospective report on 962 patients with idiopathic generalized epilepsies from different clinics in the UK suggested that valproic acid may have superior efficacy to lamotrigine in these patients [31]. A more recent retrospective assessment of 103 adults with idiopathic generalized epilepsies reported similar results: remission rates were higher with valproic acid than with lamotrigine (66% versus 45%), particularly in juvenile myoclonic epilepsy (75% versus 39%) [32]. Although some patients with juvenile myoclonic epilepsy respond well to lamotrigine, there are also occasional reports of lamotrigine aggravating myoclonic seizures [33], and the overall evidence suggests that lamotrigine is not as efficacious as valproic acid in this syndrome. With respect to other generalized syndromes, randomized monotherapy trials have been reported in childhood absence epilepsy, and suggest that valproic acid has comparable efficacy to ethosuximide [12] but possibly greater efficacy than lamotrigine [34]. Finally, valproic acid was found to be the most effective drug in a large randomized open-label monotherapy trial in 716 patients, most of whom had generalized or unclassified epilepsies [27]. In patients with idiopathic generalized epilepsies, valproic acid was more effective than either lamotrigine or topiramate, and overall the data suggested that valproic acid was superior to lamotrigine in efficacy and to topiramate in tolerability. The results of this study, however, are difficult to interpret because outcome for specific epilepsy syndromes was not reported, and because the unblinded design may have biased the assessment [35].

Despite the methodological limitations of the studies conducted to date, the available evidence, including the opinion of experts, suggests that valproic acid has superior efficacy to lamotrigine and, possibly, other drugs in the treatment of some generalized epilepsy syndromes [8–10,27,32,34]. Among the newer drugs, levetiracetam shows particularly promising activity in some generalized epilepsies, including juvenile myoclonic epilepsy [36,37], but data from comparative trials are unavailable. Adequate comparative data in generalized epilepsies are not available for many

other drugs, and these gaps in knowledge should be addressed in future studies.

Adverse effect profiles

The primary goal of antiepileptic drug therapy is complete freedom from seizures without adverse effects. In some cases, particularly when seizures can be controlled with low doses, this goal can be achieved. In other cases, the best compromise should be sought between seizure protection and adverse drug effects. While the importance of seizure freedom in ensuring a good quality of life cannot be underestimated, this should not be pursued at all costs, and patients should never be made to suffer more from the adverse effects of treatment than from the manifestations of the disease [38].

No antiepileptic drug is free from adverse effects, but there are important differences in type and frequency of adverse effects caused by individual medications. Given that many different drugs are usually available to treat a given seizure type (see Table 30.2), the comparative adverse effect profile is a primary consideration in deciding which medication should be used preferentially. Some drugs, for example felbamate and vigabatrin, are associated with such a high probability of serious adverse reactions that these agents are very rarely used as first choice, except for conditions for which safer and effective alternatives are unavailable (e.g. in the case of vigabatrin, West syndrome associated with tuberous sclerosis) [39]. Other drugs have better safety records, but all are liable to produce adverse effects which interfere with quality of life [40].

The relevance of a specific adverse effect varies across patients. For example, teratogenic potential is not a relevant consideration when prescribing a drug to a man, and the risk of causing anorexia will have different implications in an underweight person compared with an obese patient, for whom this effect may even be desirable. Because of these considerations, physicians must be aware of the full range of side-effects caused by each of the drugs, together with relative frequencies and associated risk factors, and choose the medication which is least likely to impact adversely on the individual. A discussion on how specific patients' characteristics affect the risk–benefit assessment is provided later in this chapter.

Drug interaction potential

When multiple drugs are prescribed simultaneously, clinically significant adverse drug interactions may occur (Chapter 28). There are obvious advantages in using medications with little or no capability of causing or being a target for adverse drug interactions.

In specific contexts, such as the management of individuals with co-morbidities requiring concomitant drug treatment, the drug interaction potential is a particularly important consideration in choosing an antiepileptic drug. In a person with epilepsy caused by a brain tumour, for example, it is highly desirable to use preferentially an antiepileptic drug devoid of enzyme-inducing or -inhibiting properties, in order to avoid potentially fatal interactions with antineoplastic chemotherapy [41]. Similar considerations apply to HIV-infected patients, in whom the effects of antiretroviral therapy may be negated by interactions caused by enzyme-inducing drugs [42]. Elderly patients are particularly prone to suffer from co-morbidities requiring multiple drug therapy, and enzyme-inducing antiepileptic drugs may be particularly problematic in this population due to the risk of interactions with co-medications such as antianginal and antihypertensive drugs, warfarin and statins [43]. Risks also arise from interactions in which drugs used for other conditions modify the response to antiepileptic therapy.

Another context in which the interaction potential should be considered is in using combinations of antiepileptic drugs. When treatment with an antiepileptic drug combination is indicated, it makes sense to co-prescribe preferentially drugs which are least likely to result in adverse interactions. However, there are also examples of drug combinations which are apparently beneficial, and therefore may be used advantageously. These issues are discussed in detail in Chapters 9 and 28.

The interaction potential of an antiepileptic drug is of relevance also when prescribing to patients not currently taking other medications. Because antiepileptic drugs are often taken for many years, sometimes for a lifetime, it is likely that in the future many patients will need to take other medications, for example a hormonal contraceptive, a chemotherapeutic agent or a cardiovascular drug. The efficacy and safety of such medications may be complicated by pre-existing therapy with an antiepileptic drug characterized by high interaction potential.

Impact on co-morbidities

The potential interactions between antiepileptic drugs and co-morbidities are complex. Some antiepileptic drugs have a precipitating or aggravating effect on specific co-morbidities, which may represent an absolute or relative contraindication to their use in affected patients. However, there are also co-morbid conditions which are influenced beneficially by specific antiepileptic drugs. Examples of co-morbidities influencing drug selection are given below in this chapter in the section discussing the importance of patient-related factors.

Other medication-related factors

Mechanisms of action

It may sound heretical to state that knowledge of mechanisms of drug action has little relevance for selecting a drug in the clinic, but this is the way antiepileptic drugs are mostly prescribed at present. In fact, our understanding of the pathophysiology of the epilepsies and of the modes of action of individual drugs is still too fragmentary to allow mechanism-driven rational drug selection. Although primary modes of actions have been described for most antiepileptic drugs, additional mechanisms have not been identified and their relative contribution to clinical effects in an individual patient is poorly understood. To give one example, lamotrigine is often referred to as a selective blocker of voltage-dependent sodium channels, but it has also been found

to inhibit N-type, L-type and P-type calcium channels, to increase brain γ-aminobutyric acid (GABA) levels, to increase potassium conductance, to stimulate taurine-mediated neurotransmission and to act as an antagonist or negative modulator at the 5-hydroxytryptamine 1A ($5HT_{1A}$) receptor [44]. How each of these actions could account for therapeutic and adverse effects is unclear.

While these limitations should be understood, there are situations in which knowledge of modes of action need to be considered in choosing a medication. In a patient who has shown a paradoxical aggravation of seizures on carbamazepine, for example, it would be sensible to avoid, if possible, medications such as oxcarbazepine and phenytoin, which have modes of actions similar to carbamazepine. Likewise, in patients with refractory seizures who require multiple drug therapy, the suggestion has been made that combinations of drugs possessing different modes of action should produce better responses than combinations of drugs acting through a similar mechanism, even though clinical evidence in support of this hypothesis is limited and not always consistent [45].

In time, research on the relationship between specific modes of action and clinical response in well-defined epilepsy syndromes could yield important clues for rational treatment; for example, it might be possible in the future to determine which drug produces the best response in a patient whose epilepsy is caused by a specific channelopathy, a mutation in an excitatory amino acid receptor, or an impairment in central GABAergic transmission. In fact, evidence is starting to emerge that, in certain conditions, knowledge of modes of drug action can aid in predicting responses to treatment. For example, a drug-induced selective increase in GABA concentration in the synaptic space, as produced by agents such as tiagabine and vigabatrin, seems to predict efficacy against partial seizures but also, potentially, aggravation of absence and myoclonic seizures [13].

Availability of appropriate formulations

When an immediate effect is required, such as in the management of status epilepticus or acute repetitive seizures, treatment choices are restricted to medications which have a fast onset of action, can be safely loaded in an emergency setting, and are available in a rapidly absorbed formulation. Formulations suitable for intravenous use are advantageous in most cases, but alternative formulations which ensure rapid absorption by other routes, such as the buccal, rectal or intranasal route, may be appropriate in selected situations [46].

Patients stabilized on oral treatment may be temporarily unable to take their regular medicines, for example after abdominal surgery or during an illness causing repeated vomiting. Parenteral formulations which can be used to provide therapeutic cover in these situations are not available for all drugs, and in some cases availability of a parenteral formulation should be taken into account in deciding which drug should be preferentially prescribed.

In some patients, particularly children less than 5 years of age, intake of tablets and capsules may be problematic, and other dosage forms such as solutions, suspensions, powders or granules provide useful alternatives [47]. Some liquid formulations are associated with rapid gastrointestinal absorption which, in turn, may lead to prominent fluctuations in plasma drug concentrations and increased risk of adverse effects at the time of peak, or seizure breakthrough at the time of trough. Some paediatric formulations, additionally, contain tooth-damaging ingredients such as sucrose, or have an unsatisfactory palatability, which may adversely affect compliance. Indeed, optimal paediatric formulations are not available for many antiepileptic drugs, a situation which restricts treatment choices in the younger age groups.

For certain drugs, modified-release products are available, which allow less frequent dosing, with beneficial effects on convenience and compliance. Some of these formulations also improve efficacy and tolerability by minimizing fluctuations in plasma drug levels during the dosing interval [48].

Dose escalation requirements

As discussed in Chapter 9, drugs such as phenytoin, levetiracetam, gabapentin and pregabalin can be up-titrated relatively rapidly to the fully efficacious dose range, while others, particularly primidone, lamotrigine, topiramate, zonisamide and tiagabine, require a slow dose escalation to minimize the risk of adverse effects. Whenever a rapid onset of action is required (for example, in patients with frequent seizures, or in those who developed an idiosyncratic reaction on their previous therapy and need to be switched rapidly to an alternative agent), a medication which can be up-titrated rapidly has obvious advantages [47].

There are also advantages in preferring drugs for which dose individualization is comparatively easy. Adjusting the dose of phenytoin, in particular, can be difficult due to Michaelis–Menten pharmacokinetics and large inter-patient variability in dose requirements.

Monitoring requirements

Some drugs require special monitoring procedures to ensure optimal efficacy and to minimize the risk of adverse effects. For example, individualizing phenytoin dosage can be difficult without measuring its plasma concentration [49], which may argue against the preferential use of this drug in settings where a therapeutic drug monitoring service is unavailable. Likewise, therapy with felbamate requires repeated blood chemistry and haematology tests, and this drug should not be prescribed if compliance with safety monitoring tests cannot be guaranteed.

Cost of treatment

Over 40% of the world's population live in a country where the per capita annual gross national product barely suffices to buy a year's supply of carbamazepine or valproic acid for one or two patients. Therefore, it is no surprise that, in many settings, cost is a major consideration not only in deciding which drug to use, but also in determining whether drug treatment is affordable at all. This problem is aggravated by the fact that in many developing countries the price of antiepileptic drugs is considerably higher than in the industrialized world. For most patients in developing countries, only phenobarbital is available at prices affordable by the general population, and many of the newer drugs may not be available at all [50].

Cost is an important issue also for affluent societies, particularly in view of the fact that recently licensed drugs are far more expensive than older agents. In some countries, reimbursement of

Table 30.3 Ideal properties for an easy-to-use antiepileptic drug.

Broad spectrum of activity against all seizure types
High efficacy
Good tolerability
No risk of allergic or idiosyncratic reactions (including teratogenicity)
Low interaction potential
Low variability in dosage requirements
Favourable pharmacokinetics (linear kinetics, half-life compatible with once- or twice-daily dosing)
Fast and easy dose escalation rate
No tolerance to antiepileptic effects
No withdrawal seizures
No need for intensive laboratory monitoring
Availability of convenient formulations (including convenient paediatric dosage forms and a parenteral formulation)
Low cost

medication costs by health services or insurance schemes is only applicable to specific drugs (or formulations), specific indications or patients within predefined income limits. The cost of many antiepileptic medications has decreased in recent years due to the introduction of generic products. Advantages and concerns with the use of these products are discussed in Chapter 9.

Ease of use

Not all antiepileptic drugs are equally easy to use, a consideration which impacts on drug selection. Ease of use encompasses many properties discussed above in this chapter: in particular, a broad efficacy spectrum against many seizure types, a good safety and tolerability profile, a low interaction potential, feasibility of once- or twice-daily dosing, availability of convenient formulations, and rapid and simple schemes for dose titration and individualization all contribute positively to ease of use (Table 30.3).

Old or new drugs?

When the cost of medication is not a major constraint, drug selection should be based primarily on the expected benefit to risk balance in the individual patient. When this is taken into account, the increasing use of newer drugs in the last decade may be justified by the improved tolerability profile and the lower interaction potential which characterize some of these agents. However, evidence concerning merits and demerits of individual medications should be evaluated critically. In some randomized trials which compared newer and older generation drugs, results may have been biased by specificities in the study design which discriminated against the older drug [51]. For example, when carbamazepine was used as comparator, its target dosage was sometimes higher than necessary, and an immediate-release formulation was almost invariably used despite evidence that sustained-release preparations are associated with superior tolerability [52]. When assessing risks associated with specific medications, it should also be remembered that the latency between the introduction of a drug in the market and the discovery of potentially important adverse effects can be long. It took 10 years since marketing to identify the hepatic toxicity of valproic acid, and 8 years to discover vigabatrin-induced visual field loss [39].

Approved versus off-label use

As a general rule, medications should be used according to indications approved by regulatory authorities. The approval of a specific indication is dependent on submission of adequate efficacy and safety data to regulatory agencies. Given the heterogeneity of seizure disorders, however, certain seizure types or syndromes are rarely investigated in regulatory trials. As a result, many antiepileptic drugs are not formally approved for some indications or for specific age groups, despite evidence of clinical usefulness in the same conditions from non-regulatory studies or clinical experience. The situation is further complicated by the fact that regulatory standards for approval have changed over the years, resulting in discrepancies in the quality of supportive evidence between older and newer generation drugs. Approved indications also vary from country to country; for example, many drugs which have monotherapy approval in Europe are not approved for monotherapy use in the USA [4]. Other concerns relate to the appropriateness of dose titration schemes and dosing schedules approved by regulatory authorities. These reproduce dosing procedures in regulatory trials and do not necessarily reflect optimal dosing schemes, which are mostly established during post-marketing experience [47].

In view of the above considerations, off-label prescribing is justifiable in selected situations, and in many countries there is a legal framework for this. In the USA, for example, the statutory authority of the Food and Drug Administration is focused on pre-marketing testing, and safe and effective prescribing is left to the physician's responsibility [53]. Off-label prescribing is widespread: in a recent survey of office-based physicians in the USA, 46% of all prescriptions of anticonvulsants were found to be off label (including, presumably, also indications outside epilepsy) and, remarkably, 83% of these were backed by either little or no published scientific evidence [54]. Off-label use is especially prevalent in uncommon epilepsy syndromes, particularly in infants and young children, for which few or no drugs are formally approved. Physicians prescribing off label, however, should be aware of legal liability issues, and must ensure that their decisions are backed by the best medical evidence available. In some countries, the cost of drugs prescribed off label is not reimbursed by the national health system or insurance organizations, a situation which can impact on drug selection.

The importance of patient-related factors

Since rational prescribing requires finding the best match between the properties of a drug and the characteristics of the patient, careful assessment of individual features plays a crucial role in drug selection. Some of these features relate to demographics, others to psychosocial aspects, and others to the characteristics of epilepsy, associated conditions and co-medications. In considering the importance of these factors, the patient's informed opinion should be taken into consideration.

Seizure types and epilepsy syndrome

As discussed earlier in this chapter, antiepileptic drugs differ in their spectrum of efficacy against different seizure types. There-

fore, correct identification of seizure type(s) and, whenever possible, epilepsy syndrome is very important for drug selection. Whenever a diagnosis of epilepsy is established but the precise type of seizures or syndrome is uncertain, the probability of achieving seizure control is enhanced by prescribing a drug with a broad efficacy spectrum.

Aetiology of epilepsy

Defining the aetiology of epilepsy is important to identify conditions which may require specific treatments, e.g. surgery for a brain tumour. Information on aetiology is also important to establish the epilepsy syndrome, and to formulate a prognosis. In a hospital-based observational survey of 2200 patients, 1-year remission rates on drug therapy were 82% in patients with idiopathic generalized epilepsy, 45% in those with cryptogenic partial epilepsy, 35% in those with symptomatic partial epilepsy, and only 11% in those with partial epilepsy associated with hippocampal sclerosis [55]. Patients with hippocampal sclerosis and another lesion had only 3% probability of achieving seizure freedom. In the same study, patients with temporal lobe epilepsy responded more poorly to treatment than patients with extratemporal foci. Information on aetiology is also important for early identification of candidates to epilepsy surgery.

In most epilepsy syndromes, information about aetiology is of little value in predicting which specific drug will produce the best clinical response. However, this may change in the future as our understanding of the pathophysiology of the epilepsies and mechanisms of drug action will progressively improve. One important example of how aetiological information can be relevant for drug selection is provided by evidence that symptomatic infantile spasms secondary to tuberous sclerosis respond better to vigabatrin than to hydrocortisone [56], whereas cryptogenic spasms or symptomatic spasms secondary to other aetiologies seem to respond better to ACTH or steroids than to vigabatrin [57,58]. The superiority of ACTH or steroids in controlling spasms not associated with tuberous sclerosis, however, may be limited to the initial weeks of treatment, even though there is evidence that better initial control of spasms by hormone treatment in infants without identified underlying aetiology may be associated with improved developmental outcome [59].

Evidence for a preferential response to a specific drug in relation to epilepsy aetiology in other syndromes is unsubstantial, although there are anecdotal reports of potentially useful associations. For example, in preliminary studies, seizures associated with glial tumours have been found to respond relatively well to tiagabine [60].

Electroencephalographic features

Like aetiological factors, EEG features are important for differential diagnosis and for prognosis, and therefore they have an indirect influence on the process leading to drug selection. Whether the EEG features may predict differential responses to specific antiepileptic drugs in a given epilepsy syndrome has been little investigated, but some evidence suggests that this may well be the case. Patients with a history of generalized spike-and-wave paroxysms in the EEG, for example, may be at special risk of developing absence seizures and even non-convulsive status when treated with carbamazepine [13].

Genotypes

Variation in genes controlling drug-metabolizing enzymes and/or the expression of voltage-gated sodium channels has been reported to influence dosing requirements for phenytoin and carbamazepine [61]. At present, however, no genetic test is available that could be used to predict which drug will prove the most efficacious in an individual patient. With expanding pharmacogenomic knowledge, this situation may well change in the future.

The mechanisms responsible for many adverse drug reactions are also under genetic modulation, and genetic testing is already being used to identify subjects at risk [61,62]. For antiepileptic drugs, the most notable example is the determination of the human leucocyte antigen (HLA) allele B*1502 to predict the risk of serious skin reactions (Stevens–Johnson syndrome and toxic epidermal necrolysis) in patients with ancestry from many areas of Asia, including South Asian Indians [63–65]. The absolute risk of serious skin reactions to carbamazepine is estimated at about 5–8% in HLA-B*1502 carriers, and carbamazepine should not be prescribed to subjects with this genotype unless the expected benefits clearly outweigh the risk. In the same subjects, it is advisable to also avoid other drugs potentially associated with serious skin reactions (particularly phenytoin, for which the risk of serious cutaneous reactions also appears to be linked to the HLA-B*1502 allele), provided that alternative therapies are equally acceptable. Based on these data, the Food and Drug Administration has made testing for HLA-B*1502 mandatory before prescribing carbamazepine to patients from Asian origin [61]. HLA genotyping is of little value in identifying sbjects at risk for carbamazepine-induced serious skin reactions in whites, probably due to the low frequency of the HLA-B*1502 allele in this ethnic group [66].

Age and gender

The toxicity of many antiepileptic drugs is age dependent [62,67]. For example, the incidence of valproic acid-induced liver toxicity in children below 2 years of age who are also receiving concomitant enzyme-inducing anticonvulsants is in the range of 1:600 to 1:800, compared with less than 1:20 000 in adults [12,39]. The incidence of lamotrigine-induced serious skin rashes, including Stevens–Johnson syndrome, has also been found to be greater in children than in adults (about 1:100 versus 1:1000, respectively) [63], even though the magnitude of the risk in children may have been overestimated in early studies due to use of higher initial doses and faster titration rates than currently recommended [68]. While benzodiazepines and barbiturates may affect adversely cognitive function in any age group, children are more likely to develop hyperactivity and other behavioural disturbances, and overall they tolerate these drugs poorly compared with adults [40]. Phenytoin is known to cause acne, hirsutism, gum hyperplasia and coarsening of facial features, particularly when taken during childhood, and it is preferably avoided in children and young females when appropriate alternative treatments are available. At the other extreme of age, the elderly also show an increased sensitivity to the adverse effects of many drugs. In particular, there is evidence that carbamazepine may be tolerated

relatively poorly by elderly patients [69,70], even though tolerability problems seem to be considerably reduced when the sustained-release formulation is used [52]. Lamotrigine seems to be fairly well tolerated in the elderly [52,69,70], and therefore it represents a valuable choice in these patients. The elderly are also prone to receive other drugs for the treatment of unrelated conditions, and in order to prevent potentially hazardous interactions it is generally preferable in this population to avoid enzyme-inducing drugs such as phenytoin, carbamazepine and barbiturates [71]. Drug choices in different age groups are discussed in Chapters 13, 14 and 16.

Gender also impacts on drug selection. Some antiepileptic drugs influence endocrine and sexual functions in a gender-specific manner, and therefore they have different tolerability profiles in males and females. There is increasing recognition that some antiepileptic drugs adversely affect sexual function in men [72]. The range of gender-related effects, however, is broader in females. Adverse effects of special relevance to women, such as osteoporosis or hirsutism, and potential interactions with hormonal contraceptives [43] need to be considered when selecting an antiepileptic drug for a female patient. Other major issues relate to the effects of pregnancy on drug disposition and the adverse effects of drugs on fetal development [73]. Criteria for drug selection in women of childbearing potential are discussed in Chapter 25. It should be noted that gender-related drug effects may extend beyond the endocrine and the reproductive system. For example, the frequency of skin rashes induced by a variety of antiepileptic drugs has been found to be twice as high in women as in men [74].

Co-morbidities and co-medications

Co-morbidities are a major consideration in drug selection. Some disorders may predispose to adverse reactions to specific drugs, and may even contraindicate the use of these medications in affected patients. For example, the risk of valproic acid-induced liver toxicity is greatly increased in patients with some inborn metabolic disorders, such as urea cycle defects, and valproic acid should not be used in these patients [62]. Some drugs have the potential for aggravating co-morbidity; for example, acute intermittent porphyria can be aggravated by most antiepileptic drugs, but there are agents, in particular gabapentin and levetiracetam, which can be safely prescribed in these patients [75]. Drugs which are extensively cleared by hepatic metabolism, and drugs which are potentially hepatotoxic, should be preferably avoided in patients with liver disease. Many other co-morbid conditions may be aggravated by specific antiepileptic drugs, or they may themselves predispose to adverse drug reactions [62,75]. Interactions between co-morbidity and antiseizure medications can be particularly complex in patients with learning disabilities and in those with a history of behavioural or mood disorders, and choice of treatment in these patients must be individualized carefully (Chapters 17 and 21).

Some antiepileptic drugs influence favourably specific co-morbidities [76], an observation which can be usefully exploited. For example, carbamazepine can be a rational choice for patients with focal epilepsy and trigeminal neuralgia, gabapentin or pregabalin should be considered for patients with co-morbid neuropathic pain, and valproic acid or topiramate for patients with co-morbid migraine. Other examples of medications efficacious in co-morbidities include valproic acid and carbamazepine for bipolar disorder, pregabalin for generalized anxiety disorder, lamotrigine for bipolar depression, and primidone or topiramate for essential tremor [76,77].

Co-morbidities often require treatment with additional medications. In co-morbid conditions which require (or are likely to require in the future) use of narrow therapeutic index drugs such as antineoplastic agents, anticoagulants, immunosuppressants and many anti-infectious and cardiovascular drugs, there are strong reasons for prescribing preferentially antiepileptic drugs which are unlikely to be involved in drug–drug interactions [43].

Other patient-related factors

A history of adverse reactions to previous medications is an important factor to be considered in drug selection. For example, the risk of a skin rash after starting an antiepileptic medication is five times greater among patients with a history of a rash on another antiepileptic drug than in those without [78]. Cross-reactivity for immune-mediated adverse drug reactions is particularly common with compounds sharing a similar structure: in a retrospective study of cross-reactivity among aromatic anticonvulsants, 10 of 17 patients who had a rash from phenytoin also had a rash from carbamazepine, and 10 of 25 patients who had a rash from carbamazepine also had a rash from phenytoin [79]. In these patients, it is preferable to use drugs which are structurally unrelated and have a low potential for causing serious skin rashes, such as valproic acid, levetiracetam, gabapentin and benzodiazepines.

Other factors to be considered include the patient's profession, and his or her attitude towards the risk of seizure recurrence or towards adverse effects known to be associated with specific treatments. Prescription of a medication known to cause subtle cognitive effects, for example, may have a different impact in a young student compared with a middle-aged rural worker. Drugs requiring complex dosing schemes should especially be avoided in individuals who are expected to have difficulties with compliance.

Conclusions

Each of the existing antiepileptic drugs differs fully or partially from others in clinically relevant properties such as spectrum of efficacy, contraindications, adverse effect profile, pharmacokinetic characteristics, dose optimization requirements, range of available formulations, drug–drug interaction potential and impact on co-morbid conditions. Rational drug selection should take into account each of these factors, and assess how the specificities of each medication are expected to match with the characteristics of each individual. This assessment requires not only knowledge of the properties of the various drugs, but also careful ascertaining of medical history, clinical symptoms and signs, and the patient's emotions and opinions. Personalization of treatment should not be restricted to the choice of an antiepileptic drug, but should extend to individualization of dosage, close follow-up and monitoring of clinical response, and the provision of other

measures, including psychological support, which are necessary to address each person's unique needs.

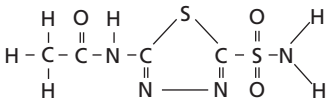
31 Acetazolamide

Miri Y. Neufeld
Tel-Aviv Sourasky Medical Center, Tel-Aviv, Israel



Primary indication	Adjunctive therapy of partial or generalized seizures (including absence) and myoclonus. Also Lennox–Gastaut syndrome. Intermittent therapy in catamenial epilepsy
Usual preparation	Tablets: 250 mg
Usual dosage	250–750 mg/day
Dosing frequency	2–3 times daily
Significant drug interactions	Salicylate and digitalis can increase acetazolamide levels. Acetazolamide can reduce primidone and carbamazepine levels
Serum level monitoring	Not routinely done
Reference range	Not applicable
Common/important adverse effects	Nausea, vomiting, diarrhoea, loss of appetite, weight loss, dysgeusia, paraesthesiae, headache, dizziness, flushing, drowsiness, fatigue, irritability, hyperventilation, depression, thirst, loss of libido, metabolic acidosis and electrolyte changes. Risk of renal calculi. Rarely, severe haematological, dermatological or systemic idiosyncratic reactions
Main advantages	Useful adjunctive therapy and also as intermittent therapy, usually well tolerated
Main disadvantages	Risk of idiosyncratic reactions. High incidence of tolerance
Mechanism of action	Carbonic anhydrase inhibition
Oral bioavailability	>90%
Time to peak levels	1–3 h
Metabolism and excretion	No metabolism. Eliminated by the kidney (20% by glomerular filtration and 80% by renal tubular excretion)
Volume of distribution	0.2 L/kg
Elimination half-life	10–15 h
Plasma clearance	–
Protein binding	90–95%
Active metabolites	None
Comment	Useful broad-spectrum drug for adjunctive therapy of resistant epilepsy. Use limited by tolerance and risk of idiosyncratic reactions

Introduction

Acetazolamide (Diamox) is a sulphonamide derivative which shares with other structurally related agents the ability to inhibit carbonic anhydrase, an effect that is considered to mediate its antiepileptic activity [1]. Carbonic anhydrase is a widely distributed enzyme with many different physiological functions [2,3]. Cohen and Cobb [4] were the first to identify antiepileptic activity in this chemical class. They found that azosulphamide, a vital dye, has an anticonvulsant action in experimental animals as well as in humans. They speculated that the effect produced by this drug resulted from inhibition of carbonic anhydrase,

Periodic paralysis
Prevention of mountain sickness

causing acid–base changes that are manifested by metabolic acidosis.

Acetazolamide was first synthesized by Roblin and Clapp [5]. The acidifying effect of acetazolamide led Bergstrom *et al*. [6] to use it for the treatment of epilepsy, although it was later shown [2,7,8] that its anticonvulsant effect is independent of systemic metabolic acidosis and correlates directly with the degree of inhibition of carbonic anhydrase in the brain. Because carbonic anhydrase is found in many tissues other than brain and because it serves numerous functions, inhibition of carbonic anhydrase by acetazolamide is associated with diverse uses (Table 31.1). Acetazolamide inhibits the secretion of aqueous humour by the ciliary process of the eye and decreases intraocular pressure, an effect that is exploited in the treatment of glaucoma [9]. Acetazolamide has been found effective in promoting diuresis [10], and in reducing cerebrospinal fluid (CSF) pressure, for instance in pseudotumour cerebri [11]. It has also been reported to be useful in the management of paroxysmal periodic ataxia [12], paroxysmal dystonia described with central demyelinating disease [13], valproate-induced tremor [14], hypokalaemic and hyperkalaemic periodic paralysis [15] and myotonia [16]. It is also used for the prevention or amelioration of symptoms associated with acute mountain sickness [17] (Table 31.1).

The efficacy of acetazolamide in patients with epilepsy was reported mainly in the 1950s [8,18–30] and only occasional studies were performed several decades later [31–35]. However, because no adequately controlled clinical trials have been conducted, the efficacy of this drug in different seizure types and syndromes, and specifications for appropriate management, are neither well established nor well documented.

Chemistry

Acetazolamide corresponds to 2-acetylamido-1,3,4-thiadiazole–5 sulphonamide. It is a white-yellowish crystalline powder, poorly soluble in water and readily soluble in alkaline solutions. Its molecular weight is 222 and its pK_a is 7.4.

Mechanism of action and activity in animal models

The anticonvulsant effect of acetazolamide is mediated by inhibition of carbonic anhydrase [7,8], which catalyses the formation of H_2CO_3 in the equilibrium reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$. The secondary reaction $H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$ is instantaneous, causing spontaneous dissociation of the carbonic acid. Carbonic anhydrase is present in high concentration in erythrocytes, gastric mucosa, the renal cortex, and in the lens and retina [2,3]. It is located in the brain in the cytoplasm and the membrane of glial cells and in the choroid plexus [36–38], as well as in myelin derived from oligodendrocytes [38,39]. Oligodendrocytes have higher carbonic anhydrase activity than astrocytes [39]. Carbonic anhydrase in the brain has an important role in the neurone–glia metabolic relationship. It is involved in regulating ionic balance throughout the brain [40]. Specifically, it catalyses the hydration of CO_2 that is generated during neuronal activity. The products of this reaction are hydrogen and bicarbonate ions that are exchanged across the glial membrane for sodium and chloride, respectively [41]. Carbonic anhydrase is involved in the maintenance of Cl^- and K^+ concentrations in glial cells [42].

Mann and Keilin [1] were the first to discover that sulphanilamide had a specific and powerful inhibiting effect on the activity of carbonic anhydrase. A study of other sulphonamides revealed that acetazolamide was several hundred times more potent than sulphanilamide as an inhibitor of carbonic anhydrase [5].

Acetazolamide shows wide-spectrum anticonvulsant activity in several animal models. It exerts a depressant action in the spinal cord, which is highly selective for the monosynaptic pathway [43]. Acetazolamide abolishes the tonic extensor component of maximal electroshock convulsions [7,43,44], thereby raising seizure threshold [44]. It also protects against seizures caused by pentylenetetrazol [43] or CO_2 withdrawal [45], as well as against audiogenic seizures [46]. The anticonvulsant activity of acetazolamide was originally thought to be a result of its acidifying effects, caused by inhibition of renal carbonic anhydrase – apparently resembling the effects of the ketogenic diet. However, by using the maximal electroshock seizure model in mice, Millichap *et al*. [7] demonstrated that acetazolamide has an anticonvulsant effect which is independent of its action on the kidney and which correlates directly with the degree of inhibition of carbonic anhydrase in the brain. Other investigators [8,47] confirmed that the anticonvulsant action of carbonic anhydrase inhibitors is correlated with inhibition of brain carbonic anhydrase and independent of inhibition of the erythrocyte enzyme or diuresis. In the brain, inhibition of glial carbonic anhydrase reduces the conversion of neuronally derived CO_2 to HCO_3, whereupon neuronal CO_2 accumulates and glial pH is lowered [7,8,47,48]. The anticonvulsant action of carbonic anhydrase inhibitors at neuronal level may be related to the demonstrated effects of CO_2 on nerve sensitivity and propagation of nerve impulses [2,49]. Both CO_2 and acetazolamide increase the electroshock seizure threshold and abolish the tonic extensor phase of seizures induced by maximal electroshock [43,49]. In addition, the effects of acetazolamide on maximal electroshock seizures and on spinal cord synaptic transmission are potentiated by CO_2 [46]. The similarities between the anticonvulsant effects of CO_2 and acetazolamide suggest that the influence of carbonic anhydrase on seizure activity is mediated through the CO_2 buffering system [48,49]. Following administration of acetazolamide and inhibition of carbonic anhydrase, analysis of both glial cells and myelin shows elevation of CO_2 in the extracellular space surrounding the neuronal cells and the axons where it could inhibit spread of neuronal activity or stabilize the axonal membrane [49]. Similar to CO_2, acetazolamide also increases γ-aminobutyric acid (GABA) levels in the brain [43], which may account for some of its anticonvulsant effects.

Pharmacokinetics

Absorption

Since acetazolamide is a weak acid, its absorption is affected by factors such as pH and lipid and water solubility [50]. After oral doses of 5–10 mg/kg daily, acetazolamide is completely absorbed from the gastrointestinal tract [51,52], whereas higher doses may be incompletely absorbed [52]. At commonly used doses, oral bioavailability is above 90%. Absorption begins in the stomach but occurs mainly in the duodenum and upper jejunum where the surface area is larger. Peak plasma concentrations of around 10–18 μg/mL were reached 1–3 h after oral ingestion of a single 250-mg dose, while the peak erythrocyte concentration was reached 1 h later and was in the order of 13–19 μg/mL [53]. Following administration of single oral 500-mg doses as a sustained-release (SR) formulation, peak plasma concentrations were obtained 3.5 h after dosing and a level of about 10 μg/mL was maintained for 10 h [54]. Oral administration of an SR form causes less fluctuation in drug plasma concentrations [55].

Distribution

Acetazolamide is extensively bound to plasma proteins (fraction bound 90–95%), and this binding is concentration dependent and reduced in the elderly [51,56]. The free (unbound) fraction increases with increasing plasma concentration. Half of the free concentration is in unionized form, and it is this component that penetrates into tissues and causes inhibition of carbonic anhydrase [50]. When binding to tissue carbonic anhydrase, acetazolamide forms an enzyme–inhibitor (EI) complex and, after 24 h, almost all of the drug is present in the various tissues in this form, most of it being found in the erythrocytes, kidney and stomach.

The plasma half-life of acetazolamide has two components. The fast component represents the distribution of the unbound diffusible drug throughout the body and is rather short (about 2 h) [53]. The EI complex has a slow dissociation constant and the drug is released slowly from tissues and is then excreted unchanged in the urine. The elimination phase is characterized by a half-life of around 10–15 h [50].

The volume of distribution of acetazolamide in humans based on total plasma concentration is 0.2 L/kg, and it is 1.8 L/kg when calculated from the free level in the plasma [50]. Following distribution, the free concentration of acetazolamide in tissues is higher than in plasma, and highest in erythrocytes. Acetazolamide penetrates slowly into the brain, where its concentration is lower than in plasma, but higher than in CSF. The concentration of acetazolamide in CSF increases more than the free concentration in plasma at high doses of the drug. This effect suggests that acetazolamide is actively transported out of the CSF and that saturation of the transport system at high concentrations results in increased drug levels in the CSF [50].

Elimination

As discussed above, the elimination half-life of acetazolamide is 10–15 h. The drug does not undergo metabolic transformation and it is excreted unchanged in urine, 20% by glomerular filtration and 80% by renal tubular excretion [2,51,52]. Renal elimination is restricted to the unbound fraction in plasma [56]. Most of a single oral dose is recovered in the urine in 24 h [52]. Elderly patients have a higher unbound fraction and a reduced clearance of unbound drug.

Drug interactions

Acetazolamide is not metabolized and therefore induction or inhibition of drug-metabolizing enzymes has no influence on plasma acetazolamide levels.

Because acetazolamide reduces the production and flow rate of CSF, it may theoretically increase the concentration of other centrally acting drugs. On the other hand, drugs that inhibit CSF production, such as digitalis, may increase the concentration of acetazolamide in the CSF and brain [50]. By alkalinizing urine, acetazolamide would be expected to increase the renal clearance of acidic drugs and to reduce the renal clearance of basic drugs.

Salicylate appears to competitively inhibit the plasma protein binding of acetazolamide and to simultaneously inhibit its secretion by renal tubules [57]. Increased free drug concentration may have been responsible for symptoms of toxicity in two elderly patients with glaucoma who were treated with aspirin and acetazolamide and developed symptoms of lethargy and confusion with metabolic acidosis [57]. In another study in three patients, acetazolamide was reported to interfere with primidone absorption, causing decreased levels of primidone in the plasma and urine [58]. Acetazolamide has been reported to increase the serum concentration of carbamazepine in children when given concomitantly [31]. The mechanism of this interaction remains obscure.

Serum level monitoring

No adequate data on the usefulness of serum drug level monitoring are available.

Efficacy

General overview of results of clinical trials

In 1952, Bergstrom *et al*. [6] were the first to use acetazolamide in the treatment of epilepsy. Given that the drug reduces acid excretion by the kidney, causing metabolic acidosis, the authors speculated that it might be similarly effective in patients with epilepsy as the use of a ketogenic diet. They administered acetazolamide 10–30 mg/kg daily as adjunctive therapy to 42 patients with intractable epilepsy (neither their ages nor type of seizures were mentioned). A decrease in seizure frequency by 50–100% was achieved in 8 of the 42 (20%) patients, and the condition did not worsen in any of the patients.

In subsequent studies, selection of patients, definition of seizure type, treatment procedures and follow-up periods have varied widely and results are therefore difficult to compare [6,18–35,50,59,60] (Table 31.2).

Most studies reported acetazolamide to be effective against refractory generalized and partial seizures. However, these reports were compiled prior to the adoption of the International Classification of Seizures and Epilepsies, and only a few studies classified seizures according to the present classification. Golla and

Hodge [23] reported on the efficacy of acetazolamide in patients with petit mal only. Oles *et al*. [32] referred to patients with partial epilepsy, and Resor and Resor [33] treated patients with juvenile myoclonic epilepsy. Many studies were relatively short term and followed the patients for several weeks [24,25] or months [22,23,26,28]. Only a few long-term studies have been conducted [18,21,29,30,35].

All the trials of acetazolamide in epilepsy except one [20] have been open label, non-randomized and uncontrolled. The only double-blind placebo-controlled study was performed by Millichap [20] in 14 children with refractory seizures secondary to brain injury. Except for one child who had myoclonic jerks alone, major seizures occurred in all patients. Acetazolamide tablets and placebo were given alternatively to successive patients in a double-blind fashion as an add-on to the existing medications. Initially, 375 mg was given daily and, according to response, the dose was increased at intervals of 2–4 weeks up to a maximum of 750 mg daily. After an adequate trial of the treatment, which varied in duration according to the response, the alternative preparation was substituted. The anticonvulsant effect of acetazolamide was also compared with that of phenytoin in five patients. The follow-up period was 5–26 weeks. Acetazolamide was superior to placebo, and comparable to phenytoin. In 8 of the 14 (57%) patients the maximal seizure reduction was more than 75%, and in five (36%) of the patients a similar control was obtained at the end of the trial period. However, most patients became tolerant to the antiepileptic effect of the drug. Some studies reported more disappointing results. Livingston *et al*. [22] evaluated a series of 58 children with various types of seizures that were treated with acetazolamide. While there was a decrease in the frequency of seizures in a few patients, no patient became seizure free. Ross [28] conducted a study on 63 patients with idiopathic, temporal lobe and symptomatic epilepsy. Only two children with petit mal had a prolonged response over 1 year, and two patients (one with idiopathic epilepsy and one with temporal lobe epilepsy) had a temporary reduction of seizures.

Absence seizures

The rate of control of absence seizures with acetazolamide varies across studies from 0% [22] to 97% [23]. All the studies performed were uncontrolled. Acetazolamide was administered as monotherapy and as an add-on drug.

Lombroso *et al*. [18] investigated 126 patients, comprising 29 patients with petit mal only, 41 with petit mal and other seizures, and 56 with seizures other than petit mal. Patients with petit mal only showed a 90–100% reduction of seizures in more than one-third of the studied cases. Interestingly, the patients who improved the most were those whose electroencephalogram (EEG) showed three spike–waves per second and had prominent slowing in the EEG during hyperventilation. In fact, Saldias *et al*. [61] showed that intravenously administered acetazolamide abolishes or decreases the paroxysmal slow-wave discharges provoked by hyperventilation. Better response to treatment with acetazolamide in patients with three spike–waves per second and with prominent slowing in the EEG pattern during hyperventilation was also reported by Chao and Plumb [30] but not by others [21,25,27].

Ansell and Clarke [21] evaluated 26 patients. Of the five patients in this group who had petit mal seizures, three showed an excellent response. In a long-term follow-up study, Lombroso and Forsythe [29] described 91 (33%) patients who had petit mal seizures, 48 (53%) of whom were treated with acetazolamide alone. A 90–100% improvement in seizure control was observed in 42% of patients for 3 months, in 25% for 1 year and in only 10% for 3 years. In 43 patients who had 50% control of their seizures, acetazolamide was used adjunctively. Following the addition, 44% had a 90–100% seizure reduction for 3 months, but this declined to 7% by 3 years. Golla and Hodge [23] treated 78 patients of different ages with petit mal seizures only by adding 250 mg acetazolamide to their previous therapy. Only two (3%) failed to improve, 34 (44%) became seizure free and the others (53%) improved significantly. The partial tolerance that the majority of patients developed after 3 months was responsive to an increase in dosage to 500 mg daily. Holowach and Thurston [27] used acetazolamide in 56 children with different types of seizures. Of 14 patients with petit mal, nine had complete remission of seizures and in five partial control was achieved. In contrast, Livingston *et al*. [22] found no improvement in 15 patients with absence seizures following treatment with acetazolamide, and in the study conducted by Ross [28], only 1 out of 11 patients with petit mal became seizure free on acetazolamide.

Myoclonic seizures

Lombroso and Forsythe [29] described 15 children aged from 6 months to 7 years with massive myoclonus who were treated with acetazolamide monotherapy: 20% had 90–100% seizure control after 3 months. However, long-term treatment probably resulted in tolerance because no patient maintained this degree of control by the second and third years of follow-up. Chao and Plumb [30] reported fair improvement in five out of seven patients with massive spasms; by contrast, Baird and Borofsky [26] noted no improvement in 16 children with infantile myoclonic seizures who received acetazolamide daily as monotherapy. In a case report of acetazolamide as an add-on drug, a dramatic improvement of action myoclonus was recorded in two patients with progressive myoclonic epilepsy [62].

Acetazolamide monotherapy (dosage range 500–1750 mg daily) was evaluated in patients with juvenile myoclonic epilepsy in a retrospective study by Resor and Resor [33]. Although initially all the patients reported complete control of myoclonus, on a long-term basis only a few remained free of myoclonic jerks.

Generalized tonic–clonic seizures

Many studies that describe patients with generalized tonic–clonic seizures do not differentiate between primary and secondary generalized seizures. Ansell and Clarke [21] described 26 patients, six of whom had 'major idiopathic epilepsy' and were treated with acetazolamide as monotherapy. Marked improvement was noted at the beginning in all patients, but only three patients remained seizure free over a follow-up of 18 months.

In the study by Resor and Resor [33], 51 patients with juvenile myoclonic epilepsy were treated with acetazolamide either because of poor response to conventional antiepileptic drugs or to avoid valproate-associated adverse effects. Fourteen out of 31 patients (45%) who had generalized tonic–clonic seizures became seizure free for 10–70 months. Holowach and Thurston [27] administered acetazolamide to four patients with grand mal seizures who

had not been controlled on their previous medications, and in three of them complete remission was noted. Of the 277 patients studied by Lombroso and Forsythe [29], 19 had grand mal seizures only. In 15 patients, acetazolamide was given as add-on treatment, and as monotherapy to the remaining four. A 90–100% improvement in seizure control was observed in 63% of all patients after 3 months, in 37% after 1 year, in 11% after 2 years and only in 5% at the end of 3 years.

In another study, Forsythe *et al*. [31] evaluated acetazolamide as an add-on treatment to carbamazepine in 54 children, 40 of whom had exclusively grand mal seizures. Twenty-four (60%) patients with generalized seizures had a seizure frequency reduction of 50–100% at the 2-year follow-up. Relapse or no control after 2 years was noted in 16 children. In contrast to the above studies, Ross [28] and Livingstone *et al*. [22] found no improvement in patients with major motor seizures following treatment with acetazolamide.

Focal seizures

Lombroso and Forsythe [29] conducted a long-term follow-up study of 24 patients with psychomotor seizures; six (26%) became seizure free after 3 months, but only 10% had a 90–100% seizure reduction for 1 and 2 years, and after 2 years none was seizure free. Chao and Plumb [30] evaluated retrospectively the value of acetazolamide in 178 patients of different ages, 48 of whom had temporal lobe or other focal seizures. In 16 (33%) of these patients, an 80–100% improvement was reported, and 14 (29%) had more than a 50% seizure reduction. Holowach and Thurston [27] used acetazolamide in 20 children with focal epilepsy who had not been controlled on their previous medications. In 12 (60%) of these children, over 90% seizure reduction was reported.

Forsythe *et al*. [31] evaluated the long-term effect of acetazolamide as add-on treatment to carbamazepine in 54 children, 14 of whom had temporal lobe seizures only. Of these patients, nine (64%) had a reduction in seizure frequency of 70–100% at the 2-year follow-up; however, at the 3- to 5-year follow-up, six of the responders were found to have relapsed.

Oles *et al*. [32] identified retrospectively 48 children and adults with refractory partial seizures who received acetazolamide as adjunct to carbamazepine: 21 (44%) had a greater than 50% decrease in seizure frequency but only three became seizure free, and three lost their response. In a prospective long-term add-on study, Katayama *et al*. [35] investigated 37 patients with refractory epilepsy. Twenty patients had localization-related epilepsy and four of these were reported to be seizure free for more than 3 years. Discouraging results were reported by Ross [28] in 12 patients with temporal lobe epilepsy. In this group, only one had a temporary reduction of seizures and in the other 11 patients there was no apparent effect.

Catamenial seizures

Body water content changes in the premenstrual phase. Gamble suggested that fluid retention has a role in the generation of seizures [63] and that excessive water ingestion facilitates seizures whereas dehydration may have the opposite effect. Acetazolamide has a diuretic action which was thought to contribute to its antiepileptic effects, and this provided the rationale for using this drug in women with catamenial seizures. However, as pointed out by Ansell and Clarke [64], no significant differences in total body water have been observed between women with epilepsy and healthy controls or women with or without catamenial epilepsy treated with acetazolamide.

Although this mechanism of action has been questioned [64], exacerbation of seizures during menstruation was found to respond well and without side-effects to acetazolamide given at dosages of 250–500 mg daily for 5–7 days prior to the onset of the menstrual period and for its duration [65]. In three women with catamenial exacerbation of generalized tonic–clonic or absence seizures, Ansell and Clarke [21] reported that only increasingly higher doses of the drug could maintain seizure control. These authors also described improvement for 3 months in two patients who were given acetazolamide just on the day before and the day of onset of menstruation; a prolonged follow-up, however, was not conducted in these women. Goetting [66] reported a case of post-anoxic myoclonus severely exacerbated premenstrually: 1000 mg acetazolamide given intermittently during 5 days starting at the onset of each exacerbation resulted in prompt and marked improvement. Ross [28], however, observed no response to acetazolamide in 8 of the 25 menstruating females with epilepsy who reported having seizures related to menstruation.

In a retrospective study, Lim *et al*. [34] conducted a telephone questionnaire addressing the relationship of seizures with the menstrual cycle. Twenty women were identified, and acetazolamide was given as an add-on therapy in all patients but one. The drug was given continuously in 55% of women, and intermittently in 45%. A greater than 59% decrease in seizure frequency was reported by 40% of the subjects, and the degree of improvement was similar in both focal and generalized seizures. There was no difference in improvement rates between continuous and intermittent dosing. Loss of efficacy was reported by 15% of patients over 6–24 months.

Tolerance

The use of acetazolamide has been limited by the development of tolerance of patients, and loss of its antiepileptic effects over time has proved to be a major drawback for the use of acetazolamide in epilepsy. Tolerance after prolonged administration of acetazolamide can be demonstrated in animal models, such as the maximal electroshock model [45,48,67,68], and is believed to be mediated by an increased amount and increased activity of carbonic anhydrase in glial cells, as well as proliferation of glial cells [45,67,68]. Patients with epilepsy have been reported to develop tolerance after variable periods of time [18,20,21,29]. Loss of efficacy was noted in some studies after several weeks [20,21] and in other studies after months [18,23] or even years [29,31,35]. The development of tolerance appears to be similar in patients with focal as well as generalized seizures. Once tolerance has developed, withdrawal of the drug for a period of time may occasionally restore the antiepileptic effect [23].

Adverse effects

Acetazolamide is a relatively safe drug. Most of the reported side-effects seem to be related to inhibition of carbonic anhydrase, with the exception of idiosyncratic reactions (Table 31.3).

Table 31.3 Adverse effects of acetazolamide.

Potentially life-threatening effects
Blood disorders: aplastic anaemia, agranulocytosis, thrombocytopenia
Renal failure
Severe skin reactions
Other adverse effects
Gastrointestinal symptoms: abdominal discomfort, nausea, anorexia, diarrhoea
Dysgeusia
Paraesthesia of hands, feet and circumoral region
Increased diuresis
Drowsiness, dizziness, fatigue
Headache
Hyperpnoea, shortness of breath
Metabolic acidosis
Nephrolithiasis
Angle closure glaucoma

Idiosyncratic reactions

Acetazolamide, like other sulphonamide drugs, may induce angle closure glaucoma through a mechanism which is considered to involve an idiosyncratic reaction in the uveal tissues, associated with expansion of the extracellular tissue of the ciliary body and choroid [69]. Immediate cessation of the offending medication is required in such cases.

Isolated cases of acetazolamide-associated aplastic anaemia have been reported. A 73-year-old man treated with acetazolamide 250 mg daily because of oedema of the lower legs developed severe bone marrow depression which resulted in death after 1 month of therapy [70]. Keisu *et al*. [71] reported 11 cases of acetazolamide-associated aplastic anaemia from spontaneous reporting in Sweden over 17 years. Most of the patients were elderly and none was being treated for epilepsy. As most of these patients were being treated with other drugs as well, Shapiro and Fraunfelder [72] questioned whether this relatively high incidence could be attributed to acetazolamide.

Idiosyncratic reactions to acetazolamide also include agranulocytosis, which was described in a 66-year-old woman treated with 250 mg of acetazolamide as an adjunct to digitalis and a low-salt diet because of atherosclerotic heart disease and peripheral oedema [73]. An 85-year-old man treated for congestive heart failure with acetazolamide, 750 mg daily, developed acute thrombocytopenia [74]. Acute renal failure has been described on rare occasions [75]. There are also a number of acute skin reactions attributed to acetazolamide, some of which can be severe, and similar to other sulphonamide derivatives, cases of Stevens–Johnson syndrome have been reported. Cross-sensitivity to acetazolamide in patients allergic to sulpha drugs can occur [76].

Common non-idiosyncratic adverse effects

These adverse effects are encountered mainly upon initiation of therapy and are mostly transient. Patients with glaucoma, perhaps because of their age, are less tolerant to the drug [77], whereas patients with epilepsy tend to have fewer adverse effects [29]. The most common side-effects include drowsiness, fatigue, dizziness, paraesthesia of hands and feet, gastrointestinal symptoms such as nausea, vomiting and diarrhoea, loss of libido, diuresis, headache and hyperventilation (Tables 31.2 and 31.3) [8,18–21,24,25,27–34,78]. In the largest study of 277 patients by Lombroso and Forsythe [29], 11% of patients reported the following adverse effects, in descending order of frequency: drowsiness, anorexia, irritability, nausea, vomiting, enuresis, headache, thirst, dizziness and hyperventilation. These effects have been reported in 8–30% of epilepsy patients in most studies [18–21,24,25,27–34]. Transient distortion of normal taste secondary to acetazolamide was ascribed to carbonated and non-carbonated beverages and food, and was speculated to be due to altered taste receptors secondary to inhibition of carbonic anhydrase [79].

Favourable side-effects have been occasionally noted during treatment with acetazolamide, including improved behaviour and mental status [18,25].

Other adverse effects

Metabolic acidosis

Acetazolamide may induce metabolic acidosis by inhibiting carbonic anhydrase in the proximal tubular epithelium of the kidney, which leads to diuresis, excessive excretion of sodium and potassium ions, and alkaline urine. Although the metabolic acidosis that is produced is mild, it can sometimes be symptomatic, especially in elderly patients and in patients with renal failure [80].

In a study by Epstein and Grant [77], 44 out of 92 (48%) patients treated with acetazolamide for chronic glaucoma complained of a symptom complex syndrome that included malaise, fatigue, weight loss, depression, anorexia and often loss of libido. Patients with this syndrome were found to be significantly more acidotic. Although these symptoms are frequently associated with mild metabolic acidosis and perhaps with a subclinical respiratory acidosis, the central nervous system nature of these adverse effects suggests that inhibition of brain carbonic anhydrase may also have been important in their pathogenesis. Symptoms of metabolic acidosis develop slowly and are often difficult to diagnose, especially in the elderly. The best-documented treatment is supplementation with sodium bicarbonate 56–70 mmol daily orally [77]. Sodium acetate administration has also been reported to be helpful [81].

Metabolic acidosis associated with acetazolamide has been speculatively linked to growth suppression in children receiving acetazolamide in combination with other antiepileptic drugs [82].

Renal stones

Acetazolamide may facilitate the formation of renal stones by inducing partial renal tubular acidosis, with resulting hypercalciuria and hypocitraturia, both of which are recognized risk factors for stone formation [83]. The occurrence of nephrolithiasis with acetazolamide has been of special concern in patients treated for epilepsy [33] and glaucoma [84]. The frequency of stone formation varies across studies. It was very rare in children with epilepsy (i.e. 1 in 277) [29] and was absent altogether in 28 patients examined for renal calculi formation in Katayama's [35] study. However, 6 out of 14 (43%) young adults with juvenile myoclonic epilepsy [33] were reported to have developed renal calculi, without a clear relationship with the administered dosage. Kass *et al*. [84] reported a frequency as high as 12% in patients with

glaucoma. Citrate supplementation and hydration may be effective in reducing stone formation [83].

Effects on bone metabolism

Available data on the effects of acetazolamide on bone metabolism are somewhat contradictory and the role of carbonic anhydrase in human bone resorption is unclear. Acetazolamide may accelerate osteomalacia by different mechanisms, which include urinary calcium and phosphate excretion and systemic acidosis [85]. Mallette [85] described two acetazolamide-treated patients with osteomalacia, but both patients were also receiving barbiturates. In post-menopausal women with glaucoma, long-term (more than 4 years) use of carbonic anhydrase inhibitor therapy was associated with a bone-sparing effect, as judged by spinal bone mineral density [86]. This effect was absent in acetazolamide-treated premenopausal women and in those who received acetazolamide for less than 2 years.

Effects on a fetus and newborn

Layton and Hallesy [87] reported that 36% of the offspring of rats fed with acetazolamide in their diet during pregnancy had a defect confined mainly to the right forepaw. The plasma levels achieved with that diet were of the same order of magnitude as those recorded in patients who receive 500–1500 mg of acetazolamide. A similar effect was observed in mice and hamsters but not in monkeys [88]. A human case of multiple congenital malformations (glaucoma, microphthalmia and patent ductus arteriosus) has been described in a letter from Lederle Laboratories in 1975, cited by Worsham *et al*. [89]. In a neonate of a 22-year-old woman treated with acetazolamide 750 mg daily because of glaucoma, a sacrococcygeal teratoma was described [89].

There are no adequate studies in pregnant women, and therefore the teratogenic risk of acetazolamide in humans has not been established.

There has been one report suggesting a possible association between treatment for glaucoma throughout pregnancy with 500 mg of acetazolamide and metabolic acidosis, hypocalcaemia and hypomagnesaemia in a single preterm infant [90].

Soderam *et al*. [91] reported that the dose of acetazolamide transferred to the child through breast milk was low, i.e. less than 0.7% of the dose per kilogram of body weight of the mother. Based on their findings, they speculated that breastfeeding by an acetazolamide-treated mother is unlikely to cause harmful effects in the infant.

Place in current therapy

Usefulness and limitations

Evidence on the efficacy of acetazolamide in epilepsy is restricted mainly to retrospective, uncontrolled studies. In these studies, conducted mostly in the 1950s, selection of patients, seizure type, methods and duration of treatment, and definition of response varied extensively, which makes it difficult to evaluate the value of the drug in seizure types and syndromes as currently classified.

Most patients treated with acetazolamide had seizures unresponsive to other antiepileptic drugs. Many studies define acetazolamide as an antiepileptic drug with a broad spectrum of action. Although some authors [22,28] failed to demonstrate its usefulness, efficacy in different types of seizures has been reported in most of the published studies. The best responses were reported in absence seizures [18,23,29], but good results were also described in patients with generalized tonic–clonic seizures [21,29,31,33], myoclonic seizures [29,30,33] and partial seizures [29–32,35]. These data suggest that acetazolamide can be beneficial in a variety of seizure types, and in some of the studies the patients had an initially spectacular effect. Acetazolamide can be helpful mainly as an add-on treatment in children and adults, with special reference to those with generalized seizures, particularly absences, but also in patients with partial seizures. The lack of effect on the hepatic drug-metabolizing enzymes makes acetazolamide valuable when drug interactions are a concern. The antiepileptic effect of acetazolamide develops promptly [27], and therefore the drug may be useful when a rapid onset of effect is needed.

The use of acetazolamide has been limited by the frequent development of tolerance. Loss of seizure control has been reported as early as several weeks after instituting treatment or after months and years, and occasionally an increase in dosage has been required to maintain a sustained effect. As cyclical dosing may reduce the development of tolerance, acetazolamide has been proposed as adjunct intermittent therapy in the management of catamenial epilepsy. However, controlled studies in women with catamenial seizures are required before acetazolamide can be recommended for this indication in routine clinical use. Other antiepileptic drugs, particularly benzodiazepines, are also known to be subject to the development of tolerance. A comparison between the degree of tolerance associated with acetazolamide and benzodiazepines has not been performed.

In this author's opinion, acetazolamide has been too quickly abandoned in favour of newer antiepileptic drugs without having undergone adequate evaluation for its potential value. In some patients, a dramatic effect has been observed, and a worthwhile effect has been reported in different types of epilepsy. Its major drawbacks are the potential for tolerance and the risk of idiosyncratic reactions. The former, however, does not occur in all patients and the latter is rare. Acetazolamide is simple and easy to use and is generally well tolerated. Even though its usefulness is likely to be limited, acetazolamide warrants re-evaluation by modern methodological standards.

Dosing recommendations

Dosages used in different studies in children and adults with epilepsy have varied from 3 to 36 mg/kg/day, whereas total dosages varied from 125 mg to 1750 mg.

The recommended maintenance dose for adults is 10–20 mg/kg, or 500–1000 mg/day, given 2–3 times daily [50,60]. Plasma levels with this dosage were reported to be 10–14 μg/mL [50]. The doses reported for children were 10–36 mg/kg [20,29,31]. Lombroso and Forsythe [29] noted that in adults and children increasing dosage above 750 mg was rarely effective and that 500 mg/day was usually the maximal useful dose in children less than 7 years of age. Monitoring plasma concentration has not been found to be generally helpful [32].

Table 31.4 High-risk groups.

Elderly patients
Patients with concomitant disorders
Renal failure
Hepatic failure
Adrenal insufficiency
Conditions associated with sodium and potassium depletion
Sulfonamide hypersensitivity
Acidotic disorders
Patients on specific co-medications or diets
Drugs causing sodium and potassium depletion
Drugs causing lithiasis or metabolic acidosis (e.g. topiramate)
Diets causing metabolic acidosis (ketogenic diet)

The starting dose should be 125 mg twice daily in children and 250 mg twice daily in adults, and it may be increased at weekly intervals. Before making the decision to increase the dosage, it should be considered whether tolerance has occurred to adverse effects and seizure control. Slow discontinuation over several weeks is recommended to prevent withdrawal seizures [60].

Individuals at higher risk include older patients with compromised renal function, who should be started out with a reduced dose to avoid acidosis [92].

Precautions and contraindications

Experience with acetazolamide shows that it is a relatively safe agent, and that it can be used for long periods without serious adverse effects. Because of rare cases of aplastic anaemia, agranulocytosis and thrombocytopenia (Table 31.3), a full blood count before initiating treatment is recommended. The usefulness of repeated haematology tests is unknown.

Patients with impaired renal function require a lower dosage, because the clearance of acetazolamide correlates with creatinine clearance [56]. Liver disease is a contraindication to the use of acetazolamide. Alkalinization of urine diverts ammonia of renal origin from urine to the systemic circulation, potentially causing hepatic encephalopathy [93]. Because of its tendency to cause potassium loss, acetazolamide is also contraindicated in Addison's disease and in adrenal insufficiency.

When acetazolamide is given with carbamazepine, monitoring of serum sodium may be indicated because both drugs may cause hyponatraemia [50], and carbamazepine levels should also be measured [31]. Special attention to ensure appropriate hydration and to monitor for potential metabolic acidosis is required if acetazolamide is given in combination with topiramate or zonisamide, because all three drugs inhibit carbonic anhydrase and may cause lithiasis and acidosis (Table 31.4).

Acetazolamide is an animal teratogen [87,88], and two cases of possible human teratogenicity related to acetazolamide have been described [89]. This should be taken into consideration when treating women of childbearing age.

32 Adrenocorticotropic Hormone and Corticosteroids

Federico Vigevano and Maria Roberta Cilio
Bambino Gesù Children's Hospital, Rome, Italy

	Adrenocorticotropic hormone (ACTH)	Prednisone/prednisolone
Primary indication	First-line treatment for infantile spasms. May be of value in other paediatric epileptic encephalopathies	First-line treatment for infantile spasms. May be of value in other paediatric epileptic encephalopathies
Usual preparations	HP Acthar® Gel: 5 mL vial (80 USP units/mL) for intramuscular or subcutaneous use Synachten Depot®: 0.5 mg/1 mL, 0.5 mg/0.5 mL, 1 mg/1 mL, 2 mg/2 mL, for intramuscular use	Prednisone: tablets: 1, 2.5, 5, 10, 20, 50 mg; oral solution: 1 mg/mL Prednisolone: tablets: 5 mg; oral solution: 3 mg/mL
Usual dosage	2 IU/kg/day intramuscularly or subcutaneously (indicative dosage – dosing schedules vary markedly across centres and countries). After an appropriate period, dosage is down-escalated gradually	2 mg/kg/day orally. After an appropriate period, dosage is down-escalated gradually
Significant drug interactions	Barbiturates may decrease the effect of ACTH	Enzyme-inducing drugs increase the metabolic clearance of prednisolone. Many drugs can inhibit the metabolism of prednisolone
Serum level monitoring	Not useful	Not routinely performed
Target range	Not applicable	Not applicable
Common/important adverse effects	Irritability, hypertension, gastritis, peptic ulcer, headache, increased intracranial pressure, increased intraocular pressure, infections, immunosuppression, suppression of the hypothalamic–pituitary–adrenal axis, Cushing's syndrome and other endocrine disorders, electrolyte disturbances, transient cerebral atrophy, myocardial hypertrophy, pancreatitis, myopathy, cataracts, osteoporosis, aseptic necrosis of femoral or humeral heads, reduced growth rate, hypersensitivity reactions	Irritability, hypertension, gastritis, peptic ulcer, headache, increased intracranial pressure, increased intraocular pressure, infections, immunosuppression, suppression of the hypothalamic–pituitary–adrenal axis, Cushing's syndrome and other endocrine disorders, electrolyte disturbances, transient cerebral atrophy, myocardial hypertrophy, pancreatitis, myopathy, cataracts, osteoporosis, aseptic necrosis of femoral or humeral heads, reduced growth rate

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

	Adrenocorticotropic hormone (ACTH)	Prednisone/prednisolone
Main advantages	High response rates in infantile spasms and extensive clinical experience	Good response rates, oral route of administration, feasibility of longer-term treatment
Main disadvantages	Parenteral route of administration, higher risk of serious adverse effects compared with corticosteroids, optimal dose and duration of treatment not established	Possibly less efficacious than ACTH in controlling infantile spasms. Significant adverse effects, particularly with prolonged treatment
Mechanism of action	Antiepileptic actions might be related to anti-inflammatory and immunosuppressant properties, as well as to inhibition of corticotropin-releasing hormone release	Antiepileptic actions might be related to anti-inflammatory and immunosuppressant properties, as well as to inhibition of corticotropin-releasing hormone release
Oral bioavailability	Not applicable	Prednisone: over 70% (in terms of metabolically derived prednisolone)
Time to peak levels after single dose	Within 1–2 h. May be delayed with sustained-release formulations	Within 1–2 h
Main routes of elimination	Enzymatic hydrolysis	Oxidative metabolism and conjugation
Volume of distribution	0.4 L/kg (value refers to 1–24β-tetracosactide, the principle contained in Synachten Depot)	0.5–0.9 L/kg (prednisolone). Volume of distribution increases with increasing doses
Elimination half-life	About 15 min, but plasma levels remain sustained for many hours when using sustained-release formulations	1.3–4 h (prednisolone), with shortest values in children and in patients taking enzyme inducers
Plasma clearance	–	1.5–6.5 mL/min/kg (prednisolone), with highest values in children, in patients taking enzyme inducers and in patients on high doses
Protein binding	–	55–95% (prednisolone). Binding decreases with increasing drug concentration
Active metabolites	Activity resides primarily in the first 20 amino acids from the N-terminal end of the chain. Partial loss of activity is observed with progressive shortening of the chain beyond the 20 amino acid residues	The effects of prednisone are mediated practically entirely through conversion to prednisolone
Comment	Considered by many authors the agent of choice for the treatment of infantile spasms, particularly in patients who do not have tuberous sclerosis	A valuable alternative to ACTH in the treatment of infantile spasms. May be valuable for longer-term treatment of other paediatric epileptic encephalopathies

Introduction

In 1958, Sorel and Dusaucy-Bauloye [1] discovered almost serendipiditously that adrenocorticotropic hormone (ACTH or corticotropin) was efficacious in controlling seizures and improving electroencephalogram (EEG) abnormalities as well as neuropsychological performance in patients with infantile spasms. The importance of this finding is noteworthy, since infantile spasms represent a severe epileptic condition which is associated with encephalopathic symptoms and an unfavourable cognitive outcome. Since then, several other publications have confirmed the efficacy of ACTH and corticosteroids in the treatment of spasms. These agents have also been applied – and continue to be applied – to the treatment of other severe forms of childhood epilepsy, even though there is a paucity of high-quality studies demonstrating their efficacy in these conditions [2].

ACTH and corticosteroids are mostly used to treat epileptic encephalopathies, a group of severe clinical entities with heterogeneous clinical presentations and variable causes. The latter include prenatal causes such as brain malformations, chromosomal abnormalities and neurocutaneous disorders, perinatal causes such as hypoxic–ischaemic injuries and neonatal hypoglycaemia, and postnatal causes such as vascular or infectious insults. Brain lesions associated with these conditions may be diffuse or focal, either uni- or bilateral. 'Idiopathic' cases are exceptional.

In epileptic encephalopathies, interictal epileptiform EEG abnormalities play a significant role in generating progressive disturbances of cerebral function. Thus, the aim of treatment is not limited to seizure control, and more often the greatest challenge is to improve the child's psychomotor development, a goal which requires suppression or reduction of interictal EEG discharges.

Chemistry

Corticotropin is a 39-amino-acid polypeptide secreted from the anterior pituitary (Fig. 32.1). Its biological activity resides in the first 20 amino acids from the N-terminal end of the chain. Human, sheep, cattle and swine corticotropin have different structures, but the first 20 amino acids are the same and, therefore, they are considered to exert identical biological effects. Commercial sources of natural ACTH generally are obtained from porcine pituitaries. Among the formulations most commonly used in epilepsy therapy, HP Acthar® Gel contains natural ACTH, while Synachten Depot® and Cortrosyn-Z® contain a polypeptide made up of the first 24 amino acids of natural ACTH.

The corticosteroids most commonly used in epilepsy therapy are prednisone, prednisolone and hydrocortisone. Prednisone [molecular formula $C_{21}H_{26}O_5$, molecular weight 358.44 (Fig. 32.1)] is a white crystalline powder very slightly soluble in water and slightly soluble in alcohol and chloroform. Prednisolone [molecular formula $C_{21}H_{28}O_5$, molecular weight 360.45 (Fig. 32.1)] is a white crystalline powder, very slightly soluble in water. Hydrocortisone (molecular formula $C_{21}H_{30}O_5$, molecular weight 362.46) is also a white crystalline powder, very slightly soluble in water and sparingly soluble in acetone and alcohol.

Mechanisms of action

Little is known on the mechanisms of the antiepileptic action of ACTH and corticosteroids, partly because little is known about the pathogenesis of epileptic encephalopathies. Various hypotheses, however, have been put forward.

In vitro, ACTH and corticosteroids stimulate the growth of neuroblasts [3], a property that might be of particular relevance for the treatment of encephalopathies occurring in the first year of life. ACTH and corticosteroids may also modulate various neurotransmitter systems. In particular, ACTH down-regulates serotonin 5-HT_2 receptors in the cerebral cortex, and modulates γ-aminobutyric acid (GABA) and dopamine receptors, an effect which, in animal models, is age dependent [4].

In addition, ACTH and corticosteroids have well-established immunosuppressant properties. In the last few years, increasing evidence has accumulated that certain forms of severe epilepsy have an inflammatory and/or immunological basis [5]. Hence, the antiepileptic actions of ACTH and corticosteroids, as well as immunoglobulins, may depend on their anti-inflammatory and immunosuppressant effects.

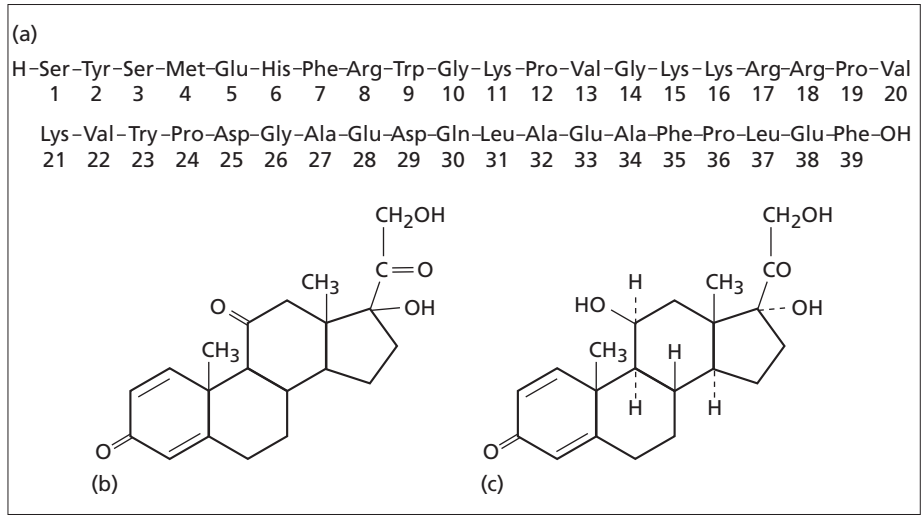

Fig. 32.1 Chemical structure of (a) ACTH, (b) prednisone and (c) prednisolone.

ACTH probably acts not only by releasing endogenous corticosteroids but also by a direct action on the central nervous system (CNS). In fact, even though ACTH fragments that do not induce the endogenous release of corticosteroids are ineffective against infantile spasms, ACTH has been found to retain efficacy against spasms in patients with adrenal insufficiency [6] or in the presence of adrenal inhibition [7]. ACTH increases the synthesis of RNA and DNA and promotes brain maturation and growth through mechanisms such as stimulation of myelinization and dendritic sprouting [8–10]. The penetration of ACTH across the blood–brain barrier in humans is unknown, but it is estimated to be quite low [10,11]. However, recently, a direct action of ACTH on amygdala neurones via activation of central melanocortin receptors has been postulated, supporting the notion that a direct, steroid-independent action may account for some of the effects of ACTH in the CNS. The binding of ACTH to melanocortin receptors on limbic neurones leads to a significant down-regulation of corticotropin-releasing hormone (CRH) gene expression, which may provide a mechanism for the efficacy of ACTH in some human epilepsies (see below) [12]. The affinity of different analogues, fragments and formulations of ACTH for these central receptors is very different from their affinity for peripheral receptors involved in steroid release. This might explain the variability in ACTH therapeutic efficacy reported in different studies in infantile spasms, in which different ACTH preparations have been used. For example, it is possible that synthetic preparations are more potent in activating melanocortin receptors than natural preparations.

At present, the most accredited hypothesis is that ACTH and corticosteroids exert their actions through the hypothalamic–pituitary–adrenal axis [12]. This hypothesis stems primarily from studies related to infantile spasms. In 1985, Nalin *et al.* [13] described decreased ACTH levels in the cerebrospinal fluid (CSF) of children with infantile spasms. It is plausible that decreased ACTH levels are associated with higher CRH levels, and it has been postulated that conditions causing infantile spasms activate a 'stress response', leading to increased CRH production and release [12]. CRH has a proconvulsant action by increasing neuronal excitability in the limbic system and the brainstem, and low concentrations of endogenous ACTH and corticosteroids increase CRH levels in the CNS [12,13]. Hence, exogenous ACTH and corticosteroids might act through a negative feedback mechanism by suppressing CRH synthesis and release. According to Jaseja [14], this hypothetical mechanism may also explain the putative superiority of ACTH over oral corticosteroids in the management of infantile spasms. Indeed, ACTH has a double action in inhibiting CRH secretion, one which involves a direct effect and one which is mediated by increased blood levels of endogenous corticosteroids. By contrast, corticosteroids exert a direct inhibiting action on CRH secretion, but their inhibiting action on endogenous ACTH secretion may indirectly attenuate their influence on CRF release.

In 1992, Mares and Velisek [15] developed an animal model of tonic seizures, considered equivalent to infantile spasms, in which seizures were induced in rats by intraperitoneal injection of *N*-methyl-D-aspartate (NMDA) on postnatal day 15. In 2007, the same group reported an refinement of this model by combining prenatal exposure to betamethasone with postnatal administration of NMDA, and demonstrated that prenatal exposure to the steroid sensitizes the rats to development of NMDA-induced spasms [16]. Interestingly, rats exposed prenatally to betamethasone were much more responsive to ACTH treatment, compared with animals unexposed to betamethasone. Imaging studies in these rats have shown that limbic areas, the hypothalamus and the brainstem are primarily involved in the generation of NMDA-induced spasms [16]. These areas correspond to those targeted by CRH. These data seem to support the hypothesis that prenatal stress facilitates the onset of spasms and that ACTH may act by antagonizing the stress response. This pathogenetic hypothesis may apply in particular to some cases of infantile spasms, such as those secondary to perinatal hypoxic–ischaemic injury, whereas it is more difficult to envisage a role for this mechanism in 'idiopathic' or 'cryptogenic' cases with no evidence of pre- or perinatal stress.

The animal model developed by Velisek and colleagues [15,16] shows seizures phenotypically similar to human infantile spasms, associated with similar ictal EEG discharges. However, these animals do not display the abnormal interictal EEG pattern called hypsarrhythmia, and the condition does not persist beyond the acute injection period. On the other hand, the tetrodotoxin animal model [17] resembles more closely the human condition. In this model, tetrodotoxin is chronically infused into the developing hippocampus neocortex of infant rats on postnatal days 10 to 12. After a minimum latency of 10 days, one-third of tetrodotoxin-exposed rats develop spasms in clusters and interictal multifocal EEG spikes and sharp waves. No data are available so far on the effect of ACTH or corticosteroids in this model.

Pharmacokinetics

ACTH

Since ACTH is rapidly degraded by proteolytic enzymes in the gastrointestinal tract, it must be administered parenterally by intramuscular or by subcutaneous route [18]. The formulations used in epilepsy treatment are not suitable for intravenous use. Natural ACTH is readily absorbed from the injection site, but with sustained-release preparations absorption is prolonged for several hours. In the USA, a natural preparation of ACTH is generally used [19], whereas synthetic preparations are commonly used in Europe and Japan [20,21]. The US preparation, Acthar Gel®, is a highly purified sterile formulation of ACTH in 16% gelatin, which provides a prolonged release of the hormone [22]. The European formulation, Synachten Depot®, is a long-acting synthetic 24-amino-acid polypeptide and zinc complex that shows the same biological activities as natural ACTH [23]. The most widely used synthetic analogue in Japan, where natural ACTH is not commercially available, is Cortrosyn-Z®, a zinc hydroxide suspension of a 24-amino-acid polypeptide similar to Synachten Depot®. Synachten Depot® and Cortrosyn-Z® exhibit the full range of activities of natural ACTH.

In humans, the plasma half-life of ACTH is about 15 minutes and elimination is due to rapid enzymatic hydrolysis [18]. With the commonly used sustained-release preparations, however, plasma levels are maintained for many hours after the injection in spite of the short elimination half-life.

Corticosteroids

Prednisone and prednisolone are the most commonly prescribed oral corticosteroids. Prednisone itself is virtually inactive and is

rapidly converted in the liver, partly through a first-pass effect, to prednisolone, which is found in plasma at much higher concentrations than prednisone itself and is responsible for the pharmacological effects.

Both prednisone and prednisolone are rapidly absorbed from the gastrointestinal tract. The active moiety, prednisolone, is highly bound (60–95%) to plasma proteins, particularly transcortin, and its fraction unbound increases with increasing drug concentration. Partly because of concentration-dependent protein binding, the clearance of total (bound + unbound) prednisolone increases with increasing dose [24]. Prednisolone clearance is also higher in children than in adults [25] and in patients co-medicated with enzyme inducers [26]. The half-life of prednisolone is in the range of 1.5–4 h, the shortest values being observed in children and in patients co-medicated with enzyme inducers. Elimination of prednisolone is primarily metabolic, with CYP3A4-mediated oxidation playing a major role in addition to other enzymes.

Hydrocortisone is the synthetic form of naturally occurring cortisol. The oral bioavailability of hydrocortisone is estimated to be close to 100% [27] and is not expected to be influenced by gender, age or liver disease [28,29]. Because of its high oral bioavailability, orally administered hydrocortisone is almost equally effective as an identical dose given intravenously. Peak concentrations are reached within 1–2 h, and the plasma half-life is about 1.5 h. Certain water-soluble esters of hydrocortisone and its synthetic congeners may be administered intravenously in order to achieve rapidly high concentrations in body fluids. More prolonged plasma levels can be obtained by intramuscular injection of a suspension of hydrocortisone, its esters and congeners. Under normal circumstances, cortisol is ≥90% bound to plasma proteins, and elimination is predominantly metabolic.

Drug interactions

The metabolism of many corticosteroids, including prednisolone and hydrocortisone, is stimulated by concomitant administration of enzyme-inducing agents such as phenytoin, carbamazepine and barbiturates [26]. This may result in reduced therapeutic efficacy of these steroids. Since ACTH acts partially via corticosteroids, these interactions may also be observed with ACTH.

Inhibitors of CYP3A4, such as certain macrolides, ritonavir and other drugs, reduce the rate of metabolism of corticosteroids and may potentiate their clinical effects.

Serum level monitoring

Although the suggestion has been made that measuring serum levels of corticosteroids may facilitate clinical management by identifying pharmacokinetic variability related to factors such as disease states and drug interactions [25], in practice the measurement of the serum concentration of these agents is not done routinely. Optimization of therapy with ACTH and corticosteroids is best guided by clinical observations, including the monitoring of EEG responses when appropriate.

Efficacy

Infantile spasms

Short-term studies

Since the work of Sorel and Dusaucy-Bauloye [1], ACTH has been used for the treatment of infantile spasms worldwide. Alongside corticosteroids and vigabatrin, ACTH continues to be considered a first-line option for this condition, although there is no consensus on which agent should be used preferentially and, particularly in the case of ACTH, on the optimal dosing schedule.

In assessing the efficacy of ACTH and corticosteroids in infantile spasms, one must remember that the objectives of therapy in this condition are not limited to controlling the seizures but should also include suppression of hypsarrhythmia and improvement of developmental outcome. Assessing these outcomes requires long-term follow-up studies that are very scarce in the literature. With respect to seizure control, the only meaningful outcome in this form of epilepsy is complete disappearance of spasms, since a 50–70% decrease in spasms frequency is clinically irrelevant. Most published studies focus exclusively on short-term results in spasms control. Assessment methodology for this outcome measure is also very important because estimates of seizure control based simply on parents' observations have been shown to differ significantly from those based on prolonged video-electroencephalography monitoring [4].

In 2004, MacKay *et al*. [30] performed an exhaustive meta-analysis of the literature on the medical treatment of infantile spasms. Their worked confirmed that, despite the widespread use of ACTH and steroids, there are few prospective studies and only five randomized trials with these agents. Moreover, treatment protocols differ significantly: for instance, in the studies considered in the meta-analysis, ACTH dosage varied from 0.2 international units (IU)/kg/day up to 150 IU/m^2/day as initial dosage, with duration of treatment at the highest (initial) dose varying from 1 to 6 weeks and a total treatment time ranging from 4 to 12 weeks. Only 14 studies with ACTH met the minimal criteria for inclusion in the meta-analysis. Of these, five were randomized controlled trials (class I–III) [20,31–34], four were prospective open-label trials (class III–IV) [35–38] and five were retrospective case series (class IV) [19,39–42]. Only one study [31] was placebo controlled and only two were cross-over studies of ACTH versus prednisone [31] or vigabatrin [20]. When only short-term effects on seizures were considered, spasm cessation was reported in 42–87% of ACTH-treated patients and occurred within 7–12 days. About one-third of patients showed relapse of spasms within 3 months after completion of the ACTH cycle.

With respect to the relationship between ACTH efficacy and dosage, a 1982 study by Riikonen [43] failed to detect significant differences in terms of spasm control, EEG improvement or incidence of relapses when two groups of patients, one treated with 'high initial doses' (120–160 IU/day) and the other with 'low initial doses' (20–40 IU/day), were compared. However, the 'low doses' used by Riikonen would be considered relatively high by current standards. In fact, in order to reduce adverse effects, increasingly lower doses have been used over time. In 2006, Oguni *et al*. [44] suggested the use of extremely low doses, i.e. 0.2 IU/kg/day, to achieve maximum efficacy with minimal adverse

effects. For the same reasons, the current consensus is also to avoid long treatment schedules and to restrict treatment duration to a maximum of 4–6 weeks.

In the meta-analysis by MacKay *et al.* [30], only five studies with oral corticosteroids met criteria for inclusion. Of these, two were randomized controlled trials (class II and III) [31,33], two were prospective open-label trials (class III) [36,45] and one was a retrospective case series (class IV) [40]. Prednisone or prednisolone was used, at the initial dosage of 2–3 mg/kg/day, for a period ranging from 4 to 20 weeks and then tapered and discontinued. Cessation of spasms was reported in 29–59% of treated cases.

The data on the comparative efficacy of ACTH and oral corticosteroids are controversial, even though some results seem to favour ACTH. In the double-blind trial conducted by Hrachovy *et al.* [31] and comparing ACTH at an initial dose of 20 IU/kg/day with prednisolone at a dose of 2 mg/kg/day in a total of 24 infants with infantile spasms, there was no difference in efficacy between the two treatments. In this study, ACTH and prednisolone were given until a response was obtained, for a maximum of 6 weeks prior to tapering. In contrast, in the single-blind randomized study by Baram *et al.* [33] comparing high-dose ACTH (150 IU/m^2/day) with prednisone 2 mg/kg/day, each given for 2 weeks in a total of 29 infants, 86% of ACTH-treated versus 28% of prednisone-treated infants achieved cessation of spasms and hypsarrhythmia. The treatment of responders was tapered off over 12 days, while non-responders were crossed over to the alternative treatment. The two infants who failed on ACTH received prednisone and responded by both clinical and EEG criteria. Of the 10 infants who failed prednisone, nine received ACTH and eight responded [33]. In another study suggesting a superiority of ACTH over corticosteroids, Snead *et al.* [40] reported cessation of spasms in all of 30 patients with infantile spasms and hypsarrhythmia treated with ACTH and in 59% of 22 patients with infantile spasms and hypsarrhythmia treated with prednisone. ACTH was given at the initial dose of 150 IU/m^2/day for 1 week and then progressively decreased, while prednisone was given at the dose of 3 mg/kg/day for 4 weeks and then gradually tapered [40]. On the other hand, Lombroso [36] did not detect any short-term difference in spasms cessation between high-dose ACTH (110 IU/m^2/day for 3 weeks, then tapered off over 5 weeks) and prednisolone (2 mg/kg/day for 8 weeks, then gradually discontinued over 12–24 weeks) in a total of 108 infants.

There are very few data on the use of parenteral corticosteroids. Yamamoto *et al.* [46] performed a comparative study in 10 patients with symptomatic infantile spasms, of whom five were treated with a single intravenous injection of 0.25 mg/kg dexamethasone palmitate administered seven times over a 3-month period (once a week in the first month, once every 2 weeks in the second month and once a month in the third month, which corresponds to a total dosage of 1.75 mg/kg), and five were treated with ACTH intramuscularly at a dose of 0.025 mg/kg/day for 6 weeks (total dosage of 0.625 mg/kg). Spasms and hypsarrhythmia disappeared in all cases, but after 3 months patients in both groups showed either a relapse of spasms or the appearance of partial seizures.

ACTH and corticosteroids are considered first-line agents in all cases of infantile spasms, with the exception of spasms associated with tuberous sclerosis. In a randomized trial, Chiron *et al.* [47] described the cessation of spasms in only 5 out of 11 infants with tuberous sclerosis treated with oral hydrocortisone, whereas all 11 infants treated with vigabatrin became seizure free. Successful treatment of infantile spasms with vigabatrin has also been reported in infants without tuberous sclerosis. In 2004, Lux *et al.* [48] conducted a randomized trial comparing vigabatrin 100 mg/kg/day with hormonal therapy (ACTH 40 IU on alternate days or prednisolone 40 mg/day) in 107 patients with infantile spasms not associated with tuberous sclerosis. After 2 weeks of treatment, spasms cessation was achieved in 40 of 55 (73%) patients randomized to hormonal treatment, compared with only 28 of 52 (54%) infants randomized to vigabatrin [48], even though long-term seizure outcome did not differ between the two treatments (see below) [49]. Evidence for a superior efficacy of ACTH over vigabatrin in infantile spasms not associated with tuberous sclerosis, at least in the short-term, has also been provided in a randomized study by Vigevano and Cilio [20].

Long-term studies

Long-term effects on spasms and on developmental outcome are difficult to evaluate. Frost and Hrachovy [4] reviewed 44 studies addressing this issue and reported an average persistence of seizures in 53% of patients after a follow-up period of minimum 31 months, with a very large variation across studies (9–86%). Most of the patients had been treated with ACTH or corticosteroids, but also with additional drugs. Cryptogenic cases were associated with a more favourable long-term outcome.

In the case series of 64 cryptogenic and symptomatic infants with infantile spasms described by Glaze *et al.* [50], there were no significant differences in outcome between those treated with ACTH and those treated with prednisone. In a prospective study of 102 cryptogenic cases comparing ACTH with other therapies such as oral steroids, benzodiazepines or conventional antiepileptic drugs (AEDs), Lombroso [36] found a significant difference in favour of ACTH for psychometric development and for achievement of a seizure-free state. In the multicentre randomized trial by Lux *et al.* [48] that found hormonal treatment (ACTH or prednisolone) more efficacious than vigabatrin in the short term, developmental and seizure outcomes were also evaluated at age 14 months. At the final assessment, spasms-free rates were similar in the two groups, with 41 of 55 (75%) patients randomized to hormonal treatment and 39 of 51 (76%) patients randomized to vigabatrin being free from spasms [48]. Neurodevelopmental outcome assessed by using the Vineland Adaptive Behavior Scale (VABS) did not differ significantly between the two groups. However, in cryptogenic patients the mean VABS score was higher in those allocated to hormonal treatment. In interpreting these findings, it should be considered that cryptogenic cases represent a heterogeneous group, since patients initially classified as cryptogenic may be subsequently reclassified as symptomatic as a result of improved diagnostic tools, such as more advanced imaging techniques.

Other epileptic syndromes

Studies on the efficacy of ACTH and corticosteroids in the treatment of other epilepsy syndromes are limited. In a recent Cochrane review, Gayatri *et al.* [2] found only one randomized placebo-controlled trial [51], in which ACTH was administered according

to a double-blind cross-over design in five patients with multiple intractable seizure types and mental retardation or developmental delay. Results were not encouraging in that only three patients had a 25–50% reduction in seizure frequency, and none was seizure free.

Results from some uncontrolled studies have been more favourable. Snead *et al*. [40], in a study of 64 children with intractable seizures including infantile spasms without hypsarrhythmia, myoclonic seizures and different generalized or partial seizures, found that seizure control was achieved in 25 of 34 (73%) children treated with ACTH, but in none of 30 children treated with prednisone. Yamatogi *et al*. [52] treated, with ACTH, 45 patients with Lennox–Gastaut syndrome at doses ranging from 10 to 30 IU/day for a period of 10–57 days. Twenty-three (51%) patients became seizure free for over 10 days, but the majority (78%) later relapsed. In a report by Sinclair [53], 7 out of 10 children with Lennox–Gastaut syndrome who were treated with prednisolone at 1 mg/kg/day for 6 weeks achieved seizure freedom, and three children had a reduction in seizure frequency. EEG, behaviour and communication were also improved, but for how long the improvement was maintained is unclear.

Encouraging results have also been reported in the treatment of patients with Landau–Kleffner syndrome and electrical status epilepticus during slow-wave sleep (ESESS). In particular, Marescaux *et al*. [54] reported cessation of seizures, normalization of the EEG and improved speech with a prolonged 3-month treatment with hydrocortisone or prednisolone in three patients with Landau–Kleffner syndrome. Similar results have been reported in ESESS, but their significance is limited by lack of information on neuropsychological functions and on incidence of relapses during long-term follow-up [55].

Transient improvement in seizure control has been described in patients with Rasmussen's encephalitis treated with corticosteroids [56], but the course of Rasmussen's encephalitis is generally catastrophic and neurosurgery seems to provide the only effective treatment in this condition.

ACTH and corticosteroids do not appear to be efficacious in myoclonic epilepsies, particularly in severe myoclonic epilepsy of infancy (Dravet's syndrome).

Adverse effects

ACTH and corticosteroids may cause significant adverse effects, including hypertension, gastritis and peptic ulcer, irritability, headache, immunosuppression, infections, Cushing's syndrome, electrolyte disturbances (e.g. sodium and fluid retention, potassium and calcium loss, hypokalaemic alkalosis), increased intracranial pressure, increased intraocular pressure, pancreatitis, subcapsular cataracts, aseptic necrosis of femoral and humeral heads, myopathy, transient cerebral atrophy or 'cerebral shrinkage', and suppression of the hypothalamic–pituitary–adrenal axis.

Irritability is present in almost all patients, and 'cerebral shrinkage' is present in about two-thirds of patients [4]. More serious side-effects have been reported, predominantly with ACTH rather than with corticosteroids, and include potentially fatal sepsis, hypersensitivity reactions and myocardial hypertrophy. These complications seem to be more common in patients receiving high-dose ACTH therapy. There is no clear evidence of differences in adverse effects profiles between natural and synthetic ACTH. However, synthetic ACTH is considered to be less antigenic and, therefore, less likely to cause hypersensitivity reactions than the natural preparation.

Prolonged use of corticosteroids, especially when continued for several months, typically leads to immunosuppression, osteoporosis, growth retardation and endocrine dysfunction (e.g. menstrual irregularities, hirsutism, cushingoid state, glucose intolerance, decreased carbohydrate tolerance, increased requirement for insulin or oral hypoglycaemics in patients with diabetes, and secondary adrenocortical, pituitary unresponsiveness). Many of these effects are of special concern during development.

Current place in therapy

MacKay *et al*. [30] and Gupta and Appleton [57] have highlighted the paucity of randomized controlled trials on the use of ACTH and corticosteroids in the treatment of paediatric epilepsies. With respect to the management of infantile spasms, there is evidence that ACTH is effective in the short-term treatment of spasms and in suppressing hypsarrhythmia. In the authors' opinion, ACTH represents the first-line agent for the treatment of infantile spasms, except for spasms associated with tuberous sclerosis. Good results are to be expected within 2 weeks of treatment onset. However, conclusive data supporting the long-term efficacy of ACTH are still lacking in the literature, and there are also inadequate data on the optimal dosage and duration of therapy.

Most authors recommend low-dose synthetic ACTH for a short period, usually less than 6 weeks. In our practice, the treatment protocol for infantile spasms involves use of synthetic ACTH (Synachten Depot®) at a dosage of 2 IU/kg intramuscularly daily for a 14-day period, followed by the same dose every other day for a 14-day period, than every 3 days for a 15-day period. Ranitidine is always associated for gastric protection, and arterial blood pressure is checked before each ACTH injection.

Efficacy results obtained with corticosteroids in infantile spasms appear to be less impressive than with ACTH, but corticosteroids may have advantages in that they can be administered orally and they may have a lower incidence of adverse effects. Prednisone and prednisolone are the most frequently used steroids, at a dosage of 2 mg/kg/day.

The value of ACTH and steroids in other forms of epilepsy, especially late-onset epileptic encephalopathies, is less clearly defined. In these conditions, oral corticosteroids are preferred because they can be used for longer periods, even several months, which allows maintained efficacy over time if a good response is obtained initially. In addition to prednisone and prednisolone, hydrocortisone is frequently prescribed, at an initial dose of 7–8 mg/kg/day, which is gradually decreased afterwards. All patients exposed to long-term corticosteroid treatment should undergo clinical and laboratory assessments at regular intervals to minimize adverse effects related to immunodepression and endocrine dysfunction. Discontinuation of treatment should be done on a gradual basis in order to give the adrenal glands time

to return to their normal pattern of secretion and avoid withdrawal symptoms resulting from the suppression of the hypothalamic–pituitary–adrenal axis.

33 Benzodiazepines used Primarily for Chronic Treatment (Clobazam, Clonazepam, Clorazepate and Nitrazepam)

Peter Camfield and Carol Camfield

Department of Pediatrics, Dalhousie University, and the IWK Health Centre, Halifax, Nova Scotia, Canada

	Clobazam	Clonazepam	Clorazepate	Nitrazepam
Primary indication	First-line and, more often, second- or third-line therapy of partial and generalized seizures (including non-convulsive status epilepticus), as add-on or as monotherapy	*Oral treatment:* second- to third-line therapy of myoclonic seizures, but also other generalized seizures and partial seizures, as add-on or as monotherapy	Second- or third-line therapy of partial and generalized seizures, mostly as add on	Second- to third-line therapy of West syndrome and myoclonic seizures, but also other partial and generalized seizures, mostly as add on
		Intravenous use: second-line therapy for premonitory or early status epilepticus		
Usual preparations	Tablets: 10 mg	Tablets: 0.5 mg, 1 mg, 2 mg	Tablets: 3.75 mg, 7.5 mg, 15 mg	Tablets: 5 mg, 10 mg
	Capsules: 10 mg	Liquid formulation: 1 mg/mL, 2.5 mg/mL		Liquid formulation: 1 mg/mL
Usual dosage	20–40 mg/day in adults; 0.5 mg/kg/day in children	Oral: 0.5–4 mg/day in adults; 0.25–4 mg/day in children	15 mg/day (adults)	5–20 mg/day in adults. In children, treatment may be started at 0.25 mg/kg/day and gradually increased according to response without exceeding 1.5 mg/kg/day and, in any case, 20 mg/day
		Intravenous bolus: 1 mg in adults and 0.1 mg/kg in children, given over 1 min		
Dosing frequency	Once or twice daily	Once or twice daily	Once or twice daily	Once or twice daily
Significant drug interactions	Clobazam clearance is increased by enzyme-inducing agents. Occasionally, clobazam may increase the plasma levels of concomitant antiepileptic drugs	Clonazepam clearance is increased by enzyme-inducing agents	*N*-desmethyldiazepam clearance is increased by enzyme-inducing agents and decreased by cimetidine	Nitrazepam clearance is increased by enzyme-inducing agents
	Co-administration of CNS depressing agents may lead to reciprocal potentiation of adverse effects	Co-administration of CNS-depressing agents may lead to reciprocal potentiation of adverse effects	Co-administration of CNS-depressing agents may lead to reciprocal potentiation of adverse effects	Co-administration of CNS-depressing agents may lead to reciprocal potentiation of adverse effects

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

	Clobazam	Clonazepam	Clorazepate	Nitrazepam
Serum level monitoring	Not useful	Not useful	Not useful	Not useful

Active metabolites	*N*-desmethylclobazam	None	*N*-desmethyldiazepam	None
Comment	The most useful benzodiazepine for chronic treatment, due to broad-spectrum activity, relatively high response rates in refractory epilepsy, and relatively good tolerability. Valuable for short-term use in periods of seizure exacerbation. May be an option for initial monotherapy in selected patients. Tolerance and withdrawal seizures represent main drawbacks	Used mainly as a second- and third-line option for the long-term treatment of myoclonic seizures, particularly in children, but can be useful in many other seizure types. Use in serial seizures and status epilepticus has fallen gradually out of favour, having been largely superseded by midazolam, lorazepam and diazepam. Tolerance, withdrawal seizures and, in children, drooling represent significant drawbacks	It is the least well-documented benzodiazepine for use in epilepsy, and it is rarely prescribed today	It is used almost exclusively in children, as a third-line add-on treatment for West syndrome and some symptomatic generalized epilepsies. Tolerance, withdrawal seizures and, in children, drooling represent significant drawbacks

CNS, central nervous system.

[a] Clorazepate is rapidly and completely decarboxylated in the stomach to *N*-desmethyldiazepam and therefore reported pharmacokinetic parameters refer to *N*-desmethyldiazepam.

Introduction

Benzodiazepines were initially developed for the treatment of anxiety, with chlordiazepoxide first marketed in about 1960. By 1965, diazepam was demonstrated to be efficacious in the treatment of status epilepticus. Chronic use of benzodiazepines in epilepsy was introduced in the early 1970s, when clonazepam, clorazepate and nitrazepam became available. Somnolence and behavioural changes were commonly associated with these benzodiazepines. Clobazam, introduced in the late 1970s, seemed to have less sedative effects than other benzodiazepines, and in 1978 Gastaut first reported its value in epilepsy treatment [1].

The benzodiazepines discussed in this chapter (clobazam, clonazepam, clorazepate and nitrazepam) are all used for the daily, chronic treatment of epilepsy in children and adults. Benzodiazepines used for emergency treatment are discussed in Chapter 34.

Clobazam is not yet licensed for the treatment of epilepsy in the USA, but is used widely in most of the rest of the world, especially in Canada [2–3]. Clonazepam is the benzodiazepine most commonly used in epilepsy treatment in many countries, while nitrazepam is used less often. Clorazepate is the least well-documented benzodiazepine for use in epilepsy and probably it is the least frequently prescribed.

Significant behavioural adverse effects have legitimately limited the use of these medications in the current treatment of epilepsy. Concerns about tolerance have been widely communicated, although this issue has not been adequately defined in studies conducted to date. In general, benzodiazepines have been relegated to second-line agents, with the possible exception of clobazam. However, they are very potent medications and may offer remarkable relief in a variety of syndromes and in most seizure types.

There are no randomized clinical trials that have compared clobazam, clonazepam, clorazepate and nitrazepam. Therefore, comments about the utility of one over the other are not evidence based and spring from clinical impression and case series.

Chemistry

All benzodiazepines are made up by the combination of a benzene ring with a diazepine ring with the nitrogen in the heterocyclic ring in the 1–4 position for clonazepam, clorazepate and nitrazepam, while clobazam has a 1–5 ring structure [4].

Clobazam (8-chloro-5-methyl-1-phenyl-1,5-benzodiazepine-2,4-dione; $C_{16}H_{13}ClN_2O_2$) is a crystalline powder with a molecular weight of 301, relatively insoluble in water; clonazepam [5-(2-chlorophenyl)-1,3-dihydro-7-nitro-1,4-benzodiazepin-2-one;$C_{15}H_{10}ClN_3O_3$] is a light-yellow crystalline powder with a molecular weight of 315.7; clorazepate (7-chloro-2-oxo-5-phenyl-1,3-dihydro-1,4-benzodiazepine-3-carboxylic acid; $C_{16}H_{11}ClN_2O_3$) is an off-white to pale yellow crystalline powder with a molecular weight of 408.9, relatively soluble in water (100–200 mg/mL); and nitrazepam (7-nitro-5-phenyl-1,3-dihydro-1,4-benzodiazepin-2-one; $C_{15}H_{11}N_3O_3$) is a yellow crystalline powder with a molecular weight of 281.3, insoluble in water. Figure 33.1 shows the specific chemical structure of each drug.

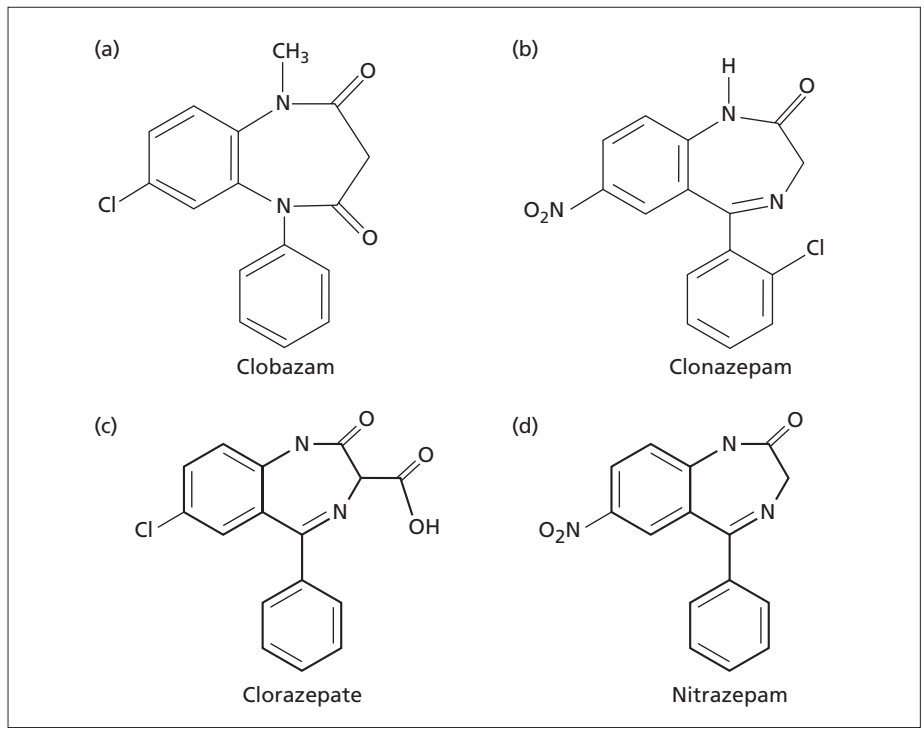

Fig. 33.1 Structures of the major compounds presented in this chapter.

Mechanism of action

All benzodiazepines are thought to exert their primary effects by binding to specific modulatory sites (the so-called benzodiazepine receptors) at the γ-aminobutyric acid (GABA) type A receptor–chloride channel complex [5]. They appear to increase the effect of GABA at the $GABA_A$ receptor by increasing the affinity of GABA for the receptor and by potentiating the response triggered by GABA binding to the receptor. This results in greater chloride influx mediated by an increased frequency of chloride channel openings, rather than by changes in channel opening time. Benzodiazepines bind at a different site from GABA – so their effect is to enhance the effects of GABA.

The $GABA_A$ receptor complex includes multiple subunits made up from 19 polypeptides in various combinations. Different subunit combinations have been further characterized. For example, the α-1-containing benzodiazepine receptor site may mediate the anxiolytic effect, the α-2 the sedation effect, the α-3 muscle relaxation and α-5 the cognitive effects [6]. The differing effects of various benzodiazepines may be related to differential binding to these subunits.

Pharmacokinetics

The main pharmacokinetic parameters of clobazam, clonazepam, clorazepate and nitrazepam are summarized in the table at the beginning of this chapter.

Absorption

Benzodiazepines are readily absorbed from the gastrointestinal tract, peak serum concentrations usually being attained in less than 4 h after a single oral dose. In the case of clorazepate, absorption is preceded by rapid decarboxylation in the acidic medium of the stomach to the active product *N*-desmethyldiazepam, for which clorazepate can be considered a prodrug. The oral bioavailability of clobazam, clonazepam, clorazepate (expressed in terms of *N*-desmethydiazepam equivalents) and nitrazepam is almost complete.

Distribution

Most benzodiazepines, including clobazam and its active *N*-desmethyl metabolite, clonazepam, clorazepate-derived *N*-desmethyldiazepam and nitrazepam, are extensively bound to plasma proteins. All these compounds are lipophilic and readily cross the blood–brain barrier, resulting in a rapid onset of action. Apparent volumes of distribution are in excess of 1 L/kg, indicating extensive penetration into tissues.

Elimination

Benzodiazepines are eliminated almost entirely by metabolism. Clobazam is cleared by *N*-demethylation and hydroxylation, clonazepam by nitroreduction, acetylation and hydroxylation, *N*-desmethyldiazepam (derived from clorazepate) by glucuronidation and hydroxylation, and nitrazepam by nitroreduction, acetylation and hydroxylation. Clobazam is converted to the active metabolite *N*-desmethylclobazam, whereas clorazepate is a prodrug for *N*-desmethyldiazepam. Elimination half-lives in non-induced healthy adults are in the order of 10–50 h for clobazam (35–45 h for *N*-desmethylclobazam), 17–55 h for clonazepam, 40–130 h for *N*-desmethyldiazepam and 20–40 h for nitrazepam. Studies in elderly patients have demonstrated that in old age the clearance of clobazam and *N*-desmethyldiazepam is decreased and half-life is increased, much more so in men than in women.

Drug interactions

The clearance of clobazam, clonazepam, *N*-desmethyldiazepam and nitrazepam is increased by concomitant treatment with enzyme-inducing agents. In the case of clobazam, this effect is associated with increased plasma levels of the active *N*-desmethyl metabolite.

Benzodiazepines generally have no major effects on the pharmacokinetics of concurrently administered drugs [7]. However, a few reports have suggested that in occasional patients clobazam may increase the plasma concentration of phenytoin, carbamazepine, carbamazepine-10,11-epoxide and valproic acid. Reports also suggest that, in rare cases, co-administration of benzodiazepines with valproic acid may result in reciprocal potentiation of their effects, and sometimes in encephalopathic symptoms. A pharmacodynamic interaction resulting in reciprocal potentiation of adverse effects may occur when benzodiazepines are co-administered with alcohol or other central nervous system (CNS) depressants.

Serum level monitoring

There is a large variation in the serum concentrations of benzodiazepines at which therapeutic and toxic effects occur. In general, dose adjustments are guided by observation of clinical response and measuring serum drug levels is of little or no value in the individualization of therapy.

Efficacy

The paucity of randomized clinical trials with benzodiazepines makes their role in chronic epilepsy treatment uncertain. Most studies have examined their use as an 'add-on' medication and not as initial therapy.

Clobazam

Clobazam has been reasonably well demonstrated to have efficacy against many seizure types as an add-on drug in children and adults [8]. In addition, in children it can be considered for first-line monotherapy [8].

In a large open-label, retrospective Canadian study, clobazam was reported to be efficacious against all seizure types in 877 patients, 51% of whom were children [9]. There were excellent responses in partial, secondary generalized, absence, akinetic and myoclonic seizures. All patients had failed one or more antiepileptic drugs (AEDs) before the introduction of clobazam, and based on survival analysis it appeared that 40% continued to receive clobazam 4 years later. This may reflect excellent efficacy,

or physicians' inertia in making therapeutic adjustments. A variety of smaller open-label studies in adults and children have reached similar conclusions.

Double-blind studies have shown definite efficacy for clobazam in partial seizures in children and adults as an add-on treatment [10,11]. The value of clobazam in refractory epilepsy has been examined in four blinded cross-over trials with a total of 196 patients, both children and adults. A recent Cochrane review concluded that 'clobazam as an add-on treatment may reduce seizure frequency and may be most effective in partial-onset seizures. However, it is not clear who will best benefit and over what time-frame' [12]. The largest of the clobazam double-blind cross-over trials involved 129 adults, mainly with resistant partial-onset seizures, and involved 12 weeks on active medication and 12 weeks on placebo [10]. The average dose of clobazam was estimated to be about 0.17–0.67 mg/kg/day. Overall, the number of seizures was significantly reduced with clobazam and 19 (15%) patients achieved seizure freedom compared with no seizure-free patients on placebo.

Clobazam has been studied as monotherapy in a Canadian study in 235 children with recent-onset partial, secondary generalized and generalized tonic–clonic seizures [8]. This study used a double-blind, double-dummy placebo design and compared clobazam ($n = 119$) with carbamazepine ($n = 78$) and phenytoin ($n = 38$) in children with newly treated epilepsy ($n = 115$) or after the failure of a first AED ($n = 120$). When the patient entered the study, the initial dose escalation was by protocol over 1–3 weeks to achieve clobazam 0.5 mg/kg/day, carbamazepine 10 mg/kg/day and phenytoin 5 mg/kg/day. Thereafter, physicians could adjust the dose as dictated by the clinical situation, including serum drug levels, but the double-dummy technique maintained the blind throughout the study. Analysis was by intention to treat and the primary endpoint was retention on the initial drug for 12 months, a measure that balances efficacy with side-effects and mimics clinical practice. Compliance was excellent and 92% of patients received ≥95% of their doses. Overall, 56% were retained on their initial drug and there was no statistical difference between clobazam and the other two medications. The rate of adverse effects leading to discontinuation of the study drug was the same for all three drugs, and seizure control was virtually identical. As noted below, 'tolerance' was no more frequent with clobazam than with the other two AEDs. Therefore, at least in children, monotherapy with clobazam has good efficacy in newly treated patients or those who have failed a first AED.

Clobazam has been studied in several special circumstances. An open-label, randomized trial compared clobazam with phenytoin in 48 patients with seizures from cysticercus granulomas [13]. Outcome was assessed after 6 months and clobazam, at a dose of 0.5 mg/kg/day, was more effective than phenytoin ($P = 0.03$).

In febrile seizures, a carefully orchestrated, double-blind trial compared intermittent clobazam administered for 48 h at the time of illness (≤5 kg body weight: 5 mg/day; 6–10 kg: 5 mg twice daily; 11–15 kg: 7.5 mg twice daily; >15 kg: 10 mg twice daily) in 19 patients with placebo in 20 patients. Recurrent febrile seizures occurred in 12.5% of subsequent febrile illnesses with placebo but in only 1.7% with clobazam ($P = 0.01$). There are many pitfalls in the intermittent treatment for febrile seizures, but if such an approach is taken, clobazam may be a reasonable option because it seems to be fairly well tolerated and not particularly sedating at a dose of about 0.5 mg/kg/day [14].

Clobazam has a quick effect on seizure control which has led to its use in catamenial epilepsy [15]. A double-blind study compared 20–30 mg of clobazam/day versus placebo in 18 women with catamenial epilepsy. The treatments were administered for the 10 days that overlapped their menses, and in 14 women clobazam was superior to placebo, usually suppressing all seizures. It has also been suggested that clobazam can provide short-term additional therapeutic cover during periods of increased seizure frequency or when patients are considered at special risk for seizure exacerbation, for example during a switch from one AED to another or for overnight travel [16,17].

Oral clobazam has also been reported to be effective in non-convulsive status in several open-label, clinical case series. In one study, 16 patients (six with absence status, one with myoclonic absence status, one with tonic status and seven with simple or partial complex partial status) were given clobazam as a single oral dose of 0.5–1.7 mg/kg with apparent complete success within 25 minutes in 15 of 16 [18]. Another study involved four adult patients with complex partial status whose seizures had failed to respond to intravenous phenytoin plus lorazepam, diazepam or midazolam [19]. Clobazam was given as a single oral dose of 60 or 70 mg, with prompt cessation of seizures with electroencephalogram (EEG) documentation.

Clonazepam

There is no doubt that clonazepam has significant efficacy for most seizure types and epilepsy syndromes although currently it is used infrequently as initial therapy because there are alternatives with fewer adverse effects [20]. Clonazepam was introduced for the treatment of epilepsy when rigorous, randomized, double-blind trials were not always required for drug registration and there are no randomized studies with a large enough sample size to indicate if clonazepam is equivalent to, or superior to, any other drug.

There is, however, a strong perception that clonazepam is particularly effective for myoclonic seizures in patients with cryptogenic and symptomatic generalized epilepsy syndromes, including progressive myoclonic epilepsies [21,22]. Based on open-label studies or small randomized trials, there is evidence that clonazepam is effective in other generalized seizure types including absence, atonic/akinetic seizures and tonic seizures [23,24]. In support of its value in absence, Browne [23] noted at least 34 published clinical series, all of which describe a 'favorable response'. Open-label, uncontrolled studies have also suggested that clonazepam may be effective in West syndrome and progressive myoclonic epilepsies [21,25]. Cryptogenic and symptomatic generalized epilepsy syndromes are typically characterized by multiple generalized seizure types. In 1975, Carson and Gilden [26] described their experience with 52 such children followed for a mean of 15 months. Clonazepam was added to their drug regime and 27% had complete seizure control while 61% had >50% reduction in seizures. Only 10% had no improvement [26].

Clonazepam also has efficacy in partial seizures in adults [27]. Several small randomized add-on studies for refractory patients and open-label studies have suggested substantial efficacy in temporal lobe epilepsy and simple partial seizures [23,24]. A

randomized trial of 36 adults with newly treated complex partial seizures suggested that monotherapy with clonazepam was equally as effective as carbamazepine at conventional doses, although this trial was clearly underpowered to prove equivalency [28].

Intravenous clonazepam is available for the treatment of status epilepticus in many countries but not in the USA. Clonazepam is thought to have a longer duration of action (~24 h) than diazepam (~2 h) but a shorter duration of action than lorazepam (up to 72 h); however, no randomized trials in status epilepticus have compared clonazepam with other benzodiazepines or any other medications. In small open-label trials, clonazepam appears to be effective in convulsive status epilepticus, absence status and partial status [23]. In the earliest study, Gastaut successfully treated eight children and 28 adults with status epilepticus with a 'slow' intravenous infusion of clonazepam (slow was not defined) [29]. One additional adult did not respond. Twenty-five patients were successfully treated with 1 mg, but others received up to 8 mg. The response was often within a minute of infusion [29]. In the next published study there were 17 episodes of status in 17 children treated with 0.01–0.09 mg/kg clonazepam as an intravenous bolus [30]. There was an initial complete cessation of seizures in all; however, in six, the seizures recurred from ~1 h to 24 h later. There were no 'serious side effects' other than drowsiness. In an additional study, intravenous clonazepam was successful in 7 of 7 patients with absence status, 7 of 14 with convulsive status and 2 of 3 with partial complex status [31].

Based on these and other studies it appears that, if clonazepam is used for status epilepticus, an initial bolus dose of 0.1 mg/kg is appropriate for children and an initial bolus dose of 1.0 mg is appropriate for adults.

Clorazepate

Clorazepate has mostly been reported as effective in short-term experiences in patients with refractory epilepsy. Its use in specific epilepsy syndromes has not been clearly assessed, as clorazepate was introduced in an era when syndromes were not clearly delineated. There is only one published double-blind, cross-over trial in adults that compared clorazepate with phenobarbital in 42 patients who were simultaneously treated with phenytoin [32]. All patients had partial seizures with or without secondary generalization. The analysis was not by intention to treat and there were a substantial number of drop-outs. There was little difference in the rate of seizure control, although physicians suggested that the clorazepate–phenytoin combination was superior based on a judgement that combined seizure control with tolerability.

All studies of chlorazepate in children have been open-label, small (<20 subjects) and without blinded or objective outcomes. The drug appears to have some effect on akinetic, absence, myoclonus and generalized tonic–clonic seizures [33,34].

Nitrazepam

There are fewer publications about nitrazepam than about clonazepam and clobazam. Most of the studies have focused on patients with severe, AED-resistant cryptogenic and symptomatic generalized epilepsies. Nitrazepam has been described as effective for myoclonic, atonic and atypical absence seizures and seems to have a significant effect in West syndrome [3]. One complex and not completely definitive trial randomized 52 children with infantile spasms to nitrazepam or adrenocorticotropic hormone (ACTH) for a 4-week course [35]. Most patients had failed previous treatments for West syndrome; however, both drugs appeared to be equally efficacious in terms of per cent reduction of spasms compared with baseline (75% had >50% reduction). Few patients became seizure free and ACTH appeared to have more serious adverse effects.

In a series of small open-label, retrospective trials, nitrazepam seemed to be effective in a variety of childhood-onset epilepsy syndromes, including Lennox–Gastaut syndrome [36,37]. One study reported 12 children with drug-resistant Lennox–Gastaut syndrome who were treated with a median dose of nitrazepam 1.5 mg/kg/day for 13–30 months. The response was modest: two became seizure free for 1.5–2 years, five had >50% reduction in seizure frequency and six had >25% reduction [37].

Tolerance

Tolerance has been noted with all benzodiazepines, with most of the relevant literature in animal studies [38,39]. The concept of tolerance is that after seizure control has been achieved with a given dose of a medication, re-emergence of seizures may occur gradually over time, and seizure frequency may eventually return to the original level. A dose increase may lead again to seizure control, again followed by a return of seizures. There are remarkably few clinical studies that demonstrate the true incidence and significance of this problem and even fewer that compare tolerance with a given benzodiazepine and any other AED. In most studies, tolerance is not clearly defined and there is no consensus about a quantitative definition. How long does the patient need to be seizure free before tolerance can occur, and at what dose? If a patient becomes only partially seizure free, can tolerance develop? If seizures are controlled with an increased dose, does this equate to tolerance? The large Canadian retrospective study of refractory epilepsy patients suggested that 9% of patients discontinued clobazam because of tolerance. The definition of tolerance was left to the discretion of the treating physician [9].

In a randomized, double-blind study of clobazam versus carbamazepine versus phenytoin in children with recently diagnosed epilepsy, we suggested that tolerance occurred when a child was seizure free for 3–6 months and then had sufficient seizures that the medication was considered a failure [9]. In this study, tolerance developed in 7.5% of patients receiving clobazam, 4.2% receiving carbamazepine and 6.7% receiving phenytoin (P = no significance). Of all patients randomized to clobazam, 23% were seizure free for the entire year of the study, which is identical to the 25% randomized to carbamazepine but superior to the 11% on phenytoin. As the study duration was 1 year for each patient, tolerance developing later in the clinical course could not be assessed.

Studies of adults with resistant temporal lobe epilepsy have not been so optimistic. When clobazam was added to their regime, a large percentage had a greatly improved seizure control, but then many lost this control over the next few weeks or

months [40,41]. Schmidt suggested that in adults with refractory partial seizures treated with clobazam, 40% had at least a 75% reduction in seizures [11,42]. This was based on a double-blind add-on study of only 20 patients with refractory complex partial seizures who were treated for 3 months. Tolerance was suggested in 56%.

What may separate benzodiazepines from other AEDs in refractory patients is the relatively high rate of initial response. The long-term response rate appears to be equivalent to, or better than, that associated with most other medications used in patients who already failed several other AEDs. The study of Singh *et al*. [40] illustrates this. Clobazam was introduced in 173 adults with uncontrolled epilepsy and 50 (29%) had a good response (>75% reduction in seizure frequency) for at least a month. Over the next 3 years (average follow-up), 25 (14%) retained their good response while 25 (14%) developed 'tolerance' in the sense that seizure frequency increased back to no better than 50% of their baseline pre-clobazam state. Tolerance developed after a mean interval of 8.9 ± 7.9 months but it is of interest that 56% of those with tolerance continued with the drug, suggesting that there was some benefit but just not as much as the initial response. Another way of looking at these data is that 50% of responders maintained their response for 3 years or longer.

Adverse effects

Benzodiazepines have significant adverse effects and careful clinical monitoring is important, particularly shortly after starting a new medication. Much of the literature about the adverse effects of benzodiazepines comes from studies of patients who received the drugs for non-epilepsy indications such as anxiety disorders, and few of the observations in patients with epilepsy are based on blinded trials. There are few randomized trials that have compared one benzodiazepine with another, or a given benzodiazepine with other medications.

To varying degrees, all benzodiazepine drugs may cause sedation, cognitive dysfunction, unsteady gait and behavioural/personality changes. The authoritative review of clonazepam by Browne [23] suggested that drowsiness was noted in 3–85% of treated patients and ataxia in 4–79%. These astonishingly wide estimates may be the result of varying rates of dose escalation, total daily dose and methodology used to assess adverse effects. Many authors have noted that somnolence and ataxia are noted most often early in the treatment and tend to be less of a problem over time. It has been very challenging to separate the effects of sedation from effects on cognition.

Particularly in children, there may be 'paradoxical' hyperactivity, irritability or aggression. Again, Brown [23] notes a wide range in frequency – from 2% to 52%! The severity of this problem ranges from mild to catastrophic. Disinhibition problems may be less problematic in adults. In a retrospective review of 323 adult patients hospitalized with psychiatric disorders, externalizing behaviour problems such as aggression or need for restraints were no more common with or without benzodiazepine use [43]. Particular concern has been expressed about recognition of behavioural side-effects in people with mental handicap, because epilepsy in this population is often complex with multiple seizure types for which benzodiazepines are a logical choice [44].

In adults, depression has been noted in about 10% of patients starting clonazepam [45]. The symptoms of depression are typically noted as soon as the drug is introduced and may resolve with dose reduction.

Sexual dysfunction in adults has been noted in a few patients, including anorgasmia, ejaculatory inhibition, decreased libido and difficulty achieving orgasm or maintaining erections [45]. It is unclear how often these effects are an issue.

When elderly people are prescribed benzodiazepines for anxiety or sleep problems, there is a doubling of the risk of 'injurious falls' and fractures [46]. It is not clear if all benzodiazepines are associated with the same level of risk.

A special concern in children and in people with significant bulbar problems is an exacerbation of swallowing problems with increased drooling and aspiration pneumonia. These issues are particularly prominent with nitrazepam and clonazepam [23,47].

Withdrawal of benzodiazepines in people with epilepsy may lead to benzodiazepine withdrawal symptoms and increased seizures. Benzodiazepine withdrawal symptoms, apart from seizures, most often include insomnia, agitation and confusion [48]. These symptoms have a sudden onset if the drug withdrawal is abrupt and can typically be avoided by slowly tapering the medication. The definition of 'slow' is unclear but probably is many weeks. Chronic use of benzodiazepines is also associated with a risk of withdrawal seizures (including status epilepticus) following dose reduction or discontinuation, particularly when a fast discontinuation rate is used and even in patients in whom the medications did not seem to have an effect on seizure frequency. No randomized trials have addressed this clinical observation. Several small studies suggest that about 30% of children who have been treated with clonazepam will have exacerbations of their seizures when the drug is withdrawn [49,50]. There is no clearly safe rate of discontinuation to avoid this problem, even with rates as slow as 0.04 mg/kg/week [50].

Benzodiazepines do not appear to be significant teratogens [51]. High-dose benzodiazepine use in pregnancy has typically been associated with the use of other medications or alcohol abuse, which makes the study of benzodiazepine-induced fetal anomalies difficult. At modest doses, benzodiazepines are not associated with an increased risk of malformations. There may be withdrawal symptoms in the infant but benzodiazepines do not appear to have pervasive effects on the long-term behavioural or cognitive outcome of children exposed prenatally. All of the benzodiazepines used in the treatment of epilepsy are excreted into breast milk; however, the levels are low and breastfeeding is not contraindicated.

Clobazam

Clobazam appears to be the best tolerated of the four drugs [1]. In the paediatric Canadian double-blind trial, clobazam showed marginal increases over carbamazepine and phenytoin in the frequency of externalizing behaviour problems [8] based on a symptom checklist administered at each follow-up visit. There was no difference in cognitive effects over a year of treatment

based on an extensive battery of neuropsychological tests [52]. Overall, potential side-effects such as somnolence or ataxia were equal between the three drugs.

Clonazepam

Personality and behavioural changes in children treated with clonazepam have been especially prominent. The frequency of these manifestations is not easily judged and in open-label studies has varied tremendously, from 2% to 50% [23]. Children have been described as 'difficult', hyperactive, aggressive, irritable or violent. For some patients, these behavioural reactions seem dose related, and there is some evidence for tolerance developing over time; however, for many children, these effects are apparent at small doses and clinically unacceptable.

Drowsiness seems to occur in about 30% of adults and ataxia occurs to a similar degree [23]. These symptoms have been observed to be most prominent in the first few days or weeks of treatment and may improve with dose reduction and the passage of time. There is no randomized study that establishes this clinical observation. Overall, it has been suggested that about 20% of patients have intolerable adverse effects requiring discontinuation of the drug [23].

Intravenous clonazepam has the potential to induce respiratory failure, similar to diazepam. The frequency of this effect is unclear from the published literature but it appears to be rare. It is almost certainly related to the dose and rapidity of infusion, but neither is clearly defined. As mentioned above, an initial bolus of 0.01 mg/kg for children or 1 mg for adults appears safe [29–31].

Clorazepate

Since clorazepate is rapidly converted to desmethyldiazepam, it is not surprising that somnolence has been reported frequently [53]. There is only a single, published, randomized trial that has compared clorazepate with phenobarbital in adults with resistant epilepsy [32]. Clorazepate had somewhat less 'toxicity' based on a non-standardized scoring system that included a variety of symptoms ranging from sleepiness to 'grossly impaired coordination'.

Nitrazepam

Nitrazepam has been associated with a high rate of bulbar dysfunction manifested by drooling, coughing, gagging and difficulty swallowing. Increased drooling is often blamed on increased secretions; however, the mechanism of this problem has been clearly shown to be swallowing discoordination [47]. At higher doses of nitrazepam, there have been several documented deaths in children with pre-existing swallowing problems, which has led to a recommendation not to exceed a daily dose of 1 mg/kg/day [54].

Place in current therapy

It is challenging to define the optimal role for benzodiazepines in the current treatment of epilepsy. In our opinion clobazam is the "star" of the group with many possible indications. Clonazepam remains a useful second-line medication. Nitrazepam has a limited role for special patients only, and clorazepate has no clear indications.

In childhood, clobazam monotherapy can be used as first-line treatment for nearly all epilepsy syndromes, with a few important exceptions. Without any supporting data, we prefer valproic acid as a first-choice AED for all idiopathic generalized epilepsies except for benign myoclonic epilepsy of infancy, where clobazam is a better tolerated first choice. Among cryptogenic and symptomatic generalized epilepsies, ACTH and vigabatrin are better choices for West syndrome, and valproic acid remains our first choice for myoclonic astatic epilepsy.

The paediatric syndromes for which we routinely use clobazam as initial monotherapy are benign myoclonic epilepsy of infancy, most unspecified cryptogenic and symptomatic generalized epilepsies, and idiopathic, symptomatic and cryptogenic partial epilepsies. The reasons to choose clobazam are its excellent, rapid efficacy and virtually no risk of serious adverse effects. We select patients with normal behaviour and tend to use other medications when there are pre-existing externalizing behaviour problems, for fear that these will be exacerbated by clobazam. Another indication for clobazam is as initial treatment immediately after the diagnosis of epilepsy, until the work-up is completed. We start with a dose of about 0.25 mg/kg/day and increase over a few weeks to 0.5 mg/kg/day. If seizure control is unsatisfactory we increase the dose up to about 1.5 mg/kg/day but do not usually go beyond this dose – our experience includes few responders at higher doses.

When a drug other than clobazam has failed in children, then clobazam can be considered for nearly all syndromes as an add-on. It can also be used as a very helpful 'bridge' when the up-titration of another drug is very slow, for example with lamotrigine.

In adults, clobazam as initial monotherapy has not been well studied and we suggest that it is considered as a second or third alternative. Because it has nearly no drug interactions, it can be added to any AED, with the option of withdrawing the pre-existing medication slowly. All types of adult-onset epilepsy may respond to clobazam.

Clonazepam is a less successful benzodiazepine than clobazam because of its adverse effects, including behavioural problems, somnolence and ataxia. It should be considered strongly for adults and children when myoclonus or other generalized seizures have failed to respond to other first-line medications. Even though clonazepam has efficacy against partial seizures, we rarely use it for this group of patients because there is a wealth of alternatives with fewer adverse effects. We introduce clonazepam very slowly, starting with approximately 0.025 mg/kg/day and gradually increase the dose to the range of 0.1 mg/kg/day.

For status epilepticus, we use lorazepam, diazepam or midazolam because intravenous clonazepam is not readily available in our country. We are aware of a number of centres in Europe that preferentially use intravenous clonazepam for status, apparently with good effect.

Nitrazepam is a powerful medication, in terms of both efficacy and adverse effects. Somnolence, drooling and swallowing problems limit its use, although in our experience it has sometimes been remarkably effective. Patients with resistant West syndrome or other cryptogenic or symptomatic generalized epilepsies are

good candidates for nitrazepam when several other medications have failed. We rarely use nitrazepam in patients with swallowing difficulties. There is little experience with nitrazepam in adults to guide its use.

Finally, there is an interesting issue when a first benzodiazepine has failed – is there any value in attempting treatment with an alternative? When clonazepam or nitrazepam has failed because of adverse effects, we will often substitute clobazam. If clobazam fails for reasons of efficacy and there are few other medication alternatives, we may attempt treatment with clonazepam or nitrazepam, occasionally with gratifying results.

Benzodiazepines should continue to be used for the treatment of epilepsy in children and adults, but the importance of careful clinical monitoring for adverse effects should be emphasized.

34 Benzodiazepines used Primarily for Emergency Treatment (Diazepam, Lorazepam and Midazolam)

Eugen Trinka
University Hospital Innsbruck, Innsbruck, Austria

	Diazepam	Lorazepam	Midazolam
Primary indication	*Adults and children:* premonitory and early status epilepticus, serial seizures, acute symptomatic seizures	*Adults and children:* premonitory and early status epilepticus (preferred drug in stage 1 of status epilepticus), serial seizures, acute symptomatic seizures	*Adults, continuous infusion:* refractory status epilepticus *Children, buccal, or intranasal route:* premonitory and early status epilepticus, serial seizures, acute symptomatic seizures
Usual preparations	Vials: 5 mg/mL, 10 mg/mL Rectal gel: 2.5 mg, 5 mg, 10 mg, 15 mg, 20 mg Rectal tubes: 5 mg, 10 mg Capsules: 2 mg, 5 mg Tablets: 2 mg, 5 mg, 10 mg Oral drops: 5 mg/mL	Vials: 2 mg/mL, 4 mg/mL Tablets: 0.5 mg, 1 mg, 2 mg, 2.5 mg Oral drops: 1 mg/mL	Vials: 1 mg/mL, 5 mg/mL Tablets: 7.5 mg, 15 mg
Usual dosage	Intravenous bolus: 10–20 mg (adults); 0.2–0.3 mg/kg (children), usual injection rate 2–5 mg/min (adults and children), strictly intravenously Rectal: 20–30 mg (adults); 0.5–0.75 mg/kg (children) Intramuscular, intranasal: not recommended	Intravenous bolus: 4–8 mg (adults); 0.1 mg/kg (children), strictly intravenously, usual injection rate 2 mg/min (adults and children)	Intravenous infusion: 0.1–0.3 mg/kg bolus at 4 mg/min (adults and children), followed by infusion at 0.05–0.4 mg/kg/h (adults) Paediatric initial infusion rates are 0.03 mg/kg/h in newborns of gestational age <32 weeks; 0.06 mg/kg/h in newborns of gestational age >32 weeks and in infants <6 months; and 0.05–0.12 mg/kg/h in children >6 months. These rates may be increased according to response Higher infusion rates have been used (and may be required), both in adults and in paediatric patients Intranasal or buccal: 5–10 mg (adults); 0.15–0.3 mg/kg (children)
Significant drug interactions	Diazepam clearance is increased by enzyme inducers and decreased by inhibitors of CYP3A4 (e.g. cimetidine, erythromycin, itraconazole) and CYP2C19 (e.g. fluvoxamine, omeprazole). Diazepam and other central nervous system depressants may potentiate reciprocally their actions when administered together	Lorazepam clearance is increased by enzyme inducers and decreased by valproic acid. Lorazepam and other CNS depressants may potentiate reciprocally their actions when administered together	Midazolam clearance is increased by enzyme inducers and decreased by CYP3A4 inhibitors such as erythromycin, clarithromycin, ketoconazole, diltiazem, verapamil or cimetidine. Midazolam and other CNS depressants may potentiate reciprocally their actions when administered together

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

	Diazepam	Lorazepam	Midazolam
Serum level monitoring	Not useful	Not useful	Not useful
Target range	Not applicable	Not applicable	Not applicable
Common/important adverse effects	Sedation, respiratory depression, hypotension, injection site reactions	Sedation, respiratory depression, hypotension, injection site reactions	Sedation, respiratory depression, hypotension
Main advantages	Rapid onset of action with the intravenous route Rectal formulation available Long-standing clinical experience in adults and children Widespread availability	Rapid onset of action by the intravenous route Long-lasting effect (>24 h) after a single injection Proven efficacy in randomized controlled trials in generalized tonic–clonic status epilepticus Long-standing clinical experience in adults and children	Water solubility permits alternative routes in the emergency treatment of seizures. Buccal and intranasal routes have proven efficacy in randomized controlled trials in children with acute seizures Rapid onset of action with all routes Intranasal and buccal routes easy and socially well accepted Lack of reactions at the infusion site Little risk of accumulation
Main disadvantages	Short duration of action due to rapid redistribution Accumulation after repeated doses and infusion, with the risk of prolonged sedation and respiratory depression Adverse effects from the polypropylene solvent	Rapid development of tolerance Adverse effects from the polypropylene solvent	Short duration of action with risk of seizure relapse
Mechanism of action	Potentiation of $GABA_A$ receptor-mediated inhibition	Potentiation of $GABA_A$ receptor-mediated inhibition	Potentiation of $GABA_A$ receptor-mediated inhibition
Bioavailability	Oral: 100 ± 14% Rectal: 80–100%	Oral: 93 ± 10%	Oral: 44 ± 17% Intramuscular: 91% Intranasal: 83 ± 19% Buccal: 74.5%
Time to peak levels after single dose	Intravenous: 3–15 min, injection rate 2–5 mg/min Rectal: 3–30 min	Intravenous: 1–5 min; injection rate 2 mg/min	Intravenous: 1–5 min; injection rate 1 mg/kg/min Intramuscular: 20–30 min Intranasal: 10–15 min Buccal: 15–90 min
Main routes of elimination	Oxidative demethylation	Glucuronidation	Oxidation
Volume of distribution	1.1 ± 0.3 L/kg	1.3 ± 0.2 L/kg	1.1 ± 0.6 L/kg
Elimination half-life	43 ± 13 h	14 ± 5 h	1.9 ± 0.6 h
Plasma clearance	0.38 ± 0.06 mL/h/kg	1.1 ± 0.4 mL/h/kg	6.6 ± 1.8 mL/h/kg
Protein binding	About 99%	About 91%	About 98%
Active metabolites	*N*-desmethyldiazepam, oxazepam	None	α-Hydroxy-midazolam
Comment	Useful alternative to lorazepam for intravenous treatment of premonitory and early status epilepticus, serial seizures and acute symptomatic seizures. Rectal diazepam administration is becoming less commonly used, because buccal and, to a lesser extent, intranasal midazolam provide a more socially acceptable alternative	Lorazepam is the preferred agent for the intravenous treatment of premonitory and early status epilepticus, serial seizures and acute symptomatic seizures	The usefulness of intravenous midazolam is mainly as a continuous infusion in the management of refractory status. The buccal and, to a lesser extent, the intranasal routes are increasingly used for pre-hospital emergency management by non-medical personnel

Introduction

Henry Gastaut was the first to describe, in 1965, the use of intravenous (i.v.) diazepam for the treatment of status epilepticus (SE) [1]. Benzodiazepines continue to be widely used in the management of acute seizure emergencies, such as serial seizures and early and established status epilepticus [2,3].

The treatment of status epilepticus is discussed in detail in Chapter 18. This chapter will review the basic pharmacology and pharmacokinetics, as well as the therapeutic and adverse effects of i.v. diazepam, lorazepam and midazolam. Alternative routes of administration for emergency uses of these drugs are also reviewed.

Chemistry

Diazepam

Diazepam (Fig. 34.1a) corresponds to 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2H-1,4-benzo-diazepin-2-one. Its chemical formula is $C_{16}H_{13}ClN_2O$, its molecular weight is 284.8 and its pK_a is 3.4 (3.2–3.7).

Diazepam is highly lipophilic but water insoluble and has to be prepared in 40% propylene glycol and 10% ethyl alcohol (Valium®, Roche) [4] or as an emulsion (Diazemuls®, Pharmacia & Upjohn) [5]. Diazepam solution can be diluted (maximum two ampoules of 5 mg/2 mL) in not less than 250 mL of 5–10% dextrose, normal saline or Ringer's if necessary. Diazemuls® can be diluted up to a maximum concentration of 200 mg per 500 mL of solvent. A rectal tube formulation is available (cremophor EL, Stesolid®, Diastat®) [6].

Lorazepam

Lorazepam (Fig. 34.1b), or 7-chloro-5-(2-chlorphenyl)-1,3-dihydro-3-hydroxy-2H-1,4-benzodiazepin-2-one, has a chemical formula of $C_{15}H_{10}Cl_2N_2O$. Its molecular weight is 321.16 and its pK_a is 1.3.

Lorazepam is only moderately lipophilic, water insoluble (0.08 mg/mL) and undissociated at physiological pH [7]. The usual preparation is a 1-mL ampoule containing 4 mg.

Midazolam

Midazolam (Fig. 34.1c) is 8-chloro-6-(2-fluorphenyl)-1-methyl-4H-imidazo[1,5-a][1,4]benzodiazepine. Its chemical formula is $C_{18}H_{13}ClFN_3$, its molecular weight is 325.8 and its pK_a is 6.15. Midazolam is an imidazobenzodiazepine that readily forms a water-soluble salt. At physiological pH the ring structure closes and the drug becomes lipid soluble and crosses the blood–brain barrier [8].

Midazolam is provided in an acidic aqueous solution (pH 3.3–3.5) and can be diluted with 5% dextrose, normal saline and Ringer's lactate [9]. The parenteral aqueous solution can be administered i.v. or intramuscularly rectally, buccally, orally and nasally [9].

Mechanisms of action

Diazepam, lorazepam and midazolam have a rapid onset of clinical effect, mainly because they are highly lipophilic and therefore rapidly penetrate the blood–brain barrier [10]. However, due to this property they also redistribute relatively rapidly from the brain to other lipophilic tissues in the body, a process which is much more important than the elimination half-life in determining the duration of the antiseizure effect after bolus doses [11,12]. The duration of anticonvulsant action after single conventional i.v. doses is short for diazepam (<2 h) and midazolam (3–4 h) and longer for lorazepam (up to 72 h) [13–16].

All benzodiazepines in clinical use share a capacity to enhance the binding of γ-aminobutyric acid (GABA) to the $GABA_A$ receptor to a variable degree, and to amplify the increase in chloride channel conductance triggered by the GABA–$GABA_A$ receptor interaction. This results in neuronal hyperpolarization. Benzodiazepines do not activate $GABA_A$ receptors directly, but rather bind to a specific site at the benzodiazepine–$GABA_A$ receptor–chloride channel complex and require the presynaptic release of GABA to express their effects [17].

The amplification of $GABA_A$ responses by benzodiazepines occurs at drug concentrations less than 100 nM. At higher concentrations, corresponding to those achieved during treatment of status epilepticus, the actions of benzodiazepines may also involve other mechanisms, including inhibition of uptake of adenosine

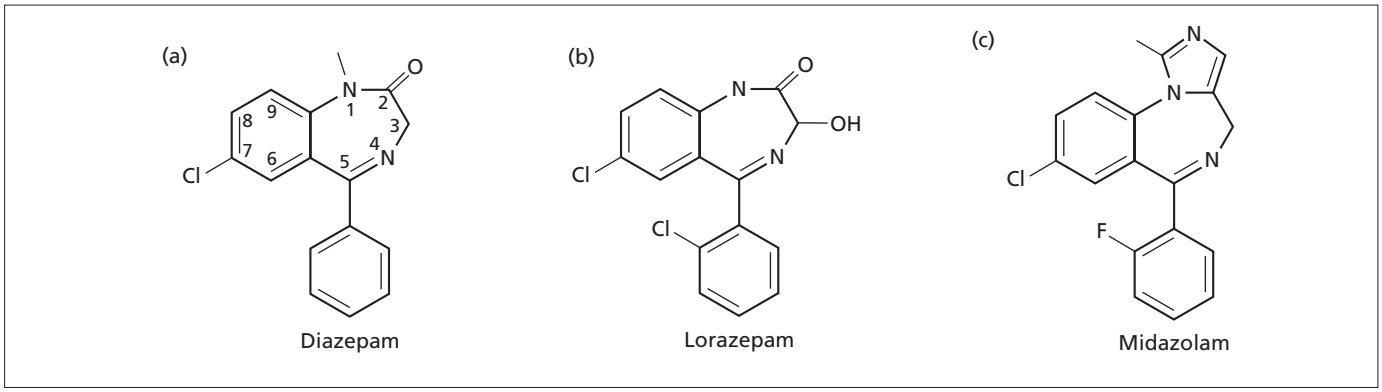

Fig. 34.1 Chemical structure of (a) diazepam, (b) lorazepam and (c) midazolam.

[18,19], as well as GABA-independent inhibition of calcium currents, calcium-dependent release of neurotransmitters and voltage-dependent block of high-frequency sodium channels [20–22].

Functional alterations of the GABA receptor during status epilepticus are reported and may be a key mechanism for treatment failures in advanced status [23–25]. Some authors therefore recommend a combination of drugs, with different mechanisms of action, early at the onset of status [26].

Pharmacokinetics

Diazepam

Absorption and distribution

After an i.v. injection of 10–20 mg diazepam at 2–5 mg/min, peak serum levels of 700–1600 μg/L are reached within 3–15 min [27,28] (Table 34.1). Serum levels sufficient to suppress seizure activity (200–600 μg/L) [29], however, are usually reached within 1 min of i.v. dosing. After intramuscular administration of a single 10- to 20-mg dose, diazepam peak serum concentrations of 35–300 μg/L are reached within 30–60 min [30,31]. The high variability and the delayed peak does not encourage use of the intramuscular route in status epilepticus.

After rectal administration of solution or gel (e.g. Stesolid® or Diastat®) diazepam is rapidly absorbed and peaks within 3 and 30 min [6,32–36]. Concentrations between 300 and 800 μg/L are reached within 4–45 min, and peak concentrations of 600–1400 μg/L within 10–60 min, after instillation of 1 mg/kg rectal tube solution. Absorption is faster in children, and effective serum levels in children are reached within 5–10 min. The bioavailability of rectal diazepam is 80–100% [33]. Variability in peak concentration and a lower bioavailability in adults may be due to patient-related factors or administration techniques. One study found unreliable bioavailability of 50% [37]. In adults with repetitive seizures, 3 of 39 rectal applications (one with 20 mg and two with 30 mg diazepam) were associated with persistent seizure activity; in two of them only subtherapeutic levels below 120 μg/L were found [36].

Distribution

After i.v. single-bolus administration diazepam distributes rapidly across the blood–brain barrier and into lipophilic tissues, and the decay of serum concentration shows distinct distribution and elimination phases, which can be described approximately by a two-compartment model. The volume of distribution ranges from 1 to 2 L/kg and is larger in women and in the elderly [38–41].

Serum diazepam levels after a single 5- to 10-mg injection fall rapidly to subtherapeutic concentrations (<200 μg/L) within 20 min. Only 3–5% of the total initial dose remains in brain tissues [38]. After repeated injections or continuous infusion, however, the decay of serum concentration is attributable not to redistribution into the peripheral compartments (fat stores), but to the much slower process of hepatic metabolism and clearance. Thus, repeated doses and continuous infusions carry a risk of sudden and unexpected potentially fatal cardiorespiratory depression.

Diazepam is highly bound (97–99%) to plasma proteins, mainly albumin and in to a lesser extent α_1-acid glycoprotein [42]. Protein binding is reduced in liver cirrhosis [43], renal failure [44–46], in neonates and in the elderly [47,48]. Cerebrospinal fluid (CSF) concentrations of diazepam and its main metabolite, *N*-desmethyldiazepam, correlate with the unbound fraction in serum [49], but concentrations of diazepam fall rapidly in the first hour after injection, a finding consistent with the relatively weak binding of diazepam to benzodiazepine receptors (which is in contrast to lorazepam).

Elimination

Diazepam is extensively metabolized by the hepatic microsomal enzymes CYP2C19 and CYP3A4 to several active metabolites, including *N*-desmethyldiazepam, temazepam and oxazepam [50,51]. The main pharmacologically active metabolite, *N*-desmethyldiazepam, has a longer half-life than diazepam and may be responsible for some of the antiepileptic effects of diazepam during prolonged use, but there is little indication for its use in the emergency treatment of status epilepticus. The elimination half-life of diazepam is between 18 and 100 h (mean 20–40 h). It is reduced by one-third in patients treated with enzyme-

Table 34.1 Diazepam pharmacokinetic parameters.

Bioavailability (%)	Fraction bound (%)	Time to peak (min) [peak concentration (μg/L)]	Volume of distribution (L/kg)	Half-life (h)	Clearance (mL/h/kg)	Primary route of elimination	Active metabolites
Oral: 100 ± 14	98.7 ± 0.2	Intravenous: 3–15 min, [700–1600] after 10–20 mg bolus at 2–5 mg/min	1.1 ± 0.3	43 ± 13	0.38 ± 0.06	Oxidative demethylation	Desmethyldiazepam, oxazepam
Rectal: 80–100	↓ elderly, neonates, hepatic failure, renal failure, hypoalbuminaemia	Rectal: 3–30 min [600–1400] after 1 mg/kg	↑ elderly, hepatic failure, hypoalbuminaemia	↑ elderly, hepatic failure	↑ hypoalbuminaemia; ↓ hepatic failure

inducing drugs. The half-life of the drug is about 10 h in infants and about 20 h in children. Neonates, however, may show a long half-life, particularly if born prematurely. The half-life of diazepam is prolonged in the elderly (about 60–90 h), in obese patients and in patients with hepatic failure (99–164 h) [43,52], partly as a result of an increased volume of distribution and partly due to reduced drug clearance. Diazepam is not excreted into the bile in significant amounts, and only 2–5% is excreted unchanged in the urine [53].

Lorazepam

Absorption

In an open-label trial in status epilepticus, a minimum effective serum level of 30.5 μg/L was found 15 min after a single bolus of 4 mg lorazepam (rate 2 mg/min) (Table 34.2). The average concentration was 60.1 μg/L at 15 min and 51.7 μg/L at 120 min [54]. In seven patients who were treated with 5 mg lorazepam i.v. for status epilepticus, mean plasma concentrations after 30 s, 1, 2, 4 and 10 min were 272, 237, 170, 106 and 80 μg/L. In a study in healthy subjects [55], serum levels after a single bolus injection of 5 mg lorazepam remained above 30 μg/L for 18 h [7]. In the Veterans Affairs (VA) trial in status epilepticus, serum lorazepam levels of 73–328 μg/L were found immediately after an infusion of 0.1 mg/kg at a maximum rate of 2 mg/min, and declined to 45–163 μg/L after 15 min. There was no difference in concentration between those patients whose status was stopped and those whose status was not controlled [7,15].

Lorazepam has also been administered by the rectal route, but unlike diazepam rectal absorption is erratic and unreliable [56]. Lorazepam is therefore not recommended for rectal administration.

Distribution

The distribution of lorazepam after i.v. injection is described by a two-compartment model with a distribution half-life between 1 and 30 min [57,58]. The apparent volume of distribution is approximately 1 L/kg (0.91–1.3) [7], and it is slightly decreased in the elderly, but increased in obese patients and in patients with liver cirrhosis [59,60].

Lorazepam is highly protein bound (>90%) and the unbound fraction is unchanged even at concentrations up to 10 000 μg/L [61]. Protein binding is decreased in the elderly, while gender has no effect on protein binding [62].

Lorazepam crosses the blood–brain barrier rapidly. Because its lipid solubility is lower than that of diazepam, there is little accumulation in body fat stores. The CSF concentration is 10–15% of the blood levels [40], suggesting a passive diffusion into the brain, determined by the free fraction. A 40-fold higher brain concentration compared with the serum levels was found in the brain of Sprague–Dawley rats, a finding which is consistent with its strong binding to benzodiazepine receptors in the brain [63].

Elimination

Lorazepam is cleared primarily by glucuronidation at the 3-hydroxy group [7] and it has no active metabolites [57]. The elimination half-life of lorazepam is 15 h (range, 8–25 h) in healthy individuals [57]. The half-life is similar in healthy elderly [60], but it is shorter in children (8–13 h) [64], and prolonged in neonates [65] and in patients with liver cirrhosis (approximately 50% increase) [59]. Due to the concomitant increase in volume of distribution, there is no effect on clearance in patients with liver cirrhosis [7]. There was no significant change in lorazepam clearance in patients with acute viral hepatitis [59] and patients with renal impairment compared with healthy controls [66].

Midazolam

Absorption

After parenteral administration of the acidic aqueous solution as a single bolus, midazolam becomes highly lipophilic at physiological pH. Therefore, there is a rapid onset of action with peak sedation after 3 min of i.v. dosing [8], but only a short duration of action is observed (Table 34.3). Peak concentrations following a single 5-mg i.v. bolus are 113 ± 16 μg/L [67]. After intramuscular injection, peak concentrations are reached within 20–30 min, with 91% bioavailability for midazolam hydrochloride [8], although much slower absorption rates may occur in some patients.

Because of the rapid hepatic clearance and consequent first-pass effect, oral bioavailability is reduced to approximately 50% in adults and 27% in children [68–70].

The buccal or intranasal routes, like the rectal route, avoid the hepatic first-pass effect. Unlike the rectal route, buccal and intra-

Table 34.3 Midazolam pharmacokinetic parameters. Reported values (mean ± SD, or range) refer to healthy adults not receiving interacting co-medications.

nasal applications are socially acceptable and widely preferred by doctors, caregivers and patients [71]. Intranasal administration of midazolam has been extensively investigated in children [72–76] and adults [77], and is associated with a bioavailability of 78% with peak plasma concentrations of 72.2 ± 27.3 μg/L at 10 min after intranasal administration of 0.1 mg/kg [78]. However, to apply a therapeutic dose of midazolam into the nose of an adult, 2–3 mL of the solution needs to be instilled, which leads to discomfort, lacrimation and local burning [79]. A useful alternative is a concentrated form of an intranasal spray (2.5 mg in 90 μL), which was well tolerated in six healthy adults, with a bioavailability of 83% and peak concentrations of 71 ± 25 μg/L after 14 ± 5 min following administration of a 5-mg dose [80]. The buccal/sublingual route offers the advantage of good tolerability, even with larger volumes of solution [81]. In a study in eight healthy volunteers [72], buccal administration of 5 mg midazolam resulted in a peak serum concentration of 55.9 μg/L (range, 35.6–77.9 μg/L) at 30 min (range, 15–90 min) and a bioavailability of 74.5%

Distribution

After i.v. injection, midazolam is widely and rapidly distributed with a distribution half-life of 6–15 min [9]. The volume of distribution is 1–2.5 L/kg [82], and is higher in obese, elderly subjects and women [83,84]. Midazolam is highly bound to plasma proteins (94–98%) [85]. In experimental animals, the drug equilibrates between plasma and the CSF within a few minutes [12].

Elimination

Midazolam is extensively metabolized by CYP3A4 and the closely related enzyme CYP3A5 [68], and less than 1% of a dose is excreted unchanged. The main metabolite, α-hydroxymidazolam, which results from oxidation of the imidazole ring [86], is pharmacologically active but has a shorter half-life than midazolam and therefore contributes little to the overall clinical effect [87]. The hydroxylated metabolite is excreted in urine in glucuronide form [85].

The elimination half-life of midazolam is short and ranges from 1.5 to 4 h [88], but is markedly prolonged (up to 10 h) in the elderly [84,89], in neonates [90,91] and, to a lesser degree, in children [85]. The clearance of midazolam ranges from 0.24 to 0.53 L/min in healthy individuals [87,88] and is reduced in patients with hepatic disease [92], congestive heart failure [93] and probably also renal failure [9].

Drug interactions

Because enzyme-inducing antiepileptic drugs (AEDs) such as carbamazepine, phenytoin and barbiturates stimulate the activity of cytochrome P450 enzymes [88] and glucuronyltransferase [88], an increase in the clearance of diazepam, lorazepam and midazolam should be anticipated in patients co-medicated with enzyme inducers. In the case of midazolam, induction of first-pass metabolism by carbamazepine or phenytoin has been shown to cause a dramatic reduction in oral bioavailability [88], but a smaller degree of interaction is expected when midazolam is administered by the i.v., intramuscular, buccal and intranasal routes, which avoid the hepatic first-pass effect.

Other interactions relate to inhibition of drug metabolism [88]. For example, midazolam clearance is decreased by drugs that inhibit CYP3A4, such as erythromycin, clarithromycin, ketoconazole, diltiazem, verapamil or cimetidine. Diazepam clearance has been found to be decreased by inhibitors of CYP3A4 (e.g. cimetidine, itraconazole, erythromycin) and by inhibitors of CYP2C19 (e.g. omeprazole and fluvoxamine). Lorazepam clearance is decreased by about 40% by co-administration of valproate [9]. The latter interaction was considered to have contributed to development of encephalopathy in a patient treated with a combination of these drugs [9], even though a pharmacodynamic interaction may have played a role in the clinical presentation.

Overall, the interactions described above are unlikely to have major clinical significance when benzodiazepines are used in single doses in emergency settings. They may, however, affect dose requirements in patients who need prolonged infusions for the management of refractory status epilepticus. More important interactions are likely to occur at pharmacodynamic level, and they consist in reciprocal potentiation of central nervous system (CNS) effects when benzodiazepines are co-administered with other CNS depressants.

Serum level monitoring

The use of benzodiazepines in an emergency setting is guided by direct evaluation of clinical response, and monitoring serum drug levels is of little or no value in this context.

Efficacy

Diazepam

Intravenous diazepam is still one of the most widely used drugs for the treatment of premonitory and early status epilepticus as well as serial seizures and ongoing acute seizures [2]. Its efficacy is supported by many clinical studies. Unfortunately, most of them were uncontrolled and not randomized. In addition, the definitions used for status epilepticus varied over time (30 min [94], 10 min [15], 5 min [95]), the populations studied were heterogeneous, sometimes with only a small fraction of patients meeting the criteria for generalized convulsive status epilepticus [1] and the primary endpoints differed substantially among the studies.

The non-randomized trials of diazepam in status epilepticus were reviewed by Browne and Penry in 1973 [96], Schmidt in 1985 [97] and Treiman in 1989 [98]. Overall, 20 non-randomized open-label trials (n = 531) of i.v. diazepam have been reviewed by Treiman. In these studies, diazepam provided lasting control of seizures in 39–100% of patients [1,34,99–116]. Further, five non-randomized studies not included in the above review [13,117–120] reported similar success rates of between 65% and 100%. However, in many of the patients (in some studies more than 50%) [110,113,118,120] who were treated with diazepam, seizures recurred shortly after initial cessation of seizure activity. The reason for a high recurrence rate is due to a fast initial fall in serum drug levels [37]. The formerly common use of a continuous infusion of diazepam after initial success [16,111] to prevent the rapid fall in serum drug levels has now fallen from favour, due to the danger of drug accumulation and redistribution with resulting severe cardiorespiratory depression.

Apart from the VA randomized trial [14] (which compared diazepam followed by phenytoin with i.v. lorazepam and with other treatments and is discussed below in the section on lorazepam), three randomized controlled trials with 289 participants compared the effect of i.v. diazepam with i.v. lorazepam [14,121,122]. The results of these studies were evaluated in three different meta-analyses [123–125]. One study in a pre-hospital setting used lower than usual initial benzodiazepine dosages (5 mg diazepam or 2 mg lorazepam) [14]. Another study included children only [122]. When the data from the randomized trials were analysed together, there was no difference in mortality between the groups. However, lorazepam was superior to diazepam in stopping status epilepticus [32/130 versus 51/134 participants, relative risk (RR) 0.64, 95% confidence interval (CI) 0.45–0.90) and with lorazepam fewer patients required a different drug or general anaesthesia (32/130 versus 52/134 participants; RR 0.63, 95% CI 0.45–0.88) (data derived from ref. 124).

Non-randomized trials using rectal diazepam for the treatment of seizure clusters, prolonged seizures and early status epilepticus have reported termination of seizures in approximately 80% within 15 min [126–128]. Two randomized placebo-controlled trials using rectal diazepam in acute repetitive seizures were performed in adults and children [129–131]. In both studies, rectal diazepam reduced the risk of ongoing seizures compared with placebo (RR 0.43, 95% CI 0.30, 0.62), with a non-significant trend towards more adverse events in the diazepam group (RR 1.50, 95% CI 0.94–2.37) [123]. One randomized study compared the efficacy of 30 mg diazepam with 20 mg diazepam rectally in adults with serial seizures [36]. A 30-mg rectal diazepam dose reduced the risk of ongoing seizures significantly (RR 0.39; 95% CI 0.18–0.86, compared with 20 mg), without difference in adverse event rate (RR 0.90; 95% CI 0.53–1.53) [36,123]. Rectal diazepam was used as active comparator in six randomized trials with intranasal midazolam [132,133] and buccal midazolam [134–137] with similar efficacy (see section below on midazolam). Evidence concerning the use of rectal (and oral) diazepam as intermittent prophylaxis against recurrent febrile seizures is discussed in Chapter 14.

Lorazepam

Lorazepam is an extremely potent anticonvulsant. Its binding characteristics to the benzodiazepine receptor are quite similar to those of clonazepam [138], but the longer duration (up to 72 h) of the clinical effect of lorazepam suggest that other mechanisms may be involved in its action. The longer duration of action of lorazepam is a very important advantage over diazepam because, when used intravenously in an outpatient setting (as commonly done in Finland, Germany, Austria and many other countries), it provides time to transport the patient safely to the nearest hospital. Additional important advantages are that the risk of seizures relapsing is reduced, and that physicians are given ample time to establish diagnosis and to determine the optimal longer-term treatment.

There has been some concern that the onset of the anticonvulsant effect of lorazepam might be slow, because of lower lipid solubility of the drug compared with diazepam [55,139]. However, this concern is not supported by results of clinical studies, which showed a rapid onset of 3 min (range 1–15 min) in neonates [140], children [141–143] and adults [54,121]. Similarly, early effects on the EEG are noticed after 30 s in healthy volunteers [144]. These results have led to general acceptance of lorazepam as first-line treatment of premonitory and early status epilepticus [2,3,145,146], an indication supported by numerous non-randomized and by five randomized controlled trials [14,15,121,122,147].

More than 483 patients were included in non-randomized trials between 1975 and 2002, with overall success rates between 63% and 100% [13,54,119,140–143,148–159]. These studies vary considerably in their design, definitions of status epilepticus, treatment protocols and types of status. Only a small proportion of patients had generalized convulsive status and most patients included in uncontrolled studies had previous epilepsy.

Five randomized studies have compared lorazepam with diazepam [14,121,122], with midazolam [147] and with phenytoin, diazepam plus phenytoin, and phenobarbital [15]. Three of these studies were double-blinded [14,15,121], one is published only in abstract form [147] and two included children [122,147]. Three meta-analyses are available [123–125]. Analysis of the data led to the conclusion that, compared with diazepam, patients treated

with lorazepam in the early phase of status epilepticus had a lower risk for seizure continuation [32/130 (25%) versus 51/134 (38%) participants; RR 0.64; 95% CI 0.45–0.90], and a lower risk of continuation of status epilepticus leading to treatment with another drug or general anaesthesia [32/130 (25%) versus 52/134 (39%) participants; RR 0.63, 95% CI 0.45, 0.88] [124]. There was no significant difference for respiratory failure/depression, hypotension and deaths between the groups [123,124]. In the VA study, lorazepam controlled 67% of all patients with overt status epilepticus and was superior to phenytoin alone (51%), although there was no statistical significant difference with respect to diazepam plus phenytoin (59.6%) or phenobarbital (63%) [15].

Midazolam

Midazolam was introduced in the early 1980s as a short-acting sedative for minor operative procedures. Kaneko reported the first case of successfully treated status epilepticus with i.v. midazolam in 1983 [160]. Soon after that, midazolam became widely used in early status epilepticus despite its obvious short duration of action and high risk of recurrence of seizure activity. In refractory status epilepticus, midazolam is used as a continuous infusion, to overcome its short-lasting clinical effect. Due to its water solubility, which is unique among the clinically used benzodiazepines, alternative routes of administration (intramuscular, intranasal, buccal/sublingual) are feasible and offer a singular advantage over other benzodiazepines.

The efficacy of i.v. midazolam in acute seizure emergencies has been demonstrated in 22 non-randomized [120,161–181] and one randomized trial [182], including more than 900 patients.

In the past years, 10 non-randomized [183–193] and seven randomized controlled trials using intranasal [132,133,194], buccal [134,136,137] and intramuscular [195] midazolam have been performed. Most studies included children, and some were performed in neonates [178,180]. Buccal, nasal and intramuscular midazolam were mainly assessed for the treatment of acute repetitive seizures and early status epilepticus, whereas most studies using i.v. midazolam as continuous infusion included patients with refractory status. Overall, more than 2000 patients treated with midazolam in various forms for acute seizures or status epilepticus have been reported.

Studies with i.v. midazolam

After the first case report [160], small case series using i.v. midazolam in the treatment of early status epilepticus found excellent response rates, up to 100% [177], but, as expected, the short duration of action led to a disappointingly high number of relapses (75%) within a short time. In a study from a large centre in Serbia, five of seven patients with early status epilepticus experienced severe respiratory depression and hypoventilation after 15 mg midazolam i.v. at a rate of 5 mg/min [120]. In children, initial doses for early status and acute seizures of between 0.1 and 0.3 mg/kg have been used, followed by continuous infusion, most often started at 0.06 mg/kg/h and increasing stepwise up to 0.48 mg/kg/h until complete suppression of seizure activity [161, 164,166,167,170,172] with excellent overall response rates between 64.5% and 98.5%. In one study, exceptionally high continuous infusion rates up to 1 mg/kg/h have been reported [164]. In children, there have been virtually no reports of local reactions or systemic adverse events in these case series, except for one study which found a 3% rate of respiratory depression requiring ventilatory support [167]. In refractory childhood status, similar doses have been used, with response rates between 76% and 100% and uniformly low adverse event rates [163,165,174,175]. Inclusion criteria in the paediatric studies varied considerably and probably not all patients qualified for the definition of status epilepticus.

In adults with refractory status epilepticus, i.v. midazolam has been given as a continuous infusion [162,168,169,173,176,179,196]. Claassen *et al*. reviewed 193 patients with refractory status epilepticus treated with i.v. midazolam (n = 54), propofol (n = 33) or pentobarbital (n = 106) and found an overall initial response rate of 80%, which was less than that found with pentobarbital (92%) [197]. Patients treated with i.v. midazolam (loading dose 0.2 mg/kg, infusion rate ranging from 0.08 ± 0.04 mg/kg/h to 0.23 ± 0.17 mg/kg/h) experienced breakthrough seizures more often (51%) than those treated with propofol (15%) and pentobarbital (12%). Withdrawal seizures were also more common with midazolam than with propofol and pentobarbital (63% versus 46% versus 43%, respectively). However, patients given i.v. midazolam experienced significantly fewer episodes of hypotension requiring pressor agents (30% versus 42% versus 77%, respectively). The authors concluded that none of these drugs is superior to the others, and that the lower response rate with midazolam is compensated by better tolerability. Naritoku and Sinha found an unexpectedly slow clearance after prolonged i.v. midazolam infusion, with terminal half-lives of 52.1 and 20.1 h, and suspected time-dependent pharmacokinetic changes after prolonged midazolam use [181]. This could contribute to a more prolonged awakening after long-term treatment of refractory status epilepticus.

One open-label randomized trial has been conducted in 40 children aged 2–12 years with refractory status (motor seizures uncontrolled after two doses of diazepam 0.3 mg/kg and a 20 mg/kg phenytoin infusion) [182]. Patients were randomized to continuous i.v. midazolam or i.v. diazepam with incremental dosages. Status was controlled in 86% of children with midazolam and 89% with diazepam, but relapse rates were significantly higher in the midazolam group (57% versus 16%). About half the patients needed mechanical ventilation and 40% had hypotension.

Studies with alternative routes of administration

Early reports using intramuscular midazolam [190–192,198,199] found good tolerability and response rates between 80% and 92%. In two studies [188,195], one of which was randomized [195], intramuscular midazolam was compared with i.v. diazepam in early status epilepticus in children. Though response rates did not differ significantly, patients in the midazolam group received their medication earlier (3.3 ± 2.0 versus 7.8 ± 3.2 min), and time to cessation of seizures was shorter (7.8 ± 4.1 versus 11.2 ± 3.6 min) [195].

Intranasal application is easy and may be advantageous in the early phase of status or in the treatment of prolonged or serial seizures in childhood. Three randomized controlled trials compared intranasal midazolam 0.2 mg/kg with i.v. diazepam 0.3 mg/kg [194] or rectal diazepam 0.3 mg/kg [133,193] in acute seizures [132,133] and prolonged febrile convulsions (>10 min) [194]. The initial response rate was uniformly excellent, between 82% and

100%, and midazolam was not inferior to the comparator. In one study, intranasal midazolam was even superior to rectal diazepam (87% versus 60%) [132]. Patients given intranasal midazolam received their treatment significantly earlier and their seizures ceased sooner than with rectal or i.v. diazepam [133,194].

Four randomized controlled trials, including 564 patients, compared the efficacy of buccal midazolam with rectal diazepam in early childhood status epilepticus [134–137]. Three studies found no difference in efficacy (buccal midazolam versus rectal diazepam: 75% versus 59% [134], 57% versus 67% [136] and 78% versus 85% [137]). However, all authors concluded that the buccal route was easier to use and socially more acceptable for initial treatment of early status in childhood. In addition, one study found buccal midazolam even more effective than rectal diazepam (56% versus 27%) [135]. Thus, buccal midazolam is now a widely accepted and effective treatment for acute seizures in childhood.

Adverse effects

Diazepam

Systemic adverse effects and CNS toxicity

Respiratory depression, hypotension and sedation are the main risks of all intravenously used benzodiazepines. After i.v. administration of diazepam for status epilepticus and other indications, mild to severe hypotension or respiratory depression occurred in 5.2% of 246 patients, including one fatal case (0.4%), reviewed by Schmidt [200]. Browne and Penry reviewed the reports on 439 patients in 35 articles and found 16 cases of respiratory depression and 10 cases of hypotension in nine reports [101,109,113,114,201–203]. In three reports, previous treatment with barbiturates was regarded as a predisposing factor for diazepam-induced respiratory depression [101,113,114]. In the randomized trials using i.v. diazepam, 7% (7/100) of the patients had hypotension [14,122] and 10% (15/153) had respiratory depression/failure [14,121,122]. When combined with subsequent i.v. phenytoin, 20% (22/113) of patients had respiratory depression/failure and 29% (33/113) had hypotension [15,204]. A meta-analysis of three randomized controlled studies comparing i.v. diazepam versus lorazepam in the treatment of status epilepticus [14,121,122] found no difference in risk of respiratory failure/depression (RR 0.78, 95% CI 0.35–1.74) or hypotension between the drugs [124]. A prospective study analysed 122 episodes treated with either i.v. or rectal diazepam in 97 children, and found an overall incidence of respiratory depression of 9%. Of the patients with respiratory depression, 72% needed ventilatory support after diazepam administration [205].

Several risk factors for respiratory depression and hypotension have been described in open studies or case reports, including previous use of barbiturates, chlordiazepoxide, methaqualone, gallamine or lidocaine [101,113,206–208], older age [209,210] and liver disease [211]. Patients with respiratory disorders and muscular disease are also likely to be at greater risk, at least for respiratory depression. Although not formally assessed, the rate at which the bolus is injected seems to be particularly crucial for the development of respiratory depression and hypotension [212,213]. A rate of 2–5 mg/min should not be exceeded [2].

In contrast to Diazemuls®, the Valium® preparation contains propylene glycol as a solvent, which may also lead to systemic effects. A syndrome of propylene toxicity with otherwise unexplained anion gap, metabolic acidosis, hyperosmolality, seizures, cardiac arrhythmias and clinical deterioration has been described [214,215]. Because the use of continuous diazepam infusion is strongly discouraged [2], this syndrome is probably very uncommon.

Local tissue irritation

Local pain, phlebitis and venous thrombosis may occur after i.v. diazepam [216,217]. A retrospective study found thrombophlebitis in only 3.5% of more that 1500 i.v. injections during gastrointestinal procedures [218,219]. A retrospective survey of 15 813 injections found no significant local vascular complications. However, severe local reactions have also been reported [220,221]. Local reactions are associated with polypropylene glycol-based preparations and are not reported with diazepam fat emulsions (Diazemuls®) [222]. The best prevention measures against local vein reactions include administration in an antecubital vein [223], flushing with saline [224] and injection rates below 5 mg/min.

The rectal solution or gel is generally well tolerated. Some patients report a burning sensation in the rectum [129,225], but there is no evidence for mucosal damage.

Paradoxical effects

Induction of tonic status epilepticus in patients with Lennox–Gastaut syndrome has been described after use of i.v. diazepam [226–228]. Seizure aggravation or induction of acute symptomatic status epilepticus by diazepam in epilepsy syndromes other than Lennox–Gastaut syndrome has not been observed.

Lorazepam

Systemic adverse effects and CNS toxicity

The most common adverse effects of lorazepam, as with other benzodiazepines, involve the CNS. Drowsiness is common and should be expected in all patients after i.v. injection. However, severe stupor or coma is rare, even after extremely high doses with serum drug levels of 300–600 μg/L [229,230]. Respiratory depression with hypoventilation was found in 10.3% of adult patients treated with lorazepam in the VA study [15]. In a study in children, only 3% had signs of respiratory depression [122]. Interestingly, respiratory depression seems to occur after the first injection, if at all, but not after repeated use [7,143]. It has been claimed that co-medication is not a major risk factor for respiratory depression/failure [231], based on studies analysing the influence of morphine and meperidine as co-medication [232,233]. However, this view was not supported by the results of a prospective randomized double-blind study in patients scheduled for coronary artery bypass graft [234]. Other co-medications were not studied, and pharmacodynamic interactions may have to be anticipated in patients concurrently treated with other CNS depressants. Patients with respiratory disorders and muscular disease are also likely to be at greater risk of respiratory depression. Drug-induced hypotension was rare in one of the double-

blind randomized trials [121], but was observed in 26% of patients who received lorazepam in the VA study [15].

Local tissue irritation

Local pain and irritation may occur, but they are less frequently reported than with diazepam [235]. Dilution of lorazepam in 20 mL of 5% dextrose or Ringer's lactate diminishes the risk of pain, local irritation and thrombophlebitis [230,236].

Paradoxical effects

Similarly to diazepam, there are few reported cases of tonic status epilepticus in patients with Lennox–Gastaut syndrome after i.v. use of lorazepam [142,153,228]. No other paradoxical effects of lorazepam have been reported.

Midazolam

Systemic adverse effects and CNS toxicity

Respiratory depression and hypoventilation are dose-related phenomena and were reported more frequently in early case series [120] and in anaesthetic studies [237], which use higher doses. Patients with respiratory disorders and muscular disease are likely to be at greater risk of respiratory depression. In childhood refractory status epilepticus treated with a continuous midazolam infusion, hypotension may occur in up to 40%, and respiratory depression requiring mechanical ventilation in up to 50% [182]. In view of the prolonged half-life and reduced clearance, systemic toxicity is more likely to occur in elderly patients. However, tolerability is good, particularly when the intramuscular, intranasal or buccal routes of administration are used in the early phase of status epilepticus.

Local tissue irritation

Due to the solubility of midazolam in water, the solution is virtually devoid of risk of causing local venous irritation or thrombophlebitis [216]. In a prospective study, venous complications were observed in 22 of 62 patients receiving i.v. diazepam for sedation, compared with 1 of 60 patients given i.v. midazolam [238].

Paradoxical effects

Seizure aggravation or induction of tonic seizures have not been observed with midazolam.

Place in current therapy

Because of its high efficacy and long-lasting effect, lorazepam is usually the preferred choice for the first-line i.v. management of premonitory and early status epilepticus, serial seizures and acute symptomatic seizures. Its efficacy in generalized convulsive status epilepticus has been demonstrated in randomized controlled trials. Its advantages and disadvantages are summarized in Table 34.4.

Midazolam, administered by the buccal route, is a widely used first-choice agent for emergency management of acute seizure disorders by non-medical personnel, prior to admission to hospital. The intranasal route may also be used for this indication, particularly in children, but its value compared with the buccal route is less established (Table 34.5). The main limitation of midazolam when given by bolus injection or by the buccal or intranasal route is its short duration of action, which may result in re-emergence of seizure activity. In a hospital setting, midazolam's main value is in providing a treatment option, as a continu-

Table 34.4 Indications, dosing information and advantages versus disadvantages of lorazepam in the emergency treatment of seizure disorders.

Indications	*Adults and children:* premonitory and early status epilepticus (preferred drug in stage 1 of status epilepticus), serial seizures, acute symptomatic seizures
Usual dosages	*Intravenous bolus (undiluted):* 4–8 mg (adults), 0.1 mg/kg (children), usual injection rate 2 mg/min (adults and children) strictly intravenously *Intramuscular, intranasal, rectal:* not recommended *Continuous intravenous infusion:* not recommended
Advantages	Rapid onset of action by the intravenous route Long-lasting effect (>24 h) after a single injection Proven efficacy in randomized controlled trials in generalized tonic–clonic status epilepticus Long-standing clinical experience in adults and children Extensively studied pharmacology and pharmacokinetics Little risk of accumulation
Disadvantages	Sedation, respiratory depression, hypotension Polypropylene solvent in the solution may cause reactions at the injection site and systemic adverse effects with prolonged use

Table 34.5 Indications, dosing information and advantages versus disadvantages of midazolam in the emergency treatment of seizure disorders.

Indications	*Adults and children* *Continuous intravenous infusion:* refractory status epilepticus *Buccal or intranasal route:* premonitory and early status epilepticus, serial seizures, acute symptomatic seizures
Usual dosages	*Intravenous:* 0.1–0.3 mg/kg bolus at 4 mg/min (children and adults) followed by infusion of 0.05–0.4 mg/kg/h (adults). Paediatric initial infusion rates are 0.03 mg/kg/h in newborns of gestational age <32 weeks; 0.06 mg/kg/h in newborns of gestational age <32 weeks and in infants <6 months; and 0.05–0.12 mg/kg/h in children >6 months. These rates may be increased according to response (see text) Higher infusion rates have been used (and may be required), both in adults and in paediatric patients *Intranasal or buccal:* 5–10 mg (adults); 0.15–0.3 mg/kg (children) *Rectal:* not recommended
Advantages	Water solubility permits alternative routes in the emergency treatment of seizures Rapid onset of action with all routes of administration Buccal and intranasal administration have proven efficacy in randomized controlled trials in children with acute seizures Intranasal and buccal routes easy and socially well accepted Lack of reactions at the infusion site Little risk of accumulation
Disadvantages	Short duration of action with risk of seizure relapse Sedation, respiratory depression, hypotension

Table 34.6 Indications, dosing information and advantages versus disadvantages of diazepam in the emergency treatment of seizure disorders.

Indications	*Adults and children:* premonitory and early status epilepticus, serial seizures, acute symptomatic seizures
Usual dosages	*Intravenous bolus (undiluted)*: 10–20 mg (adults), 0.2–0.3 mg/kg (children), injection rate 2–5 mg/min (adults and children) strictly intravenously *Rectal:* 20–30 mg (adults); 0.5–0.75 mg/kg (children) *Continuous intravenous infusion:* not recommended
Advantages	Rapid onset of action by the intravenous route Rectal formulation available Long-standing clinical experience in adults and children Extensively studied pharmacology and pharmacokinetics Widespread availability
Disadvantages	Short duration of action, due to rapid redistribution Sedation, respiratory depression, hypotension Accumulation after repeated doses and infusion, with increased risk of prolonged sedation and respiratory depression Polypropylene solvent in the intravenous solution may cause reactions at the injection site and systemic adverse effects with prolonged use

ous i.v. infusion, for the management of refractory status epilepticus.

Diazepam is more widely available throughout the world than either lorazepam or midazolam. Whenever lorazepam is unavailable, diazepam provides a very valuable alternative as an i.v. injection to treat premonitory and early status epilepticus, serial seizures and acute symptomatic seizures (Table 34.6). Its main disadvantage is the shorter duration of action compared with lorazepam due to rapid redistribution, and its risk of accumulation and redistribution after repeated doses. Rectal diazepam administration is a valuable option to treat emergency seizure situations when the i.v. route is not feasible, for example in a number of pre-hospital settings, particularly in the absence of skilled health-care personnel. However, there is a trend for rectal diazepam to be replaced by buccal or intranasal midazolam, which is more favourably socially accepted.

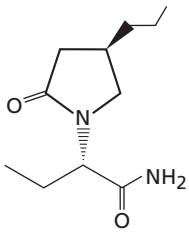
35 Brivaracetam

Philipp von Rosenstiel[1] *and Emilio Perucca*[2]

[1]UCB Pharma Inc., Smyrna, GA, USA

[2]Institute of Neurology IRCCS C. Mondino Foundation and Clinical Pharmacology Unit, University of Pavia, Pavia, Italy



Primary indication	Adjunctive therapy of partial seizures (potential additional indications are under assessment)
Usual preparation	Tablets: 2.5, 10, 25, 50 mg Oral solution: 1, 10 mg/mL Intravenous formulation: 10 mg/mL
Usual dosage	5–100 mg/day (tentative dose range)
Dosing frequency	Twice daily
Significant drug interactions	Enzyme-inducing antiepileptic drugs and rifampicin decrease plasma brivaracetam levels. Brivaracetam may increase the plasma levels of phenytoin and carbamazepine-10,11-epoxide
Serum level monitoring	Not routinely done
Target range	Not applicable
Common/important adverse effects	Headache, somnolence, fatigue, nausea and dizziness
Main advantages	High responder rates and excellent tolerability
Main disadvantages	Limited clinical experience. Efficacy spectrum in different seizure types not yet defined
Mechanism of action	Binds to synaptic vesicle 2A (SV2A) protein. Weak blocker of voltage-gated sodium channels
Oral bioavailability	Almost complete
Time to peak levels	1–3 h
Elimination	Cleared primarily by metabolism (<10% excreted unchanged in urine) through hydrolysis of the acetamide group and secondarily through hydroxylation mediated by CYP2C9, CYP2C19, CYP3A4 and, to a negligible extent, CYP2B6 and CYP2C8
Volume of distribution	0.5 L/kg
Elimination half-life	6–11 h
Plasma clearance	0.7–1.3 mL/min/kg (values in the upper portion of the range are observed in patients co-medicated with enzyme-inducing antiepileptic drugs)
Protein binding	≤20%
Active metabolites	None known
Comment	Potentially a useful antiepileptic drug, but more data are needed to establish its optimal dose range and its place in current therapy

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

The discovery that the synaptic vesicle protein 2A (SV2A) is the principal site involved in the antiepileptic effect of levetiracetam (Keppra®) [1] stimulated UCB to search for analogues with higher affinity for SV2A than levetiracetam. Brivaracetam (ucb 34714) was identified after a primary *in vitro* screening of over 10 000 compounds, a secondary screening of 900 compounds in the mouse audiogenic seizure model, and a tertiary screening of 30 drug candidates in various other epilepsy models [2].

Brivaracetam is a novel pyrrolidone derivative with 10-fold higher binding affinity for SV2A than levetiracetam [2]. In contrast to levetiracetam, brivaracetam also displays an ability to inhibit voltage-dependent sodium channels [3]. Results of studies in animal models of epilepsy and seizures indicate that the compound has higher potency than levetiracetam, and a potential for superior efficacy in a broad range of seizure types [4]. Efficacy and tolerability results from phase IIb adjunctive therapy studies in patients with uncontrolled partial-onset seizures have been promising [5,6]. Brivaracetam is, at the time of writing, in phase III development.

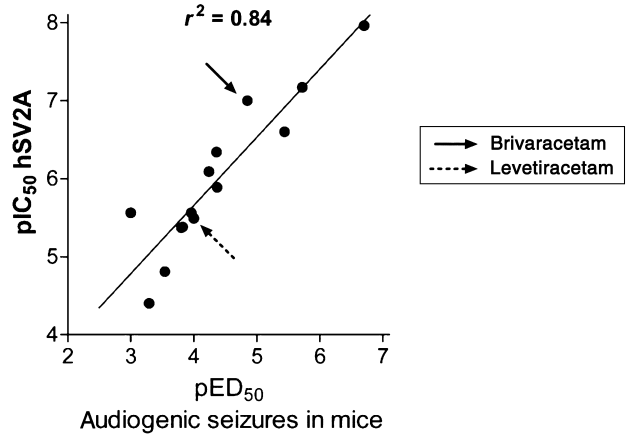


Fig. 35.1 Correlation between binding affinity to human synaptic vesicle protein 2A (hSV2A) and antiseizure potency of racetam compounds. Binding affinity (pIC_{50}) was measured in transiently transfected COS-7 cells, and antiseizure potencies [shown as the –log ED_{50}s (pED_{50}s)] were measured in the mouse audiogenic seizure model. There is a good correlation between antiseizure potency in audiogenic mice and affinity to hSV2A. Reproduced from ref. 1 with permission [© (2004) National Academy of Sciences, USA].

Chemistry

Brivaracetam {[2*S*]-2-[(4*R*)-2-oxo-4-propylpyrrolidinyl] butanamide} is a 2-pyrrolidone derivative, freely soluble in water, with a molecular weight of 212 [2].

Pharmacology

Mechanisms of action and activity in experimental models

Mechanisms of action

Preclinical studies have shown that brivaracetam binds to SV2A, with a 10-fold higher affinity than levetiracetam [2]. SV2A has been implicated in the modulation of synaptic vesicle exocytosis and neurotransmitter release [7,8] and binding to this protein is considered to be the primary mechanism for brivaracetam's anticonvulsant activity [1,2,9,10]. Indeed, there is a strong correlation between ligand affinity for SV2A and anticonvulsant potency in animal models of both partial and generalized epilepsy (Fig. 35.1) [1,10].

Additional mechanisms may contribute to the anticonvulsant activity of brivaracetam. In particular, the compound has been found to possess some inhibitory activity at neuronal voltage-dependent sodium channels, on which levetiracetam is inactive (Table 35.1) [3], and to reverse the inhibitory effects of a number of negative allosteric modulators, such as zinc and β-carbolines, on γ-aminobutyric acid (GABA)- and glycine-gated currents [12].

Table 35.1 Comparisons of the mechanisms of action of brivaracetam and levetiracetam.

	Brivaracetam	Levetiracetam
SV2A (pK_i)	7.1	6.1
Reversal of inhibition by zinc on GABA-gated currents (20 μmol) in hippocampal neurones	Reversal (1–100 μmol)	Reversal (30–1000 μmol)
Reversal of inhibition by zinc on glycine-gated currents (100 μmol) in spinal cord neurones	Reversal (3–100 μmol)	Reversal (0.1–100 μmol)
Inhibition of high voltage-activated calcium channel currents (IC_{50} value)	Inactive up to 1 mmol/L	13.9 μmol
Inhibition of voltage-gated sodium channel currents (IC_{50} value)	7 μmol	Inactive up to 1 mmol/L

GABA, γ-aminobutyric acid; IC_{50}, inhibitory half-maximal concentration; pK_i, –log of the unlabelled drug equilibrium constant.

Activity in experimental models of seizure and epilepsy

In two *in vitro* models of epileptic activity in rat hippocampal slices, brivaracetam (1–10 μmol/L) inhibited epileptiform responses induced by a high potassium/low calcium ions perfusion fluid or by addition of 5 μmol/L bicuculline methiodide (BMI) to the normal perfusion liquid. Brivaracetam showed higher efficacy and potency than levetiracetam in these models [4]. In particular, brivaracetam (3.2 μmol/L) reduced the occurrence of spontaneous bursts, while levetiracetam (32 μmol/L) was inactive against spontaneous bursts. BMI-induced increase in population spike amplitude was inhibited by brivaracetam even at 0.1 μmol/L, with the greatest effect observed at 3.2 μmol/L.

Brivaracetam shows potent activity in many *in vivo* models of seizures and epilepsy (Table 35.2) [4]. Unlike levetiracetam, brivaracetam is effective in inhibiting seizures induced in the classical

Table 35.2 Brivaracetam provides better seizure protection than levetiracetam in animal models of seizures and epilepsy.

	Brivaracetam	Levetiracetam
Acute seizure tests in normal animals		
Maximal electroshock seizures in mice		
ED_{50}, mg/kg i.p.	113	>540
Pentylenetetrazol seizures in mice		
ED_{50}, mg/kg i.p.	30	>540
Fully kindled animals		
Corneally kindled mice		
ED_{50}, mg/kg, i.p.	1.2	7.3
Hippocampal-kindled rats		
MAD, mg/kg, p.o.	0.2	54
Amygdala-kindled rats		
Motor seizure severity, MAD, mg/kg i.p.	21.2	170
Reduction of afterdischarge duration at highest tested dose (percentage)	69	13
Genetic models of chronic epilepsy		
Audiogenic susceptible mice		
ED_{50}, mg/kg, i.p.	2.4	30
Genetic Absence Epilepsy Rat from Strasbourg, MAD, mg/kg, i.p.	6.8	5.4
Seizure suppression at highest tested dose	Complete	Partial

ED_{50}, dose which effectively protects 50% of the animals against the convulsive endpoint; i.p., intraperitoneal; MAD, minimal active dose providing significant protection against the seizure endpoint; p.o., per os (oral).

maximal electroshock and pentylenetetrazole seizure tests, albeit at relatively high doses. Audiogenic seizure-susceptible mice were better protected against clonic convulsions induced by acoustic stimuli when treated with brivaracetam than with levetiracetam [ED_{50} values = 2.4 versus 30 mg/kg, intraperitoneally (i.p.)]. In corneally kindled mice (3 mA, 3 s, twice daily), brivaracetam provided more potent protection than levetiracetam against secondarily generalized motor seizures (ED_{50} = 1.2 versus 7.3 mg/kg, i.p.). In the corneal kindling development model, pretreatment of mice twice daily with brivaracetam (0.21–6.8 mg/kg, i.p.) prior to corneal stimulation (3 mA, 3 s, twice daily) also resulted in a more potent and persistent inhibition of kindling development than observed with levetiracetam.

In hippocampal-kindled rats, a model of localization-related epilepsy, brivaracetam provided more potent protection against seizures than levetiracetam (minimal active dose = 0.21 versus 54 mg/kg, oral) [4]. In fully amygdala-kindled rats (50 Hz, 1 s, 500 μA monophasic square-wave pulses, once daily, 5 days per week), brivaracetam induced a nearly complete suppression of both motor seizure severity and after-discharge duration.

Brivaracetam significantly suppressed spontaneous spike-and-wave discharges in the Genetic Absence Epilepsy Rat from Strasbourg (GAERS), a model predictive of activity against absence epilepsy [4].

Brivaracetam also possesses more potent antiseizure and antimyoclonic activity than levetiracetam in a model of cardiac arrest-induced posthypoxic myoclonus in rats [13]. Potent anticonvulsant activity was also demonstrated in a rat model of acute, partially drug-resistant, self-sustaining status epilepticus induced by perforant path stimulation [14]. In this model, treatment with brivaracetam (20 mg/kg) shortened the cumulative duration of active seizures to 11% of the duration of controls. In comparison, 200 mg/kg levetiracetam and 10 mg/kg diazepam reduced seizure duration to 35% and 15% of control values, respectively. Brivaracetam was also shown to potentiate the effects of diazepam in this model: low doses of brivaracetam (1 mg/kg) or diazepam (1 mg/kg) alone had little effect but, when combined, they reduced the duration of active seizures to 3% of controls.

Overall, the activity profile of brivaracetam in these models is suggestive of broad-spectrum efficacy against partial and generalized seizure types.

Evidence of activity in non-epilepsy indications

Brivaracetam (2.1–68 mg/kg, i.p.) has been compared with gabapentin (30 or 60 mg/kg) in the mononeuropathic (chronic constriction injury) model and in the streptozotocin-induced diabetic model of neuropathic pain [15,16]. In both models, brivaracetam showed significant activity, increasing vocalization thresholds and displaying dose-dependent antihyperalgesia.

Brivaracetam has also been investigated in animal models of essential tremor [17]. At non-sedative doses (up to 120 mg/kg, i.p.), the compound reduced the elicited tremor index by up to 66%.

Toxicology data

In studies conducted in mice, rats and dogs, brivaracetam demonstrated low acute oral toxicity [18]. Transient dose-related central nervous system (CNS) effects were observed, generally at oral doses of 100 mg/kg and above. Brivaracetam also resulted in a slight respiratory stimulant effect above 100 mg/kg, and at 300 mg/kg it delayed stomach emptying and reduced gastrointestinal transit. No significant effects were noted on the cardiovascular system. The maximum non-lethal oral single dose in rats was above 1000 mg/kg and a no-effect level of 500 mg/kg was established based on clinical signs.

Repeated-dose oral administration of brivaracetam in animals has indicated the liver as the target organ. The non-observed adverse effect level (NOAEL) following 26 weeks of repeated administration was 15 mg/kg/day in dogs and 450 mg/kg/day in rats. In monkeys, after 39 weeks of repeated administration, the NOAEL was 900 mg/kg/day. Thus, for a dose of 100 mg/day in adult humans, the dog, the rat and monkey long-term toxicity studies provide margins of safety for hepatotoxicity of 1.2-fold in dogs, compared with 9- to 16-fold in rats and 81-fold in the monkeys.

Genotoxicity studies showed no evidence of mutagenicity or clastogenicity [18]. No adverse effects on fertility and early embryonic development were detected up to the highest tested oral dose of 400 mg/kg/day (safety margins of 18- and 30-fold in males and females, respectively). Brivaracetam has demonstrated no teratogenic potential in either the rat or the rabbit (safety margins of 57- and 14-fold in rat and rabbit fetuses, respectively). Neonatal development was also unaffected up to a dose of 300 mg/kg/day (safety margin of 13-fold in rat pups).

Pharmacokinetics

Following oral administration to healthy subjects, brivaracetam is characterized by linear pharmacokinetics over a wide dose range (10–600 mg as a single dose and from 200 mg/day to 800 mg/day as multiple doses), with moderate inter-subject variability [19,20]. After single doses above 600 mg, a slightly more than dose-proportional increase in area under the plasma brivaracetam concentration versus time curve (AUC) has been observed. Steady state is reached within 1 week of repeated administration (Table 35.3).

Absorption

Brivaracetam is rapidly and almost completely absorbed, peak plasma concentrations being achieved after approximately 0.5–3 h following oral intake in the fasting state [19,20]. The drug is efficiently absorbed throughout the entire gastrointestinal tract, with a relative AUC (stomach = 100%) of 101%, 98% and 97% following delivery in the proximal jejunum, distal jejunum and ascending colon, respectively (UCB, data on file).

Co-administration with a high-fat meal resulted in a delayed median time to peak plasma concentration from 0.5 to 3.5 h post dose and a 28% reduction in peak plasma concentrations, while the extent of absorption (AUC) remained unchanged [19].

Single doses of an intravenous formulation of brivaracetam (10–150 mg) have been administered to healthy volunteers as either a 15-min infusion or a bolus dose of 10 mg/12 s [21]. Brivaracetam 10 mg administered as a 15-min intravenous infusion and as an intravenous bolus (10 mg/12 s) was bioequivalent to a single dose of brivaracetam 10 mg oral tablet. The pharmacokinetic parameters of brivaracetam (25 mg–150 mg) after intravenous infusion (15 min) and bolus (10 mg/12 s) were similar and dose proportionality was observed for each, from 25 to 150 mg.

Table 35.3 Plasma and urinary pharmacokinetic parameters after the first dose (day 1) and during a 12-h dosing interval on day 7 and day 14 of multiple dosing with brivaracetam 100 mg twice daily in nine healthy volunteers.

Parameter	Brivaracetam 100 mg twice-daily dosing		
	Day 1	Day 7	Day 14
C_{max} (μg/mL)	2.2 (14)	3.5 (22)	3.5 (20)
AUC (μg·h/mL)[a]	27.5 (23)	27.7 (21)	28.0 (24)
t_{max} (h)[b]	2 (1–4)	2 (1–3)	2 (1–2)

[a] AUC extrapolated to infinity after the first dose on day 1, AUC over 12-h dosing interval on days 7 and 14.
[b] Median (range).

Distribution

Brivaracetam is not extensively bound to plasma proteins (≤20%). The volume of distribution is 0.5 L/kg, a value that is close to the volume of distribution of total body water [22].

There is a strong correlation between brivaracetam saliva and plasma levels (r = 0.97, n = 241). The slope (standard error) is 0.88 (0.01), and closely corresponds to the free fraction of the drug in plasma as measured by equilibrium dialysis [20].

Elimination

In studies conducted in healthy volunteers, the elimination half-life of brivaracetam was found to be in the range of 6–11 h (mean, 7.7 h). The apparent oral clearance (CL/*F*) in these subjects is in the order of 0.7–0.9 mL/min/kg [19,20]. Following repeated administration, there is a modest time-dependent increase in metabolic clearance of brivaracetam at 800 mg/day with twice-daily administration, which is insignificant at 400 mg/day and below [20].

Brivaracetam is eliminated by hepatic metabolism and, to a much lesser extent (<10% of the dose), by direct urinary excretion (Fig. 35.2) [22]. Faecal excretion accounts for less than 1% of the dose. Excretion in expired air is undetectable. After administration of radiolabelled drug, the main circulating species is unchanged brivaracetam, amounting to 90% of the total plasma radioactivity [22]. The major metabolic pathways include hydrolysis of the acetamide group, hydroxylation mediated by several cytochrome P450 (CYP) enzymes (CYP2C19, CYP2C9, CYP3A4, with minor contributions of CYP2C8 and CYP2B6) and a combination of these (UCB, data on file). Although the renal clearance of the parent compound is low (about 0.04 mL/min/kg), its metabolites have a high renal clearance [20]. More than 95% of a radioactive dose is recovered in urine within 72 h, as the acidic (M9: 34.2% of the dose), ω-1 hydroxylated (M1b: 15.9%), and ω-1 hydroxylated acid (M4b: 15.2%) metabolites, and 8.6% as the parent drug (Fig. 35.2) [22]. There is no evidence of brivaracetam undergoing chiral inversion (i.e. conversion to other enantiomeric forms of the molecule). The hydrolysed metabolite and the two products of hydroxylation in the ω-1 position of the propyl chain are not pharmacologically active.

In a population pharmacokinetic study which utilized plasma concentrations obtained during two phase IIb adjunctive therapy studies in adult patients with refractory partial epilepsy, age, gender, race and creatinine clearance did not influence brivaracetam pharmacokinetic parameters. Differences in body weight and concomitant use of enzyme-inducing antiepileptic drugs (AEDs) accounted for most of the inter-individual variability, with an overall moderate influence on brivaracetam concentrations at steady state [23].

Pharmacokinetics in special populations

Elderly subjects

The pharmacokinetics of brivaracetam has been investigated in healthy elderly subjects after a 200-mg single dose and after

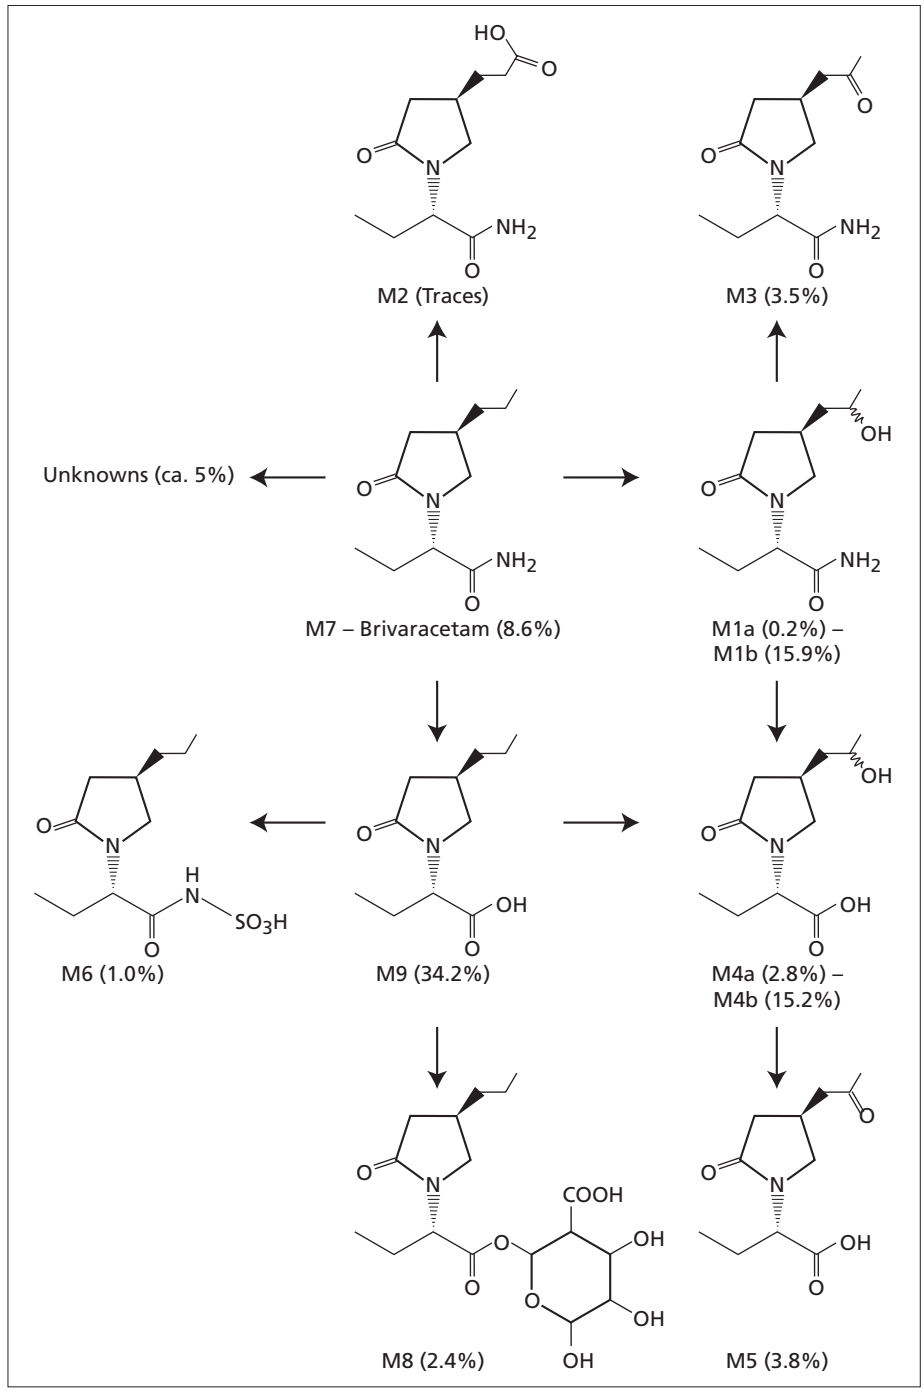

Fig. 35.2 Proposed metabolic pathways of brivaracetam in man following oral administration of a single 150-mg dose. Percentages in brackets refer to the mean fraction of the dose (%) recovered in urine within 48 h [22]. Forms 'a' and 'b' for metabolites M1 and M4 indicate occurrence of two stereoisomers at the position of the hydroxyl group [M1a and M4a (tentative) in 'up' position; M1b and M4b in 'down' position]. Reproduced from ref. 22 with permission (American Society for Pharmacology and Experimental Therapeutics).

200 mg twice-daily multiple dosing for 10 days [24]. After a single dose, absorption was rapid, with median time to peak plasma concentration occurring at 1.5 h. Plasma concentrations decayed monoexponentially, with a median half-life of 7.7 h (range 6.5–9.8 h) and 8.6 h (range 7.8–11.4 h) in the 65–75 years (n = 10) and >75 years (n = 6) groups, respectively. CL/F values (geometric means) at steady state were slightly lower in elderly males (0.74 mL/min/kg) than in young healthy males (0.83 mL/min/kg). The study concluded that these age-related pharmacokinetic differences are not expected to require dose adjustments in elderly patients.

Impaired renal function

The pharmacokinetics of a single oral dose of brivaracetam (200 mg) was investigated in nine severely renally impaired patients with a creatinine clearance (CL_{CR}) <30 mL/min/1.73 m^2, not requiring dialysis, in comparison with nine healthy subjects (UCB, data on file). Peak plasma brivaracetam concentrations

did not differ between patients with renal impairment and controls [mean ratio 99.7%; 90% confidence interval (CI) 85–117%] whereas total exposure as reflected by $AUC_{0-\infty}$ was slightly increased in the patients (mean ratio 121%; 90% CI 101–145%). The renal clearance of brivaracetam in the renally impaired group was reduced by 63% (from 4.48 to 1.66 mL/min/1.73 m^2). Peak plasma concentrations of the acidic, hydroxyl and hydroxy acid metabolites were increased 2.4-, 2.0- and 11.7-fold, and AUC values for the same metabolites were increased 3.2-, 4.1- and 21.5-fold, respectively. The renal clearance of these inactive metabolites was decreased 10-fold in renally impaired subjects compared with healthy controls. Overall, the modest increase in AUC of parent drug in the presence of renal impairment is unlikely to affect dose requirements, but cautious monitoring of clinical response to determine the possible need for dose adjustment is recommended if brivaracetam is prescribed in these patients. In the course of the clinical development of brivaracetam, it was identified that there were insufficient experimental toxicology data on the safety of the hydroxy acid metabolite, which accumulates at high concentrations in subjects with severe renal impairment. Therefore, the safety of the hydroxy acid metabolite was assessed in a battery of subsequent safety pharmacology studies in rodents and dogs (UCB, data on file). No adverse effects were observed on the CNS, gastrointestinal tract, or respiratory or cardiovascular systems. In the 14-day continuous intravenous infusion toxicity study in the Wistar rat, the hydroxy acid metabolite was of low toxicity, as demonstrated by very few findings observed after 14 days of treatment at doses up to 10 000 mg/kg/day. In this study there were no major differences between findings at 2000 and 10 000 mg/kg/day. At these high dose levels there were only small increases in kidney weights without any histological correlate and periportal hepatocellular degeneration without any modification of liver weight. A minor decrease in total white blood cell counts was observed at 10 000 mg/kg/day, mainly in male rats. No adverse effects were identified at the low dose of 500 mg/kg/day. Genotoxicity was evaluated *in vitro* in bacterial and mammalian cells and *in vivo* in rats. This hydroxy acid metabolite was neither mutagenic nor clastogenic. Although safety studies are not fully completed yet, based on already available findings it is not anticipated that longer-term exposure to this metabolite will result in any significant adverse effects.

Impaired hepatic function

A single oral 100-mg dose of brivaracetam was administered to 26 subjects stratified according to the Child–Pugh classification for mild (n = 6) moderate (n = 7) and severe (n = 7) hepatic impairment, and to six matched healthy controls. Plasma and urine concentrations of unchanged drug and metabolites were measured over 96 h [25]. The mean half-life of brivaracetam was 9.8 h, 14.2 h, 16.4 h and 17.4 h in healthy controls and in subjects with mild, moderate and severe hepatic impairment, respectively. Brivaracetam exposure in terms of AUC values (geometric means) was 29.7 μg/h/mL in healthy controls, and 44.6 μg/h/mL, 46.7 μg/h/mL, and 47.1 μg/h/mL in subjects with mild, moderate and severe hepatic impairment, respectively.

Compared with healthy control subjects, exposure to brivaracetam was increased by 50–60% in subjects with mild, moderate or severe hepatic impairment, without significant differences in relation to the degree of hepatic dysfunction. Exposure to the acid metabolite was increased by about 60–90% across Child–Pugh classes, whereas exposure to the hydroxy acid metabolite was increased 40–50% in the least liver-impaired subjects, only slightly increased in subjects with moderate impairment, and decreased by approximately 50% in the most severely affected. Exposure to the hydroxy metabolite decreased progressively by 40–80% with increasing hepatic dysfunction.

Overall, these findings indicate that the relative contribution of brivaracetam metabolic pathways is altered in subjects with hepatic impairment, with an increase in the formation of the acid metabolite and a decrease in the formation of the hydroxy metabolite. The adverse events reported in this study were mild to moderate, and their incidence was similar in the four groups. Dosage adjustments are not considered mandatory in patients with hepatic impairment, but a reduction in the starting and maintenance dosage may be considered on a case-by-case basis, also in relation to clinical response.

Drug interactions

Effect of other drugs on brivaracetam pharmacokinetics

In a population pharmacokinetic analysis of data from two adjunctive therapy studies in patients co-medicated with other AEDs, brivaracetam CL/*F* was estimated to be 5.15 L/h in the presence of enzyme-inducing AEDs compared with 3.63 L/h in the absence of enzyme inducers [23]. The difference is probably explained by stimulation of brivaracetam metabolism by enzyme-inducing AEDs such as carbamazepine, phenobarbital and phenytoin. Based on these data, enzyme-inducing AEDs would be expected to reduce plasma brivaracetam concentrations by about 30% and to shorten the brivaracetam half-life to approximately 5 h. However, a dose–response modelling, based on phase II data, has shown that concomitant enzyme-inducing AEDs did not affect the percentage of patients who are likely to respond or the extent of change in seizure frequency [26].

Preliminary data from CYP2C8 inhibition/induction studies indicated that repeated dosing with gemfibrozil 600 mg twice daily for 7 days had no significant effect on the plasma concentration of unchanged brivaracetam [27]. On the other hand, repeated administration of the enzyme inducer rifampicin 600 mg once daily for 8 days stimulated the biotransformation of brivaracetam via hydroxylation, decreased brivaracetam levels by 50% and shortened the brivaracetam half-life from 8.2 h to 4.5 h [27] (UCB, data on file).

Effect of brivaracetam on the pharmacokinetics of other antiepileptic drugs

Experiments conducted *in vitro* have shown that brivaracetam may inhibit epoxide hydrolase and, to a lesser extent, the CYP enzymes CYP3A4 and CYP2C19. In addition, it may induce weakly CYP3A4 [18].

In adjunctive therapy trials, brivaracetam (5–150 mg/day) did not cause any significant changes in the plasma concentration of concomitantly administered lamotrigine, levetiracetam, the mono-

hydroxy derivative of oxcarbazepine, valproic acid and topiramate [28].

In healthy volunteers, administration of brivaracetam 400 mg/day, which is at least four times above the dose expected to be required in patients with epilepsy, resulted in a slight (13%) reduction in the plasma levels of carbamazepine and a 2.5-fold increase in the levels of carbamazepine-10,11-epoxide [18]. The interaction is dose dependent: in patients with epilepsy, the carbamazepine-10,11-epoxide/carbamazepine ratio increased from 0.15 at baseline to 0.25, 0.31 and 0.44 at brivaracetam doses of 100, 200 and 400 mg/day, respectively (UCB, data on file). These changes in ratio are primarily ascribed to increases in the levels of carbamazepine-10,11-epoxide, since plasma carbamazepine concentration is not affected at brivaracetam doses below 400 mg/day.

Equivocal findings have been reported on the influence of brivaracetam on plasma phenytoin levels. In a formal interaction study in healthy volunteers who received single 600-mg doses of phenytoin in the absence and in the presence of concurrent treatment with brivaracetam (400 mg/day), a slight decrease in plasma phenytoin concentrations was observed during brivaracetam co-administration (UCB, data on file). However, in a study in patients with epilepsy on stable phenytoin therapy, addition of brivaracetam 400 mg/day resulted in an approximate 20% increase in phenytoin exposure at steady state (UCB, data on file). In a pooled analysis performed of data from phase II studies in patients with epilepsy, a similar increase in plasma phenytoin concentration by about 20% on average was observed after addition of brivaracetam at doses of 20 and 50 mg/day (UCB, data on file). In both the formal interaction study and the phase II studies, a high degree of inter- and intra-individual variability was observed, both between baseline measurements and under treatment. This is exemplified by a 2.3-fold increase in peak plasma phenytoin concentration in one patient in the formal interaction study, while in another subject peak concentration was reduced by 54%. Moreover, interpretation of the data from the phase II studies is made difficult by the small number of subjects who received phenytoin in these studies. In summary, the reason for the increase in phenytoin concentration being apparently unrelated to brivaracetam dose is unclear and larger patient numbers will be necessary for a better understanding of the relevance of the findings obtained so far.

Effect of brivaracetam on the pharmacokinetics of other drugs

Brivaracetam, given at the dosage of 400 mg/day, which is well above the highest dose investigated in phase II–III trials (150 mg/day), caused a moderate reduction of 20–30% in the extent of exposure and a 10–15% reduction in the peak plasma levels of ethinylestradiol and levonorgestrel in 24 healthy women receiving stable doses of an oral contraceptive (UCB, data on file). In the same study, there were no changes in the levels of estradiol, progesterone, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), or sex hormone-binding globulin (SHBG), and there was no evidence of ovulation. A second oral contraceptive study with brivaracetam 100 mg/day demonstrated an absence of interaction at that dose (UCB, data on file). Furthermore, continuation of brivaracetam dosing during the contraceptive-free week showed that trough levels of brivaracetam remained unchanged 1 week after interrupting the contraceptive.

Preliminary findings of a study aimed at assessing the effect of repeated brivaracetam administration at doses of 5, 50 and 150 mg/day over 1 week on CYP3A4 activity, using midazolam as a probe substrate, indicated the absence of induction of CYP3A4 activity by brivaracetam (UCB, data on file).

Serum level monitoring

There is currently no indication that monitoring plasma brivaracetam levels may aid in individualizing therapy, except for compliance assessment.

Efficacy

Proof-of-concept in photosensitive epilepsy

A single-blind, placebo-controlled phase IIa study assessed the effect of single doses of brivaracetam (10, 20, 40, or 80 mg) on the photoparoxysmal electroencephalographic response in 19 patients with photosensitive epilepsy [29]. Each patient received a single dose of placebo (day –1) and a single dose of brivaracetam (day 1) in the morning, at least 30 min after a light breakfast.

Of the 18 evaluable patients, none achieved complete abolishment of the photosensitivity response after placebo, compared with 78% after brivaracetam (Fig. 35.3). All subjects receiving the 80-mg dose of brivaracetam exhibited complete suppression of photosensitivity. The onset of drug action was fast (about 0.5 h after dosing), and its duration was twice as long after the 80-mg dose (59.5 h) as after lower doses. The area under the effect curve was linearly correlated with the area under the plasma concentration curve (Fig. 35.3).

Randomized controlled studies in refractory partial epilepsy

Two randomized, double-blind, placebo-controlled, adjunctive-therapy, parallel-group, phase IIb studies evaluated the efficacy and tolerability of different doses of brivaracetam in patients with refractory partial epilepsy receiving up to two concomitant AEDs [5,6]. Patients aged 16–65 years who had at least four partial-onset seizures, with or without secondary generalization, during a 4-week prospective baseline period were eligible for randomization. Prior or concomitant use of levetiracetam was permitted under the study protocols.

In study N01114, patients received placebo (n = 52) or brivaracetam 50 (n = 53) or 150 mg/day (n = 52) in two divided doses over a 3-week titration and a 7-week maintenance period. A statistically significant per cent reduction over placebo in weekly partial-onset seizure frequency during the 7-week maintenance period (primary efficacy variable) was not reached at either dose. Estimated per cent reductions over placebo were 14.7% (P = 0.093) and 13.6% (P = 0.124) for the 50 and 150 mg/day doses, respectively. However, a clear differentiation from placebo was observed for the 50 mg/day dose on several secondary efficacy analyses. In particular, a treatment effect was shown in weekly partial-onset seizure frequency per cent reduction from baseline (38.2%, P = 0.017, at 50 mg/day and 30.0%,

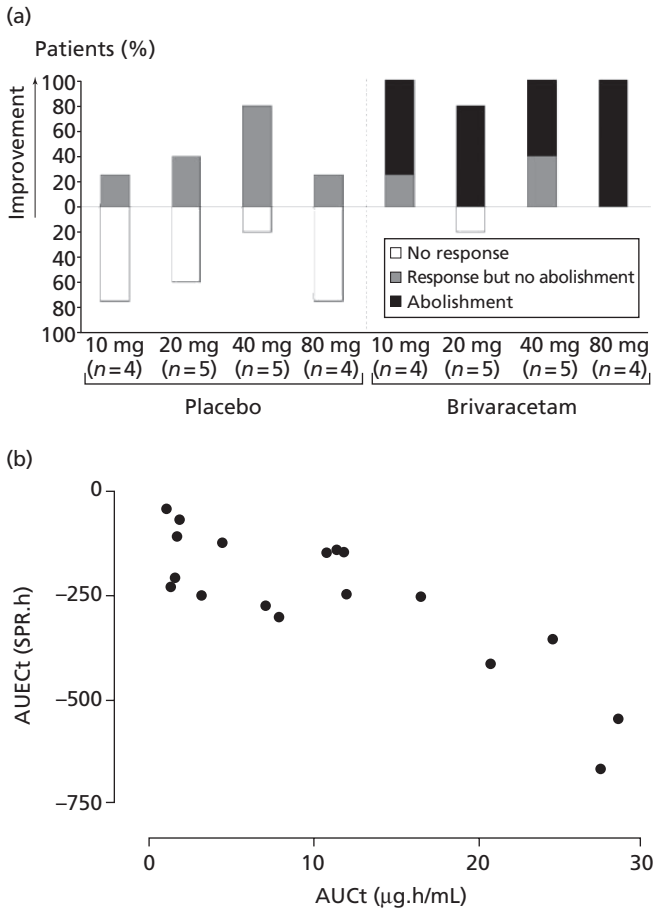

Fig. 35.3 Proof-of-concept placebo-controlled study of brivaracetam (single oral doses) in patients with photosensitive epilepsy. Reproduced from ref. 29 with permission from AAN Enterprises, Inc. (a) Standard photosensitivity range (SPR) response classification (comparison with pre-dose response) for the eye closure condition in relation to the administered dose of brivaracetam. Response = decrease of SPR by ≥3; abolishment, decrease of SPR to 0 at any tested time point. (b) Scatterplot of the area under the effect curve ($AUEC_t$, SPR change from pre-dose) versus area under the brivaracetam plasma concentration curve (AUC_t). Pearson $R = 0.82$; Spearman rho = 0.73.

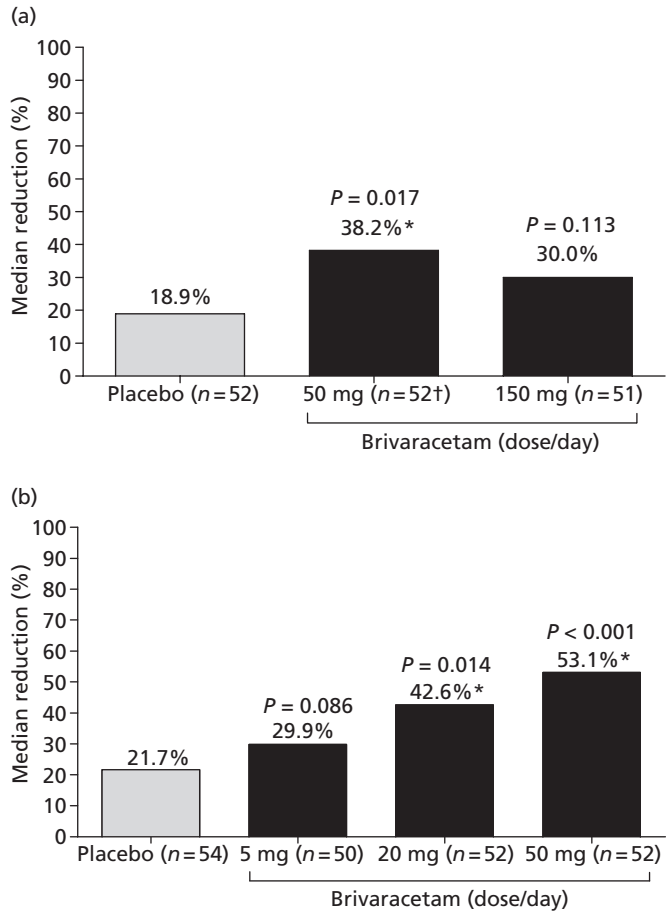

Fig. 35.4 Median per cent reduction in weekly partial-onset seizure frequency from baseline during the 7-week evaluation period in two adjunctive therapy randomized controlled trials of brivaracetam in patients with refractory partial epilepsy. (a) Study N01114 [6]. (b) Study N01193 [5]. *Statistically different from placebo; *P*-values are based on the Wilcoxon–Mann–Whitney test. †One patient had a seizure frequency of zero at baseline and reduction in partial-onset seizure frequency could not be evaluated in this patient.

$P = 0.113$, at 150 mg/day, compared with 18.9% on placebo) (Fig. 35.4a). Responder rates (percentage of patients with at least 50% reduction in seizure frequency compared with baseline) during the 7-week maintenance period were 39.6% and 33.3% in the 50 and 150 mg/day groups compared with 23.1% in the placebo group [6]. Estimated odds ratios (ORs) for responder rates (brivaracetam/placebo) were 2.16 ($P = 0.077$) at 50 mg/day and 1.66 ($P = 0.261$) at 150 mg/day (UCB, data on file). Thus, the higher brivaracetam dose (150 mg/day) did not appear to add therapeutic benefit. Freedom from partial-onset seizures during the entire 10-week treatment period was achieved in 9.4% of patients at 50 mg/day, 5.8% at 150 mg/day, and 1.9% on placebo [6].

In study N01193, patients received placebo ($n = 54$) or brivaracetam 5 ($n = 50$), 20 ($n = 52$) or 50 mg/day ($n = 52$) in two divided doses without titration for 7 weeks. The estimated per cent reduction in weekly partial-onset seizure frequency during the treatment period over placebo (primary efficacy variable) was 9.8% ($P = 0.240$) at 5 mg/day, 14.9% ($P = 0.062$) at 20 mg/day and 22.1% ($P = 0.004$) at 50 mg/day. This dose–response relationship was consistent with the results of secondary efficacy analyses. Per cent reduction in weekly partial-onset seizure frequency from baseline was 29.9% ($P = 0.086$) at 5 mg/day, 42.6% ($P = 0.014$) at 20 mg/day and 53.1% ($P < 0.001$) at 50 mg/day, compared with 21.7% on placebo (Fig. 35.4b). Responder rates were 32.0% at 5 mg/day (OR over placebo, 2.66; $P = 0.047$), 44.2% at 20 mg/day (OR, 4.27; $P = 0.002$) and 55.8% at 50 mg/day (OR, 7.21; $P < 0.001$), compared with 16.7% on placebo. Proportions of patients free from partial-onset seizures during the 7-week treatment period were 8.0%, 7.7% and 7.7% at 5, 20 and 50 mg/day, respectively, compared with 1.9% on placebo [5] (UCB, data on file).

Dose– and exposure–response modelling, based on the pooled data from the two studies, demonstrated a dose–response relationship for adjunctive brivaracetam therapy in 73% of patients, with an ED_{50} of 21 mg/day [26]. There was no improvement on switch-

ing from a dose–response to an exposure (plasma concentration)–response relationship. Age, body weight, gender, number of concomitant AEDs or the use of enzyme-inducing AEDs had no significant effect on the percentage of patients who improved or on the magnitude of the response.

Two randomized, double-blind, placebo-controlled, adjunctive therapy studies in adults with partial epilepsy (N01252, N01253; www.clinicaltrials.gov) will provide further information on the efficacy and safety of different doses of brivaracetam (20, 50 and 100 mg/day and 5, 20 and 50 mg/day, respectively) over a 12-week treatment period without titration. Several studies with brivaracetam are currently ongoing; two open-label extension studies in which patients from the phase II and phase III studies can continue to receive brivaracetam at flexible doses between 5 and 150 mg/day, and two conversion to monotherapy trials comparing brivaracetam at doses of 50 and 100 mg/day with a historical low-dose active control group, which are currently enrolling patients with uncontrolled partial-onset seizures (N01276, N01306; www.clinicaltrials.gov).

Randomized controlled studies in patients with other epilepsy syndromes

A double-blind, placebo-controlled, adjunctive therapy study (N01254; www.clinicaltrials.gov) will assess the safety and tolerability of brivaracetam in the dose range of 20–150 mg/day, in two divided daily doses, over a period of 16 weeks (8 weeks dose-finding and 8 weeks maintenance) in patients with inadequately controlled partial-onset or primary generalized seizures despite treatment with up to three concomitant AEDs.

Brivaracetam has received orphan drug designation in 2005 by the Food and Drug Administration for the treatment of symptomatic myoclonus, and by the European Medicines Agency for the treatment of progressive myoclonic epilepsies. Two randomized, double-blind, placebo-controlled, parallel-group studies of brivaracetam (5 and 150 mg/day in one study, 50 and 150 mg/day in the other, in two divided doses) as adjunctive treatment in 50 and 56 patients, respectively, with genetically ascertained Unverricht–Lundborg type progressive myoclonic epilepsy have been recently completed (N01187, N01236; www.clinicaltrials.gov). These patients suffered from moderate to severe action myoclonus and had failed, or were currently treated with, valproic acid and clonazepam. Previous and/or concomitant use of levetiracetam or piracetam was permitted. Both studies failed to reach the primary endpoint of reducing the severity of action myoclonus as measured by the Unified Myoclonus Rating Scale (UMRS).

Studies in other indications

The potential efficacy of brivaracetam (200 and 400 mg/day) in patients with postherpetic neuralgia has been assessed in a 4-week exploratory double-blind, randomized, placebo-controlled, parallel-group study (N01162, UCB, data on file). A total of 152 patients with pain for ≥6 months (pain scores ≥4 on an 11-point Likert scale) were included. In this trial, brivaracetam was well tolerated but did not show superiority to placebo in relieving the pain associated with postherpetic neuralgia.

Adverse effects

An overall safety analysis has been performed based on data from 18 phase I–IIa studies (UCB, data on file). A total of 327 subjects were included, of whom 112 received placebo and 318 received brivaracetam. The population included 201 healthy volunteers, 16 elderly volunteers, 81 subjects with epilepsy and 29 subjects with renal or hepatic impairment. Brivaracetam doses ranged between 10 and 1400 mg with single administration and between 200 and 800 mg/day following repeated administration in two divided daily doses. The maximal tolerated dose was 1000 mg after single doses, and was not reached (>800 mg/day) following multiple doses. The most commonly reported treatment-emergent adverse events (TEAEs) affecting ≥10% of patients were dizziness, somnolence, fatigue and headache. The median onset time of adverse events was ≤1 h and their duration appeared to be short. The incidence of adverse events decreased with subsequent administrations of brivaracetam. There was no indication of haematological or liver toxicity.

A further safety and tolerability evaluation was based on pooled data from the two phase IIb adjunctive therapy studies in patients with epilepsy [30]. Brivaracetam (5–150 mg/day) was overall well tolerated, and retention of patients was high in both studies (N01114: brivaracetam 95%, placebo 92%; N01193: brivaracetam 96%, placebo 91%). The proportion of patients with TEAEs was similar in the brivaracetam (all doses; 154/259, 59.5%) and the placebo (64/106, 60.4%) groups (Table 35.4). Adverse events leading to discontinuation of study medication occurred in eight brivaracetam patients (3.1%) and three placebo patients (2.8%). The most frequent TEAEs affecting ≥5% of patients are shown in Table 35.5. No significant difference in incidence was observed between the brivaracetam and the placebo groups for any of these events. No clinically significant changes in laboratory parameters or vital signs were observed in any treatment group.

Table 35.4 Summary of treatment-emergent adverse events (AEs) based on pooled data from brivaracetam randomized placebo-controlled phase IIb studies (N01114 and N01193).

	Brivaracetam, all doses (n = 259), n (%)	Placebo (n = 106), n (%)
Total number of AEs	376	168
Subjects with at least one AE	154 (59.5)	64 (60.4)
Subjects with AEs leading to discontinuation	8 (3.1)	3 (2.8)
Subjects with AEs leading to dose change	5 (1.9)	1 (0.9)
Subjects with drug-related[a] AEs	70 (27.0)	33 (31.1)
Subjects with severe AEs	6 (2.3)	5 (4.7)
Subjects with serious AEs	4 (1.5)	4 (3.8)
Subjects with drug-related[a] serious AEs	1 (0.4)	2 (1.9)

UCB, data on file.
Only adverse events with an incidence of ≥5% in any treatment group are listed.

A randomized, double-blind, placebo- and positive-controlled thorough electrocardiographic study of multiple doses of brivaracetam in 182 healthy subjects to assess potential effects on the QT interval demonstrated the absence of any effects of brivaracetam on cardiac repolarization both at high therapeutic doses (150 mg/day) and at doses far in excess of those expected to be required in therapeutic use (800 mg/day) [31].

In the pharmacokinetic study of the intravenous solution, single brivaracetam doses ranging from 10 to 150 mg were well tolerated as 15-min infusions and as bolus injections (10 mg/12 s). All TEAEs were of mild or moderate severity, the most frequent (reported by ≥10% of patients) being headache, somnolence, fatigue, dizziness, feeling drunk and dysgeusia [21]. Physical examination, vital signs, electrocardiogram (ECG) and laboratory parameters showed no clinically significant abnormalities, and observed abnormalities in 24-h Holter ECG recordings were judged as not clinically significant and unrelated to the study drug by the investigator.

Place in current therapy

Since phase III studies have not been completed, at present there are insufficient data to determine the place of brivaracetam in epilepsy therapy. Phase II adjunctive therapy controlled trials in partial-onset seizures have shown that brivaracetam can be associated with high responder rates and excellent tolerability. If these results are confirmed in phase III studies, brivaracetam may prove a useful drug for the management of patients with refractory partial epilepsy. The possibility of initiating treatment with effective dosages without titration and with good tolerability would be particularly valuable features.

Brivaracetam shares with levetiracetam not only a similar structure, but also a common target at the SV2A binding site. Brivaracetam, however, has additional pharmacological actions not shared by levetiracetam, and in some animal models its effectiveness is superior to that of levetiracetam. Whether similar findings also apply in human epilepsy is unknown. In adjunctive therapy trials in partial epilepsy, levetiracetam-treated patients were not excluded, but the data available so far do not allow a conclusion on whether brivaracetam efficacy and tolerability are altered by previous or concomitant exposure to levetiracetam. Further data on this issue, and on the putative advantages of brivaracetam over levetiracetam, would be desirable. Additional areas where further data are required relate to brivaracetam's optimal dose range, and its spectrum of efficacy in different seizure types. While broad-spectrum efficacy is predicted by results in animal models, confirmation from controlled clinical studies in specific epilepsy syndromes is warranted.

The role of an AED in the therapeutic algorithm can only be defined after significant experience in the routine clinical setting has been acquired. While this is not yet the case with brivaracetam, results from the initial clinical trials indicate that this compound has promising features, which could contribute to its success for the treatment of epilepsy in the future.

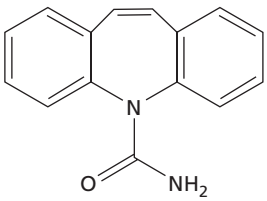
Matti Sillanpää[1], *Leena Haataja*[1], *Torbjörn Tomson*[2] *and Svein I. Johannessen*[3]

[1] University of Turku, Turku, Finland
[2] Karolinska University Hospital, Stockholm, Sweden
[3] Rikshospitalet University Hospital, Oslo, Norway



Primary indications	First-line or adjunctive therapy of partial and generalized tonic–clonic seizures
Usual preparation	Tablets: 100, 200, 400 mg; chewtabs: 100, 200 mg; sustained-release formulations: 200, 400 mg; suspension: 100 mg/5 mL; suppositories: 125, 250 mg
Usual dosages	Adults: starting dose is 100–200 mg/day, increased over 2–4 weeks to 400–600 mg/day. Maintenance dosages are usually in the range of 400–1600 mg/day (patients on concomitant enzyme inducers may require higher doses). Children: starting dose is up to 5 mg/kg/day, increased over 2–4 weeks to 10–20 mg/kg/day. Maintenance dosages are usually in the range of 5–30 mg/kg/day (10–40 mg/kg/day in infants)
Dosing frequency	2–4 times/day. Sustained-release formulations are usually administered twice daily
Significant drug interactions	Phenytoin and barbiturates decrease serum carbamazepine levels. Valproic acid and valpromide increase serum carbamazepine-10,11-epoxide levels. Felbamate decreases the serum levels of carbamazepine and increases the levels of carbamazepine-10,11-epoxide. Verapamil, erythromycin, dextropropoxyphene and many other drugs may increase carbamazepine levels. Carbamazepine is an enzyme inducer and stimulates the metabolism of many other antiepileptic drugs and drugs used to treat concomitant conditions. The central nervous system adverse effects of carbamazepine may be potentiated by lamotrigine and by oxcarbazepine
Serum level monitoring	Useful
Reference range	4–12 μg/mL (17–51 μmol/L)
Common/important adverse effects	Drowsiness, fatigue, dizziness, ataxia, diplopia, blurring of vision, dyskinesias, rash and other idiosyncratic reactions (including serious reactions affecting the bone marrow and other organs), hyponatraemia, cardiac dysrhythmias, decreased bone mineral density
Main advantages	Extensive clinical experience, highly effective and usually well tolerated
Main disadvantages	Transient adverse effects on initiating therapy. Occasional severe toxicity. Potential to precipitate or aggravate some generalized seizure types, particularly absence and myoclonic seizures. Enzyme-inducing effects and high drug interaction potential
Mechanism of action	Blockade of voltage-gated sodium channels
Oral bioavailability	75–85%. Bioavailability may be lower with sustained-release formulations

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Time to peak levels	4–8 h (or even longer, depending on formulation)
Elimination	Primarily metabolic through oxidation, hydroxylation, glucuronidation and sulphuration. Metabolism is mediated largely by cytochrome CYP3A4
Volume of distribution	0.8–2.0 L/kg
Elimination of half-life	At steady state, 5–26 h (very variable). Half-life is longer after a single dose and shortens during multiple-dose treatment due to autoinduction. Shortest half-life values occur in children and in patients co-medicated with enzyme inducers
Plasma clearance	At steady state, 1.06–3.59 L/h (very variable). Clearance is lower after a single dose and increases during multiple-dose treatment due to autoinduction. Highest clearance values occur in children and in patients co-medicated with enzyme inducers
Protein binding	75%
Active metabolites	Carbamazepine-10,11-epoxide
Comment	A drug of first choice for the treatment of partial seizures and generalized tonic–clonic seizures in children and adults

Introduction

The origin of carbamazepine dates back to the year 1899, when Thiele and Holzinger [1] described iminodibenzyl and its weak antiepileptic effect. This effect became substantially stronger when a carbamyl group was added at the 5 position of iminodibenzyl and combined with iminostilbene making a double bond between the 10 and 11 positions, resulting in a tricyclic compound which corresponds to carbamazepine. Since the mid-1960s, carbamazepine has been successfully used all over the world.

Chemistry

Carbamazepine corresponds chemically to 5H-dibenz(b,f)azepine-5-carboxamide. It is a white or yellowish-white, crystalline, odourless and tasteless powder. The molecular weight is 236.3. Carbamazepine is virtually insoluble in water, but soluble in absolute alcohol and benzene, chloroform, dichlormethane and other organic solvents. Its lipophilicity plays an important role in facilitating passage across biological membranes and barriers, including the blood–brain barrier.

The chemical structure of carbamazepine is similar to that of certain psychotropic drugs, such as imipramine, chlorpromazine and maprotiline. Carbamazepine may then be considered as a member of a family of polycyclic psychoactive drugs, and its activity in a number of psychiatric disorders, mainly as a mood stabilizer, has been clinically demonstrated. On the other hand, there are some features of its two-dimensional structure which are in common with certain antiepileptic drugs (AEDs) such as clonazepam, phenobarbital, phensuximide and phenytoin [2].

Pharmacology

The original studies of Theobald and Kuntz [3] in animal models revealed that carbamazepine shows potent activity against seizures induced by maximal electroshock, and a less potent effect in preventing experimental seizures induced by pentylenetetrazol. *In vitro* studies in hippocampal slices demonstrated that carbamazepine reduces burst firing in a calcium-free environment, implying a direct membrane effect, and not a direct neurotransmitter-mediated action [4]. Overall, the pharmacological profile of carbamazepine in animal models of seizures and epilepsy resembles that of phenytoin, and is predictive of activity against partial seizures and generalized tonic–clonic seizures [5]. Carbamazepine aggravates seizures in animal models of absence and myoclonic seizures, such as the Genetic Absence Epilepsy Rat from Strasbourg (GAERS) [6].

The main action of carbamazepine is mediated through inhibition of voltage-activated sodium channels and, consequently, inhibition of action potentials and excitatory neurotransmission. High-frequency, repetitive neuronal firing is therefore limited [7]. The inhibitory potency is strongly dependent on use and accumulates with prolonged activation [5]. This is a classic mechanism of anticonvulsant action that is also shared by phenytoin, oxcarbazepine and, in addition to other mechanisms, by lamotrigine, zonisamide, topiramate and felbamate [5]. Some sodium channel blockers also have affinity for voltage-gated calcium channels, and inhibition of these channels may contribute to decrease excitatory neurotransmission. This mechanism is also important for the inhibitory effect exerted by some of these drugs on neuropathic pain [5,8].

Carbamazepine, like valproic acid, modulates intracellular signalling pathways which have been shown to be important in the

pathophysiology of bipolar disorder [9,10]. Many target proteins and signalling pathways may be involved in the clinical efficacy of carbamazepine and other mood stabilizers in bipolar disorder. Most studies conducted in this area are preclinical, and the effects of AEDs are usually compared with the effects on inositol concentrations by lithium [8]. Actions by carbamazepine and valproic acid on these proteins could explain their neurotrophic and neuroprotective properties that ameliorate impairments of cellular plasticity and resilience underlying the pathophysiology of mood disorders [11].

Pharmacokinetics

Absorption

The gastrointestinal absorption of carbamazepine is rather slow and variable, probably due to its slow dissolution in the gastrointestinal fluids. Peak serum concentrations are usually attained between 4 and 8 hours after oral administration of immediate-release tablets, but may be considerably longer depending on the formulation employed. The bioavailability of immediate-release tablets, chewable tablets swallowed whole and chewable tablets chewed before swallowing is estimated to be similar, in the order of 75–85% [12]. The bioavailability of many sustained-release formulations, however, is about 15–35% lower than that of immediate-release formulations, resulting in lower serum concentrations at steady state when patients are switched from immediate- to sustained-release dosage forms. Sustained-release formulations are also absorbed more slowly than immediate-release tablets and produce more stable serum drug concentrations during the day and at night, even when given twice daily, than immediate-release tablets given three times daily [13]. Conversely, oral suspensions are absorbed more rapidly and produce higher peak concentrations than tablets [12]. Food has not been shown to significantly affect the gastrointestinal absorption of carbamazepine [12].

Preparations of carbamazepine produced by different manufacturers may vary in bioavailability. To avoid the risk of breakthrough seizures or adverse effects, frequent changes in formulation are best avoided [14]. The bioavailability of moistured tablets is reduced up to 50% by storage of carbamazepine formulations in hot, humid conditions, which alter its form. Consequently, carbamazepine tablets should be stored in a dry, cool and dark place.

After rectal administration of a carbamazepine oral mixture, absorption appears to be significantly slower than after oral administration, but the overall bioavailability is similar provided that defecation does not occur during the first 2 hours. Rectal administration of suppositories has also been tested, and it has been suggested that it may need to be about 30% higher to compensate for lower bioavailability by this route [15].

Distribution

The apparent volume of distribution of carbamazepine varies reportedly from 0.8 to 2.0 L/kg in human adults. In neonates and infants it is 1.5-fold to 2-fold greater than in older children and adults.

Carbamazepine is highly bound (75–80%) to plasma proteins, including albumin and α_1-acid glycoprotein. A wider variation in binding is found in infants and children. The plasma protein binding of the active metabolite carbamazepine-10,11-epoxide is about 50% [13].

There is a significant positive correlation between brain and serum concentrations, with a ratio of about 1.1 for carbamazepine and 1.2–1.6 for carbamazepine-10,11-epoxide. There seems to be a non-specific binding of carbamazepine and carbamazepine-10,11-epoxide to brain tissue constituents [16].

Elimination

Only negligible amounts of carbamazepine are excreted unchanged in urine. Elimination occurs virtually entirely by metabolism. In the study of Faigle and Feldman [2], 72% of the radioactivity associated with a radiolabelled carbamazepine dose was detected in urine and 28% in the faeces.

Metabolic pathways include epoxidation, hydroxylation, glucuronidation and sulphuration. The main metabolic pathway is epoxidation, which is catalysed primarily by the cytochrome P450 enzyme CYP3A4 and results in the formation of carbamazepine-10,11-epoxide. This metabolite is pharmacologically active and accumulates in serum at clinically relevant concentrations, contributing to both therapeutic and adverse effects. Carbamazepine-10,11-epoxide is subsequently hydrolysed to the inactive metabolite trans-10,11-dihydroxy-carbamazepine.

Carbamazepine metabolism follows first-order kinetics and may vary considerably across subjects, resulting in a poor correlation between dose and serum concentration of both parent drug and its metabolites.

The metabolism of carbamazepine undergoes autoinduction. This is already detectable, but not fully expressed, by the second day after the first dose. In the first few weeks of treatment, autoinduction and the consequent increase in drug clearance cause a progressive decrease in serum carbamazepine concentrations, and increments in daily dosage may be needed to maintain the serum drug concentration within a given target range. Autoinduction is also dose dependent, i.e. drug clearance increases with increasing dosage and increasing serum drug concentration.

After a single dose, the half-life of carbamazepine varies between 20 and 65 h, but after autoinduction is completed (about 20–30 days after starting treatment), half-lives are in the range of 5–26 h for carbamazepine and 3–23 h for carbamazepine-10,11-epoxide.

Carbamazepine metabolism is also subject to heteroinduction by concomitantly administered enzyme-inducing antiepileptic drugs (AEDs) [2,12].

Relationship between serum concentration and dosage

Due to dose-dependent autoinduction, the pharmacokinetics of carbamazepine is non-linear, i.e. serum drug concentrations increase less than proportionally with each increment in dosage [17]. On the other hand, since the ratio of carbamazepine-10,11-epoxide to carbamazepine increases with increasing dosage, serum carbamazepine concentrations at higher dosages tend to underestimate the amount of pharmacologically active compound in blood.

Because of the relatively short half-life of carbamazepine under steady-state conditions, serum carbamazepine concentrations may show marked fluctuations during a dosing interval, with high peak plasma concentrations, which may result in intermittent

adverse effects. Fluctuations are particularly marked in children and in patients co-medicated with enzyme inducers, and may be minimized by more frequent daily administration or by use of a sustained-release formulation.

Pharmacokinetics in special groups

Children

The bioavailability of carbamazepine is similar in children and adults, but in infants the extent of absorption may be reduced and more variable. The bioavailability of carbamazepine may be reduced greatly by malabsorption states, and protein–energy malabsorption in particular. The volume of distribution of carbamazepine is 1–1.5 times higher in infants than in children and adults.

In children, there is a wide variation in carbamazepine clearance and half-life, in relation to the child's age, co-medication and duration of treatment. The carbamazepine-10,11-epoxide to carbamazepine ratio also varies widely, but increases with increasing dosage and decreases progressively with age. Higher clearance rates are correlated with early childhood years, small body mass, high daily dosage and male gender. Diurnal fluctuations in serum carbamazepine concentrations are also greater in children than in adults, and to minimize adverse effects associated with high peak plasma levels a sustained-release formulation is often used in children able to take solid medications [12].

Elderly

Both autoinduction and heteroinduction by enzyme-inducing AEDs are retained in the elderly, but the lower metabolic rate results in moderately decreased carbamazepine clearance in elderly subjects compared with non-elderly adults [18]. This, together with an increased sensitivity to the effects of carbamazepine in old age, contributes to dosage requirements being lower in the elderly than in the young.

Pregnancy

During the first trimester, serum carbamazepine concentrations are reportedly reduced compared with the prepregnant state, but the data are controversial. Total serum carbamazepine concentrations may be lower toward the end of pregnancy, but changes in unbound serum concentrations are generally less prominent. Overall, clinically significant changes in carbamazepine pharmacokinetics do not appear to be common during pregnancy, although in occasional patients dosage adjustments may be needed [19–21].

The cord blood–maternal concentration ratio of carbamazepine ranges from 0.5 to 0.8. The fetal brain to serum ratio is similar to that observed in adults, probably due to the fact that both carbamazepine and carbamazepine-10,11-epoxide are easily transferred to fetal tissues. The carbamazepine half-life in neonates of mothers on continuing carbamazepine medication has been reported to range from 8.2 to 27.7 h [12].

Breastfeeding

There is a wide variation in milk to serum carbamazepine concentration ratio, with a range of 0.15–0.80. Full-term neonates of normal birth weight (3000–3500 g) born to mothers receiving carbamazepine medication have been estimated to receive a dose of 0.5–0.7 mg/kg through breast milk. Mothers taking carbamazepine may breastfeed their infants, provided that the infant is observed for possible adverse effects (e.g. excessive somnolence or skin rashes). Monitoring of serum carbamazepine concentrations in breastfed infants is not mandatory. Very rare cases of neonatal transient hepatic dysfunction have been reported [22].

Hepatic disease

Mild or moderate liver dysfunction does not affect carbamazepine metabolism. However, a decrease in plasma protein binding may occur. More severe dysfunction may result in decreased carbamazepine clearance [12].

Other diseases

In patients with renal disease, no significant changes in carbamazepine pharmacokinetics have been noted. In heart failure, the congestion of major vital organs may result in slower absorption [12].

Drug interactions

Drug interactions with carbamazepine are common. Since carbamazepine is primarily metabolized by CYP3A4, concomitant medications that induce or inhibit CYP3A4 may have prominent effects on carbamazepine clearance and modify significantly serum carbamazepine concentrations at steady state. Carbamazepine itself is a potent inducer of drug-metabolizing enzymes, and by this mechanism it affects in an important way the pharmacokinetics of many concomitantly administered drugs [23–25].

If interacting co-medications cannot be avoided, careful observation of clinical response and, whenever appropriate, monitoring of serum drug concentrations will aid in minimizing potentially adverse clinical consequences [25].

Interactions between carbamazepine and other AEDs

Interactions resulting in altered serum concentration of carbamazepine or altered carbamazepine response

Serum carbamazepine concentrations are lowered by combination therapy with phenobarbital, phenytoin, primidone, oxcarbazepine and felbamate (Table 36.1).

Valproic acid, valpromide and felbamate may cause an increase in the concentrations of carbamazepine-10,11-epoxide. An increase in serum concentration of carbamazepine-10,11-epoxide has been reported occasionally after addition of lamotrigine, but such interaction has not been confirmed in most studies. The appearance of central nervous system (CNS) adverse effects, which is sometimes observed following addition of lamotrigine in carbamazepine patients, appears to mainly be due to a pharmacodynamic drug interaction [23–25].

Carbamazepine metabolism does not appear to be affected by gabapentin, levetiracetam, pregabalin, tiagabine, topiramate or vigabatrin.

Interactions resulting in altered serum concentration of the other AEDs

Carbamazepine stimulates the rate of metabolism of most co-administered AEDs, including valproic acid, tiagabine,

[a] Little effect on serum carbamazepine concentration, but marked increase in serum carbamazepine-10,11-epoxide, particularly with valpromide.
[b] The decrease in serum carbamazepine concentration is associated with an increase in serum carbamazepine-10,11-epoxide.
[c] Possible appearance of neurotoxic effects may be related to a pharmacodynamic interaction.
[d] Variable effects have been reported in some studies.

ethosuximide, lamotrigine, topiramate, oxcarbazepine and its monohydroxy derivative, zonisamide, felbamate, rufinamide, many benzodiazepines and, to some extent, levetiracetam [23–25]. The clinical significance of these interactions is usually modest because the consequences of the reduction in serum level of the affected AED are compensated for by the added pharmacological effect of carbamazepine. However, in some cases, seizure control may be adversely influenced. Dosage adjustments of the AED affected by the interaction are most commonly required for valproic acid, lamotrigine and tiagabine, because the decrease in the serum concentrations of these drugs after adding carbamazepine can be quite prominent (50–75%).

Particular caution is required when carbamazepine is withdrawn from the therapeutic regimen of patients taking co-medications, the metabolism of which have been increased by carbamazepine. In fact, the concentration of these drugs may increase to toxic levels after removal of carbamazepine, unless their dosage is adjusted appropriately. This is especially true for valproic acid, lamotrigine and tiagabine.

The effects of carbamazepine on the pharmacokinetics of phenobarbital and primidone are somewhat variable (Table 36.2). In patients on primidone, carbamazepine may decrease the serum levels of primidone and increase those of metabolically derived phenobarbital.

Interactions between carbamazepine and other drugs

Interactions resulting in altered serum concentrations of carbamazepine

Many drugs other than AEDs affect carbamazepine metabolism (Table 36.3). Several drugs, including known inhibitors of CYP3A4, can precipitate signs of carbamazepine toxicity by increasing serum carbamazepine concentrations [23–25]. This needs to be taken into consideration when selecting drugs within a given pharmacological class: for example, clarithromycin, tro-

Ticlopidine
Verapamil

B Drugs causing a decrease in serum carbamazepine concentration

Probenecid
St John's wort

Modified from refs 23 and 25.

leandomycin and erythromycin increase serum carbamazepine concentrations markedly and should be preferably avoided in patients taking carbamazepine, whereas other macrolides such as azithromycin, dirithromycin, rokitamycin and spiramycin do not inhibit CYP3A4 and can be given safely to carbamazepine-treated patients [26]. Grapefruit juice may also inhibit CYP3A4, and has a modest elevating effect on serum carbamazepine concentrations.

Interactions whereby other drugs decrease serum carbamazepine levels are less common. Probenecid appears to reduce the serum concentration of carbamazepine by increasing its biotransformation to carbamazepine-10,11-epoxide [27]. St John's wort may also reduce serum carbamazepine concentrations.

Interactions resulting in altered serum concentrations of other drugs

Carbamazepine induces the metabolism of many other drugs, including steroids (including hormonal contraceptives), oral anticoagulants, ciclosporin A, many anti-cancer agents and many psychotropic drugs (Table 36.4).

Most of these interactions are clinically significant [23–25]. The interaction is greatest with drugs which undergo significant first-pass metabolism, such as itraconazole, praziquantel, indinavir and most dihydropyridine calcium antagonists. In enzyme-induced patients the serum concentration of these drugs may decrease 5- to 10-fold, and the practical management of these patients may be very difficult. Drug interactions involving oral contraceptives, oral anticoagulants, immunosuppressants and chemotherapeutic agents may have serious consequences when they result in therapeutic failure of the affected drug [25]. If the dosage of the affected drug has been increased to compensate for its enhanced clearance, serious consequences may also arise when carbamazepine therapy is withdrawn. In that situation, the serum concentration of the affected drug may increase to toxic levels, unless dosage is carefully readjusted.

In some instances, when the affected drug is converted to toxic metabolites, enzyme induction by carbamazepine may result in potentiation of toxicity rather than in reduced pharmacological effect. A possible example is provided by some evidence that the concomitant use of carbamazepine and isoniazid may increase isoniazid-induced liver toxicity, putatively due to accelerated production of hepatotoxic isoniazid metabolites.

Pharmacodynamic interactions between carbamazepine and other drugs

The combination of lithium and carbamazepine may cause enhanced neurotoxic effects in spite of serum lithium concentrations remaining within the therapeutic range. This interaction is probably pharmacodynamic in nature.

Because carbamazepine is structurally related to tricyclic antidepressants, the use of carbamazepine in combination with monoamine oxidase inhibitors (MAOIs) is not recommended. Before administering carbamazepine, MAOIs should be discontinued for a minimum of 2 weeks, or longer if the clinical situation permits.

Concomitant medication of carbamazepine and some diuretics (hydrochlorothiazide, furosemide) may lead to symptomatic hyponatraemia.

Carbamazepine may antagonize the effects of non-depolarizing muscle relaxants (e.g. pancuronium). Although pharmacokinetic effects may contribute to this interaction, a pharmacodynamic mechanism is probably also involved. The dosage of non-depolarizing muscle relaxants may need to be raised and patients should be monitored closely for a more rapid recovery from neuromuscular blockade than expected.

Carbamazepine, like other psychoactive drugs, may potentiate the CNS depressant effects of ethanol.

Serum level monitoring

There are no prospective controlled trials that define therapeutic concentrations for carbamazepine, as is the case for most other AEDs [28]. Studies, however, suggest that most patients optimally treated with carbamazepine have serum concentrations in the order of 4–12 μg/mL (17–51 μmol/L) [29]. The optimal concentration may be lower in patients on co-medication with other AEDs. There is, in any case, a considerable overlap between serum carbamazepine concentrations in well-controlled patients and those with adverse effects.

Carbamazepine has a narrow therapeutic index, and the relationship between dose and carbamazepine concentration is unpredictable. In addition, the susceptibility of carbamazepine metabolism to important drug interactions supports the need to individualize carbamazepine treatment using therapeutic drug

monitoring. Since carbamazepine has a relatively short half-life, sampling time in relation to dose ingestion is important. Ideally, blood samples should be drawn before the morning dose, but in some situations (e.g. in patients with intermittent adverse effects) separate determinations both at the time of trough and at the expected time of peak may be desirable. Carbamazepine-10,11-epoxide is not routinely measured, though there are patients in whom high concentrations of this metabolite can be responsible for otherwise unexplained toxicity [29].

Efficacy

Carbamazepine is indicated for the treatment of partial-onset and generalized tonic–clonic seizures but not for absence, myoclonic and most other generalized seizure types. Its efficacy has been evaluated in a large number of clinical trials including patients of different ages, with inclusion criteria usually based on seizure type rather than epilepsy syndrome.

Partial-onset seizures

Other than phenytoin, carbamazepine is the only AED considered to be established as efficacious or effective as initial monotherapy for adults with newly diagnosed or untreated partial-onset seizures by the criteria of the Commission of Therapeutic Strategies of the International League against Epilepsy (ILAE) level A recommendation [30]. No other drug has been shown to be more effective than carbamazepine for this indication in randomized controlled trials. Carbamazepine is therefore established as standard treatment for partial-onset seizures in adults and represents an adequate reference for comparative trials according to the ILAE criteria [30]. In fact, there have been many double-blind and open-label randomized controlled studies which compared the efficacy of carbamazepine and other AEDs in patients with partial-onset seizures of different ages.

Adults

In the Veterans' Affairs multicentre double-blind study carried out in the USA, 622 adults with previously untreated or undertreated partial and secondary generalized seizures were randomized to carbamazepine, phenobarbital, phenytoin or primidone [31]. The follow-up period was 2 years or up to withdrawal for lack of efficacy or adverse effects. Overall success rates in terms of retention on the allocated treatment were highest with carbamazepine and phenytoin, intermediate with phenobarbital and lowest with primidone. Carbamazepine provided complete control of all partial seizures more often than primidone or phenobarbital. Carbamazepine was subsequently compared with valproic acid using a similar methodology [32]. In total, 480 adults with previously untreated or undertreated partial-onset seizures were randomized. Seizure freedom rates were similar at 1 and 2 years' follow-up, although patients with predominantly complex partial seizures did significantly better with carbamazepine in terms of time to first seizure. Another double-blind randomized trial compared carbamazepine and vigabatrin in 459 patients, aged 12–65 years, with newly diagnosed partial-onset seizures [33]. Seizure freedom at 1 year was significantly higher with carbamazepine (58%) than with vigabatrin (38%), although vigabatrin was better tolerated. In a more recent double-blind trial using a non-inferiority design, adults with newly diagnosed partial-onset or generalized tonic–clonic seizures (but excluding patients with clinical or EEG features suggestive of idiopathic generalized epilepsy) were randomized to controlled-release carbamazepine (400–1200 mg/day, $n = 285$) or levetiracetam (1000–3000 mg/day, $n = 291$) [34]. Approximately 80% in each treatment group were considered to have partial-onset seizures. The two drugs were equally effective, with 73% seizure free for at least 6 months at the last evaluated dose in the per-protocol analysis. Of those achieving remission on carbamazepine, 85% did so at the lowest dose level (400 mg/day). The proportion of patients seizure free and the time to first seizure were similar for carbamazepine (immediate-release tablets) and lamotrigine in a double-blind randomized trial including 260 newly diagnosed adult patients with partial-onset or generalized tonic–clonic seizures, but in this trial more patients on carbamazepine withdrew because of adverse events [35]. Topiramate, 100 mg/day or 200 mg/day, was compared with carbamazepine, 600 mg/day, in a double-blind randomized study of 390 newly diagnosed patients for whom the treating physician considered carbamazepine to be standard treatment [36]. Approximately 75% of these patients had partial-onset seizures. No significant difference was observed in efficacy measures. Carbamazepine was also compared with oxcarbazepine in a double-blind randomized study including 235 patients with newly diagnosed partial-onset or generalized tonic–clonic seizures [37]. Similar proportions were seizure free on carbamazepine (60%) and oxcarbazepine (52%) during the 48-week maintenance phase, but more patients on carbamazepine were withdrawn because of skin rashes.

Among open-label randomized studies, SANAD [38] is by far the largest. In this study, 1721 patients with epilepsy, for whom carbamazepine was deemed to be preferable to valproate as an initial treatment choice, were randomized to carbamazepine, gabapentin, lamotrigine, oxcarbazepine or topiramate. Of the randomized patients, 88% were considered to have symptomatic or cryptogenic partial epilepsy. For time to 12-month remission carbamazepine was significantly better than gabapentin and had a non-significant advantage over lamotrigine, topiramate and oxcarbazepine. However, lamotrigine was significantly better than carbamazepine with respect to time to treatment failure. This advantage was mainly explained by fewer withdrawals for adverse events with lamotrigine. Reported differences in tolerability need to be interpreted with some caution in open-label studies. Selection of an unnecessarily high target dose and use of immediate-release rather than sustained-release carbamazepine tablets in an unknown proportion of patients could also have contributed to a poorer tolerability of carbamazepine in this study.

Other open-label randomized studies have compared carbamazepine with valproate, phenytoin and phenobarbital in patients with either partial-onset or primary generalized tonic–clonic seizures. In one of these studies, 300 adults with newly diagnosed seizures (about half with partial-onset seizures) were randomized to either carbamazepine or valproate [39]. In the partial-onset seizure group, 12-month remission rates were similar (72% for valproate and 76% for carbamazepine). In another open-label study, Heller *et al.* [40] randomized 243

adults with previously untreated tonic–clonic or partial-onset seizures (n = 102) to phenobarbital, phenytoin, carbamazepine or valproate. No significant differences were found for efficacy measures at 1, 2 or 3 years of follow-up. Although results were not presented for partial-onset seizures separately, the authors found no interaction between the drugs and seizure type on the outcome.

The elderly

The efficacy of carbamazepine in elderly patients with newly diagnosed epilepsy has been assessed in three double-blind randomized comparative trials [41–43]. Brodie *et al*. [41] randomized 150 patients aged 65 years and above to immediate-release carbamazepine (n = 48) or lamotrigine (n = 102). Withdrawals due to adverse events were more common with carbamazepine (42%) than with lamotrigine (18%), but there was no difference between the two drugs in time to first seizure. Because of fewer drop-outs due to poor tolerability, a greater percentage of lamotrigine-treated patients remained seizure free during the last 16 weeks of the 24-week treatment duration (39%, compared with 21% in the carbamazepine group). A large US study randomized 593 patients aged 60 years and over to either immediate-release carbamazepine (target dose 600 mg/day), lamotrigine (150 mg/day) or gabapentin (1500 mg/day) [42]. The primary outcome measure was retention in the trial for 12 months. There were no significant differences in seizure-free rates at 12 months among those remaining in the study (64% with carbamazepine, 51% with lamotrigine and 47% with gabapentin). However, early termination for adverse events was more common with carbamazepine (31%) than with lamotrigine (12%). The latest study compared flexible-dosage sustained-release carbamazepine with lamotrigine in 185 newly diagnosed patients, 65 years or older, with partial-onset or generalized tonic–clonic seizures [43]. Similar percentages of patients completed the 40-week study period, 67% with carbamazepine and 73% with lamotrigine. The proportion completing the study and seizure free in the last 20 weeks was also similar, 57% with carbamazepine and 52% on lamotrigine. Adverse events leading to withdrawal occurred in 14% of patients in the lamotrigine group and 25% in the carbamazepine group. Overall, the tolerability of carbamazepine was more favourable in this trial using a sustained-release formulation than in the other two trials.

Children

By the criteria of the ILAE Commission on Therapeutic Strategies, there are no class I or II randomized controlled trials of carbamazepine in children with partial-onset seizures. A double-blind randomized trial compared carbamazepine 600 mg/day with valproate 1250 mg/day or topiramate 100 or 200 mg/day in newly diagnosed epilepsy (patients with partial-onset seizures in the majority of cases) [36]. In the paediatric subgroup of patients with partial-onset seizures, time to exit (primary outcome measure) was similar for the different treatment arms. Two open-label randomized trials compared carbamazepine with other old-generation AEDs in children with newly diagnosed partial-onset and primary generalized tonic–clonic seizures. In the first of these trials, Verity *et al*. [44] randomized children to valproate (n = 130) or carbamazepine (n = 130) and followed them up for 3 years. Carbamazepine and valproate showed similar efficacy in controlling both primary generalized seizures and partial-onset seizures with or without secondary generalization. Adverse effects were mild and necessitated drug withdrawal in only a few children. In the second study, 167 children aged 3–16 years, with tonic–clonic or partial seizures, were randomly allocated to treatment with phenobarbital (n = 10; assignment to this group was stopped after adverse effects occurred in six of the first 10 randomized children), phenytoin (n = 54), carbamazepine or valproate (n = 49) [45]. Overall, 73% of patients achieved 1-year remission by 3 years of follow-up, with minor differences between the three assessed drugs. There seemed to be no effect of the type of seizures on the outcome. Among the drugs for which randomization was allowed until completion of the study, phenytoin was more likely to result in withdrawal (9%) than carbamazepine (4%) or valproate (4%).

Primary generalized tonic–clonic seizures

In addition to partial seizures, carbamazepine is approved by many regulatory agencies for the treatment of primary generalized tonic–clonic seizures. Nevertheless, documentation in terms of double-blind randomized clinical trials in this indication is sparse. By the criteria of the ILAE Commission on Therapeutic Strategies, there are no class I or II randomized controlled trials demonstrating the efficacy of carbamazepine (or any other AED) in the treatment of generalized tonic–clonic seizures in adults or children. In fact, there are no double-blind randomized monotherapy studies specifically targeting patients with primary generalized tonic–clonic seizures. The best available evidence is derived from trials in which such patients constitute a subset of the included population, and results are difficult to interpret not only because of the small sample sizes but also because of the possibility that in some patients secondary generalized seizures without an evident focal onset may have been erroneously classified as primary generalized.

Similar proportions of patients in each group were seizure free in the subset of adults with generalized tonic–clonic seizures included in the double-blind randomized trial comparing carbamazepine with oxcarbazepine [37]. Likewise, the same percentage of patients on carbamazepine and lamotrigine became seizure free and were retained on treatment in the subgroups with generalized tonic–clonic seizures included in a trial that enrolled mostly patients with partial-onset seizures [35]. Similar proportions of the paediatric and adult patients with generalized tonic–clonic seizures were seizure free in the last 6 months of treatment in the trial comparing carbamazepine, valproate and two different dosages of topiramate [36].

Open-label randomized trials including mixed groups of patients with partial-onset and generalized tonic–clonic seizures have compared carbamazepine with phenytoin and valproate [46], with valproate only [39], and with phenytoin and valproate [40]. In the study by Callaghan *et al*. [46] comprising a total of 181 patients, a reduction by 51% to 100% in seizure frequency in the subgroup with primary generalized tonic–clonic seizures was reported in 75% of patients on carbamazepine compared with 81% and 78% of patients on phenytoin and valproate, respectively. Significantly more patients with generalized convulsive seizures became seizure free with phenytoin than

with carbamazepine [46]. In another trial comparing carbamazepine and valproate in mixed seizure types, there was no difference between the two treatments in 12-month remission rates in the subset of 138 patients with primary generalized tonic–clonic seizures [39]. In a third trial, in which seizure outcome was not reported separately for partial-onset and for generalized tonic–clonic seizures, seizure control did not differ significantly among the groups randomized to carbamazepine, phenytoin and valproate [40].

A meta-analysis based on class III evidence concluded that there is no reliable evidence to differentiate in efficacy carbamazepine from valproate in patients with primary generalized tonic–clonic seizures [47]. Another meta-analysis found no significant differences between carbamazepine and phenytoin for outcomes examined for generalized tonic–clonic seizures [48].

Although the available evidence suggests that carbamazepine is effective in the treatment of primary generalized tonic–clonic seizures, it should be borne in mind that other data suggest that carbamazepine precipitate or aggravate other generalized seizure types, particularly absence and myoclonic seizures, in patients with generalized epilepsy syndromes [49,50]. It appears that even primary generalized tonic–clonic seizures can be sometimes aggravated in a subset of patients with idiopathic generalized epilepsies.

Epilepsy syndromes

Benign epilepsy with centrotemporal spikes

Carbamazepine has not been assessed in randomized clinical trials in the treatment of benign epilepsy with centrotemporal spikes. Nevertheless, it is often used if treatment is considered for this indication, based on its proven efficacy in patients with partial-onset seizures in general [30].

Idiopathic generalized epilepsies

Although carbamazepine can be effective in the treatment of generalized tonic–clonic seizures, it is generally avoided when these seizures occur in the context of childhood or juvenile absence epilepsy or juvenile myoclonic epilepsy, due to the risk of precipitating or aggravating absences and myoclonic seizures. Carbamazepine may even precipitate non-convulsive status epilepticus in these patients [49].

Symptomatic generalized epilepsies

Trials with carbamazepine are hardly successful if corticotropin, valproate or vigabatrin have failed. In some patients with symptomatic myoclonic–astatic epilepsy or Lennox–Gastaut syndrome, carbamazepine can improve at least temporarily seizure control, usually when used in combination with other AEDs.

Combination therapy

Carbamazepine is often combined with other AEDs in patients who fail to respond to monotherapy. Although specific combinations have rarely been evaluated, when using combination therapy, pharmacokinetic interactions with other AEDs need to be taken into consideration. In addition, there may be pharmacodynamic interactions. Adverse pharmacodynamic interactions seem to be more common when carbamazepine is combined with the related drug oxcarbazepine [51]. CNS-related adverse effects also frequently occur when carbamazepine is combined with lamotrigine, though this can be managed with a reduction of the carbamazepine dose [52].

Efficacy in non-epilepsy conditions

In many countries, carbamazepine's efficacy in trigeminal neuralgia was demonstrated even before the drug was licensed for epilepsy [53]. Carbamazepine remains a first-line treatment for this indication. Randomized controlled trials have also shown efficacy in other neuropathic painful disorders, such as diabethic neuropathy [54]. The efficacy of carbamazepine in the maintenance treatment of bipolar disorders has also been shown in randomized trials, where the drug seems most effective in preventing manic episodes [54].

Adverse effects

In clinical trials, approximately 10–25% of patients randomized to carbamazepine discontinued treatment because of adverse effects [31,33,34,38,55]. The frequency is even higher in some studies in the elderly [35,42]. Adverse effects are either idiosyncratic, most often a rash, or dose-related CNS effects. The frequency of CNS-related adverse effects depends on titration rate, target dosage as well as type of formulation [56]; in particular, CNS tolerability seems to be better with sustained-release than with immediate-release formulations [43]. Titration rate and target dosage also affect the risk of some idiosyncratic effects [57].

The prevalence of adverse effects declines with duration of treatment. CNS-related adverse effects such as sedation, cognitive disturbances, change in mood and diplopia, as well as gastrointestinal symptoms, were considerably less frequent after 12 months than early in treatment in a large Veterans' Affairs double-blind randomized study [32]. This has been attributed in part to autoinduction of carbamazepine metabolism resulting in a gradual decline in serum drug concentrations over the first few weeks. However, development of tolerance at pharmacodynamic level seems to be a more important determinant of the time-dependent reduction in adverse effects.

Carbamazepine is overall better tolerated than some other older generation AEDs, such as primidone and phenobarbital [31]. Data on differences in tolerability between carbamazepine and valproate are conflicting [32,39,44]. Carbamazepine has been the comparator in a large number of randomized controlled trials of newer generation AEDs in patients with newly diagnosed epilepsy. Most of these studies indicate a better tolerability, particularly lower rash rates, with the newer AEDs [33,35,37,38,41,42,55,58]. However, it has been suggested [56] that the use of suboptimal drug formulations, dosages and titration rates may have contributed to the apparent poorer tolerability of carbamazepine compared with lamotrigine [35,38,41,42] gabapentin [38,42,55], oxcarbazepine [37] and vigabatrin [55,58]. When sustained-release carbamazepine was used with a slow titration and with an adequately low target dosage in two double-blind randomized trials, overall tolerability was essen-

Table 36.5 Frequency (% of exposed patients) of different adverse events reported by patients treated with carbamazepine in two large randomized trials.

	Marson *et al.*, 2007 [38]	Brodie *et al.*, 2007 [34]
Number randomized	378	291
Adverse event		
Headache	3.7	25.4

Rash	10.1	5.5
Dizziness	3.7	13.7
Nausea	2.4	10.7
Weight gain	2.4	6.5

tially comparable to that observed with lamotrigine [43] and levetiracetam [34].

The most common adverse events reported by patients on carbamazepine in the two largest randomized monotherapy trials are listed in Table 36.5. The SANAD study [38] was a pragmatic unblinded long-term trial in which physicians could use either sustained-release or immediate-release carbamazepine, whereas the study by Brodie *et al.* [34] was a double-blind comparison between controlled-release carbamazepine and levetiracetam. These, and other differences between the two trials, may have contributed to the different frequencies of adverse events, which were mostly CNS related in both studies.

CNS effects

The most common adverse CNS effects of carbamazepine are dose related, occur mostly at the beginning of treatment and are reversible. Those most common include drowsiness, dizziness, asthenia, ataxia, diplopia and blurring of vision. Less common neurological adverse effects include dystonic movements, choreoathetosis and other dyskinesias and asterixis.

Psychic disturbances are relatively uncommon adverse effects of carbamazepine therapy, at least compared with other major AEDs. They include restlessness, insomnia, agitation, anxiety, mania and other psychoses.

At usual doses, carbamazepine appears to have little effect on cognitive function. The large randomized Veterans' Affairs study that compared carbamazepine with phenytoin, phenobarbital and primidone in 622 patients used an extensive battery of neuropsychological tests. In this comparison, patients on carbamazepine had the most favourable scores [59]. A follow-up Veterans' Affairs study that compared carbamazepine with valproic acid observed no differences in cognitive or behavioural scores between the two treatments and no deterioration in neuropsychological tests compared with pre-treatment [60]. In a study of seizure-free children, withdrawal of older generation AEDs, including carbamazepine, had very limited effects on cognitive function [61].

An open-label comparative trial reported improved cognitive functions on repeated testing in patients randomized to vigabatrin, whereas no change was seen in patients randomized to carbamazepine [58]. This was interpreted as lack of a practice effect on test performance in the carbamazepine group. Levetiracetam produced fewer adverse neuropsychological effects than carbamazepine in a randomized, double-blind, two-period cross-over design [62], but two more recent reports found no significant differences in overall adverse CNS effects between these drugs [34,63]. No significant differences in cognitive effects were found between tiagabine and carbamazepine used as monotherapy in newly diagnosed adults with partial epilepsy [64]. As discussed above, in randomized controlled trials tolerability (including adverse CNS effects) has been reported to be significantly poorer with carbamazepine than with lamotrigine [35,38,41,42], oxcarbazepine [37] and gabapentin [42,55]. This difference, however, could be partly related to study designs and suboptimal use of carbamazepine.

Cutaneous hypersensitivity reactions (including cutaneous reactions associated with systemic symptoms)

Skin rashes occur typically in 5–15% of patients started on carbamazepine, but in up to 19% of cases in the elderly [41]. Rash rates appear to be lower in children, being estimated at approximately 5% in paediatric epilepsy groups. The vast majority of these reactions are benign. They tend to occur within the first 8 weeks of treatment and disappear on drug withdrawal. There is a considerable cross-reactivity with some other AEDs such as phenytoin, phenobarbital, oxcarbazepine and probably also with lamotrigine. Between 30% and 60% of patients who experienced a rash on carbamazepine will have a recurrence if switched to any of these drugs [57,65]. Therefore, if possible, such drugs should be avoided in patients with previous skin reactions to carbamazepine.

Serious and even life-threatening hypersensitivity skin reactions can occur with carbamazepine, but these constitute only a very small proportion of all cutaneous reactions observed in patients treated with this drug. Drug-related rash with eosinophilia and systemic symptoms (DRESS), toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS) all belong to this category [57]. DRESS, also known as the anticonvulsant hypersensitivity syndrome, is characterized by fever, skin manifestations, eosinophilia, atypical lymphocytosis, lymphadenopathy, arthralgia and multiorgan involvement [57] and has been estimated to occur in 1.0–4.1 cases per 10 000 treated with carbamazepine [66]. SJS and TEN are characterized by bullous skin reactions combined with mucosal and sometimes also systemic involvement. Their incidence has been estimated at 0.5–2 per 10 000 carbamazepine exposures, which is comparable to risk estimates for lamotrigine, phenobarbital and phenytoin [66,67]. The risk of SJS appears to be higher in the Chinese Han ethnic group and in some other Asian groups than in whites, and recent research in Chinese patients has demonstrated a highly significant association between the presence of the HLA-B*-1502 allele of the human leucocyte antigen and a greatly increased risk of SJS and TEN [57,68,69]. Because the frequency of the HLA-B*-1502 allele is much greater in some Asian populations than in whites, the recommendation has been made that subjects belonging to these ethnic groups should undergo genotyping for HLA-B*-1502 before starting carbamazepine, and that carbamazepine should be preferably avoided in patients with this genotype. Like trivial skin rashes, severe hypersensitivity reactions associated with carbamazepine generally occur in the first 3 months of treatment. Any indication of such symptoms necessitates immedi-

ate withdrawal of the drug. Since it may be difficult to distinguish between early symptoms of severe hypersensitivity reactions and benign rashes, the occurrence of a rash during the first few months of carbamazepine treatment normally prompts withdrawal of the drug.

Desensitization by rechallenge with low and slowly increasing doses has been described to be successful in some patients with carbamazepine-associated rash, but this procedure is generally not recommended unless there has been a careful evaluation of the risk–benefit balance. In general, the risk of hypersensitivity reactions seems to be reduced if carbamazepine is introduced at a low dose and with a slow up-titration to the target maintenance dose. Rapid introduction of carbamazepine should therefore be avoided whenever the clinical situation permits.

Haematological adverse effects

Carbamazepine may induce a folate deficiency. This effect develops during chronic use, is possibly related to enzyme induction, and it is often associated with a modest macrocytosis. Frank megaloblastic anaemia is, however, rare.

Several cases of carbamazepine-induced blood dyscrasias have been reported. The incidence of aplastic anaemia has since been estimated at 0.5–2 per 100 000 patients exposed [57]. Agranulocytosis is also quite rare. In a population-based study, carbamazepine contributed to 5 out of 177 identified cases of agranulocytosis [70], with an odds ratio of 11.0 (1.2–102.6) compared with unexposed persons in the general population, in which the incidence is estimated to be 3.5 per million person-years.

Thrombocytopenia occurs in sporadic cases, whereas a clinically insignificant decrease in white cell counts under 4000–5000 cells/mm^3 is common and can be found in about one-third of carbamazepine-treated patients during the first 6 months of therapy. A leucopenia with decreasing number of cells needs consideration, but in most cases leucopenia is transient and very seldom prompts withdrawal of the treatment.

Because of the rarity of the serious haematological reactions and the questionable preventive effectiveness of blood cell counts, regular laboratory monitoring is generally not considered justified.

Hepatotoxicity

Carbamazepine may induce two types of clinically significant liver pathology. One is hypersensitivity-induced granulomatous hepatitis associated with cholestasis, and the other is a 'toxic-type' hepatitis without cholestasis. Acute hepatotoxicity is, in any case, rare. Its incidence has been estimated at 16 cases per 100 000 treatment years, based on data from a spontaneous adverse drug reaction reporting system [71]. It usually appears early, in most cases within 3–4 months after initiation of treatment.

In contrast to acute hepatotoxicity, a modest and benign elevation of liver enzymes is a common phenomenon, seen in 5–22% of patients on carbamazepine treatment. An increase in γ-glutamyltransferase is particularly frequent, and is regarded as an epiphenomenon of the induction of microsomal liver enzymes caused by carbamazepine. An isolated increase in γ-glutamyltransferase does not justify drug withdrawal. In most cases, modest elevations in aminotransferases are clinically insignificant.

Endocrinological effects

Antidiuretic hormone and hyponatraemia

Treatment with carbamazepine can result in hyponatraemia, although the risk is significantly lower than with oxcarbazepine. Hyponatraemia is in most cases modest and asymptomatic and does not require withdrawal of the drug or other actions [72]. It may, however, become occasionally severe and evolve to water intoxication, necessitating a restriction in water intake and a change in AED treatment. The risk of hyponatraemia increases with increasing carbamazepine dosage and with increasing serum carbamazepine concentration, and is generally more common in the elderly than in the young. The mechanism behind the hyponatraemic effect of carbamazepine is unclear. A drug-induced elevation in antidiuretic hormone levels, a sensitization of the renal tubules to the action of antidiuretic hormone, and other mechanisms have all been suggested.

In addition to causing a decrease in plasma sodium, carbamazepine may reduce the plasma concentrations of calcium and chloride.

Thyroid hormones

Carbamazepine is known to reduce the serum concentrations of thyroid hormones, particularly total and free thyroxine, whereas effects on serum triiodothyronine are more variable. These hormonal changes are usually of no clinical relevance [73,74]. However, a hypothyroid state may develop in patients with preexisting thyroid disease on thyroxine replacement therapy, since carbamazepine-associated enzyme induction results in accelerated catabolism of thyroid hormones and, consequently, increased thyroxine dosage requirements.

Sex hormones

Carbamazepine and enzyme-inducing AEDs can lower bioactive sex hormone concentrations, partly by decreasing their serum concentrations and partly by increasing serum sex hormone-binding globulin [75]. The net effect can be a diminished bioactivity of testosterone and estradiol. Effects on sex hormone concentrations appear to be reversible on withdrawal of treatment, even after years of carbamazepine use [76]. The clinical consequences of carbamazepine-induced changes in sex hormones could be diminished potency in men and menstrual disturbances in women. The frequency of these adverse effects is, however, uncertain (see Chapter 25 for a detailed discussion on reproductive function in people with epilepsy).

Bone metabolism

Some AEDs adversely affect bone mineralization, resulting in an increased risk of fractures. Enzyme-inducing AEDs, including carbamazepine, have been most commonly associated with alterations of biochemical parameters of bone turnover and with a decrease in serum 25-hydroxyvitamin D levels in cross-sectional studies [77]. Similar findings have, however, been reported also with valproate [77].

A recent prospective follow-up study of young women on monotherapy with carbamazepine, lamotrigine, phenytoin or valproate reported significant femoral bone loss over 1 year in

the phenytoin-treated women [78]. In contrast, those on carbamazepine, lamotrigine or valproate did not show detectable changes in bone turnover or bone mineral density. Further studies are needed to elucidate in more detail the effects of carbamazepine on bone metabolism and the potential consequences thereof.

Cardiac adverse effects

Carbamazepine may cause cardiac adverse effects, including bradycardia, Adams–Stokes attacks, aggravation of sick sinus syndrome, other conduction disturbances, tachyarrhythmias and development of congestive heart failure. Cardiac complications have been classified into two groups [79]. One group consisted exclusively of sinus tachycardia and was observed mostly in association with high serum carbamazepine levels, generally as a result of deliberate overdose. The other group consisted of potentially life-threatening bradyarrhythmias or atrioventricular conduction delay and was observed predominantly in older patients (more commonly in females), usually at serum carbamazepine concentrations within the reference range.

Overall, adverse cardiac effects in patients receiving therapeutic doses of carbamazepine are relatively uncommon, and probably occur mainly in susceptible individuals with pre-existing cardiac abnormalities [80]. Therefore, an electrocardiogram is recommended before initiation of carbamazepine treatment, particularly in the elderly.

Very rarely, the heart may be involved in systemic hypersensitivity reactions to carbamazepine, including eosinophilic myocarditis.

Teratogenic effects and postnatal development

Recent data from large-scale prospective registries suggest a rate of major congenital malformations of 2.2–3% in association with carbamazepine monotherapy [81]. This is lower than in earlier studies and not so greatly increased over the rate expected in the general population as previously thought. The prevalence of major malformations in the offspring of mothers treated with carbamazepine in monotherapy is lower than with valproic acid and comparable to that reported with lamotrigine [81].

In a case–control study based on 8005 cases of malformations in an international registry, 299 infants had been exposed *in utero* to carbamazepine [82]. Among these infants, the only significant malformations were hypertelorism and localized skull defects, spina bifida on monotherapy and cardiac malformations on polytherapy. Earlier reports have also indicated an increased risk of neural tube defects (absolute risk: 0.5–1%) after carbamazepine exposure [83]. This finding is important in guiding prenatal diagnostic tests.

Prospective population-based studies do not suggest any adverse effects on postnatal cognitive development in children exposed to carbamazepine *in utero* [84], although more data are needed.

Early studies suggested potential adverse effects of carbamazepine (and other AEDs) on intrauterine growth. Wide *et al*. [85], however, assessed body measures in infants exposed prenatally to AEDs in a Swedish population over a period of 25 years in comparison with data from the general population. There was a clear trend towards normalization of the head circumference over the time period considered, in parallel with a shift from polytherapy towards monotherapy, despite an increasing use of carbamazepine.

Miscellaneous adverse effects

Cholesterol metabolism may be affected by carbamazepine in both children and adults, leading to elevations in high-density lipoprotein (HDL) cholesterol concentrations and HDL to total cholesterol ratio.

Renal effects are rare and include proteinuria, haematuria, oliguria and renal failure. Acute renal failure has been described in a few patients on carbamazepine treatment, and attributed to acute interstitial nephritis, acute tubular necrosis or membranous glomerulopathy. Few patients have also had interstitial nephritis and exfoliative dermatitis, nephrotic syndrome or a combination of nephropathy, haemolytic anaemia and thrombocytopenia.

Like other enzyme-inducing AEDs, exposure to carbamazepine *in utero* has been associated with vitamin K deficiency in the newborn.

Adverse effects and quality of life studies

Gillham *et al*. [86] compared the impact of carbamazepine and lamotrigine on health-related quality of life using a modified Side Effect and Life Satisfaction (SEALS) inventory divided into five subscales: worry, temper, cognition, dysphoria and tiredness. A total of 260 patients with newly diagnosed epilepsy were randomized to 48 weeks of treatment with carbamazepine or lamotrigine. The only significant difference, which was in favour of lamotrigine, was at week 4. This is in line with previous experiences with carbamazepine suggesting that tolerability improves after the first weeks of treatment and is comparable to that of other major AEDs during long-term therapy.

The randomized unblinded SANAD trial included quality-of-life measures in its comparisons of carbamazepine, lamotrigine, gabapentin and topiramate in adults with newly diagnosed partial epilepsy [38]. This large study found no important differences or trends for scores between these treatments on the Adverse Events Profile, the Neurotoxicity Scale, the EQ-5D scale or for global quality of life.

Massive overdose and intoxication

In adults on carbamazepine treatment, the lowest known lethal dose has been estimated at approximately 60 g. A 6-year-old child survived 10 g and a 3-year-old child survived 5 g. The maximum tolerable dose varies within wide limits and depends on the time elapsed since ingestion. Several hundred patients with massive overdoses, fatalities included, have been reported.

In adults, carbamazepine concentrations of ≥40 μg/mL (≥170 μmol/L) have been significantly associated with serious dysfunctions of several organ systems, including cardiac conduction disorders, respiratory failure, seizures and coma.

Four clinical stages of carbamazepine intoxication have been described [87]: (a) coma and seizures [serum concentrations >25 μg/mL (106 μmol/L)]; (b) moderate stupor, combativeness, hallucinations, choreiform movements [15–25 μg/mL (64–106 μmol/L)]; (c) mild drowsiness, ataxia [11–15 μg/mL (46–64 μmol/L)]; and (d) possibly mild ataxia, but otherwise normal neurological examination [<11 μg/mL (<46 μmol/L)]. Sudden and potentially catastrophic relapse to stages (a) to (c) may occur unexpectedly during stage (d).

Determinations of serum drug concentrations are important in predicting the severity of intoxication. In children, however, the serum concentration of carbamazepine may not predict accurately the severity of toxic manifestations. In children, the carbamazepine half-life may be prolonged and the carbamazepine-10,11-epoxide concentration is increased, sometimes at levels even higher than the concentration of the parent drug.

In addition to symptomatic therapy, carbamazepine intoxication may be managed with repeated gastric lavage and haemoperfusion. Forced diuresis, cathartics, peritoneal dialysis, plasmapheresis and haemodialysis should be avoided. Seizures should be treated with benzodiazepines.

Place in current therapy

Carbamazepine is a first-line AED for the treatment of children and adults with partial-onset seizures, with or without secondary generalization. Given that no other drug has been shown to be more effective, and in view of its usually good tolerability, carbamazepine can be considered as the drug of first choice for this patient population. Other treatment alternatives could be considered as first choice in the elderly, in whom carbamazepine appears to be less well tolerated, and in patients on other medications, in whom the high interaction potential of carbamazepine could complicate clinical management. Carbamazepine is also effective against generalized tonic–clonic seizures, and it could be regarded as one of the possible first-line drugs for this indication. However, other drugs are often preferred in patients with idiopathic generalized epilepsies, because carbamazepine lacks efficacy against absence and myoclonic seizures and may even precipitate or aggravate these seizure types.

Carbamazepine remains a first-line treatment for trigeminal neuralgia, and is also useful in other neuropathic pain syndromes. It may also be useful as a mood stabilizer in patients with bipolar disorder.

Dose and titration rates

Carbamazepine is commercially available as immediate-release and sustained-release tablets, as a suspension and as suppositories. However, no formulations are available for parenteral use. Sustained-release formulations are usually preferred to improve tolerability and can generally be used on a twice-daily regimen. With immediate-release formulations, patients receiving relatively high doses and patients with a fast metabolism of carbamazepine (e.g. children and patients co-medicated with enzyme-inducing AEDs) benefit from dividing the daily dose into three or even four administrations per day. This aids in preventing excessive fluctuations in serum drug concentrations and in avoiding high peak concentrations associated with adverse effects.

A slow and gradual titration to the initial target maintenance dose is important to reduce the risk of adverse effects. In children, treatment is often initiated with a daily dosage of no more than 5 mg/kg body weight, which is gradually increased over 2–4 weeks to an initial target maintenance dose of 10–20 mg/kg body weight per day. Adults are usually started on 100–200 mg/day, to be increased to an initial target maintenance dosage of approximately 400 mg/day over 2–4 weeks [88]. Dosage is subsequently adjusted based on clinical response, in accordance with the general principles of AED treatment.

In general, maintenance dosages after dose optimization are in the order of 5–30 mg/kg/day in children, while infants usually require higher dosages (10–40 mg/kg/day). The majority of adults with newly diagnosed epilepsy who respond to carbamazepine monotherapy do so at low dosages (400–600 mg/day). Optimal maintenance dosages in individual patients may range from 400 to 1600 mg/day and higher doses (up to 2400 mg/day) may be needed in difficult-to-treat patients co-medicated with enzyme-inducing AEDs. When carbamazepine is combined with other drugs, dosage may need to be adjusted to compensate for pharmacodynamic as well as pharmacokinetic interactions. In the case of pharmacokinetic interactions, dose adjustment is facilitated by monitoring serum carbamazepine concentrations.

Laboratory monitoring

It is advisable to take a blood sample for a complete blood count, determination of liver enzymes and serum electrolytes before starting treatment with carbamazepine, as with any other AED. The value of continued regular haematology and blood chemistry tests to identify rare idiosyncratic adverse effects is questionable, and repeated tests are not generally justified unless there are clinical signs or symptoms requiring special investigation. However, it is reasonable to repeat the initial laboratory check at a scheduled visit 2–4 months after initiation of treatment. The need for subsequent testing will depend on the clinical evolution. A routine electrocardiogram is also justified before starting carbamazepine to identify those few patients who may be at risk for cardiac adverse effects and to obtain a baseline for future comparison.

Therapeutic monitoring of serum carbamazepine concentrations is well established. A reference range of 4–12 μg/mL (17–51 μmol/L) has been suggested. Strict adherence to reference ranges, however, is not advisable because the optimal therapeutic concentration varies across individuals in relation to a wide variety of factors [29]. Carbamazepine dosage is best adjusted according to clinical response rather than to a predefined range of serum concentrations. However, it is useful to establish empirically the optimal serum concentration of the drug in individual patients. This is ideally done by determining the trough (before morning dose) carbamazepine concentration at steady state on the patient's maintenance dose. A further sample is drawn under the same conditions if the dosage is increased due to unsatisfactory seizure control. Once the individual optimal (therapeutic) concentration has been determined, this can serve as a useful reference to determine whether subsequent possible changes in clinical response are related to an alteration in serum drug levels. Based on these considerations, a case can be made for measuring the serum carbamazepine concentration a few weeks after the patient has reached the target dose, when the optimal dose has been established, when seizure control is poor or deteriorated (also as a check for compliance), when dose-related adverse effects are suspected, or when drug–drug interactions or other conditions are anticipated which can affect the pharmacokinetics of carbamazepine. In general, there is little value in measuring the unbound serum carbamazepine concentration, and the total

concentration is sufficient. Routine determination of the active metabolite carbamazepine-10,11-epoxide metabolite is usually not justified.

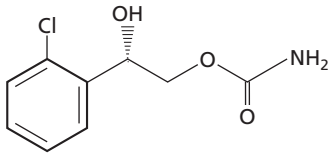
37 Carisbamate

Gerald P. Novak[1] *and Martin J. Brodie*[2]

[1] Director, J&J Pharmaceutical R&D, Titusville, NJ, USA
[2] Epilepsy Unit, Western Infirmary, Glasgow, UK



Primary indications	Adjunctive therapy of refractory partial-onset seizures with or without secondary generalization (potential additional indications are being considered)
Usual preparation	Tablets: 100 mg, 200 mg and 400 mg
Usual dosages	300–800 mg/day (tentative)
Dosing frequency	Twice daily
Significant drug interactions	Antiepileptic drugs which induce uridine glucuronosyltransferase (UGT) decrease plasma carisbamate concentrations by stimulating its metabolism. Plasma carisbamate concentrations may be moderately decreased by steroid oral contraceptives. Carisbamate causes a modest decrease in the plasma concentrations of lamotrigine and a moderate increase in the plasma levels of tolbutamide
Serum level monitoring	There is insufficient information on the value of monitoring serum carisbamate levels
Reference range	Not clearly defined
Common/important adverse effects	Headache, diplopia, vertigo, dizziness, somnolence, nausea, vomiting, gait disturbance, abnormal coordination
Main advantages	Good tolerability at dosages at least up to 800 mg/day
Main disadvantages	Modest responder rates in trials conducted to date, possibly due to doses lower than optimal. Metabolism susceptible to enzyme induction
Mechanism of action	Blockade of voltage-gated sodium channels. Additional mechanisms are likely
Oral bioavailability	≥90%
Time to peak levels	0.5–3 h fasting (2.5–5 h when taken with food)
Elimination	Primarily by metabolism, including glucuronide conjugation and hydrolysis of the carbamate ester followed by oxidation
Apparent volume of distribution (V_d/F)	Approximately 50 L
Elimination of half-life	10–13 h (may be shorter in patients co-medicated with UGT-inducing drugs)
Apparent plasma clearance (CL/*F*)	3.4–4.2 L/h (may be higher in patients co-medicated with UGT-inducing drugs)
Protein binding	47%
Active metabolites	None known
Comment	Potentially a useful antiepileptic drug, but more data are needed to establish the optimal dose range and its place in current therapy

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Carisbamate (*S*-2-*O*-carbamoyl-1-*o*-chlorophenyl-ethanol) is a novel agent under development for the treatment of epilepsy. Carisbamate displayed a favourable profile in preclinical models of epilepsy, demonstrating broad-spectrum anticonvulsant activity. It was shown subsequently to possess efficacy and tolerability in a phase II clinical trial, and two phase III clinical trials have recently been completed. This chapter will review the preclinical data, pharmacokinetics, efficacy, safety and tolerability of this compound.

Chemistry

Carisbamate is a white to off-white powder that is freely soluble in propylene glycol and ethanol and has limited water solubility. The molecular formula of carisbamate is $C_9H_{10}ClNO_3$, and its molecular structure is depicted in the summary table on the opening page of this chapter. The chiral centre of the molecule is carbon 1, and carisbamate comprises the S-enantiomer. The molecular weight of carisbamate is 215.63; its melting point is 132–136°C.

Pharmacology

Activity in experimental models of seizures and epilepsy

The antiepileptic activity of carisbamate was assessed in a battery of well-characterized rodent seizure models (including models of therapy-resistant seizures and epilepsy). Results obtained from these studies confirm that it possesses a high potency and a favourable therapeutic index, and suggest a broad spectrum of activity against a variety of seizure types, including generalized tonic–clonic seizures, complex partial seizures, generalized absence seizures and myoclonic seizures [1–3].

In mice, carisbamate exhibited potent activity in the maximal electroshock (MES), pentylenetetrazol, bicuculline and picrotoxin seizure models. Carisbamate was also active in the MES model in rats (Table 37.1) [1]. The median effective dose (ED_{50}) values for oral administration in the MES test were 7.7 mg/kg in mice and 4.4 mg/kg in rats [1]. In mice, carisbamate significantly elevated the threshold for intravenous pentylenetetrazol-induced seizures when tested at a dose high enough to produce motor impairment [1]. The results from the intravenous pentylenetetrazol and MES tests suggest that carisbamate has the ability to control seizures by both elevating seizure threshold

Table 37.1 Carisbamate displays a broad-spectrum anticonvulsant profile in mouse and rat seizure models.

Species, route	Test	Time of test (h)	ED_{50} (mg/kg)	95% CI	Protective index[a]
Mice, i.p.	Rotorod	0.25	46.4[b]	35.9–65.6

[a] Protective index = TD_{50}/ED_{50}.

[b] Median toxic dose (TD_{50}).

[c] Protective index was calculated with TD_{50} obtained in CF#1 mice and ED_{50} in Frings mice.

[d] In addition to blocking the clonic seizures, carisbamate also blocks tonic extension induced by s.c. pentylenetetrazol and s.c. picrotoxin; ED_{50} (95% CI): 14.3 (8.78–23.4) and 5.48 (3.67–8.19) mg/kg.

[e] Complete suppression of status epilepticus for at least 90 minutes in two of five rats at 30 mg/kg; in the remaining rats, seizures resumed at a lower severity (stage 3).

and preventing seizure spread. Moreover, the results from the intravenous pentylenetetrazol seizure threshold and Genetic Absence Epileptic Rat of Strasbourg (GAERS, see below) study suggest that carisbamate does not lower seizure threshold. Carisbamate also reduced seizure severity in the corneal-kindled rat model of partial epilepsy, and reduced seizure severity and afterdischarge duration in the hippocampal-kindled rat model.

In contrast to carbamazepine, phenytoin, lamotrigine and topiramate, carisbamate was effective in both the lamotrigine-resistant amygdala-kindled rat, and the 6-Hz seizure model, two models that are thought to have predictive value for pharmacoresistant epilepsy [1]. In the 6-Hz seizure model, carisbamate retained potent anticonvulsant activity as the stimulus intensity was increased from 22 to 44 mA [1]. In the lamotrigine-resistant amygdala-kindled rat, carisbamate caused a dose-dependent reduction in behavioural seizure score and afterdischarge duration. Carisbamate has also been demonstrated to delay the development of amygdala kindling when administered prior to each kindling stimulation during the kindling acquisition phase [4]. These results suggest that carisbamate might have disease-modifying effects in this model. In addition, carisbamate is effective in treating fully kindled rats, even when the animal has been kindled in the presence of carisbamate. In contrast, rats kindled in the presence of low-dose lamotrigine are resistant to a higher dose of lamotrigine [4].

Carisbamate has been evaluated in two genetic models of epilepsy, the GAERS and the Wistar Audiogenic Sensitive (AS) rat. In the GAERS, which is a model predictive of activity in absence seizures, carisbamate administered intraperitoneally (i.p.) at doses of 10, 30 and 60 mg/kg dose-dependently reduced the expression of spike-and-wave discharges as measured by electroencephalography; spike-and-wave discharges were significantly suppressed at 30 mg/kg and completely suppressed at 60 mg/kg [5]. In Wistar AS rats, carisbamate given i.p. significantly delayed seizure onset at 10 mg/kg and completely suppressed seizure-related behaviours at 20 and 30 mg/kg [5].

When administered i.p. in rats, carisbamate prevented the onset of lithium–pilocarpine-induced status epilepticus. Following intravenous administration, carisbamate interrupted fully established lithium–pilocarpine-induced status epilepticus (Table 37.1) [1]. In a hippocampal neuronal model of status epilepticus, carisbamate (100 μmol) significantly decreased depolarization-induced sustained repetitive firing. Carisbamate did not block low-Mg^{+}-induced high-frequency spiking in this model. However, this latter form of *in vitro* status epilepticus is not effectively blocked by conventional AEDs that are known to be effective in treating status epilepticus in humans [6]. Carisbamate performed well in suppressing spontaneous motor seizures in the kainate post-status epilepticus rat model of temporal lobe epilepsy. When administered at 10 or 30 mg/kg i.p. in this model, carisbamate significantly reduced relative seizure frequency (74% reduction at 30 mg/kg, $P < 0.0001$) [3] and was more effective than topiramate; that is, spontaneous seizures were completely suppressed by carisbamate in a larger fraction of the rats studied (seven of eight rats at 30 mg/kg i.p. for carisbamate versus one of eight rats at 100 mg/kg i.p. for topiramate) [2].

In the lithium–pilocarpine model of post-status epilepticus-induced epileptogenesis in male Sprague–Dawley rats, carisbamate displayed both neuroprotective and antiepileptogenic effects. When carisbamate (30, 60, 90 or 120 mg/kg) was injected i.p. at 1 and 8 h after the onset of lithium–pilocarpine-induced status epilepticus and the administration was continued twice daily for 6 days, the drug at all doses reduced neuronal loss, preserving neurones in the CA1 region of the hippocampus, the dorsolateral region of the lateral thalamus and the basolateral amygdala [7]. At 60 mg/kg, significant neuroprotection was also observed in the anterior part of the amygdala and layer II of the piriform cortex, and at 90 and 120 mg/kg, carisbamate further afforded marked neuroprotection in the posterior part of the medial amygdala, the ventrolateral part of the lateral thalamus, the mediodorsal thalamus and deep layers of the piriform, and ventral entorhinal cortices [7]. More importantly, carisbamate dose-dependently delayed or prevented the development of spontaneous recurrent seizures. At the higher doses of 90 and 120 mg/kg, 45% of the rats did not develop spontaneous recurrent seizures by the end of the 5-month-long study [7].

Studies in models predictive of activity in other indications

In addition to the investigations in seizure models, carisbamate has been assessed for its efficacy in a model of neuropathic pain. A study by White *et al*. [8] demonstrated that carisbamate prevents the development of mechanical allodynia produced by amygdala kindling in rats. The mechanism by which carisbamate attenuates mechanical allodynia has yet to be determined, but it is likely that carisbamate modulates the pathways involved in the central and/or peripheral sensitization of the nervous system following amygdala kindling. This finding suggests that carisbamate may be effective for the treatment of neuropathic pain [8].

Mechanisms of action

The precise mechanisms of action of carisbamate remain under investigation. Carisbamate was found to inhibit voltage-dependent brain-type sodium channels in a concentration- and state-dependent manner [9]. However, this mechanism of action probably does not explain the broad spectrum of activity that carisbamate possesses in preclinical seizure models. Therefore, additional work is necessary to further elucidate the actions of carisbamate at molecular level.

Non-clinical toxicology

Carisbamate has demonstrated efficacy in rodent seizure models at doses well below those that produce central nervous system (CNS) toxicity. The neurotoxicity of carisbamate has been evaluated by the rotorod and inclined-screen tests in mice, and by observed minimal motor impairment in rats. The single-dose oral median toxic dose (TD_{50}) was ≥137 mg/kg, resulting in a protective index (the ratio of TD_{50}/ED_{50}) of ≥17 (the median ED_{50} in the MES test was 7.7 mg/kg for mice and 4.4 mg/kg for rats). The intravenous maximum tolerated single dose in mice and rats was in the range of 360–600 mg/kg; these doses resulted in decreased activity, ataxia, sedation and prostration [10].

Repeated-dose oral toxicity studies were carried out in adult rats (up to 6 months) and in adult dogs (up to 12 months). No significant organ toxicity occurred even at exposures that were two- to three-fold greater than anticipated human therapeutic exposures. Toxicity was also evaluated in juvenile rats administered carisbamate orally from postnatal day 12 to 54. Adverse CNS effects were elicited only at doses of 80 mg/kg and 160 mg/kg, and carisbamate had no effect on learning, memory or reproductive function [10].

Carisbamate tested negative for genetic toxicity in the bacterial reverse mutation test, the *in vitro* human lymphocyte chromosomal aberration assay and the *in vivo* oral mouse bone marrow assay [10].

Pharmacokinetics

Overview of pharmacokinetic properties

Carisbamate is rapidly absorbed following oral administration. Maximum plasma concentrations are observed 0.5–3 h after single-dose administration under fasted conditions. Data on absolute bioavailability have not been obtained since an intravenous formulation for use in humans is not available. However, absorption must be nearly complete because an average of 93.8% or more of radioactivity was recovered in the urine following single-dose oral administration of a radiolabelled dose of carisbamate to eight healthy male subjects [11].

Food intake has minimal impact on the extent to which carisbamate is absorbed, as assessed by the area under the plasma concentration versus time curve (AUC). A delay in the mean time of maximum concentration (t_{max}) values of approximately 2 h and a decrease in the mean maximum plasma concentrations (C_{max}) of carisbamate by approximately 20% was seen when carisbamate was given in a fed state (Johnson and Johnson, data on file).

The apparent volume of distribution (V_d/F; ~45–56 L) of carisbamate is close to total volume of body water, indicating that the drug does not distribute extensively to tissues. The distribution of carisbamate between whole blood and plasma was close to unity, consistent with the previous observation of low to moderate protein binding of carisbamate in humans. Data from *in vitro* studies indicate that carisbamate is approximately 47% bound to human plasma proteins, independent of the total concentrations (Johnson and Johnson, data on file).

The majority of carisbamate is eliminated by two major metabolic pathways: O-glucuronidation of either the *S*-enantiomer (44% of the dose) or the *R*-enantiomer produced through chiral inversion (11% of the dose), and hydrolysis of the carbamate ester followed by oxidation (36% of the dose). Only a fraction of carisbamate undergoes hydroxylation on the benzene ring followed by sulphate conjugation (5% of the dose) [11]. Trace amounts of two premercapturic acid conjugates of carisbamate (<0.3% of the dose) were observed in the urine [11]. Carisbamate and its metabolites are excreted primarily in the urine (~94 ± 7% of the dose) with a small percentage excreted in the faeces (~2.5 ± 2% of the dose). Only about 2.4% of the total radioactivity recovered in the urine was unchanged drug in the radiolabelled study previously mentioned. The fraction of unchanged drug in the faeces was not determined. Total recovery in both urine and faeces was approximately 96% within 120 h after dosing [11].

Carisbamate has been demonstrated to have linear pharmacokinetics. Dose proportionality was evident after single doses ranging from 100 to 1500 mg and after twice-daily administration of 100–750 mg given as a capsule formulation to healthy subjects. The half-life of carisbamate in subjects not taking enzyme inducers was determined to be between 10.6 and 12.8 h, allowing for twice-daily dosing. Steady-state conditions are typically achieved within 3 days. The apparent oral clearance (CL/*F*) in healthy subjects is 3.4–4.2 L/h, which is less than 5% of liver blood flow and indicative of a low hepatic first-pass effect. Renal clearance was determined to be 0.042–0.094 L/h, confirming that carisbamate is eliminated primarily by metabolism. Because the pharmacokinetics of carisbamate has been shown to be consistent after single and repeat administration, it may be concluded that carisbamate does not induce or inhibit its own metabolism [2,12].

Pharmacokinetics in special groups

Elderly subjects

The pharmacokinetics of carisbamate were evaluated after twice-daily administration of 100 mg, 250 mg and 500 mg to the following three groups, each of which consisted of six healthy subjects: (1) medically stable elderly adults aged 65–74 years; (2) medically stable elderly adults aged ≥75 years; and (3) non-elderly healthy adults aged 18–55 years. Small and clinically insignificant differences in the mean C_{max} and $AUC_{12\,h}$ values were observed [13].

Renal disease

When the pharmacokinetics of a single 200-mg dose of carisbamate was evaluated in patients with renal dysfunction, only clinically insignificant differences were observed in the mean plasma C_{max} and $AUC_{0–48h}$ values of unchanged carisbamate for subjects with moderate (creatinine clearance, 30–50 mL/min) to severe (creatinine clearance, <30 mL/min) renal impairment compared with subjects with normal renal function. However, the mean C_{max} and $AUC_{0–48h}$ of two glucuronide metabolites of carisbamate were up to 7.5 times higher in subjects with moderate and severe renal impairment and up to 50 times higher in subjects with end-stage renal disease (ESRD) relative to healthy subjects. A 4-h haemodialysis session reduced the AUC and C_{max} of the glucuronide metabolites by approximately 50% in subjects with ESRD, showing that they are effectively cleared from the plasma through dialysis (Johnson and Johnson, data on file).

Hepatic disease

The pharmacokinetics of carisbamate was evaluated in subjects with mild and moderate hepatic impairment and compared with the pharmacokinetics in subjects with normal hepatic function (10 subjects in each cohort). Following a single 200-mg dose of carisbamate, mean systemic exposure (plasma AUC) of carisbamate was approximately 16% greater

in subjects with mild hepatic impairment (Child–Pugh score 5–6) and 107% greater in subjects with moderate hepatic impairment (Child–Pugh score 7–9) compared with subjects with normal hepatic function. Furthermore, the pharmacokinetic profile of carisbamate in subjects with moderately impaired liver function was characterized by a prolongation in the mean terminal half-life (20.7 h) when compared with healthy subjects (10.5 h) [14].

Drug interactions

Studies *in vitro*

In human liver microsomes, carisbamate, at concentrations well above the maximal human exposure, inhibited CYP3A4 (IC_{50} = 695 μg/mL) and CYP2C9 (IC_{50} > 1000 μg/mL). In cultured primary human hepatocytes, carisbamate at 200 μg/mL (approximately 5–7 times the maximal human exposure) modestly induced CYP2B6 and CYP3A4/5 (activity increased 6.7 and 7.8 times, respectively). CYP2C9 was inhibited as well (activity decreased by 60%). Thus, carisbamate showed little propensity to interact with CYP at clinically relevant concentrations (Johnson and Johnson, data on file).

Studies *in vivo*

Three studies evaluating potential interactions with carbamazepine [15], lamotrigine [16] and valproic acid [16] were conducted and involved the following sequential treatments: (1) carisbamate monotherapy for 10 days (500–1000 mg/day); (2) monotherapy with the other antiepileptic drug (AED) for 11–28 days; and (3) concomitant administration of the two drugs for 10–17 days. Mean carisbamate exposure was reduced by approximately 40% and the terminal half-life was reduced from 10.4 h to 7.4 h by the co-administration of carbamazepine (600 mg/day), but carisbamate (1000 mg/day) did not affect the pharmacokinetics of carbamazepine. Lamotrigine (100 mg/day) had no significant effect on carisbamate pharmacokinetics, but the mean 12-h AUC value of lamotrigine was reduced approximately 22% by carisbamate (1000 mg/day). There was no significant interaction between valproic acid (1000 mg/day) and carisbamate (1000 mg/day); exposures of both drugs were well within the bioequivalency range (80–125%).

The potential interaction of carisbamate with other drugs has also been studied. When carisbamate (400 mg/day) was administered for 2 weeks to patients with epilepsy taking a wide range of phenytoin doses regimens, the mean steady-state plasma AUC values of carisbamate were up to 52% lower relative to the values in subjects who received carisbamate alone (Johnson and Johnson, data on file). This interaction was unidirectional and carisbamate did not alter the steady-state plasma concentrations of phenytoin. Carisbamate (400 mg/day, administered for 2 weeks) has been shown to have no effect on the pharmacokinetics or pharmacodynamics of a single dose of warfarin or ethanol (Johnson and Johnson, data on file).

There are some data to suggest that oral contraceptives lower carisbamate exposure: in one study, the mean steady-state AUC of carisbamate (1000 mg/day for 10 days) was reduced by 20–30% with concomitant administration in three consecutive cycles of an oral contraceptive containing 0.035 mg ethinylestradiol and 1 mg norethindrone (Johnson and Johnson, data on file). However, in another study the exposure of carisbamate (400 mg/day for 2 weeks) was reduced only 14% by an oral contraceptive containing 0.025 mg ethinylestradiol and 0.18–0.25 mg norgestimate (Johnson and Johnson, data on file). Carisbamate at dosages of 1000 mg/day reduced exposures of ethinylestradiol by no more than 13%, and norethindrone by no more than 5%; thus, impairment of contraceptive efficacy by carisbamate is unlikely.

Three *in vivo* studies evaluating the potential of carisbamate to affect the activity of cytochrome P450 enzymes CYP3A4, CYP2C9 and CYP2D6, using the probe substrates midazolam, tolbutamide and desipramine, respectively, involved the following sequential treatments: (1) a single dose of the enzyme probe drug; (2) carisbamate monotherapy (500–1000 mg/day) for 9 days; and (3) a single dose of the probe drug given concomitantly with carisbamate on day 9. The results indicated that carisbamate may be a weak CYP2C9 inhibitor, as this regimen increased the AUC_{∞} of tolbutamide by 31%. This regimen of carisbamate had little effect, however, on desipramine and midazolam, suggesting that carisbamate does not significantly affect CYP2D6- or CYP3A4-mediated metabolism (Johnson and Johnson, data on file).

Serum level monitoring

At present, there is insufficient information on the potential value of monitoring serum carisbamate levels.

Efficacy

Proof of-concept photosensitivity study

The initial clinical data on carisbamate's efficacy came from a multicentre, non-randomized, single-blind, placebo-controlled, proof-of-concept study that assessed the effect of carisbamate on the photoparoxysmal response to intermittent photic stimulation in 18 patients with photosensitive epilepsy [17]. The patients, all of whom were on a regimen of concomitant AEDs such as valproic acid, underwent standardized intermittent photic stimulation under three eye conditions (during eye closure, eyes closed and eyes open) each hour for up to 8 h on three consecutive days, after receiving placebo on day 1, carisbamate on day 2 and placebo on day 3. Doses of carisbamate on day 2 ranged from 250 to 1000 mg, and photosensitivity was evaluated at frequencies from 2 to 60 Hz. A dose-dependent reduction in photosensitivity was produced in the 13 evaluable patients (four patients each at the 500-mg and 750-mg dose level and five patients at the 1000-mg dose level): three patients (one in the 500-mg group and two in the 1000-mg group) exhibited complete suppression, and seven additional patients exhibited clinically significant suppression. All five patients in the 1000-mg group demonstrated reduction or complete suppression of the photoparoxysmal response. The onset of effect of carisbamate was rapid (occurring within 2 h of the time the dose was given for the 1000-mg dose), and the duration of effect was dose dependent and long lasting (clinically significant reductions of photosensitivity were observed for up to 32 h after doses of 750 or 1000 mg).

Randomized controlled trials in patients with partial-onset seizures

The efficacy and safety of carisbamate as adjunctive treatment of adults with partial-onset seizures has been assessed in three multicentre, randomized, double-blind, placebo-controlled studies.

Study 1 evaluated the safety and efficacy of daily dosages of 100, 300, 800 and 1600 mg of carisbamate added to up to three concomitant AEDs in patients with partial-onset seizures from 18 to 70 years in age ($n = 537$). These patients had a median duration of epilepsy of 22 years and had previously been exposed to a median of six different AEDs; 17% had been exposed to more than 10 AEDs and, overall, 36% of patients were receiving three concomitant AEDs. To be eligible for randomization, all patients had to have at least three partial-onset seizures per 28-day period during a prospective 8-week baseline period; the median was 10 per 28 days across all treatment groups (range, 3–445 per 28 days). The 16-week double-blind treatment phase included a 4-week titration phase. An intention-to-treat analysis was conducted for the primary outcome variable (per cent reduction in partial-onset seizure rate during the 16-week double-blind treatment phase relative to the 8-week prospective baseline phase) and each of the carisbamate doses was compared with the placebo using a Wilcoxon rank sum test stratified by pooled centres, with adjustment for multiplicity using a stepwise procedure. The 300 mg/day, 800 mg/day and 1600 mg/day doses were significantly more effective than placebo in reducing the frequency of partial-onset seizures (Fig. 37.1). The difference from placebo was evident for each of these dose groups within the first month of treatment and was maintained until the end of the double-blind period. For the responder rate (proportion of patients having a ≥50% reduction from baseline in partial-onset seizure frequency), each of the carisbamate doses was compared with placebo using the generalized Cochrane–Mantel–Haenszel test controlling for pooled analysis centre, with adjustment for multiplicity using a stepwise procedure. Carisbamate doses of 300 mg/day and 1600 mg/day were also associated with statistically significant overall responder rates (Fig. 37.2) [18].

[a]Pairwise comparison of carisbamate treatment group versus placebo from Wilcoxon rank sum test.

Two subsequent studies, identical in design, evaluated the safety and efficacy of daily dosages of 200 and 400 mg added to one or two concomitant AEDs in patients over 16 years of age ($n = 565$ in study 2 and 562 in study 3) [19]. In study 2, median duration of epilepsy was 19 years; median number of prior AED exposures was five (and 16% had 10 or more); 77% of patients were receiving two concomitant AEDs; and median seizure rate during the prospective 8-week baseline period was 9 per 28 days (range, 2–626). In study 3, median duration of epilepsy was 15 years; median number of prior AED exposures was four (and 8% had 10 or more); 69% of patients were receiving two concomitant AEDs; and median seizure rate during the baseline period was 7 per 28 days (range, 2–279). Subjects attained their target dosage immediately after randomization as there was no titration period. The chief outcome variables were per cent reduction in partial-onset seizure rate in the double-blind treatment phase compared with baseline (comparing each dose with placebo using a Wilcoxon rank sum test stratified by country and adjustment for multiplicity using a stepwise procedure) and responder rate (compared each dose with placebo using the generalized Cochrane–Mantel–Haenszel test controlling for country, with a stepwise adjustment for multiplicity). Most patients completed the double-blind treatment phase (93% in study 2 and 94% in study 3). Efficacy was demonstrated for both outcome variables for the 400-mg dosage only in study 2, but not in study 3. Efficacy outcomes for the 200-mg daily dosage did not differ from placebo in either study (Figs 37.1 and 37.2).

Since the clearance of carisbamate is increased by carbamazepine and phenytoin, drugs that are known to induce uridine glucuronosyltransferase (UGT), the efficacy of carisbamate in the presence and in the absence of UGT-inducing AEDs was analysed. Phenytoin, carbamazepine and phenobarbital were considered significant UGT inducers. Although little difference in efficacy (relative to placebo) between induced and non-induced subgroups was observed in study 1, a different pattern of results was seen in studies 2 and 3 (Tables 37.2 and 37.3). For both the 200-mg and 400-mg daily dosages, in both of these studies, non-induced subjects had a greater reduction in seizure rate and a greater responder rate than induced subjects. These findings suggest that the effects of induction status on exposure may have had an

Table 37.3 Responder rates (patients with ≥50% reduction from baseline in partial-onset seizure frequency) by treatment group in relation to enzyme induction status in three randomized parallel-group placebo-controlled adjunctive therapy studies of carisbamate in patients with refractory partial epilepsy (intent-to-treat analysis set).

[a] Pairwise comparison of carisbamate treatment group versus placebo from generalized Cochran–Mantel–Haenszel test for non-zero correlation.

impact on efficacy in the lower dosage range used in the latter studies.

Adverse effects

In study 1, carisbamate has been shown to be safe and well tolerated at all dose levels tested [20]. The most frequently reported treatment-emergent adverse events across all carisbamate treatment groups were headache (n = 128, 30%), dizziness (n = 66, 15%), somnolence (n = 58, 14%) and nausea (n = 47, 11%). Some adverse events were elicited with greater frequency only at the highest dose. These included headache, diplopia, vertigo, vomiting, gait disturbance and abnormal coordination, occurring more commonly in the 1600 mg/day group than in all other groups. None of the other carisbamate dose groups differed by more than 5% from placebo for these adverse events. Three other adverse events appeared to be dose related: nausea (incidence more than 5% greater than placebo for doses ≥800 mg/day), dizziness (for doses ≥300 mg/day) and somnolence (all doses) (Fig. 37.3) [18]. Notably, no cognitive or behavioural adverse events occurred more commonly than placebo. The frequency of rash was low: 4% of placebo-treated and 2% of carisbamate-treated patients overall. Discontinuation rates in the carisbamate dose groups were low. Adverse events that resulted in discontinuation occurred in 8% of the placebo group, and 5% (100 mg/day), 6% (300 mg/day), 12% (800 mg/day) and 19% (1600 mg/day) of the carisbamate dose groups. For patients treated with carisbamate, dizziness [n = 8 (2%)] and headache [n = 7 (2%)] were the most common adverse events leading to withdrawal, with the majority of reports occurring in the 1600 mg/day group. Two or fewer patients in any other dose group withdrew as a result of these adverse events [18].

The tolerability of the 200-mg and 400-mg daily dosages in studies 2 and 3 was comparable to placebo. Among the common adverse events (≥5% in any group), only two occurred more frequently for carisbamate than for placebo: dizziness (for 400 mg/day: 12% and 13% in studies 2 and 3, respectively versus 7% for placebo in both studies) and somnolence (for 400 mg/day: 5% and 9%, respectively; for placebo: 4% and 1%, respectively).

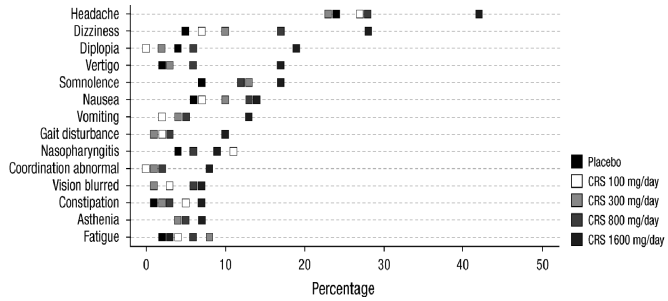

Fig. 37.3 Percentage of patients reporting treatment-emergent adverse events in a randomized parallel-group placebo-controlled adjunctive therapy trial which explored carisbamate (CRS) dosages between 100 and 1600 mg/day in patients with refractory partial epilepsy (study 1, safety analysis population). Only adverse events reported by at least 7% of patients in any carisbamate group are shown. Reproduced from ref. 20 with permission.

Rates of discontinuation because of adverse events were no more than 5% in any treatment group, and were similar for placebo and for both dosages of carisbamate.

Across all three placebo-controlled trials, serious adverse events occurred with approximately equal frequency for placebo (n = 19/496 patients, 3.8%) and for carisbamate (40/1213, 3.3%; range, 3–5% for any dosage). The most common serious adverse events have been injuries (placebo, 5/496, 1.0%; carisbamate, 9/1213, 0.7%) and seizure related (placebo, 10/496, 2.0%; carisbamate, 7/1213, 0.6%). The only serious adverse events that occurred in more than one subject were status epilepticus (placebo, five subjects), psychosis (carisbamate, three subjects), toxic hepatitis (carisbamate, two subjects) and hyponatraemia (carisbamate, two subjects). No deaths were reported. No patients had a serious drug-related rash.

Elevations of serum alanine aminotransferase (ALT) three times above normal values occurred in six patients treated with carisbamate in these three trials, with an apparent dose relationship: placebo, 0/496; pooled carisbamate 100–300 mg/day, 0/586; carisbamate 400 mg/day, 2/377 (0.5%); carisbamate 800 mg/day, 1/108 (0.9%); and carisbamate 1600 mg/day, 3/105 (2.9%). These patients were asymptomatic, and all ALT elevations resolved, in some cases with continued treatment with carisbamate at the same or lower dosage. There were no other patterns of clinically significant abnormalities in laboratory evaluations in these studies [20].

Summary and preliminary assessment of therapeutic potential

Carisbamate is a novel AED that has demonstrated broad-spectrum anticonvulsant activity in preclinical studies. Preclinical studies also suggested that carisbamate may be a useful treatment for other neurological conditions, such as neuropathic pain.

In humans, carisbamate shows linear pharmacokinetics, virtually complete absorption from the gastrointestinal tract, a half-life compatible with twice-daily dosing and extensive metabolism, primarily by glucuronide conjugation, with less than 2% excreted in the urine in unchanged form. Studies also suggest that carisbamate possesses a low potential for the formation of reactive metabolites. Extensive evaluations of potential drug–drug interactions have revealed that carisbamate has a low propensity to alter the pharmacokinetics of co-administered drugs. With respect to the co-administration of other AEDs, carisbamate causes a slight and clinically insignificant decrease in the levels of lamotrigine, and no significant interaction with valproic acid. Of clinical importance, however, is the fact that AEDs which induce UGTs, such as carbamazepine, phenytoin, phenobarbital and primidone, have the potential to reduce the plasma concentration of carisbamate.

Three randomized controlled trials have provided evidence supporting the efficacy of carisbamate at doses of 300–1600 mg/day as adjunctive treatment in highly refractory patients with partial-onset seizures. At efficacious dosages of 300 mg/day, 400 mg/day and 800 mg/day, the compound displayed a favourable adverse event profile resulting in an overall low discontinuation rate, and no or only limited cognitive and behavioural/psychiatric side-effects. The most frequently reported treatment-emergent adverse events in clinical trials have been headache, dizziness, somnolence and nausea.

Results from further ongoing clinical trials will allow us to define in more detail the therapeutic potential of carisbamate in the treatment of epilepsy.

38 Eslicarbazepine Acetate

Luis Almeida[1], *Meir Bialer*[2] *and Patricio Soares-da-Silva*[1,3]
[1] BIAL – Portela & Co, Portugal
[2] The Hebrew University of Jerusalem, Jerusalem, Israel
[3] University of Porto, Portugal

Primary indication	Adjunctive therapy of partial seizures (potential additional indications are under assessment)
Usual preparation	Tablets: 400 mg, 600 mg and 800 mg Suspension: 50 mg/mL
Usual dosage	800–1200 mg/day (tentative dose range)
Dosing frequency	Once daily
Significant drug interactions	Enzyme-inducing antiepileptic drugs decrease plasma eslicarbazepine levels. Eslicarbazepine acetate decreases the plasma levels of steroid oral contraceptives
Serum level monitoring	There is insufficient information on the value of monitoring serum eslicarbazepine levels
Reference range	Not established as yet
Common/important adverse effects	Dizziness, blurred vision, diplopia, visual disturbances, nausea and vomiting, fatigue, incoordination, headache, somnolence
Main advantages	Usually well tolerated, once-daily dosing
Main disadvantages	Limited clinical experience. Efficacy spectrum probably restricted to partial epilepsies
Mechanism of action	Blockade of voltage-gated sodium channels[a]
Oral bioavailability	Almost complete (in terms of the active metabolite eslicarbazepine)
Time to peak levels	2–3 h[a]
Metabolism and excretion	Hydrolysed rapidly to eslicarbazepine, which is excreted in urine in free and conjugated form. Minor metabolites include (*R*)-licarbazepine, oxcarbazepine and their conjugates
Volume of distribution	About 2.7 L/kg[a]
Elimination half-life	13–20 h[a]
Plasma clearance	About 55 mL/h/kg
Protein binding	30%[a]
Active metabolites	Eslicarbazepine. Minor active metabolites include oxcarbazepine and (*R*)-licarbazepine
Comment	Potentially a useful antiepileptic drug, but more data are needed to establish its place in current therapy

[a] Pharmacokinetic parameters refer to eslicarbazepine, for which eslicarbazepine acetate can be considered a prodrug.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Introduction

Eslicarbazepine acetate (BIA 2-093) is a novel voltage-gated sodium channel blocker that was identified as a promising candidate for clinical development through a drug discovery programme initiated in the mid-1990s by Bial (Portela & Co., S.A.) [1]. Eslicarbazepine acetate was designed to be a single (*S*)-enantiomer member of the established family of dibenz[b,f]azepine derivatives represented by carbamazepine and oxcarbazepine [2]. In its chemical structure, eslicarbazepine acetate shares with carbamazepine and oxcarbazepine the dibenzazepine nucleus bearing the 5-carboxamide substitute, but it is structurally different at the 10,11-position [3]. This molecular variation results in differences in metabolism [4]. Unlike carbamazepine, eslicarbazepine acetate is not metabolized to carbamazepine-10,11-epoxide and is not susceptible to metabolic autoinduction. Unlike oxcarbazepine, which is a prochiral prodrug metabolized presystemically to both eslicarbazepine [also called (*S*)-licarbazepine or (*S*)-MHD] and (*R*)-licarbazepine [also called (*R*)-MHD] [5], eslicarbazepine acetate is a prodrug of only eslicarbazepine, which is the active entity responsible for eslicarbazepine acetate pharmacological effects in humans.

This chapter will review preclinical and clinical pharmacokinetic, efficacy and safety data of eslicarbazepine acetate in epilepsy. Studies in other indications (neuropathic pain, fibromyalgia and migraine prophylaxis) are currently ongoing.

Chemistry

Eslicarbazepine acetate corresponds chemically to (*S*)-10-acetoxy-10,11-dihydro-5H-dibenz[b,f]azepine-5-carboxamide (Fig. 38.1). Its molecular formula is $C_{17}H_{16}N_2O_3$ and its molecular weight is 296.32. Eslicarbazepine acetate is a white to off-white, odourless and non-hygroscopic, crystalline powder with a melting point of 184–187°C. Eslicarbazepine acetate is very slightly soluble (<1 mg/mL) in aqueous buffer solutions at different pH; its intrinsic dissolution is within 0.06 and 0.07 mg/min/cm^2 for a pH in the range of 1.2–6.8. Eslicarbazepine acetate is freely soluble in dichloromethane, sparingly soluble in acetone, acetonitrile, methanol and tetrahydrofuran, and slightly soluble in absolute ethanol and 2-propanol. Eslicarbazepine acetate is a neutral compound and as such it is non-ionizable at physiological conditions.

The structure of eslicarbazepine acetate has been determined and confirmed by elemental analysis, ultraviolet, infrared, mass and nuclear magnetic resonance spectroscopy. Eslicarbazepine acetate is a thermally stable and photostable substance. Eslicarbazepine acetate's physical appearance and chromatographic behaviour remain unchanged at a storage temperature of 30°C and relative humidity (RH) of 65% for up to 3 years as well as under accelerated conditions of 40°C/75% RH for 6 months.

Plasma and urine concentrations of eslicarbazepine acetate and its metabolites can be monitored by solid-phase extraction followed by high-performance liquid chromatography (HPLC), with ultraviolet or mass spectrometric detection [6–12].

Pharmacokinetic and activity profile in animal models and mechanisms of action

Pharmacokinetic differences across species

Eslicarbazepine acetate disposition varies significantly across species. In general, following oral administration to animals or humans, no or minimal measurable concentrations of the parent drug (eslicarbazepine acetate) were observed. In the rat, eslicarbazepine acetate was mainly metabolized to oxcarbazepine, with eslicarbazepine and (*R*)-licarbazepine as minor metabolites. In the mouse, the hamster and the rabbit, eslicarbazepine was the major metabolite and oxcarbazepine and (*R*)-licarbazepine were minor metabolites. In the Beagle dog, eslicarbazepine was a major metabolite and oxcarbazepine and (*R*)-licarbazepine were minor metabolites, but measurable amounts of eslicarbazepine acetate were observed up to 2 h after administration. In the cynomolgus monkey, measurable amounts of eslicarbazepine acetate were found up to 1.5 h after administration, with eslicarbazepine representing up to 96.5% of active moieties; no measurable amounts of oxcarbazepine and (*R*)-licarbazepine were found. In humans, eslicarbazepine

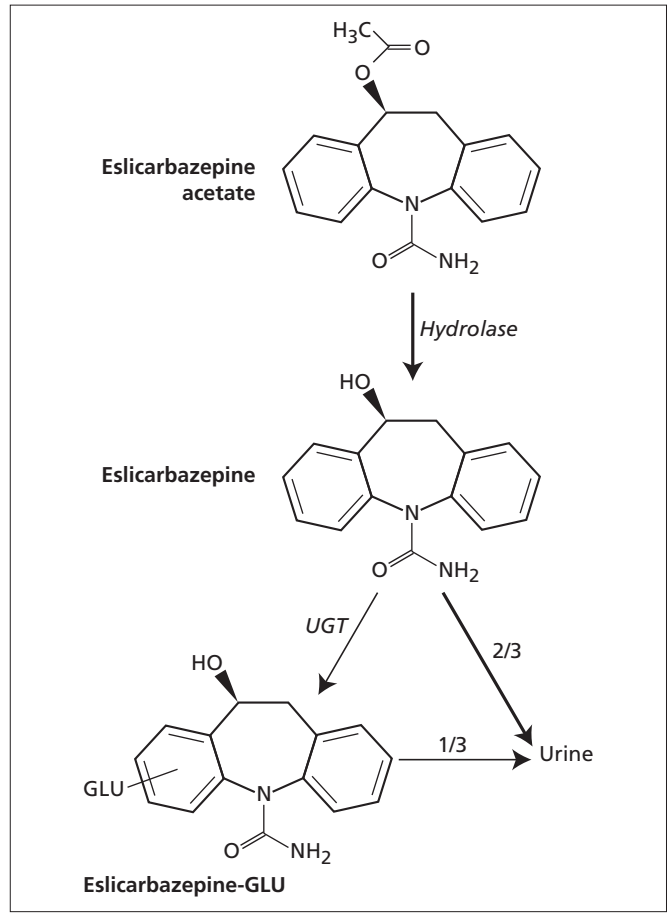

Fig. 38.1 Main metabolic and elimination pathway of eslicarbazepine acetate following oral administration to humans. More than 90% of an eslicarbazepine acetate dose is excreted in urine as eslicarbazepine [two-thirds in unconjugated form and one-third as a glucuronide conjugate (-GLU)]. UGT, uridine diphosphate-5′-glucuronosyltransferase.

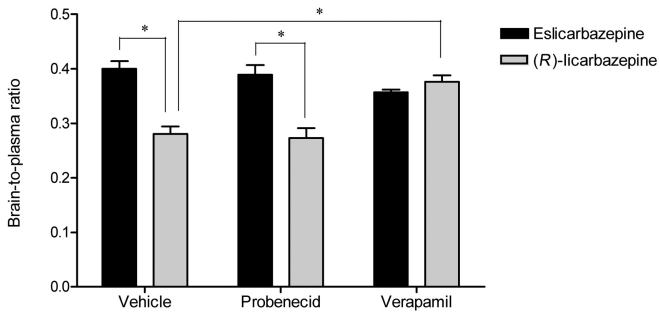

Fig. 38.2 Brain-to-plasma concentration ratios of eslicarbazepine and (*R*)-licarbazepine in nuclear magnetic resonance imaging mice pretreated with vehicle, probenecid (100 mg/kg, p.o.) or verapamil (20 mg/kg, p.o.) and subsequently (30 min later) given eslicarbazepine or (*R*)-licarbazepine (100 mg/kg, i.p.). Samples were collected at 1 h post dose. Columns indicate means of five determinations per group; vertical lines indicate the corresponding SEM. $*P < 0.05$.

acetate was extensively metabolized mainly to eslicarbazepine; (*R*)-licarbazepine and oxcarbazepine were minor metabolites [13].

In the mouse, following the administration of eslicarbazepine or (*R*)-licarbazepine, the ratio of the areas under the concentration–time curves (AUC) in brain ($AUCbrain_{eslicarbazepine}$/$AUCbrain_{(R)\text{-licarbazepine}}$) was greater than AUC ratios in plasma ($AUCplasma_{eslicarbazepine}$/$AUCplasma_{(R)\text{-licarbazepine}}$; 1.87 versus 1.10), suggesting that distribution of eslicarbazepine into the brain is more extensive than that for (*R*)-licarbazepine [14]. It is thus apparent that (*R*)-licarbazepine has considerably more difficulty penetrating the brain. In fact, the brain-to-plasma ratio for eslicarbazepine, considering either the peak concentration (C_{max}) or AUC, was found to be twice as high as that for (*R*)-licarbazepine [14]. This clearly indicates that there is enantioselectivity in crossing the blood–brain barrier.

To assess whether differences in brain penetration of eslicarbazepine and (*R*)-licarbazepine were related to susceptibility for efflux through P-glycoprotein (P-gp) or multidrug resistance protein (MRP), mice were pretreated with verapamil or probenecid [13]. As shown in Figure 38.2, verapamil and probenecid failed to affect the eslicarbazepine brain-to-plasma concentration ratio. By contrast, verapamil, but not probenecid, markedly increased the (*R*)-licarbazepine brain-to-plasma ratio. This indicates that eslicarbazepine is not a substrate for either P-gp or MRP, whereas (*R*)-licarbazepine is a substrate for P-gp but not for MRP. It is interesting to note that the (*R*)-licarbazepine brain-to-plasma ratio after verapamil treatment was equal to that of eslicarbazepine in vehicle-treated animals. These findings are in line with previous evidence that racemic (*R*,*S*)-licarbazepine appears to cross the blood–brain barrier not by simple passive diffusion, but rather by a P-gp-mediated active transport [15]. Since eslicarbazepine and (*R*)-licarbazepine have different pharmacodynamic and pharmacokinetic properties, they should be evaluated individually utilizing enantiospecific methods.

Mechanisms of action and activity in experimental models

The precise mechanism of action of eslicarbazepine acetate and eslicarbazepine is unknown. However, *in vitro* electrophysiological studies indicate that eslicarbazepine acetate and eslicarbazepine inhibit sodium currents in a voltage-dependent way by competitively interacting with the inactivated voltage-gated sodium channels, thereby preventing their return to the active state. Eslicarbazepine acetate and eslicarbazepine interact with the neurotoxin receptor site 2 of the voltage-gated sodium channel, but not with receptor site 1 [16]. Eslicarbazepine acetate inhibits sodium currents in a voltage-dependent way by interacting predominantly with the inactivated state of the channel in mouse neuroblastoma cell line N1E-115. Over the range of neuronal resting membrane potentials likely to be encountered in the brain *in situ*, eslicarbazepine acetate displayed a similar inhibitory potency to carbamazepine [16]. Eslicarbazepine, (*R*)-licarbazepine and oxcarbazepine also inhibited voltage-gated sodium channels in neuroblastoma N1E-115 cells. The potency of inhibition was highly sensitive to the holding potential, increasing with depolarization. For each different holding potential, carbamazepine exhibited the highest inhibitory potential (Table 38.1). All compounds had a much higher affinity for the inactivated (K_I) state of the channel, but the affinities of eslicarbazepine acetate, eslicarbazepine and (*R*)-licarbazepine were approximately two-, four- and four-fold lower than that of carbamazepine, respectively. The affinities of these compounds for the resting (K_R) state of N1E-115 endogenous sodium channels (calculated based on the fits of the voltage dependence of the channel availability) differed significantly. However, no significant difference was found concerning the affinity of carbamazepine and oxcarbazepine for the inactivated state of the channel. The affinity of eslicarbazepine for sodium channels in the resting state was about 15- to 5-fold lower than that of carbamazepine, oxcarbazepine and (*R*)-licarbazepine, a feature that may translate into an enhanced inhibitory selectivity of eslicarbazepine for rapidly firing 'epileptic' neurones over those with normal activity [17].

Table 38.1 Comparative affinities of eslicarbazepine acetate, its metabolites and carbamazepine for the resting (K_R) and inactivated (K_I) state of the sodium channel. Results are means ± SEM of four to five experiments.

Compound	Affinity (μmol)	
	K_R	K_I
Carbamazepine	1410 ± 598	74 ± 20
Oxcarbazepine	2964 ± 699	67 ± 8
Eslicarbazepine acetate	10166 ± 7291	146 ± 77
Eslicarbazepine	21006 ± 4497	245 ± 37
(*R*)-licarbazepine	3843 ± 825	285 ± 53

Eslicarbazepine acetate was tested in several models predictive of anticonvulsant efficacy, such as the maximal electroshock seizure (MES) test in rats and mice and the corneal kindling in mice [13]. In the MES test, eslicarbazepine, acetate was found to be equally potent to carbamazepine, and more potent than oxcarbazepine, 2 h and 4 h after administration by gastric tube; 8 h after administration the drugs were equipotent [3]. In NMRI mice, eslicarbazepine acetate (administered orally 60 min before the test) significantly decreased the number of tonic convulsions observed in the MES test at all doses (10, 25, 50, 75, 100 and 150 mg/kg) (Fig. 38.3). With the exception of one measurable sample at 100 mg/kg, eslicarbazepine acetate was not detected in plasma 60 min after dosing. Since eslicarbazepine acetate is extensively metabolized by first-pass effect to eslicarbazepine,

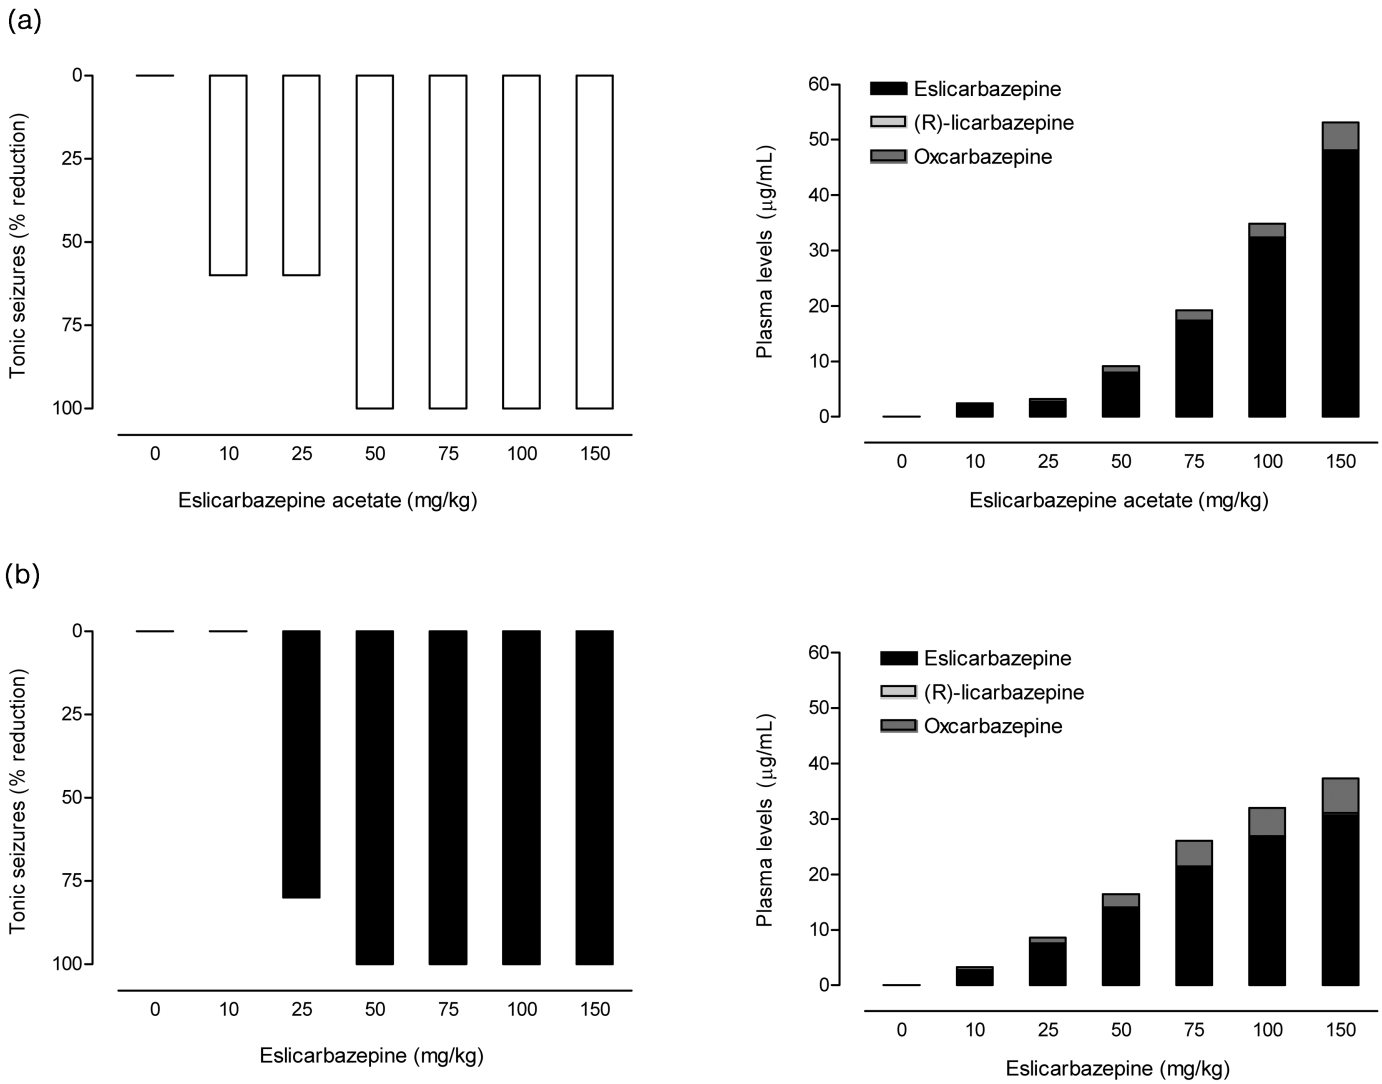

Fig. 38.3 Anticonvulsant effects in the maximal electroshock (MES) test (left panels) and plasma concentrations of eslicarbazepine acetate metabolites (right panels) 1 h after p.o. administration of eslicarbazepine acetate (a) or eslicarbazepine (b) in the mouse.

which represented approximately 90% of the systemic drug exposure (AUC), the anticonvulsant activity observed with eslicarbazepine acetate can be attributed to the activity of eslicarbazepine. Administration of eslicarbazepine at 25 mg/kg and above (50, 75, 100 and 150 mg/kg) also significantly decreased the number of tonic convulsions in the MES test. The concentrations of eslicarbazepine increased with increasing dose of eslicarbazepine acetate in all mice.

The effects of eslicarbazepine acetate were also evaluated in the 6-Hz psychomotor seizure model in the mouse [13]. In the first set of experiments, eslicarbazepine acetate was tested at 1, 2.5, 5, 10, 25 and 50 mg/kg, administered orally 30 min before the test (44 mA, 3 s, 0.2 ms pulse width, 6 Hz, via corneal electrodes). The seizure score (maximum possible score = 2) was significantly decreased at 2.5, 5 and 10 mg/kg (–0.5, $P < 0.05$), at 25 mg/kg (–0.5, $P < 0.01$) and at 50 mg/kg (–1.0, $P < 0.001$) compared with the vehicle control. In another set of experiments, eslicarbazepine acetate was tested at 5, 10, 25, 50, 100 and 150 mg/kg, administered orally 60 min before the test (rectangular current: 32 mA, 3 s, 0.2 ms pulse width, 6 Hz, via corneal electrodes). All of these doses of eslicarbazepine acetate decreased forelimb seizure score compared with vehicle control. The seizure score decreased significantly for all doses between 10 mg/kg and 150 mg/kg (10 mg/kg: –0.4, $P < 0.05$; 25 mg/kg: –0.4, $P < 0.05$; 50 mg/kg: –0.6, $P < 0.05$; 100 mg/kg: –1.3, $P < 0.001$; and 150 mg/kg: –1.0, $P < 0.001$).

In NMRI mice, eslicarbazepine acetate significantly retarded kindling development (Fig. 38.4) [18]. At dosages of 30 and 100 mg/kg eslicarbazepine acetate, the average number of stimulations to reach a fully kindled generalized seizure was increased by 217% and 280%, respectively. These data provide evidence for an anticonvulsant effect of eslicarbazepine acetate on partial-onset seizures. However, disease-modifying effects may also be involved. Eslicarbazepine acetate may not merely suppress seizure activity but may also inhibit the generation of a hyperexcitable network and therefore provide an antiepileptogenic effect [18]. Administration of eslicarbazepine also had an inhibitory effect on acquisition of kindling, whereas (*R*)-licarbazepine did not affect

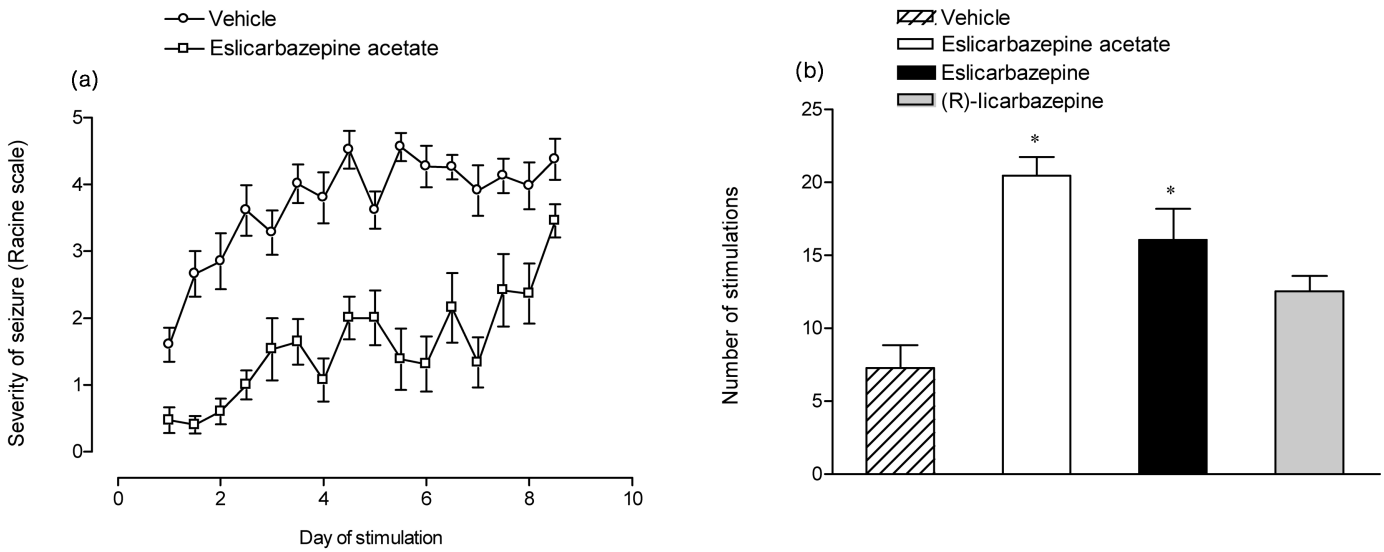

Fig. 38.4 (a) Effect of twice-daily eslicarbazepine acetate (100 mg/kg, i.p.) for 12 days on acquisition of kindling (i.e. development of seizure severity) upon repeated transcorneal stimulation. (b) Effects of twice-daily eslicarbazepine acetate (100 mg/kg, i.p.), eslicarbazepine (100 mg/kg, i.p.) and (*R*)-licarbazepine (100 mg/kg, i.p.) for 12 days on the number of stimulations necessary to induce a seizure with a severity score of 5 on the Racine scale in the mouse corneal kindling model. Mice were stimulated twice daily (inter-stimulation interval 6–7 h) on 12 consecutive days. Data are mean values ± SEM. $*P < 0.05$ versus vehicle.

the number of stimulations necessary to induce a specific seizure stage, and did not exert any relevant effect on mean seizure severity during kindling progression (Fig. 38.4).

Oral treatment with eslicarbazepine acetate was also tested in an animal model in which partial seizures can be elicited repeatedly on different days without changes in threshold or seizure patterns [19]. In rats treated with threshold doses of picrotoxin (perfused through the hippocampus), the average number of seizures was 2.3 ± 1.2, and average seizure duration was 39.5 ± 8.4 s. Pretreatment with eslicarbazepine acetate (30 mg/kg) 2 h before picrotoxin microperfusion prevented seizures in 75% of the rats. Lower doses of eslicarbazepine acetate (3 and 10 mg/kg) did not completely suppress seizures; however, after 10 mg/kg, significant reductions in seizure duration (24.3 ± 6.8 s) and seizure number (1.6 ± 0.3) were observed. No adverse effects of eslicarbazepine acetate were observed in the behavioural/EEG patterns studied, including sleep–wakefulness cycle, at the doses tested. Eslicarbazepine acetate also protected against seizures induced in rats and mice by the chemoconvulsants metrazole, bicuculline, picrotoxin and 4-aminopyridine [20].

Intrahippocampal microperfusion of latrunculin A (4 μmol) induces long-term changes in neuronal excitability leading to onset of sporadic spontaneous seizures [21]. Oral doses of eslicarbazepine acetate 10 and 30 mg/kg resulted in marked attenuation of seizures induced by latrunculin A microperfusion in the rat hippocampus. The molecular mechanisms behind latrunculin A seizures are still unknown, but the increase in extracellular glutamate concentrations observed during latrunculin A microperfusion are completely reversed by eslicarbazepine acetate. This fits well with the observation that eslicarbazepine acetate is a potent blocker of the 4-aminopyridine-evoked [22] or veratridine-evoked [23] release of glutamate.

In comparison with carbamazepine and oxcarbazepine, eslicarbazepine acetate causes less neurological impairment in rats and mice following intraperitoneal administration and, consequently, it has a higher protective index ($PI = TD_{50}/ED_{50}$). In a study in which cultured hippocampal neurones were treated for 24 h with carbamazepine or oxcarbazepine (300 μmol), the neurones showed degeneration and swelling of neurites, but this effect was not observed in neurones treated with eslicarbazepine acetate (300 μmol) [24].

Toxicology

There have been no findings considered to be of concern for human use based on conventional preclinical studies of safety, pharmacology, toxicology, genotoxicity, reprotoxicity and carcinogenicity. In acute toxicology studies, eslicarbazepine acetate oral LD_{50} values were 500 mg/kg (mice and rats) and 100 mg/kg (mice) and <50 mg/kg (rats) when administered by an intravenous bolus. An increase in activated partial thromboplastin time (aPTT) was reported in chronic toxicity studies in Beagle dogs, but no similar change was reported in other species, including humans. An increase in plasma cholesterol was reported in rats and dogs but not in other species, including humans.

Clinical pharmacokinetics

Eslicarbazepine acetate is currently available in the form of tablets and suspension for oral administration. Its clinical pharmacokinetics has been studied following oral administration to healthy young and elderly adults, adults and paediatric patients with epilepsy, and patients with renal and hepatic impairment.

Pharmacokinetics in healthy subjects and patients with epilepsy

Following oral administration to humans, eslicarbazepine acetate is rapidly and extensively biotransformed to eslicarbazepine by

first-pass hydrolytic metabolism [7]. Plasma levels of eslicarbazepine acetate usually remain below the limit of quantification. The bioavailability of eslicarbazepine following oral administration of eslicarbazepine acetate is high and >90% of an orally administered eslicarbazepine acetate dose is recovered as metabolites in urine [7]. The pharmacokinetics of eslicarbazepine acetate is unaffected by the presence of food [25].

At concentrations up to 100 μg/mL (about twice its C_{max} at steady state following eslicarbazepine acetate multiple dosing of 2400 mg once daily) [26], the plasma protein binding of eslicarbazepine is on average 30%, and its binding to blood cells is 46%. Eslicarbazepine binding to plasma proteins and blood cells is concentration independent. Eslicarbazepine binding to plasma proteins was unaffected by warfarin, diazepam, digoxin, phenytoin and tolbutamide. Similarly, the binding of [^{14}C]warfarin, [^{14}C]diazepam, [^{3}H]digoxin, [^{14}C]phenytoin and [^{14}C]tolbutamide was not significantly affected by the presence of eslicarbazepine [17].

For the quantification of eslicarbazepine acetate metabolites in plasma or urine, achiral and chiral methods have been used in pharmacokinetic studies. When a chiral method is used, the assay distinguishes between eslicarbazepine and its minor metabolite (*R*)-licarbazepine [7,10,12]. When an achiral method is used, the assay does not allow the separation of eslicarbazepine and (*R*)-licarbazepine, and the enantiomeric mixture has been reported as BIA 2-005 [8,9].

After single oral doses of eslicarbazepine acetate ranging from 20 mg to 1200 mg, approximately dose-proportional increase in BIA 2-005 C_{max} and a greater than dose-proportional increase in its AUC have been found [8]. The half-life of BIA 2-005 ranged between 9 h with eslicarbazepine acetate 20 mg and 17 h with eslicarbazepine acetate 1200 mg. Oxcarbazepine was shown to be a minor metabolite in both plasma and urine, representing approximately 1% of plasma exposure (AUC) to BIA 2-005 [8].

Following repeated oral dosing of eslicarbazepine acetate 400 mg, 800 mg and 1200 mg once daily to healthy subjects, peak plasma BIA 2-005 concentrations were reached 2.5–3 h after drug intake. Thereafter, plasma BIA 2-005 concentrations declined with an apparent half-life ranging between 10 h (400 mg once daily) and 13 h (1200 mg once daily) [9]. During multiple dosing, peak plasma BIA 2-005 concentrations and AUC values during a dosing interval at steady state increased in an approximately dose-proportional manner. The mean observed accumulation ratio (R_{ac}) or accumulation index of BIA 2-005 was 1.4–1.7 following 400–1200 mg once-daily dosing, consistent with an effective half-life in the order of 20–24 h, calculated from the quotient $R_{ac} = 1/(1 - \exp^{-\lambda z.\tau})$ where λ_z is the linear terminal slope of the log-plasma concentration versus time plot and τ is the dosing interval [27]. Steady-state plasma concentrations of BIA 2-005 were reached 4–5 days after repeated eslicarbazepine acetate dosing, which is also consistent with an effective half-life of 20–24 h.

In a group of healthy subjects administered eslicarbazepine acetate 800 mg once daily, the chiral method was used to monitor plasma and urine levels of eslicarbazepine acetate and its metabolites as free (unconjugated) and glucuronide conjugates [7]. The mean plasma concentrations of eslicarbazepine acetate and its metabolites during a 24-h dosing interval at steady state are shown in Figure 38.5. Using AUC_{ss} as a measure of systemic exposure, eslicarbazepine corresponded to approximately 91% of the sum of all circulating eslicarbazepine acetate-related entities (parent compound and metabolites). The minor metabolites in plasma [(*R*)-licarbazepine, oxcarbazepine and glucuronide conjugates of eslicarbazepine, (*R*)-licarbazepine and oxcarbazepine] corresponded to 9% of total systemic exposure [7]. The main eslicarbazepine acetate metabolic pathways, based on these data, are illustrated in Figure 38.1.

In 51 adults with epilepsy treated with eslicarbazepine acetate 400 mg (n = 7), 800 mg (n = 26) or 1200 mg once daily (n = 18) concomitantly with one or two AEDs (with carbamazepine being taken by 67% of patients), eslicarbazepine exposure in plasma was roughly dose proportional [13]. Peak eslicarbazepine concentrations at steady state were reached 2 h after eslicarbazepine acetate dosing and declined thereafter in a multiphasic manner, with a mean half-life of 13–20 h. The exposure in plasma of the minor metabolites (*R*)-licarbazepine and oxcarbazepine was also linear and dose proportional.

Trough plasma eslicarbazepine concentrations were determined in 571 adults with epilepsy treated with eslicarbazepine acetate 400 mg (n = 160), 800 mg (n = 222) and 1200 mg (n = 189) once daily concomitantly with one to three antiepileptic drugs (AEDs), with carbamazepine being again the most commonly prescribed co-medication (about 60% of patients) [13]. Mean (95% CI) eslicarbazepine trough concentrations at steady state were 2.1 (1.9–2.4) μg/mL with 400 mg, 5.1 (4.5–5.6) μg/mL with 800 mg and 8.1 (7.3–8.9) μg/mL with 1200 mg. In a population pharmacokinetic analysis of data obtained in these patients, eslicarbazepine pharmacokinetics was best described as a one-compartment open model, with a first-order absorption (absorption rate constant, k_a = 1.25 h^{-1}), an apparent volume of distribution (V_d/F) of 188 L and an apparent oral clearance (CL/*F*) of 3.82 L/h. Eslicarbazepine acetate did not affect its own metabolism or clearance and consistently no time dependency was observed in eslicarbazepine pharmacokinetics for up to 1 year of treatment [13].

Eslicarbazepine and other eslicarbazepine acetate metabolites are mainly eliminated in the urine [7,12]. Following multiple dosing of eslicarbazepine acetate (800 mg once daily) to healthy subjects, 92% of the eslicarbazepine acetate dose was excreted in urine as eslicarbazepine, two-thirds (67%) as free (unconjugated) form and one-third (33%) as the glucuronide conjugate [7]. The remaining 8% of the eslicarbazepine acetate dose was excreted in urine as (*R*)-licarbazepine, oxcarbazepine and glucuronide conjugates of eslicarbazepine acetate, eslicarbazepine, (*R*)-licarbazepine and oxcarbazepine.

Pharmacokinetics in special populations

A study in healthy young (18–40 years) and elderly (≥65 years) subjects showed that the pharmacokinetics of eslicarbazepine acetate was not significantly affected by age [6] or gender [10]. Similarly, bioavailability and apparent oral clearance of eslicarbazepine following administration of eslicarbazepine acetate to adults (17–76 years) with epilepsy were not affected by age or gender [13].

The pharmacokinetics of eslicarbazepine acetate in paediatric age were characterized in an open-label phase IIa study which included children with epilepsy aged 2–6 (n = 11) and 7–11 (n = 8) years and adolescents aged 12–17 years (n = 10), treated with one to three concomitant AEDs [28]. The study consisted of three consecutive 4-week periods with once-daily administration

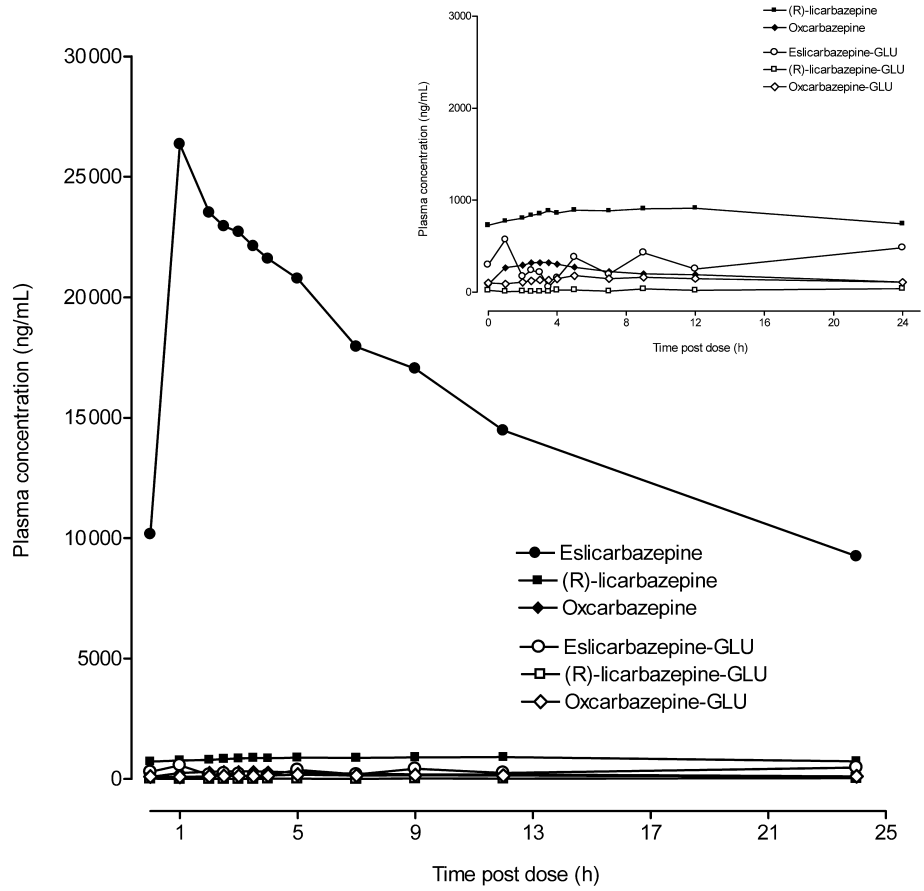

Fig. 38.5 Mean plasma concentration–time profiles during a 24-h dosing interval at steady state of eslicarbazepine acetate metabolites following the last dose of an 8-day treatment with eslicarbazepine acetate 800 mg once daily in eight healthy subjects. GLU, glucuronide conjugate. The inset magnifies the minor metabolites profiles.

of eslicarbazepine acetate 5 mg/kg/day in weeks 1–4, 15 mg/kg/day in weeks 5–8 and 30 mg/kg/day or 1800 mg/day, whichever was less, in weeks 9–12. Similar to adults, eslicarbazepine acetate was rapidly metabolized to eslicarbazepine. In all age groups, eslicarbazepine peak concentrations were reached 1–3 h after eslicarbazepine acetate dosing, and peak concentrations and AUC values at steady state were dose proportional. Eslicarbazepine peak concentrations were similar between age groups following administration of identical eslicarbazepine acetate doses/kg, but AUC values were age dependent due to faster clearance of eslicarbazepine in younger children than in adolescents.

To assess the effect of renal function on eslicarbazepine acetate pharmacokinetics, a study was conducted in which a single dose of eslicarbazepine acetate 800 mg was administered to five groups (n = 8 each): one with normal renal function, three with different degrees of renal dysfunction (mild, moderate and severe) and a fifth with end-stage renal disease requiring haemodialysis [12]. Eslicarbazepine C_{max} did not differ significantly between groups. However, eslicarbazepine $AUC_{0-\infty}$ increased significantly in the mild, moderate and severe renal impairment groups. A significant relationship was found between creatinine clearance (CL_{CR}) and eslicarbazepine renal clearance. The pharmacokinetics of the minor eslicarbazepine acetate metabolites eslicarbazepine glucuronide, (*R*)-licarbazepine, (*R*)-licarbazepine glucuronide, oxcarbazepine and oxcarbazepine glucuronide was also significantly affected by renal function. Tubular reabsorption probably explains the finding that eslicarbazepine renal clearance (7.3 mL/min) was lower than glomerular filtration rate in the subjects with normal renal function (CL_{CR} > 80 mL/min) [12]. The total amount of eslicarbazepine recovered in urine was similar in the groups with normal renal function and mild renal impairment, but was markedly decreased in the moderate and severe renal impairment groups. Major eslicarbazepine acetate metabolites recovered in urine were eslicarbazepine and eslicarbazepine glucuronide. However, in the moderate and severe renal impairment groups, the fraction of eslicarbazepine acetate dose excreted in urine as eslicarbazepine decreased while the fraction excreted as eslicarbazepine glucuronide increased, indicating that renal excretion of eslicarbazepine is more affected than eslicarbazepine glucuronide by renal impairment [12]. Because eslicarbazepine acetate pharmacokinetics is renal function dependent, dose adjustment is required in subjects with renal impairment. Analysis of existing data supports the recommendation of no dose adjustment in patients with a CL_{CR} > 60 mL/min and a half-dose for patients with CL_{CR} of 30–60 mL/min [12]. There are not enough data to establish a recommendation for dose adjustment in patients with CL_{CR} < 30 mL/min. Dialysis was effective in completely removing eslicarbazepine acetate metabolites from circulation [12].

To asses the role of liver function on eslicarbazepine acetate conversion to eslicarbazepine and on the glucuronidation of eslicarbazepine and minor primary metabolites, eslicarbazepine acetate pharmacokinetics was evaluated following multiple dosing (800 mg once daily for 8 days) to patients with moderate liver impairment (Child–Pugh score of 7–9, n = 8) and to healthy subjects (n = 8) who served as a control group [7]. Eslicarbazepine acetate pharmacokinetics was not affected by moderate hepatic impairment. Although there were more subjects with measurable

plasma eslicarbazepine acetate concentrations in the hepatic impairment group than in the control group, plasma eslicarbazepine acetate concentrations remained very low (<0.1% of eslicarbazepine concentrations). No significant differences were found in eslicarbazepine acetate and eslicarbazepine concentration–time profiles in patients with and without portal-systemic shunting, suggesting that eslicarbazepine acetate hydrolysis to eslicarbazepine during first passage is not affected by portal-systemic shunting [7]. In addition, there were no significant differences between liver-impaired and control patients in the pharmacokinetics of the glucuronide metabolites, and the relative proportion of other minor metabolites remained unchanged. Thus, moderate liver impairment has no relevant effect on glucuronidation or on the formation of (*R*)-licarbazepine and oxcarbazepine [7]. No data are available for patients with severe liver impairment.

Drug interactions

Effect of other drugs on eslicarbazepine acetate pharmacokinetics

Eslicarbazepine acetate metabolism was not inhibited by incubating [^{14}C]eslicarbazepine acetate with the AEDs acetazolamide, clobazam, clonazepam, gabapentin, lamotrigine, phenobarbital, phenytoin, primidone or valproic acid [17]. In a population pharmacokinetic analysis in patients with epilepsy, eslicarbazepine CL/*F* was found to be increased in patients treated with inducing AEDs (carbamazepine, phenobarbital and phenytoin). Lamotrigine, valproic acid, topiramate, gabapentin, clobazam and levetiracetam did not affect eslicarbazepine exposure [13].

Effect of other drugs on eslicarbazepine acetate pharmacokinetics

In human liver microsomes, eslicarbazepine appeared to have a minimal or no inhibitory effect on the activity of the cytochrome P450 (CYP) enzymes CYP1A2, CYP2A6, CYP2B6, CYP2D6 and CYP2E1, CYP3A4 and CYP4A9/11 as well as on uridine diphosphate-5′-glucuronosyltransferases (UGTs) UGT1A1 and UGT1A6, and epoxide hydrolase (EH) [29]. A moderate inhibitory effect was found on CYP2C9-mediated tolbutamide 4-hydroxylation, and IC_{50} values for eslicarbazepine on CYP2C19 activity (utilizing tolbutamide as a CYP2C19 probe) were 232 μg/mL. Studies with eslicarbazepine in fresh human hepatocytes showed no induction of CYP1A2, CYP3A4 and phase II hepatic enzymes involved in glucuronidation and sulphation [29].

Population pharmacokinetic analyses in patients with epilepsy showed that eslicarbazepine acetate did not influence to a clinically relevant extent the CL/*F* of carbamazepine, levetiracetam, valproic acid, clobazam, gabapentin or phenobarbital [13]. An increase in plasma phenytoin concentrations was observed following short-term co-administration of eslicarbazepine acetate (1200 mg once daily) and a controlled-release phenytoin formulation (300 mg once daily) to healthy subjects, which could be explained by inhibition of CYP2C9 and CYP2C19. However, no relevant effect of eslicarbazepine acetate on plasma phenytoin levels was seen in the analysis of patients with epilepsy [13]. Although both eslicarbazepine acetate metabolites and lamotrigine undergo glucuronidation, studies in healthy subjects [30] and in patients with epilepsy [13] showed no clinically relevant effect of eslicarbazepine acetate on lamotrigine pharmacokinetics. Eslicarbazepine acetate (1200 mg once daily) caused a small decrease in topiramate systemic exposure in healthy subjects, but no relevant changes occurred on trough plasma concentrations of concomitant AEDs in patients administered eslicarbazepine acetate maintenance doses of 400 mg and 800 mg once daily. Overall, the magnitude of concomitant eslicarbazepine acetate effects on the plasma levels of all concomitant AEDs assessed appears not to be clinically relevant and would not require dose adjustment of any of the above AEDs.

Co-administration of eslicarbazepine acetate (1200 mg once daily for 8 days) with warfarin showed a mild but significant decrease in *S*-warfarin exposure, with no significant effect on *R*-warfarin pharmacokinetics or on coagulation [international normalized ratio (INR)] [31]. A study in healthy subjects showed no effect of eslicarbazepine acetate 1200 mg once daily on digoxin pharmacokinetics [32].

Administration of eslicarbazepine acetate 1200 mg once daily to women decreased the systemic exposure to levonorgestrel and ethinylestradiol from a combined oral contraceptive, which was most likely caused by induction of CYP3A4 [13]. Thus, concurrent use of eslicarbazepine acetate and oral contraceptives may result in decreased contraceptive effectiveness.

Serum level monitoring and pharmacokinetic/pharmacodynamic relationships

A pharmacokinetic/pharmacodynamic analysis in the pooled population of eslicarbazepine acetate phase III studies in patients with epilepsy was performed using non-linear mixed-effect modelling (NONMEM) [13]. Efficacy variables derived from the seizure frequency standardized for 4 weeks were best fitted by a combination of a baseline, a placebo effect and an effect of eslicarbazepine acetate described by an E_{max} pharmacodynamic model. The antiepileptic effect of eslicarbazepine acetate, as assessed by seizure frequency, increased with the increase of eslicarbazepine acetate dose. Concomitant administration of other AEDs did not affect eslicarbazepine exposure–response relationships, although carbamazepine and phenobarbital did decrease eslicarbazepine plasma exposure (AUC). Overall, the results of this analysis demonstrated a continuous relationship, with moderate inter-subject variability, between antiepileptic efficacy and eslicarbazepine concentrations or plasma exposure that was not affected by concomitant AEDs.

The above analysis, however, does not provide sufficient information on the value of monitoring serum eslicarbazepine levels. A reference serum eslicarbazepine concentration in patients receiving eslicarbazepine acetate therapy has not yet been clearly established.

Efficacy

Efficacy in placebo-controlled clinical trials

Evidence of efficacy of eslicarbazepine acetate as adjunctive therapy in adults with partial-onset seizures with or without sec-

ondary generalization was obtained in a phase II study and three phase III studies.

The phase II study was a multicentre, double-blind, randomized, placebo-controlled study conducted in 143 refractory patients aged between 18 and 65 years with four or more partial-onset seizures per month, despite treatment with one or two AEDs [33]. Carbamazepine and oxcarbazepine were not allowed as concomitant AEDs. The study consisted of a retrospective 2-month baseline followed by a prospective 12-week treatment period and a 1-week tapering off. Patients were randomly assigned to one of three treatment groups: eslicarbazepine acetate once daily ($n = 50$), eslicarbazepine acetate twice daily ($n = 46$) or placebo ($n = 47$). The daily dose was titrated from 400 mg to 800 mg and to 1200 mg at 4-week intervals. After 12 weeks of treatment, the proportion of responders (patients with a ≥50% seizure reduction) in the intention-to-treat (ITT) population (primary efficacy analysis) was 54% with eslicarbazepine acetate once daily, 41% with eslicarbazepine acetate twice daily and 28% with placebo. The difference compared with placebo was statistically significant for the once-daily group only ($P < 0.01$). The results suggested that an eslicarbazepine acetate once-daily regimen was as efficacious as (or possibly more efficacious than) the same daily dose given in a twice-daily regimen, and the once-daily regimen was therefore adopted in phase III studies. The once-daily dosing allows higher peak plasma concentration of the eslicarbazepine acetate active entity eslicarbazepine than the twice-daily dosing of the same daily dose, which suggests that efficacy following eslicarbazepine acetate once-daily treatment correlates better with the peak plasma concentration at steady state (a parameter that reflects extent and rate of absorption) than with AUC_{ss} (a parameter that reflects only extent of absorption) [33].

The phase III programme consisted of three pivotal, multicentre, double-blind, randomized, placebo-controlled studies (BIA-2093-301, BIA-2093-302 and BIA-2093-303) in 1049 adult refractory patients enrolled by 125 sites in 23 countries. The studies consisted of an 8-week baseline period, a 2-week titration period (no titration in the 400-mg and 800-mg arms of study BIA-2093-302), a 12-week maintenance period, and a 4-week tapering-off period (only in studies BIA-2093-301 and BIA-2093-303). At randomization, patients were meant to have four or more partial-onset seizures per 4 weeks during the baseline period, despite treatment with one or two concomitant AEDs in studies BIA-2093-301 and BIA-2093-303, and one to three AEDs in study BIA-2093-302. All marketed AEDs, except oxcarbazepine and felbamate, were allowed as concomitant AEDs.

In the phase III pooled population [13], 81% of patients were white, mean age was 37 years (range 17–77 years) and mean epilepsy duration was 22 years (range 1–71 years). In study BIA-2093-301, 468 patients enrolled in the baseline period and 402 (86%) were randomized to treatment. In study BIA-2093-302, 503 enrolled and 395 (79%) were randomized, and in study BIA-2093-303, 330 enrolled and 253 (77%) were randomized. After carbamazepine (approximately 60% of all patients enrolled), the most commonly used concomitant AEDs were valproic acid, lamotrigine, levetiracetam, topiramate, phenytoin, phenobarbital and clobazam, which were taken by up to 30% of patients in any treatment group. Between 64% and 75% of patients received two concomitant AEDs. The key efficacy endpoints were seizure frequency standardized per 4 weeks (primary analysis in all studies), median relative reduction in standardized seizure frequency, and responder rate (proportion of patients with at least 50% reduction in standardized seizure compared with baseline). The prespecified (a priori) primary efficacy analysis was conducted on the natural log transformation of the standardized seizure frequency.

Standardized seizure frequency over the 12-week maintenance period in the individual studies is shown in Figure 38.6. Standardized seizure frequency was compared between each active treatment group and the placebo group using an analysis of covariance (ANCOVA) that modelled seizure frequency as a function of baseline seizure frequency and treatment. In the pooled population, standardized seizure frequency during the maintenance period was significantly different from placebo with eslicarbazepine acetate 800 mg and 1200 mg once daily, in both the ITT and per-protocol (PP) analysis. In the PP population, the difference between the eslicarbazepine acetate 400 mg and placebo group was also statistically significant. The responder rate was also higher in the eslicarbazepine acetate 800 mg and 1200 mg groups than in the placebo group in the ITT population and the PP population (Table 38.2). Relative reduction in standardized seizure frequency during the maintenance period was statistically significant for the 800 mg and 1200 mg eslicarbazepine acetate groups compared with placebo (Table 38.3). Analyses performed on each of the three key efficacy endpoints to demonstrate the robustness of the findings were consistent with the results shown for the models used above.

Analyses of the secondary efficacy variables showed a level of efficacy in the 800 mg and 1200 mg eslicarbazepine acetate groups consistent with that observed for the key efficacy variables. The response to treatment was evident already in the first week of the titration period and reached its peak in the first week of the maintenance period. The responder rate was 46% in the eslicarbazepine acetate 800 mg group and 53% in the eslicarbazepine acetate 1200 mg group in the first week of the maintenance period, and remained stable through the last week of the maintenance period. During the maintenance period, the median number of days with seizures per 4 weeks decreased only from 5.9 to 5.3 in the placebo group, but from 6.5 at baseline to 4.3 in the 800 mg eslicarbazepine acetate group ($P = 0.0054$ versus placebo) and from 6.3 to 3.8 in the 1200 mg group ($P = 0.0007$). The proportion of patients who completed the study and were seizure free during the maintenance phase (expressed as a percentage of those who reached the maintenance phase) increased with increasing eslicarbazepine acetate dose, from 2% of eslicarbazepine acetate 400 mg patients and 3% of placebo patients, to 4% of eslicarbazepine acetate 800 mg patients and 8% of eslicarbazepine acetate 1200 mg patients. During the tapering-off period (studies BIA-2093-301 and BIA-2093-303 only), the standardized seizure frequency remained essentially constant in the placebo group relative to the end of the maintenance period and increased slightly in the eslicarbazepine acetate groups without any sign of a rebound effect. The efficacy of eslicarbazepine acetate was not altered when given concomitantly with carbamazepine (pre-dose plasma concentrations of 6.9 ± 2.6 mg/L), lamotrigine (4.3 ± 2.8 mg/L) or valproic acid (54.8 ± 31.1 mg/L), the most widely used concomitant AEDs. The median decrease in seizure frequency was similar in patients not taking carbamazepine (placebo, 15%; 400 mg, 24%; 800 mg, 39%; 1200 mg, 38%) and those taking carbamazepine (placebo, 14%; 400 mg, 23%; 800 mg, 33%; 1200 mg, 44%).

Long-term benefit in open-label extensions of phase III studies

Of the 857 patients who completed the double-blind phase of studies BIA-2093-301, BIA-2093-302 and BIA-2093-303, 833 (97%) entered long-term treatment with eslicarbazepine acetate (extension phase) and 612 (73.5%) patients completed 1 year of treatment [13]. Investigators could titrate eslicarbazepine acetate dosage according to clinical response. In all studies, the mean daily dose was approximately 900 mg (median, 800 mg), and this was stable throughout the 1-year follow-up period. The last observation carried forward method was used in the ITT efficacy analyses. The decrease in seizure frequency relative to baseline was sustained over the 1-year treatment period. In study BIA-2093-301, median seizure frequency during the first 4 weeks of the extension phase was 39% lower than during baseline and continued to decrease, being reduced (compared with baseline) by 48% in weeks 5–16 and 56% in weeks 41–52. Responder rate during weeks 1–4 was 41% and continued to increase over time, from 48% in weeks 5–16 to 53% in weeks 41–52. The proportion of seizure-free patients per 12-week interval increased over time, ranging from 9% of patients during weeks 5–16 to 13% during weeks 41–52. In study BIA-2093-302, median seizure frequency decreased by 32% in weeks 1–4 and by 38% in weeks 5–16 to 39% in weeks 41–52; responder rate was 37% during

the first 4 weeks and thereafter ranged between 38% and 42%. The proportion of seizure-free patients per 12-week interval increased from 5% in weeks 5–16 to 11% in weeks 41–52%. In study BIA-2093-303, median seizure frequency was reduced by 48% in weeks 1–4 and by between 54% and 58% in the remaining treatment period. The responder rate was 46% in weeks 1–4 and thereafter ranged between 53% and 56%. The proportion of seizure-free patients per 12-week interval increased over time, from 6% (weeks 5–16) to 18% (weeks 41–52).

Quality of life was assessed using the Quality of Life in Epilepsy Inventory-31 (QOLIE-31) questionnaire, and depressive symptoms were assessed using the Montgomery–Asberg Depression Rating Scale (MADRS). Statistically significant improvements (last assessment versus baseline) were found in the health-related outcomes for both these questionnaires in all the open-label extensions to the phase III studies.

Table 38.3 ANCOVA of relative reduction (%) in standardized seizure frequency in the pooled population of phase III studies with eslicarbazepine acetate as adjunctive therapy in patients with partial epilepsy. Standardized seizure frequencies were calculated over the maintenance period.

Treatment	*n*	LS mean (%)	SE	95% CI	*P*-value
ITT population					
Placebo	278	–8.5	5.30	(–18.9 to 1.9)	–
Eslicarbazepine acetate 400 mg	192	–17.7	6.22	(–29.9 to –5.4)	n.s.

PP population					
Placebo	223	–14.6	4.90	(–24.1 to –5.0)	–
Eslicarbazepine acetate 400 mg	164	–23.6	5.68	(–34.8 to –12.5)	<0.05
Eslicarbazepine acetate 800 mg	208	–33.1	4.92	(–42.7 to –23.4)	<0.0001
Eslicarbazepine acetate 1200 mg	161	–41.7	5.38	(–52.2 to –31.1)	<0.0001

ANCOVA, analysis of covariance; CI, confidence interval; ITT, intent-to-treat; LS, least square; n.s., not statistically significant; PP, per-protocol; SE, standard error. Results are based on an ANCOVA model with treatment, study, baseline seizure frequency and number of concomitant antiepileptic drugs at baseline as factors. Dunnett's multiple comparison procedure was used for the comparison of the active treatment means to the placebo mean.

Adverse effects

To date, more than 2500 subjects have received eslicarbazepine acetate in completed or ongoing phase I to phase III studies.

Adverse events in adults with epilepsy

In the phase II study [33], the percentage of patients reporting treatment-emergent adverse events (AEs) was similar in the three treatment groups: 38.0% in the 400–1200 mg once daily group, 41.3% in the 200–600 mg twice daily group and 44.7% in the placebo group. Most of the AEs (68.3%) were of mild intensity. The most frequent were headache, dizziness and nausea. AEs leading to discontinuation occurred in a similar proportion in patients treated with placebo (10.6%) and eslicarbazepine acetate (9.4%).

In the double-blind phase of the integrated phase III studies there was a dose-dependent increase in AEs with increasing dose of eslicarbazepine acetate (Table 38.4) [13]. This was also observed for possibly related AEs and AEs leading to discontinuation. AEs occurred mainly during the first weeks of treatment; no difference was found between eslicarbazepine acetate and placebo in incidence of AEs after 6 weeks of treatment. In the 1-year open-label extension of study BIA-2093-301, 50.3% of patients reported AEs, 26.8% reported possibly related AEs, 6.2% reported serious AEs and 4.5% reported AEs leading to discontinuation. The majority of AEs in either the double-blind phase of the integrated phase III population or the extension phase of study BIA-2093-301 were reported by <3% of patients in any treatment group (Table 38.5). The most common AEs, in both the placebo and combined eslicarbazepine acetate groups were dizziness, somnolence, headache and nausea.

Hyponatraemia <125 mmol/L was recorded in only four patients: one (0.5%) on eslicarbazepine acetate 400 mg, two (0.7%) on eslicarbazepine acetate 800 mg and one (0.4%) on eslicarbazepine acetate 1200 mg. Hypernatraemia (>146 mmol/L) was recorded in one (0.3%) patient on placebo, one (0.5%) on eslicarbazepine acetate 400 mg and one (0.4%) on eslicarbazepine acetate 800 mg. The incidence of rash was also low and dose dependent: one (0.3%) patient on placebo, one (0.5%) on eslicarbazepine acetate 400 mg, three (1.1%) on eslicarbazepine acetate 800 mg and nine (3.2%) on eslicarbazepine acetate 1200 mg. The majority of patients in the eslicarbazepine acetate

Table 38.4 Summary of treatment-emergent adverse events (AEs) in the pooled population of phase III studies with eslicarbazepine acetate as adjunctive therapy in patients with partial epilepsy.

Type of AE	Number (%) of patients			
	Placebo (*n* = 289)	Eslicarbazepine acetate 400 mg (*n* = 196)	Eslicarbazepine acetate 800 mg (*n* = 284)	Eslicarbazepine acetate 1200 mg (*n* = 280)
All AEs	134 (46.4)	119 (60.7)	178 (62.7)	189 (67.5)
Possibly related AEs	72 (24.9)	75 (38.3)	134 (47.2)	154 (55.0)
Serious AEs	4 (1.4)	9 (4.6)	10 (3.5)	9 (3.2)
AEs leading to discontinuation	13 (4.5)	17 (8.7)	33 (11.6)	54 (19.3)

[a] 1-year open-label extension.

(84.8%) and placebo (90.3%) treatment groups had AEs of mild or moderate intensity. While the overall frequency of mild AEs was similar in all treatment groups, the frequency of moderate and severe events was highest in the eslicarbazepine acetate 1200 mg group. With respect to nervous system AEs, 4.6% of 800 mg eslicarbazepine acetate patients, compared with 8.2% of 1200 mg patients, reported severe AEs. However, this difference cannot be attributed to any single type of event, with the exception of dizziness, which was reported as severe by 4.3% of patients in the eslicarbazepine acetate 1200 mg group compared with 2.1% of patients in the 800 mg group.

The incidence of patients reporting AEs was related to the starting dose in the integrated phase III studies. From the start of treatment to 4 weeks after the titration period, AEs were reported by 33.2% of patients in the placebo group, 44.9% in the 400 mg group and between 35% and 45% in all titration regimens that started at 400 mg and increased to 800 mg or 1200 mg. In contrast, the frequency of AEs in this time frame was 51.3% in patients who began treatment at 600 mg and 73.3% to 77.6% in patients who began at 800 mg.

The proportion of patients with AEs leading to treatment discontinuation was highest in the eslicarbazepine acetate 1200 mg group (19.3%) and lowest in the placebo group (4.5%). The increased incidence of patients discontinuing in the eslicarbazepine acetate groups was primarily due to vertigo, diplopia, blurred vision, nausea and vomiting, fatigue, abnormal coordination, dizziness, headache and somnolence. The overall incidence of serious AEs was low in all treatment groups (<5% of patients). The most common serious AEs (more than two patients in any group) were abnormal coordination, vomiting, drug toxicity (a mEDRA term that includes several types of symptoms reported by the investigators that can be a sign of toxicity/intoxication), diplopia and grand mal convulsion, none of which were reported in placebo-treated patients.

In placebo-treated patients, the incidence of AEs was 50% in patients receiving concomitant carbamazepine versus 40% in patients not receiving carbamazepine. In the eslicarbazepine acetate groups, the incidence of AEs in patients receiving concomitant carbamazepine treatment was 68–73% versus 51–61% in patients receiving eslicarbazepine acetate without carbamazepine. The observation that in both the eslicarbazepine acetate and the placebo groups the incidence of AEs was higher in patients co-medicated with carbamazepine suggests that concomitant treatment of eslicarbazepine acetate and carbamazepine appears not to result in a supra-additive effect on the incidence of AEs.

Adverse events in children with epilepsy

In a phase IIa study of 31 children [28], eslicarbazepine acetate 5 mg/kg/day and 15 mg/kg/day dose regimens were well tolerated. All drug-related AEs reported at these doses were mild in intensity, except for one case of psychomotor agitation of moderate intensity with the lowest dose. At the dosage of 30 mg/kg/day, AEs were more frequent, tended to be more severe and were mainly related to the nervous system. The AE profile in children was in line with that observed in adults.

Adverse events in healthy subjects

To date, eslicarbazepine acetate has been administered to more than 700 healthy subjects in phase I studies. The most common AEs reported with eslicarbazepine acetate treatment in these sub-

jects included headache, somnolence/tiredness, dizziness, and paraesthesia affecting the mouth, lips or tongue; in addition, nausea, vomiting and upper respiratory tract infection/inflammation were reported in some studies. In general, the observed AEs were mild to moderate in severity, limited in duration and manageable. The maximum tolerated eslicarbazepine acetate dose in healthy subjects was established to be 2400 mg once daily, with eslicarbazepine acetate treatment starting without titration [13].

Other safety parameters

There were no clinically significant changes, no dose- or age-dependent patterns, and no clinically relevant individual abnormalities in laboratory parameters, vital signs or physical examinations in the phase I, phase II or phase III studies [13]. There were also no safety concerns from the electrocardiogram (ECG) parameters assessed from 12-lead ECGs. In a moxifloxacin-controlled thorough QT/QTc study in healthy subjects, eslicarbazepine acetate 1200 and 2400 mg once daily showed no effect on ECG intervals or morphology [13].

Place in current therapy

Despite a broad range of AEDs currently available, about 30% of patients with epilepsy are uncontrolled with available treatments and a further 25% suffer from manifestations of drug toxicity. Eslicarbazepine acetate is a novel AED chemically related to carbamazepine and oxcarbazepine that mainly undergoes metabolic hydrolysis followed by glucuronidation with minimal CYP-mediated metabolism.

The phase III studies allowed the inclusion of patients who were concomitantly taking carbamazepine. Although carbamazepine and eslicarbazepine acetate are chemically related, they do not share any common metabolite(s). Therefore, it was considered justified not to exclude carbamazepine-treated patients from eslicarbazepine acetate phase II and III trials. Indeed, when the efficacy of eslicarbazepine acetate in relation to the most common co-medications in the phase III study (carbamazepine, lamotrigine and valproic acid) was assessed, it was found that the degree of improvement on eslicarbazepine acetate was the same, irrespective of the type of concomitant AEDs.

One question that needs to be considered is why eslicarbazepine acetate should be used as an adjunctive therapy with other sodium channel-blocking AEDs, such as carbamazepine, lamotrigine or phenytoin, at therapeutic doses, and why we see additive efficacy when eslicarbazepine acetate is used together with these AEDs. The answer to this must include consideration of several factors, including aspects such as additional mechanisms of action of individual AEDs different from sodium channel blockade and the biopharmaceutical properties and pharmacokinetic profile of the eslicarbazepine acetate active entity eslicarbazepine. It has been postulated that one reason for pharmacoresistance is that voltage-gated sodium channels in resistant patients are altered in their protein subunits so that their sensitivity to AEDs is diminished [34]. It is possible that, in such patients, voltage-gated sodium channels are more responsive to a specific sodium channel blocker than to another. Thus, it may be possible to elicit a stronger response by providing adjunctive therapy with a different sodium channel blocker. Furthermore, regulation of seizure-induced transcriptional plasticity differs in different neuron types [35,36] and may make some channel proteins more responsive to one sodium channel-blocking AED over another. Post-transcriptional modifications of ion channel proteins due to seizures, such as changes in the degree of phosphorylation, have been shown to alter the sensitivity of the channel proteins to AEDs. For example, increased phosphorylation of a channel protein changed the responsiveness of that protein to topiramate [37]. There is also previous evidence demonstrating the additive efficacy from combining different sodium channel blockers, even though in the case of the oxcarbazepine–carbamazepine combination this may be associated with relatively high intolerability rates [38]. There are thus both mechanistic concepts and empirical experience that substantiate the use of eslicarbazepine acetate as adjunctive therapy with other sodium channel-blocking AEDs.

Although neurological and psychiatric events are known side-effects of AEDs, the incidence of psychiatric events was low (<1%) with eslicarbazepine acetate. The neurological AEs – somnolence, dizziness, headache and abnormal coordination – had a dose-dependent incidence with eslicarbazepine acetate treatment, but in the integrated phase III population, none of the neurological events were reported by >15% of patients in any eslicarbazepine acetate treatment groups. In studies of similar design and duration, neurological events were reported by between 8% and 43% of patients treated with prebagalin 600 mg/day [39] and by between 5% and 16% of patients treated with levetiracetam 1000–2000 mg/day [40], which are two of the more recent and widely used AEDs. Thus, although one has to be cautious in making comparisons across trials, eslicarbazepine acetate offers a similar or lower risk of experiencing the neurological and psychiatric events commonly associated with AED treatment.

In conclusion, the favourable efficacy and safety profiles of eslicarbazepine acetate 800 and 1200 mg, including the sustained efficacy for at least 1 year and the lack of major concerns related to rash, hyponatraemia or body weight increase, indicate that eslicarbazepine acetate is a valuable addition to the current armamentarium of AEDs as an adjunctive therapy for refractory partial-onset seizures. Eslicarbazepine acetate has not been assessed in generalized epilepsies, but, based on its structural and mechanistic similarities with carbamazepine and oxcarbazepine, it may be expected to be potentially aggravating on some primary generalized seizure types, particularly myoclonic and absence seizures.

With its once-daily dosing and simple titration regimen, eslicarbazepine acetate offers a more favourable dosing regimen compared with many of the currently available AEDs, which are dosed several times a day and involve complex and long-term titration schemes. The use of eslicarbazepine acetate will no doubt increase in the future, and the resulting clinical experience will be crucial to define its place in the treatment algorithm.

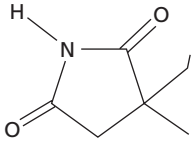
39 Ethosuximide

Tracy A. Glauser[1] *and Emilio Perucca*[2]
[1]Children's Hospital Medical Center C-5, Cincinnati, OH, USA
[2]Institute of Neurology, IRCCS C. Mondino Foundation and Clinical Pharmacology Unit, University of Pavia, Pavia, Italy



Primary indications	First-line or adjunctive therapy of generalized absence seizures; also helpful in absence status epilepticus and in some generalized epilepsies in childhood, particularly those associated with absence or myoclonic seizures
Usual preparations	Capsules: 250 mg; syrup: 250 mg/5 mL
Usual dosages	Initial: 250 mg (adults); 10–15 mg/kg/day (children). Maintenance: 750–1500 mg/day (adults); 15–40 mg/kg/day (children)
Dosing frequency	2–3 times/day
Significant drug interactions	Ethosuximide levels are reduced by co-medication with carbamazepine, phenytoin, phenobarbital and rifampicin. Valproic acid may exert synergistic effects with ethosuximide in patients refractory to either drug given alone, and may have variable and inconsistent effects on ethosuximide levels. Serum valproic acid levels may be decreased by ethosuximide. Ethosuximide levels are increased by isoniazid
Serum level monitoring	Ethosuximide therapy is usually optimized based on clinical and EEG response. Monitoring serum ethosuximide levels, however, may be useful in selected cases
Reference range	40–100 mg/L
Common/important adverse effects	Gastrointestinal symptoms, drowsiness, ataxia, diplopia, headache, dizziness, hiccoughs, sedation, behavioural disturbances, acute psychotic reactions, extrapyramidal symptoms, blood dyscrasias, rash, lupus-like syndrome, other severe idiosyncratic reactions
Main advantages	Well-established treatment for absence epilepsy without the risk of hepatic toxicity carried by valproic acid
Main disadvantages	Adverse effects common. Unlike valproic acid, ethosuximide does not protect against generalized tonic–clonic seizures
Mechanisms of action	Inhibition of neuronal T-type calcium channels. Other actions may contribute to clinical effects
Oral bioavailability	90–100%
Time to peak levels	Usually within 1–5 h
Elimination	Primarily by oxidation, largely catalysed by cytochrome CYP3A4
Volume of distribution	0.6–0.7 L/kg
Elimination half-life	25–70 h (shortest values in children and in subjects co-medicated with enzyme inducers)
Plasma clearance	7–20 mL/kg/h (highest values in children and in subjects co-medicated with enzyme inducers)
Protein binding	<10%
Active metabolites	None
Comment	Ethosuximide is an alternative to valproic acid as a treatment of first choice in childhood absence epilepsy. It is useful in other syndromes associated with absence and/or myoclonic seizures

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Ethosuximide was introduced in the 1950s as an effective and relatively well-tolerated drug for the treatment of absence seizures. Trimethadione and its analogue paramethadione, introduced in the 1940s, were the first agents that had demonstrated efficacy against absence seizures, but were associated with significant toxicity [1]. These toxicity issues prompted the discovery and testing in the 1950s of different members of the succinimide family (ethosuximide, methsuximide and phensuximide), and ethosuximide showed the greatest efficacy against absence seizures and the least toxicity [2]. Ethosuximide has been considered as a first-line therapy for absence seizures since its introduction in 1958 [3].

Chemistry

Ethosuximide (2-ethyl-2-methylsuccinimide, molecular weight 141.2) is a chiral molecule containing a five-member ring, two negatively charged carbonyl oxygen atoms with a ring nitrogen between them and one asymmetric carbon atom.

It has a melting point of 64–65°C, along with a weakly acidic p*K*a of 9.3, and a partition coefficient of 9 (chloroform/water; pH 7). Ethosuximide is freely soluble in ethanol and water (solubility 190 mg/mL) [4]. A white crystalline material, ethosuximide is used clinically as a racemate and is commercially available in 250-mg capsules or 250 mg/5 mL syrup.

Pharmacology

Activity in experimental models of seizures and epilepsy

Ethosuximide blocks clonic seizures produced by subcutaneously administered pentylenetetrazole or bicuculline, but it is ineffective against maximal electroshock-induced tonic seizures, except at anaesthetic doses [5]. Likewise, ethosuximide is ineffective against kindled seizures or the evolution of the kindling process, except for some weak activity at neurotoxic concentrations [5,6]. This activity profile suggests that ethosuximide exerts its anticonvulsant effects by raising seizure threshold rather than by blocking the spread of seizures, and predicts efficacy against absence rather than partial-onset and generalized tonic–clonic seizures [7]. Ethosuximide's major metabolite, 2-(1-hydroxyethyl)-2-methylsuccinimide, demonstrated no significant activity against pentylenetetrazole-induced clonic seizures in mice [8].

Ethosuximide demonstrates activity against spontaneously occurring absence seizures in various animal models, including the mutant tottering mouse, the Genetic Absence Epilepsy Rat from Strasbourg and the double-mutant spontaneously epileptic rat [9–11]. It also demonstrates activity against spike–wave seizures induced by systemic administration of γ-hydroxybutyrate in rodents and primates [7,12–14], and against fuorothyl-induced clonic convulsions in Mongolian gerbils [15]. Pretreatment with ethosuximide has been found to attenuate in a dose-dependent manner non-convulsive seizures induced by brain ischaemia [16].

Activity in experimental models relevant to other indications

Recent studies have shown that ethosuximide shows analgesic activity in various nociceptive pain models. Models in which activity has been demonstrated include chemotherapy-induced peripheral neuropathic pain, capsaicin-induced mechanical hyperalgesia, the rat-tail flick reflex test, the formalin model of persistent pain and acute peripheral thermal nociception in rats [5].

Mechanisms of action

Ethosuximide's presumed mechanism of action against absence seizures is reduction of low-threshold T-type calcium currents in thalamic neurones [17,18], though actions at cortical level may also be important [19].

The spontaneous pacemaker oscillatory activity of thalamocortical neurones involves low-threshold T-type calcium currents [20]. These oscillatory currents are considered to be the generators of the 3-Hz spike-and-wave rhythms noted in patients with absence epilepsy [20]. Voltage-dependent blockade of the low-threshold T-type calcium current was demonstrated at clinically relevant ethosuximide concentrations in thalamic neurones isolated from rats and guinea pigs [17,18,20]. Gating of these T-type calcium channels is not altered by ethosuximide [2,18]. Based on these findings, it is proposed that ethosuximide's effect on low-threshold T-type calcium currents in thalamocortical neurones prevents the synchronized firing associated with spike–wave discharges [17]. Likewise, an action on T-type calcium channels in sensory neurones has been proposed as the main mechanism responsible for the effects of ethosuximide in models of neuropathic pain [5].

In recent years, evidence has been presented that additional mechanisms beyond blockade of T-type calcium channels may contribute to the actions of ethosuximide [5]. These include a reduction in persistent sodium- and calcium-activated potassium currents in thalamic and layer V cortical pyramidal neurones, a reduction in cortical γ-aminobutyric acid (GABA) levels and, possibly, a decrease in pathologically increased glutamate levels in the motor cortex [5].

Pharmacokinetics

Ethosuximide shows linear pharmacokinetics. The drug is used as a racemate, but in most pharmacokinetic studies no differentiation was made between the two enantiomers. In a study conducted in 33 patients on chronic ethosuximide treatment, the ratio between the enantiomers in plasma was close to unity, indicating that the disposition of the drug in humans is non-stereoselective and that measurement of total ethosuximide levels for therapeutic monitoring is reasonable and appropriate [4,21]. The non-stereoselective disposition of ethosuximide was unaffected by pregnancy, placental transfer or passage into breast milk in a small study (three pregnancies in two women taking ethosuximide) [22].

Absorption

Although there is no intravenous formulation that can be used as a reference standard to determine absolute bioavailability in humans, the absorption of ethosuximide is considered to be rapid

and nearly complete (90–100%) in children and adults [3,23–25]. Peak plasma concentrations are generally reached between 1 and 4 h [24–27] or 3–7 h [28,29] after oral intake. The syrup has a faster absorption rate than the capsules but the two formulations are bioequivalent in extent of absorption [5,23,29].

Distribution

Ethosuximide distributes homogeneously throughout the body. Ethosuximide concentrations in saliva, tears and cerebrospinal fluid (CSF) are similar to plasma ethosuximide concentrations [30–34]. In three studies (involving 6, 15 and 19 patients) the correlation coefficients for the relationships between saliva and serum concentrations were 0.99, 0.99 and 0.74, respectively [32–34]. A fourth study, which examined ethosuximide concentrations in paired parotid saliva and plasma samples in 10 patients, showed that the average saliva to plasma ratio was 1.04 and appeared to be constant over the measured time intervals [32]. Based on these results, it has been concluded that saliva can be used in lieu of plasma for the therapeutic monitoring of ethosuximide.

In humans, ethosuximide's apparent volume of distribution is about 0.6–0.7 L/kg in adults and in children, implying distribution through total body water [23,24,26]. The binding of ethosuximide to plasma proteins is <10% [5].

Ethosuximide crosses the placenta in humans and has been detected in cord serum and amniotic fluid at concentrations similar to maternal serum concentrations [5,35]. Ethosuximide was detected in the urine or plasma of a newborn infant of a woman receiving chronic ethosuximide therapy in two separate reports [36,37]. The newborn infant's serum ethosuximide concentration was similar to that observed in the mother [37].

Ethosuximide is also excreted in the breast milk of mothers on chronic ethosuximide therapy. In multiple studies the average breast milk to maternal serum concentration ratio ranged from 0.8 to 0.94 [37–40]. The serum ethosuximide concentrations in breastfeeding infants of mothers on chronic ethosuximide therapy were 30–50% of their mother's serum ethosuximide concentrations [39,40].

Elimination

Metabolism is the main route of ethosuximide elimination in humans and animals. The drug undergoes extensive oxidative biotransformation (about 80%) to pharmacologically inactive metabolites, with only minor amounts (10–20%) being excreted unchanged in the urine, bile and faeces [5,41]. *In vitro* studies suggest that in humans the oxidation of ethosuximide is catalysed mainly by the cytochrome P450 (CYP) enzyme CYP3A4, with a minor contribution of CYP2E1 [42].

The major metabolite recovered in the urine of patients receiving ethosuximide is 2-(1-hydroxyethyl)-2-methylsuccinimide, of which at least 40% is excreted as a glucuronide conjugate [4]. Two other ethosuximide metabolites recovered (often as a glucuronide conjugate) from the urine of patients receiving ethosuximide are 2-ethyl-3-hydroxy-2-methylsuccinimide and 2-(2-hydroxyethyl)-2-methylsuccinimide. This latter metabolite can undergo subsequent metabolism by the hepatic mixed-function oxidase system to form the fourth major metabolite, 2-carboxymethyl-2-methylsuccinimide [4] (Fig. 39.1). Many of these metabolites occur as different stereoisomers. A recent study using a chiral assay identified 2-ethyl-2-hydroxymethylsuccinimide as an additional metabolite [43].

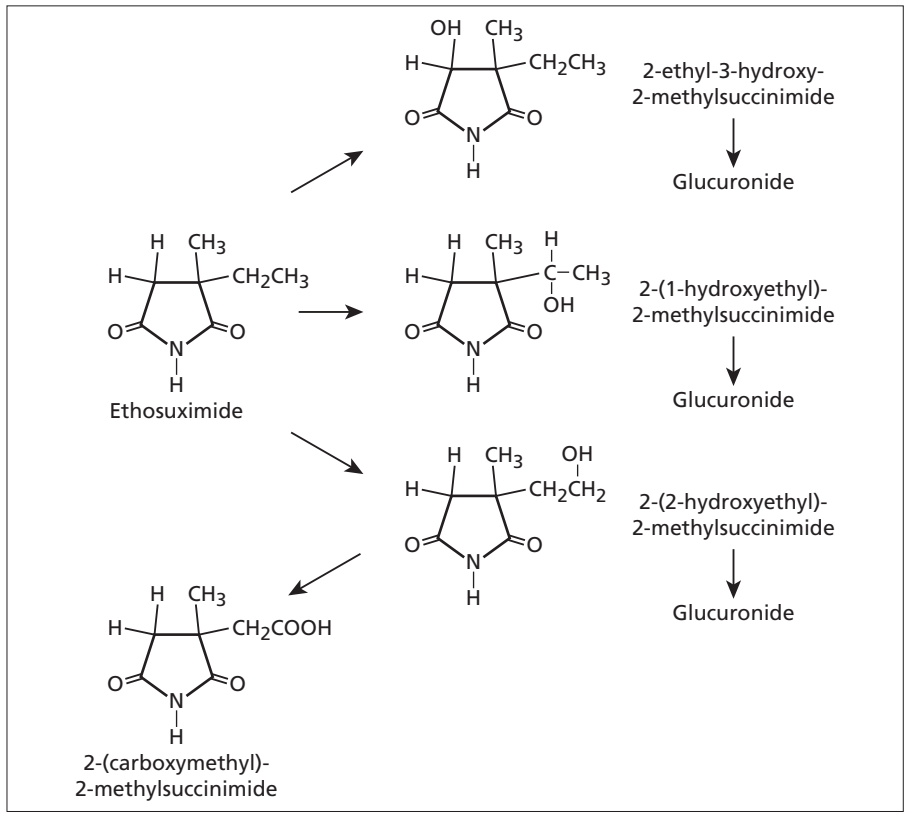


Fig. 39.1 Structure and biotransformation pathways of ethosuximide. Reproduced with permission from ref. 4.

In humans, ethosuximide's elimination follows first-order kinetics. Its apparent oral clearance in adults averages about 10 mL/kg/h [25,26] and in two children it was 13 mL/kg/h and 16 mL/kg/h [23]. This is much lower than the rate of hepatic plasma flow (0.9 L/kg/h), implying that ethosuximide does not undergo a significant first-pass effect and that its clearance is not blood flow limited. The clearance of ethosuximide has been reported to decrease slightly after repeated dosing. Ethosuximide does not induce the hepatic microsomal CYP enzymes or the uridine diphosphate glucuronosyltransferase (UDPGT) system [44–46]. Autoinduction does not occur, unlike in rats [46,47].

Ethosuximide has a relatively long half-life that varies with age. Ethosuximide's mean half-life in adults not receiving enzyme inducers was reported to range from 40 to 70 h compared with 30–40 h in children [23–29,47,48]. There are large variations reported in ethosuximide's half-life (15–68 h) in the paediatric studies [23,24,49]. The half-life of ethosuximide has been reported to be 32–41 h in neonates [37,39]. The time to reach steady-state concentrations following a dosage change is 6–7 days for children and 12 days for adults. Clearance is reported to be lower in women than in men [50]. Dose size and repeated dosing do not affect ethosuximide half-life [24,49].

Pharmacokinetics in special populations

As discussed in the section above, children have higher ethosuximide clearance values and shorter half-lives than adults [23–29,47,48].

There is very limited information on potential changes in ethosuximide pharmacokinetics during pregnancy. Available evidence suggests that ethosuximide clearances increases during prenancy compared withy the pre-pregnant state [51].

The effects of liver and renal disease on ethosuximide elimination have not been formally studied. Theoretically, liver disease would be expected to impair ethosuximide elimination due to ethosuximide's substantial hepatic oxidative metabolism, while the effect of renal disease on ethosuximide elimination should have much less impact. Haemodialysis can readily remove ethosuximide. One report estimated that approximately 50% of the body's ethosuximide was removed over a 6-h dialysis interval and that ethosuximide half-life dropped to 3–4 h during dialysis [52]. In a separate case report, peritoneal dialysis was able to decrease ethosuximide concentrations in a child taking both ethosuximide and phenobarbital [53].

Drug interactions

Effects of other drugs on ethosuximide pharmacokinetics

Concomitant therapy with enzyme-inducing antiepileptic drugs (AEDs) such as carbamazepine, phenytoin and barbiturates increases the rate of ethosuximide metabolism. As a result, ethosuximide's clearance is significantly accelerated (leading to a drop in the serum concentration) when ethosuximide is used concurrently with phenobarbital, primidone, phenytoin or carbamazepine [26,54–56]. In a formal comparative study in adults, ethosuximide's apparent oral clearance was found to be, on average, 15.3 mL/kg/h in patients taking enzyme-inducing AEDs, compared with 9.2 mL/h/kg in controls not taking enzyme inducers [26]. The half-life was also shorter in patients on enzyme inducers than in controls (54 h versus 29 h respectively). Discontinuation of concomitant carbamazepine therapy in one study resulted in a 48% increase in plasma ethosuximide concentrations [57]. The magnitude of the effect of enzyme-inducing AEDs on ethosuximide pharmacokinetics varies considerably between patients [54].

The effect of valproic acid on the pharmacokinetics of ethosuximide is variable, with different studies showing ethosuximide's clearance increased, decreased or unchanged when concomitant valproic acid therapy was employed [44,47,48,55,58–61].

There have not been any formal pharmacokinetic interaction studies examining potential ethosuximide interactions with felbamate, gabapentin, lamotrigine, tiagabine, topiramate, oxcarbazepine, levetiracetam, pregabalin, vigabatrin or zonisamide.

Interactions with non-antiepileptic medications have been occasionally reported. The clearance of ethosuximide is substantially increased by co-medication with rifampicin, a CYP3A4 inducer [56]. In one report, use of ethosuximide and isoniazid, a potent inhibitor of CYP enzymes, resulted in increased serum ethosuximide concentrations and psychotic behaviour [62].

Effect of ethosuximide on the pharmacokinetics of other drugs

Ethosuximide has a low potential for drug interactions due to its lack of effect on most drug-metabolizing enzymes. Most authors conclude that ethosuximide therapy does not have a clinically significant effect on the pharmacokinetics of phenytoin, phenobarbital or carbamazepine, although there are scattered reports of some changes in serum phenytoin or phenobarbital concentrations when ethosuximide is used in combination with phenytoin or primidone [58,63–69]. There is neither an alteration in the plasma protein binding of carbamazepine or phenytoin nor a change in the formation of phenobarbital from primidone when ethosuximide is used [70].

One study reported a decrease in serum valproic acid concentration following the addition of ethosuximide [from 120.0 ± 20.1 μg/mL pre-ethosuximide to 87.0 ± 13.1 μg/mL during co-therapy with ethosuximide ($P < 0.01$)] [71]. Following cessation of ethosuximide, valproic acid levels rose by 36.7%. The mechanism underlying this effect is unknown.

Ethosuximide has not been found to interact with oral contraceptive hormones [5].

Pharmacodynamic drug interactions

Despite equivocal evidence from animal studies [72,73], clinical observations suggest that valproic acid and ethosuximide may display a favourable pharmacodynamic interaction, in that patients refractory to either drug given alone may respond well to the combination [74–76].

Serum level monitoring

Although ethosuximide treatment is usually individualized by direct observation of clinical response supplemented by electro-

encephalogram (EEG) recordings, measurements of serum ethosuximide concentrations may be valuable as an aid to dosage adjustments in patients with difficult-to-control seizures or suspected drug toxicity, in patients susceptible to pharmacokinetic alterations (e.g. during pregnancy, in disease states, or when adding or withdrawing potentially interacting drugs) or as a check for compliance. The majority of patients are expected to respond at serum ethosuximide concentrations between 40 and 100 μg/mL, but in some cases serum levels below or above this range may be required [77].

Efficacy

Although there are no high-quality double-blind controlled monotherapy trials rigorously proving ethosuximide's efficacy against typical absence seizures [78,79], a powerful anti-absence effect of ethosuximide was suggested by two open studies conducted in the 1970s by Browne *et al*. [80] and Sherwin *et al*. [81], and since then there has been general consensus that ethosuximide is an effective first-line monotherapy for typical absence seizures.

In the trial by Browne *et al*. [80], ethosuximide's efficacy was examined with a well-constructed methodology for patient selection and assessment. In order to enrol, each patient's absence seizures were required (a) to meet a predetermined clinical definition of an absence seizure; and (b) be witnessed by the principal investigator. Seizure frequency was then assessed by five separate measures, including (a) ward staff observation; (b) trained observer observation; (c) parent's observation; (d) physician observation (including during patient hyperventilation); and (e) standardized video-electroencephalographic recording. These five measures were combined into a 'seizure index'. Thirty-seven patients enrolled. By the eighth week of treatment, 19% (7/37) were seizure free with a 100% reduction in seizure index. Overall, during ethosuximide therapy, 49% (18/37) demonstrated ≥90% reduction in seizures while 95% (35/37) exhibited a ≥50% reduction in seizures. The anti-absence effect was noted rapidly (within a week) for any given ethosuximide dose. Plasma ethosuximide concentrations ranged from 16.6 to 104.0 μg/mL (doses 6.5–36.7 mg/kg) and, based on the seizure index, the authors suggested an optimal range of plasma ethosuximide concentrations of 40–100 μg/mL.

The second major open-label non-comparative trial, conducted by Sherwin *et al*. [81], also had a prospective longitudinal design and used therapeutic drug monitoring to maximize clinical response. Seventy patients enrolled. The group was 54% (38/70) female with ages ranging from 4 to 28 years (median 12 years). Thirty-eight patients (54%) had only absence seizures, while the remaining had either absence seizures with tonic–clonic seizures (30%) or absence seizures and one or more other generalized seizure types (16%). Approximately half the patients were on other AEDs in addition to ethosuximide. Patients received between 9.4 and 73.5 mg/kg/day and were evaluated at 6-month intervals. Introduction of ethosuximide therapy resulted in complete control of absence seizures in 47% (33/70) of the patients. None of these patients had plasma ethosuximide concentrations below 30 μg/mL, and only 9% had levels below 40 μg/mL. During the next 2.5 years, attempts were made to achieve plasma ethosuximide concentrations above 40 μg/mL in the remaining patients (53%, 37/70) with uncontrolled absence seizures. Improved compliance and higher ethosuximide dosages led to significantly higher ethosuximide plasma concentrations in 19 patients; 10 of these 19 patients became free from absence seizures. At the 2.5 years follow-up mark, 61% (43/70) of the group was free from absence seizures. In these patients, ethosuximide's effectiveness persisted over the next 2.5 years (total 5 years) of follow-up. Ethosuximide, however, was not able to control absence seizures in patients with absence seizures and tonic–clonic seizures on combination AED therapy.

A number of controlled comparative trials have provided evidence that ethosuximide and valproic acid have similar efficacy against absence seizures [82–86]. These studies utilized clinical observation only ($n = 2$), video-electroencephalographic telemetry only ($n = 1$) or both techniques ($n = 2$) to assess response to therapy. Success was defined as 100% seizure control. In these comparative trials, ethosuximide therapy resulted in 100% seizure reduction in 58% of patients utilizing clinical observation and 57% of patients using video-electroencephalographic telemetry. Serum ethosuximide concentrations ranged from 26 to 114 μg/mL. In comparison, valproic acid therapy resulted in 100% seizure reduction in 63% of patients (using clinical observation) or 55% of patients (using video-electroencephalographic telemetry), with serum valproic acid concentrations ranging from 32 to 131 μg/mL.

One open-label study found the combination of ethosuximide and valproic acid effective in five patients with absence seizures refractory to either drug given in monotherapy [74]. Subsequently, many authors have recommended ethosuximide and valproic acid combination therapy for patients with absence seizures resistant to monotherapy [29,87]. Similarly, in patients with both absence and tonic–clonic seizures, ethosuximide has been used in combination with another AED effective against tonic–clonic seizures, such as valproic acid, carbamazepine or phenytoin. Despite being reported as 'highly effective' against atypical absence seizures [87], patients with atypical absence seizures are generally more resistant to drug treatment and ethosuximide is almost always used as part of combination therapy in these patients due to the high incidence of co-existing seizure types.

There is some evidence that ethosuximide is useful in the prevention and treatment of absence status epilepticus at serum concentrations greater than 120 μg/mL [88,89]. There are also reports of ethosuximide being effective in patients with severe myoclonic epilepsy in infancy [90], childhood epileptic encephalopathy (Lennox–Gastaut syndrome) [91], juvenile myoclonic epilepsy [92,93], epilepsy with myoclonic absences [93,94], eyelid myoclonia with absences [76,93], early-onset absence epilepsy and paroxismal dyskinesia [95], epilepsy with continuous spikes and waves during slow-wave sleep [75] and Landau–Kleffner syndrome [96], Angelman's syndrome [97], photosensitive seizures [98] and gelastic seizures [29,99]. Evidence of effectiveness in these conditions typically comes from uncontrolled studies and small case series, and in many difficult-to-control patients ethosuximide is often combined with other AEDs, particularly valproic acid. There are also no controlled studies investigating ethosuximide's effectiveness against simple partial, complex

partial or secondary generalized tonic–clonic seizures. However, recent reports suggest that ethosuximide can be effective in the treatment of epileptic negative myoclonus associated with childhood partial epilepsy [100,101].

Adverse effects

Ethosuximide's adverse effects can be divided into four categories: (a) commonly observed; (b) infrequent, but clinically relevant; (c) rare, potentially life-threatening; and (d) manifestations of overdose. Like most drugs, the most commonly observed adverse effects are directly related to the primary and secondary pharmacological effects of the drug and are usually predictable, dose dependent, host independent and resolve with dose reduction. The infrequent but clinically relevant adverse effects may result from multiple mechanisms including (a) dose-dependent and readily reversible effects related to the drug's main pharmacological actions; (b) idiosyncratic reactions; (c) effects of long-term therapy related to the cumulative dose; and (d) other delayed effects, such as teratogenicity. Most idiosyncratic drug reactions cannot be predicted based upon the known pharmacological effect of the drug, do not demonstrate a simple dose–response relationship, are host dependent, and some can be serious and life threatening [102].

Common adverse effects

Twelve large clinical trials (each involving over 50 patients) published between 1958 and 1966 detailed the spectrum of ethosuximide's adverse effects [103–114]. Browne [115] summarized these studies and found that the overall incidence of ethosuximide-related adverse effects ranged from 26% to 46% (Table 39.1). In half of these large trials, 37% or more of the subjects experienced ethosuximide-related adverse effects [115].

Gastrointestinal effects

The most common concentration-dependent adverse effects involve the gastrointestinal system. These include nausea (the most common), abdominal discomfort, anorexia, vomiting and diarrhoea [3,29,115,116]. Symptoms usually occur at the onset of therapy, are mild in severity, affect 20–33% of children and resolve promptly after dose reduction [29,115]. In some patients, gastrointestinal effects are transient and no dose reduction is needed; in others, dividing the total daily dosage and administering the smaller doses at meal time helps lessen the symptoms [115]. Infrequently, gastrointestinal symptoms are severe enough to cause discontinuation of the drug.

Table 39.1 Summary of adverse effect profiles noted in early studies involving 50 or more subjects receiving ethosuximide (12 reports, 1958–1966).

Adverse effect	Range of reported frequencies (median) (%)
Any adverse effect	26–46 (37)
Gastrointestinal distrurbances (nausea, abdominal discomfort, anorexia, vomiting and diarrhoea)	4–29 (13)
Drowsiness	0–16 (7)
Rash	0–6 (0)
Ataxia	0–1 (0)
Dizziness	0–4 (1)
Hiccoughs	0–5 (0)
Irritability	0 (0)

Modified from ref. 115 with permission.

Neurological effects

The second most common form of concentration-dependent adverse effects relate to the central nervous system (CNS) [115]. Similar to the gastrointestinal effects, drowsiness usually occurs at the onset of therapy and resolves promptly when the ethosuximide dose is reduced [115].

Additional CNS effects include insomnia, nervousness (12% of children), dizziness, hiccoughs, lethargy, fatigue, ataxia and behaviour changes (e.g. aggression, euphoria, irritability, hyperactivity) [5,79,116]. A direct relationship between behavioural changes and ethosuximide therapy is not certain since poor study methodology makes analysis of existing reports difficult at best. The lack of reliable methods for objectively measuring behaviour changes, the confounding variables of polypharmacy and the lack of serum AED concentrations during the studies are examples of these methodological concerns.

Headaches occur in approximately 14% of children taking ethosuximide. In contrast to the other neurological side-effects described above, headaches do not appear to be concentration dependent, may not respond to dose reduction and may be persistent [116,117].

Assessing ethosuximide's effects on cognition is difficult. Few clinical trials have examined the issue in a controlled fashion, accounting for confounding variables such as serum drug concentrations, underlying mental retardation, concomitant AEDs or seizure type. Memory, speech and emotional disturbances were noted on psychometric testing in 25 children receiving ethosuximide for various seizure types in one early report [118]. However, all the patients were also on barbiturates, 60% of the cohort had intelligence quotient (IQ) scores below 83, serum ethosuximide concentrations were not measured and no matched control group was used. In contrast, ethosuximide therapy resulted in significant improvement in verbal and full-scale IQ scores without change in motor performance or personality test scores in a cohort of children without epilepsy but with learning disorders and 14 and 6 per second positive spikes on EEG [119]. Similarly, psychometric performance improved significantly over 8 weeks of ethosuximide therapy in 17 of 37 (46%) children with absence seizures in a well-designed study [80]. This improvement was significantly different compared with a control group of patients tested in the same fashion over the same interval. Only 25% of the study group had IQ scores less than 83 and only 32% were on other AEDs [80].

Infrequent, but clinically relevant adverse effects

Psychiatric effects

Some patients taking ethosuximide have developed episodes of psychotic behaviour manifested by anxiety, depression, visual

hallucinations, auditory hallucinations and intermittent impairment of consciousness [105,120–122]. The patient's age (young adults in their teens or twenties) and a history of mental illness are risk factors for these adverse effects [115]. The acute psychotic episodes appeared following ethosuximide-induced seizure control with associated EEG improvement. The episodes resolved when ethosuximide was stopped and seizures returned, possibly illustrating the phenomenon of 'forced normalization'. Psychotic symptoms have recurred when ethosuximide was re-started in patients with previous ethosuximide-related psychotic episodes. Among all anti-absence AEDs, this 'forced normalization' reaction occurs with highest frequency with ethosuximide and is not dose dependent [6,123]. This type of adverse effect seldom occurs in young children with no previous history of psychiatric disease receiving ethosuximide for typical absence seizures [115].

Neurological effects

No evidence of ethosuximide-associated seizure exacerbation is found in most studies [80,107,112,114]. Exacerbation of myoclonic and absence seizures and transformation of absence into 'grand mal' seizures in patients receiving ethosuximide are reported in scattered publications [124,125]. This 'exacerbation' effect is likely to be simply a consequence of the relatively high incidence of generalized tonic–clonic seizures in patients with absence seizures, coupled with ethosuximide's lack of efficacy against generalized tonic–clonic seizures. A recent report also failed to identify any evidence for a precipitating effect of ethosuximide on generalized tonic–clonic seizures [126].

Long-term cumulative-dose adverse effects of ethosuximide are infrequent. Extrapyramidal reactions (e.g. severe bradykinesia, akasthesias, akathisia, dyskinesias and parkinsonian syndrome) have been noted after several years of ethosuximide treatment [106,127].

Haematological effects

The incidence of ethosuximide-related granulocytopenia ranged from 0% to 7% in early studies [115]. This symptom has been considered probably dose dependent since it often resolved with dose reduction without requiring termination of ethosuximide therapy. It is critical to distinguish between this probably dose-dependent haematological adverse effect and ethosuximide-associated idiosyncratic bone marrow depression (see below). Careful clinical and laboratory monitoring is essential in making this distinction.

Other organ systems

Ethosuximide therapy is not reported to cause serious endocrine adverse effects [115]. Ethosuximide can precipitate an attack of acute intermittent porphyria [117,128].

Little information is available about the overall risks that maternal ethosuximide use poses to the fetus. There are currently not enough data to assess accurately the teratogenic effect of ethosuximide in humans. One study found that 2 out of 13 newborns born to 10 women with epilepsy taking ethosuximide had major malformations (bilateral clefting, hare-lip) [39]. In addition, the cohort had a higher rate of minor abnormalities compared with a pair-matched control group of newborns of women without epilepsy. The mothers of these two seriously affected newborns were on ethosuximide in combination with phenobarbital in one case and primidone in the other. In another small series, one of five infants born to a mother taking ethosuximide was malformed [129].

Rare, potentially life-threatening adverse effects

Ethosuximide has been associated with a wide variety of idiosyncratic reactions [5,102,116] including allergic dermatitis, rash, erythema multiforme, Stevens–Johnson syndrome, systemic lupus erythematosus, a lupus-like syndrome, blood dyscrasias (aplastic anaemia, agranulocytosis), liver toxicity, autoimmune thyroiditis and diminished renal allograft survival.

The most common idiosyncratic reactions involve the skin. Allergic dermatitis and rash frequently resolve following ethosuximide withdrawal, but some patients may require steroid therapy. Patients developing Stevens–Johnson syndrome require hospitalization for more aggressive therapy.

Ethosuximide-associated blood dyscrasias can involve any or all cell lines ranging from thrombocytopenia to pancytopenia and aplastic anaemia. Only eight cases of ethosuximide-associated aplastic anaemia were reported between 1958 and 1994, with onset 6 weeks to 8 months after ethosuximide initiation [130]. Six patients were on polypharmacy, five taking either phenytoin or ethotoin in combination with ethosuximide. Despite therapy, five of the eight patients died.

Manifestations of overdose

The manifestations of acute ethosuximide overdose include nausea, vomiting and symptoms of CNS depression including stupor and coma leading to respiratory depression. The management of ethosuximide overdose involves life support measures, symptomatic treatment, procedures to decrease drug absorption and procedures to enhance drug elimination. Life support measures involve initial and immediate evaluation and stabilization of the patient's airway, breathing and circulation. Symptomatic treatment focuses on the subsequent care for each of the patient's overdose symptoms as they occur. No specific antidote exists for an ethosuximide overdose.

Methods to decrease absorption

Since ethosuximide overdose can rapidly lead to significant alteration of consciousness, induction of emesis is not recommended [131]. Administration of activated charcoal as an aqueous slurry may reduce absorption in conscious patients able to protect their airway. The effectiveness of activated charcoal is greatest if given within 1 h of an ethosuximide overdose [131]. The recommended dose of activated charcoal is 1 g/kg of weight for infants up to 1 year old, 25–50 g in children between 1 and 12 years old and 25–100 g in adults. The optimal dose has not been established [132]. If emesis or rapid deterioration of consciousness occurs or is impending, only personnel skilled in airway management should administer activated charcoal to minimize the potential for aspiration. The contraindications for the use of activated charcoal are a patient with an unprotected airway or if the therapy increases the risk or severity of aspiration [132].

Gastric lavage with a large-bore orogastric tube may be considered if a potentially life-threatening amount of ethosuximide has been ingested and the procedure can be performed within 1 h

of the ingestion [133]. Gastric lavage should not be employed routinely in the management of patients following an overdose of ethosuximide due to the risk of significant morbidity associated with the procedure.

Methods to enhance drug elimination

Haemodialysis may be useful in the treatment of an ethosuximide overdose. This is based on an observed extraction efficiency of 61–100% in one study of four patients with chronic renal disease (supported by haemodialysis) who received a single dose of 500 mg of ethosuximide 4 h prior to dialysis. In this study, the elimination half-life of ethosuximide was reduced by dialysis to an average of 3.5 h [52]. There have been no reports of haemoperfusion use in ethosuximide overdose. Both exchange transfusion and forced diuresis have little place in the treatment of ethosuximide overdose since ethosuximide has low protein binding and little of the parent ethosuximide compound is excreted unchanged in the urine.

Place in current therapy

Indications

Ethosuximide and valproic acid are considered as treatment of choice for first-line monotherapy against typical absence seizures in an expert consensus guideline [134]. Paediatric consensus guidelines generally regard ethosuximide and valproic acid as treatment of choice for childhood absence epilepsy, whereas in juvenile absence epilepsy valproic acid is generally preferred because when adolescence is approached the risk of generalized tonic–clonic seizures increases [135,136].

Ethosuximide adjunctive therapy may be beneficial for (a) patients with typical or atypical absence seizures not controlled on ethosuximide or valproic acid monotherapy or (b) patients with both absence and tonic–clonic seizures, when absence seizures are not controlled by the concomitant drug [29,87,137]. There is no evidence supporting a role for ethosuximide monotherapy or ethosuximide adjunctive therapy in patients with only primary generalized tonic–clonic seizures or in patients with only simple partial, complex partial or secondary generalized tonic–clonic seizures.

Additional conditions where ethosuximide may be useful include absence status epilepticus [88,89], severe myoclonic epilepsy in infancy [90], childhood epileptic encephalopathy (the Lennox–Gastaut syndrome) [91], juvenile myoclonic epilepsy [92,93], epilepsy with myoclonic absences [93,94], eyelid myoclonia with absences [76,93], early-onset absence epilepsy and paroxismal dyskinesia [95], epilepsy with continuous spikes and waves during slow-wave sleep [75] and Landau–Kleffner syndrome [96], Angelman's syndrome [97], photosensitive seizures [98], gelastic seizures [29,99] and epileptic negative myoclonus associated with childhood partial epilepsy [100,101]. In some of these syndromes, ethosuximide is usually combined with other drugs possessing a broader spectrum of antiseizure activity.

Dose and titration rates

A common starting dose for children is 10–15 mg/kg/day. Subsequent titration is performed according to the patient's clinical response. In older children and adults ethosuximide is often initiated at 250 mg/day and increased by 250-mg increments until the desired clinical response is reached. Ethosuximide can be administered either as once-, twice- or even thrice-daily dosing (with meals) to maximize seizure control while minimizing adverse effects. The interval between dosage changes for older children and adults varies from 3 days to every 12–15 days.

In younger children, maintenance dosages frequently range from 15 to 40 mg/kg/day [87]. For older children and adults, common maintenance doses are 750–1500 mg/day. When used in elderly patients, ethosuximide should be titrated using smaller increments with longer intervals between changes. The time to reach steady-state concentration following a dosage change is 6–7 days for children and 12 days for adults.

If the clinical situation warrants discontinuing ethosuximide (e.g. intolerable side-effects without seizure control or ≥2 years free of absence seizures), then gradual reduction over 4–8 weeks is recommended. If necessary, abrupt discontinuation is probably safe due to ethosuximide's long half-life.

Laboratory monitoring

There is no evidence that monitoring of blood counts during ethosuximide therapy allows early prediction of ethosuximide's idiosyncratic haematological reactions. Patient education is important. Patients need to watch for fever, sore throat and cutaneous or other haemorrhages, and alert their physician immediately if these symptoms occur. However, one recommendation for blood monitoring has been that 'periodic blood counts be performed at no greater than monthly intervals for the duration of treatment with ethosuximide and that the dosage be reduced or the drug discontinued should the total white-blood-cell count fall below 3,500 or the proportion of granulocytes below 25% of the total white-blood-cell count' [138].

Ethosuximide should always be titrated to clinical response (i.e. maximal seizure control with minimal adverse effects). The generally accepted reference range for serum ethosuximide concentration is 40–100 μg/mL, but some patients with refractory seizures or absence status may need serum concentrations up to 150 μg/mL. In selected cases, monitoring of serum ethosuximide concentration may aid in maximizing seizure control and in identifyng non-compliance [81].

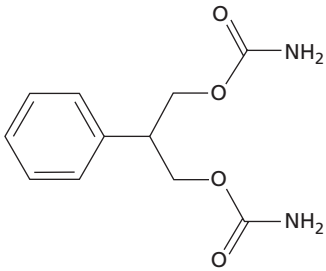
40 Felbamate

Ilo E. Leppik and James R. White
University of Minnesota and MINCEP Epilepsy Care, Minneapolis, MN, USA



Primary indications	Add-on treatment of Lennox–Gastaut syndrome and partial and secondary generalized seizures in patients refractory to other agents
Usual preparations	Tablets: 400, 600 mg; syrup: 600 mg/5 mL
Usual dosages	Initial: 1200 mg/day (adults); 15 mg/kg/day (children). Maintenance: 1200–3600 mg/day (adults); 15–80 mg/kg/day (children)
Dosing frequency	2–4 times/day
Significant drug interactions	Felbamate increases the serum levels of phenobarbital, phenytoin, valproic acid, *N*-desmethylclobazam and carbamazepine-10,11-epoxide. Felbamate lowers serum levels of carbamazepine and contraceptive sterioids. Phenytoin, carbamazepine and, possibly, phenobarbital lower serum felbamate levels. Valproic acid increases serum felbamate levels
Serum level monitoring	May be useful in selected cases
Reference range	30–60 mg/L
Common/important adverse effects	Liver toxicity and aplastic anaemia are rare but serious. Additionally, insomnia, headache, anorexia, weight loss, fatigue, dizziness, lethargy, mood and behavioural changes, ataxia, visual disturbances, gastrointestinal symptoms or rash
Main advantages	Highly efficacious in some patients with Lennox–Gastaut syndrome
Main disadvantages	Liver toxicity and aplastic anaemia. Other adverse effects are frequent on initial therapy, and with polytherapy
Mechanisms of action	Blockade of sodium channels, potentiation of $GABA_A$-mediated inihibition and antagonism of NMDA-mediated responses
Oral bioavailability	90%
Time to peak levels	1–6 h
Elimination	Hydroxylation and then conjugation (60%) and renal excretion in unchanged form (40%)
Volume of distribution	0.8 L/kg
Elimination half-life	11–25 h (lowest in patients co-medicated with enzyme inducers)
Plasma clearance	20–40 mL/kg/h in adults (highest in patients co-medicated with enzyme inducers). Higher values are reported in children
Protein binding	20–25%
Active metabolites	None
Comment	Highly effective in severe refractory cases, but use limited by hepatic and haematological toxicity

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Felbamate (Felbatol®, Taloxa®) was synthesized by Wallace Laboratories in the USA in 1954 [1]. The Antiepileptic Drug Development (ADD) programme of the National Institutes of Health (NIH) identified its potential for anticonvulsant activity in the 1980s [2,3]. Extensive clinical trials ensued, resulting in Food and Drug Administration (FDA) approval on 30 July 1993 for use in the USA as adjunctive and monotherapy in adults with partial seizures with or without secondary generalization, and as adjunctive therapy in children with Lennox–Gastaut syndrome. The unexpected development of aplastic anaemia prompted the FDA and manufacturer Carter Wallace to issue a strong warning regarding continued use of felbamate on 1 August 1994. Reports of felbamate-associated hepatic failure also engendered further concern. As a result, felbamate is not indicated as a first-line treatment and its use should be reserved for a few patients who respond inadequately to alternative antiepileptic drugs (AEDs) and whose epilepsy is severe enough that the risk of aplastic anaemia and/or liver failure is deemed acceptable by the patient compared with the benefits conferred by its use. Because of the effectiveness of this drug in many patients, felbamate remains on the market in the USA and is available for limited use in other countries.

Chemistry

Felbamate (2-phenyl-1,3-propanediol dicarbamate) has a chemical formula corresponding to $C_{11}H_{14}N_{12}O_{14}$ and a molecular weight of 238.43. It is chemically related to the anti-anxiety drug meprobamate. Felbamate is a white crystalline powder, with a melting point of 151–152°C, and is relatively insoluble in water and ethanol.

A number of methods have been developed to measure felbamate and its metabolites in biological samples. A high-performance liquid chromatography method for the simultaneous analysis of felbamate, phenytoin, 5-(*p*-hydroxyphenyl)-5-phenylhydantoin, carbamazepine, carbamazepine-10,11-epoxide and carbamazepine 10,11-diol in serum that could separate the compounds of interest and three internal standards in less than 15 min has been developed using a mobile phase optimization technique [4]. Some methods can measure felbamate concentrations in as little as 0.1 mL of plasma [5]. Other methods can measure felbamate and its three metabolites in brain and heart tissue homogenates [6].

Pharmacology

Activity in experimental models of seizures and epilepsy

Animal model testing demonstrated a broad spectrum of activity against different seizure types. Felbamate inhibits seizures induced by maximal electroshock, pentylenetetrazol and picrotoxin, but seizures induced by bicuculline and strychnine are not affected [2]. The drug is protective against epileptiform activity induced by the potassium channel blocker 4-aminopyridine [7]. Thus, felbamate seems to both increase seizure threshold and prevent seizure spread [2]. This profile in animal models would predict action against both partial and generalized (including absence) epilepsies in humans. Felbamate has also been found to be active in two rat models of status epilepticus [8,9], and to be effective in preventing the expression of stage 5 kindled seizures in corneal-kindled rats [3].

Table 40.1 Protective index (median toxic dose/median effective dose) of felbamate and standard antiepileptic drugs in various animal models of seizures.

Drug	Maximal electroshock	Pentylenetetrazole	Picrotoxin	NMDA	Kindling
Felbamate	16.3	5.51	5.2	146	35.8
Carbamazepine	8.1	NP	37.2	16	>17.3
Ethosuximide	NP	3.4	1.8	4	NP
Phenytoin	6.9	NP	NP	71	NP
Valproic acid	1.6	2.9	1.1	5.8	7.3

Adapted from refs 2, 3 and 36.
NP, not protective.

The anticonvulsant effects of felbamate against seizures induced by maximal electroshock are enhanced by combination with non-protective doses of phenytoin, carbamazepine, valproic acid or phenobarbital in mice. This effect could not be accounted for by a pharmacokinetic mechanism and thus implies a pharmacodynamic interaction [10]. Also, a single subprotective dose of felbamate combined with diazepam enhanced the effects of diazepam against seizures induced by maximal electroshock, pentylenetetrazol and isoniazid [11]. In addition to its anticonvulsant action, felbamate has a neuroprotective effect in various animal models [9,12,13]. Felbamate has a very favourable protective index in animals compared with other AEDs (Table 40.1).

Mechanisms of action

Although the specific mechanism by which felbamate exerts its anticonvulsant effects is unknown, evidence exists for a number of possible mechanisms. The *N*-methyl-D-aspartate (NMDA) receptor is the site of action where felbamate was found to be effective against NMDA-induced clonus in mice [3]. Inhibition of [^{3}H]-5,7-dichlorokynurenic acid (a high-affinity glycine receptor antagonist) binding corresponding with peak plasma and brain concentrations of felbamate has been demonstrated [14]. Felbamate may have dual actions in the brain, both inhibiting NMDA responses and potentiating the effects of γ-aminobutyric acid (GABA) by an action at a site on the $GABA_A$ receptor which is distinct from the binding sites of GABA and benzodiazepine drugs [2,15,16]. Felbamate has also been found to be effective in blocking sustained repetitive firing in mouse spinal cord neurones, suggesting inhibition of sodium channel conductance [3].

Pharmacokinetics

Absorption

Felbamate is rapidly and completely absorbed after oral administration, with peak serum concentrations occurring 1–6 h after

intake [17–19]. The bioavailability is similar for the tablets and the suspension, and is not affected by food [20,21].

Distribution

Animal studies have shown that felbamate distributes rapidly into a number of tissues, including brain [22], and crosses the placenta [23]. Felbamate extraction into brain in a single transcapillary passage was found to be 5–20%, and the drug was found to distribute relatively uniformly throughout the brain [24]. The apparent volume of distribution is estimated at about 0.8 L/kg.

In humans, 20–25% of the total plasma concentration is bound to plasma proteins, primarily to serum albumin.

Elimination

The half-life of felbamate in healthy volunteers is approximately 20 h and ranges from 13 to 23 h when given as monotherapy to adult patients with epilepsy [17,20]. Multiple dosing does not appear to alter the elimination half-life. In patients with epilepsy receiving either phenytoin or carbamazepine, however, the half-life of felbamate was shorter, approximately 13–14 h with a range of 11.4–19.6 h [19]. Thus, phenytoin and carbamazepine increase the rate of felbamate elimination, whereas valproic acid has the opposite effect [20,25].

Felbamate is partly eliminated unchanged in urine and is partly metabolized in the liver via hydroxylation followed by conjugation. A number of potentially toxic metabolites may be formed [26–28]. This hepatic metabolism sets the stage for drug interactions with concomitantly administered medications metabolized via similar pathways.

In human volunteers, 40–49% of a felbamate dose is recovered in the urine as the parent compound, with the rest as various metabolites [17]. Metabolites do not contribute significantly to activity in animal models of epilepsy [2]. However, in humans, felbamate may be metabolized to lead to the formation of 2-phenylpropenal, an α,β-unsaturated aldehyde (atropaldehyde) which is a potent electrophile [29]. Atropaldehyde has been proposed to play a role in the development of liver and bone marrow toxicity during felbamate therapy. It undergoes rapid conjugation with glutathione in most individuals. This has led to analysing urine samples from patients receiving felbamate for two atropaldehyde-derived mercapturic acids, as a possible method for monitoring patients [30].

Pharmacokinetics in special populations

In agreement with results from animal studies [22,31], the apparent oral clearance of felbamate has been found to be 20–65% higher in children, particularly young children, than in adults [32–34]. Thus, children may need a higher dose per kilogram than adults. Drug interactions affecting felbamate clearance in children are similar to those in adults. In a study of children using the non-linear mixed effects model (NONMEM) programme for describing pharmacokinetics, the clearance of felbamate was found to be increased by 49% and 40%, respectively, when the drug was used in combination with carbamazepine and phenytoin. Conversely, valproic acid and older age were found to decrease felbamate clearance [32].

In a study that assessed felbamate pharmacokinetics in 24 elderly (66–78 years) and 11 young (18–45 years) subjects, felbamate clearance after a single dose was found to be about 20% lower in the elderly than in the young (31.2 versus 25.1 mL/min). Felbamate was also less well tolerated in elderly subjects than in young subjects, as shown by higher rates of adverse event reporting and dropouts when multiple doses were given. It was concluded that elderly subjects require lower initial dosing and slower dose titration of felbamate than non-elderly adults [35].

As would be expected from a drug 40–50% eliminated unchanged in the urine, persons with renal failure will need lower doses of felbamate, with urinary clearance representing only 9–22% of overall clearance in these patients [36]. In patients with creatinine clearance values between 5 and 10 mL/min, the apparent oral clearance of felbamate was one-half that found in healthy control subjects.

Drug interactions

As discussed above, the metabolism of felbamate is accelerated by concomitant treatment with phenytoin or carbamazepine, resulting in an increase in felbamate clearance by about 40–50% [19,37,38]. Conversely, valproic acid decreases felbamate clearance by up to about 20% [20,21,25].

Felbamate may both induce and inhibit cytochrome P450 (CYP) drug-metabolizing enzymes [39–42]. Induction of carbamazepine metabolism by felbamate is responsible for a modest reduction (about 20%) in serum carbamazepine levels in patients started on add-on therapy with felbamate. In one study, serum carbamazepine concentrations decreased from 7.5 μg/mL during placebo treatment to 6.1 μg/mL during felbamate treatment ($P < 0.05$) [43]. On the other hand, mean carbamazepine-10,11-epoxide concentrations increased from 1.8 μg/mL during placebo baseline periods to 2.4 μg/mL during felbamate treatment [43]. The effect was evident after the first week of treatment and reached a plateau in 2–4 weeks [44]. Enzyme induction is also probably responsible for a decrease in serum levels of steroid oral contraceptives in women co-medicated with felbamate [45]. However, the most common interactions described in humans with felbamate involve inhibition of the metabolism of co-administered drugs, with a consequent increase in their serum concentration. Felbamate significantly increases the concentrations of phenytoin, and phenytoin dose decreases of about 20% were needed in the first major study of felbamate as an add-on drug to maintain stable phenytoin concentrations [46–48]. Felbamate has been found to increase the serum concentrations of phenobarbital [49,50] and *N*-desmethylclobazam metabolically derived from clobazam [51]. Valproic acid levels are also increased by felbamate. In one study of 10 patients on valproic acid monotherapy, valproic acid levels increased by 18% in the presence of 1200 mg felbamate per day and by 31% with felbamate doses of 2400 mg/day [52].

Although few studies are available regarding interactions with drugs other than AEDs, it can be anticipated that the elimination of other substances cleared by CYP enzymes will be either induced or inhibited by felbamate.

Serum level monitoring

In the initial double-blind study in patients with partial-onset seizures, most serum levels of felbamate ranged between 20 and 45 μg/mL [46]. However, in post-marketing experience, concentrations between 40 and 100 mg/mL have been commonly found in persons responding favourably (Leppik, personal experience). In general, felbamate dosage can be individualized solely on the basis of clinical response. However, because there is a wide range of clearances for felbamate resulting from co-medication and other sources of individual variability, concentrations are not readily predictable from the doses, and measurement of blood levels can be useful to guide dosing.

A recent review has suggested a reference range for felbamate concentrations of 30–60 mg/L [53]. It was stressed, however, that variability in response at these concentrations is considerable and that higher concentrations may confer additional benefit, though they are also associated with a higher probability of adverse effects [53].

Efficacy

The first evidence that felbamate may be effective in humans came from a study of the pharmacokinetics of this drug [19]. Since then, a number of controlled trials have been performed, some of which used novel study designs, including use of presurgical patients, monotherapy studies with 'active placebos', and a study in patients with Lennox–Gastaut syndrome [54–56]. Many of these designs have been used subsequently in new AED development.

The first pivotal study was an NIH-sponsored, double-blind, placebo-controlled, two-centre add-on trial in patients with partial-onset seizures [46]. The mean seizure frequencies during the 8-week analysis periods in the 56 patients completing the study were 34.9 during the felbamate period and 40.2 during the placebo period ($P = 0.007$). Another NIH-sponsored study in patients with partial-onset seizures involved a triple cross-over of felbamate and placebo while carbamazepine was maintained as the stable AED. Initial analysis showed no significant difference in seizure frequency between placebo and felbamate periods, but when a correction was made for the lower carbamazepine level noted during felbamate periods, the data suggested a significant antiseizure effect of felbamate [57].

Two blinded studies using felbamate in patients with partial seizures undergoing presurgical evaluation have been performed [54,58]. In a multicentre study, 64 subjects were randomized to receive felbamate (30) or placebo (34) after the presurgical evaluation had been completed. Felbamate was titrated to 3600 mg over 3 days. The primary outcome variable was time to fourth seizure. Patients were hospitalized for 8 days for observation and, if they remained in the study, they were discharged and followed as outpatients for an additional 21 days. In the felbamate group, 54% made it to the end of the observation period without a fourth seizure, whereas only 12% of the placebo group made it to this endpoint (Kaplan–Meier analysis, $P = 0.002$) [54]. In the same study, during the presurgical evaluation phase as other AEDs were being lowered, the mean number of seizures was 2.05/day; during the felbamate treatment period, inpatient and outpatient, the seizure rate decreased to 0.29/day ($P = 0.001$) [59]. In a single-centre study following a similar protocol but 10 days' observation, the median time to fourth seizure was 6.26 days for the felbamate group and 2.54 for the placebo group ($P = 0.041$) [58]. Both of these studies were proof of principle studies to demonstrate the effectiveness of felbamate in intractable patients. Some patients remained on other AEDs, and these designs were not intended to be used as models of monotherapy.

Two subsequent studies of felbamate monotherapy using an 'active placebo' consisting of low-dose valproic acid have formed the basis of its recommended use as the sole AED in refractory patients with partial-onset seizures [55,60]. Additional open-label studies have demonstrated the effectiveness of felbamate in drug-refractory partial epilepsy [61,62].

In studies conducted before the discovery of serious hepatic and haematological toxicity, retention rate on felbamate in a clinical setting was favourable, as it was in a post-marketing study in which 91 of 132 refractory patients had enough clinical efficacy and lack of side-effects to warrant continuance of felbamate for 3 months or more after initiation [63].

The efficacy of felbamate in the Lennox–Gastaut syndrome was evaluated in a double-blind add-on parallel study involving 73 patients, mostly in the paediatric age range [56]. Felbamate or placebo was added to standard AEDs for 70 days. The dosage of felbamate was titrated to a maximum of 45 mg/kg of body weight per day or 3600 mg/day, whichever was less. Patients treated with felbamate had a 34% decrease in the frequency of atonic seizures ($P = 0.01$) and a 19% decrease in the frequency of all seizures ($P = 0.002$). A 'quality of life' measure, the global evaluation score, was significantly higher in the felbamate group than in the placebo group [56]. The improvement that occurred in the double-blind study was sustained for at least 12 months in subsequent open-label follow-up studies [64]. Additional open-label studies have confirmed the effectiveness of felbamate in the Lennox–Gastaut syndrome [65].

In a practice advisory statement in the USA, felbamate was classified as showing class I evidence efficacy for partial seizures in adults as adjunctive and monotherapy, and Lennox–Gastaut syndrome as adjunctive therapy. Class III evidence was found for primary generalized tonic–clonic seizures, absence seizures and partial seizures in children [66].

Adverse effects

In animal models, felbamate showed little toxicity [67]. Studies of carcinogenicity after high doses demonstrated a statistically significant increase in hepatic cell adenomas in some rodents, and an increase in benign interstitial cell tumours of the testes in male rats [68]. No teratogenic effects have been found in reproductive or teratology studies in rats and rabbits [68]. No evidence for bone marrow or hepatic toxicity was observed in any of the preclinical studies.

In human studies, felbamate was better tolerated as monotherapy, adverse experiences being more common when felbamate was used with other AEDs [55]. The most common adverse effects of felbamate as monotherapy were anorexia, vomiting, insomnia,

nausea and headache. The most common adverse effects in polytherapy trials included anorexia, vomiting, insomnia, nausea, dizziness, somnolence and headache [68,69]. In data provided by Carter Wallace, in clinical testing 12% (120 of 977 adults) discontinued felbamate because of adverse effects. In order of increasing frequency greater than 1%, adverse effects leading to discontinuation included weight decrease (1.1%), rash (1.2%), nausea (1.4%), various neurological symptoms (1.4%), and anorexia (1.6%) or psychological symptoms (2.2%) [68]. In studies with children, 6% (22 of 357) had felbamate discontinued, with symptoms leading to its discontinuance similar to those seen in adults. In one post-marketing use study, felbamate was initiated in 132 persons with chronic, refractory epilepsy after its release. Three or more months after initiation, felbamate had been discontinued in 24 patients because of adverse effects. Gastrointestinal symptoms were the most common single reason given, and dermatitis occurred in four patients [63].

In the clinical trials leading to felbamate approval, there had been no significant changes in laboratory tests among patients on felbamate, specifically white cell blood count, haematocrit and serum glutamate oxaloacetate transaminase (aspartate aminotransferase). However, as felbamate came into wider use, reports of serious adverse events surfaced. Thrombocytopenia was described in one report [70]. Scattered cases of aplastic anaemia came to the attention of the FDA by mid-1994, and three cases were reported in July alone. This unexpectedly high rate in conjunction with increasing use led the FDA to issue a warning on 1 August 1994, stating that 'Physicians should prescribe this drug only if it is absolutely necessary'. Information collected for the September 1994 FDA advisory panel meeting indicated that there had been 25 cases of aplastic anaemia reported (24 in the USA and one in Spain) [71]. In addition, 11 cases of hepatitis with four deaths had been reported. As of May 1995, Carter Wallace had evidence of 31 domestic post-marketing reports of aplastic anaemia and 14 cases of hepatitis with eight deaths (Table 40.2).

A thorough review of aplastic anaemia cases was performed. Of the cases reported, 23 (74%) met all of the criteria of the International Agranulocytosis and Aplastic Anemia Study [72]. Felbamate was judged to be the only cause in three cases, and the most likely cause in 11, for a total of 14 cases. Using a denominator of 110 000 persons exposed, the 'most probable' incidence was calculated to be 127 per million (lower limit, 27; upper limit, 209), with the general population rate for aplastic anaemia being 2 per million [72].

Table 40.2 Haematological reactions reported for patients receiving felbamate as of September 1994.

Reaction	*n*	Serious	Died
Aplastic anaemia	25	25	6
Pancytopenia	15	14	3
Leucopenia	29	18	1
Thrombocytopenia	16	10	2
Anaemia	4	4	0
Two of the above	14	11	1

Patient history and demographics suggest several features that may identify the high-risk patient. A prior history of AED allergy or toxicity, especially rash, was observed in 52%; a history of prior cytopenia in 42%; and evidence of immune disease, especially lupus erythematosus, in 33%. A case-by-case review of patients who developed aplastic anaemia revealed that an underlying immunological disease process was observed 34 times more frequently than expected, and if two of the above three factors were present, the patient's relative risk for aplastic anaemia quadrupled (Table 40.3). Only three patients had all three factors – cytopenia, allergy and an immunological process – among the entire aplastic anaemia cases and control groups available to the drug's manufacturer (Wallace), and all three developed aplastic anaemia. Only one paediatric patient (aged 18 years) was diagnosed with aplastic anaemia, and she had a prior diagnosis of systemic lupus erythematosus [73].

Duration of therapy is also an important factor. Duration of therapy prior to aplastic anaemia ranged from 23 to 339 days (mean 173 days) [73]. No cases reported up to the time of the review occurred in persons treated for more than 1 year, although in one additional case subsequently reported, the patient had been on felbamate for 8 years [74].

A total of 18 cases of hepatic failure were reported in patients receiving felbamate prior to September 1994. Evaluation of these reports indicates that 78% were female, 50% were aged 17 years or older, and the mean time to presentation was 217 days (25–939 days). A panel of hepatologists met independently to review the data on these cases and concluded that only seven had a probable association with felbamate, whereas the others were complicated by status epilepticus, viral hepatitis, shock liver or acetaminophen toxicity [73]. Using all reported cases of hepatic failure, the estimated incidence would be 164 per million, but using the numerator of seven, the incidence of hepatic failure would be estimated at 64 per million, or a risk estimate for hepatic failure of 1 per 18 500–25 000 exposures. Statistics regarding valproic acid reported hepatic-related fatality estimates of one case in 10 000–49 000 for the combined population, and 1 in 500–800 cases in high-risk young children under the age of 2 years receiving valproic acid polypharmacy [75]. These data suggest that the hepatotoxicity associated with felbamate is in the general range seen with valproic acid [73]. However, the age range differs markedly, with felbamate safer in the paediatric population but worse in adults, with just the opposite for

valproic acid. For both felbamate-induced aplastic anaemia and hepatotoxicity, females are at much greater risk (67% and 78%, respectively).

Felbamate is excreted in the urine and one case of urolithiasis with a felbamate stone in a 15-year-old boy has been reported [76]. One case of crystalluria and renal failure in an intentional overdose case with serum felbamate concentrations of 200 mg/mL has been observed [77]. Toxic epidermal necrolysis after initiation of felbamate has also been reported [78].

Place in current therapy

Update on risk to benefit ratio and indications

Although felbamate has been approved by the FDA for more than 15 years, a relative paucity of information exists about its clinical use. The most up-to-date review on the felbamate literature is described in a 2006 expert panel consensus on the use of felbamate [74]. New exposures to felbamate are estimated at between 3200 and 4200 patients annually; over the past 10 years, approximately 35 000 patients have been started on felbamate. Since 1994, one case of aplastic anaemia has been reported, which was described in 2000 in a 42-year-old woman who had been taking felbamate for 8 years and had a prior history of melanoma. One case of thrombocytopenia in a 14-year-old girl was reported in 2007. Felbamate was discontinued, thrombocytopenia resolved completely, but 4 months later aplastic anaemia occurred, thought to be unrelated to felbamate. Two cases of liver failure (one in 1995 and one in 1996) have been reported in felbamate patients since 1994; one was related to status epilepticus and the other was thought to be secondary to felbamate use.

Additional information has become available on the long-term effects of felbamate exposure. A prospective database affiliated with an epilepsy centre identified 77 long-term users of felbamate (data collected between 1986 and 2006) [62]. Laboratory and clinical outcomes are described in these patients, with an average treatment time of 7.5 years and a longest treatment time of 20 years. The study demonstrated significant weight loss in the first year of felbamate use, but weight loss was not sustained over long-term use. Significant reductions were noted in generalized tonic–clonic seizures and simple partial seizures. No clinically significant changes in laboratory parameters pertinent to liver or bone marrow function were seen; these results support the concept that the most serious felbamate adverse reactions are idiosyncratic [62].

Based on the 2006 expert panel consensus [74], felbamate should be regarded as a highly efficacious AED in patients refractory to first-line agents. Patients considered unsuitable candidates for felbamate include patients with new-onset epilepsy and patients with a history of adverse haematological events, hepatic dysfunction, autoimmune disease or a strong family history of autoimmune disease. The expert panel concluded that felbamate appears to have a risk–benefit ratio that allows it to be used in selected patients with refractory epilepsy. A similar conclusion was reached in 1999 by a joint American Academy of Neurology and American Epilepsy Society practice advisory [66].

Dosing recommendations

In adults, felbamate can be initiated at 1200 mg/day in three or four divided doses, with increases to 2400 and 3600 mg/day in weekly or biweekly increments of 600 or 1200 mg, as tolerated, as outpatients. In inpatient settings, felbamate can be titrated over a few days, especially if the other AEDs have been, or are being, eliminated or reduced [54]. In the outpatient environment, the doses of other AEDs should be reduced, generally by 20–33% upon initiation, and by further reductions as felbamate dose is increased. Most adverse effects can be eliminated by reducing doses of concomitant AEDs, especially if the goal is to attain monotherapy with felbamate. Some patients have tolerated doses as high as 7200 mg/day as monotherapy. A useful method to determine more precise doses for titrating patients is to start at approximately 20 mg/kg and increase to 40 mg/kg and then 50 mg/kg, 60 mg/kg or higher as needed.

Initiating felbamate in the presence of other AEDs can be difficult because of the drug interactions and propensity to develop adverse effects attributable to a greater total burden of AEDs. Nevertheless, careful attention to the general principle of reducing other AEDs vigorously in the presence of adverse effects, and increasing felbamate doses if levels have not exceeded 60 μg/mL, will permit patients to have an adequate exposure to this drug. In a patient with refractory epilepsy with particularly intense seizures or a propensity for status epilepticus, it may be best to err on the side of less aggressive concomitant AED adjustments initially rather than to decrease concomitant AEDs, as the patient develops signs and symptoms of concentration-related toxicity. In studies of adults, doses have ranged from 1800 to 4800 mg/day.

In children, recommended starting doses have been 15 mg/kg/day with weekly incremental increases to 45 mg/kg/day. Again, concomitant AEDs should be reduced by 20% or more upon initiation and reduced further as symptoms and blood levels indicate. It may be expected that doses for children may be larger than those for adults, and in our experience we have used doses of up to 80 mg/kg.

Felbamate is available as 400-mg tablets (scored, yellow, capsule shaped) useful for children; 600-mg tablets (peach-coloured scored, capsule shaped) and suspension (600 mg per 5 mL).

Laboratory and clinical monitoring

The FDA and Carter Wallace recommend full haematological evaluations prior to initiation of felbamate therapy, frequently during therapy and for a significant period of time after discontinuation of felbamate. Liver function tests are recommended every 1–2 weeks while on felbamate. It is not at all certain, however, that routine monitoring of haematological and hepatic parameters will be effective in detecting reactions. More important than laboratory testing is a careful review of the medical history and the avoidance of use of felbamate in patients who have a high-risk profile. Patients on felbamate should be taught the warning signs of aplastic anaemia and liver toxicity, and should have complete biochemistry and haematology tests done whenever any of these appear. These signs and symptoms include severe lethargy, nausea and vomiting, flu-like symptoms, easy bruising and unusual bleeding.

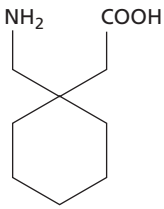
41 Gabapentin

Ernest R. Somerville[1] *and Andrew W. Michell*[2]

[1]Prince of Wales Clinical School, University of New South Wales, Australia
[2]National Hospital for Neurology and Neurosurgery, London, UK



Primary indications	Adjunctive therapy or monotherapy of partial or secondary generalized seizures
Usual preparation	Capsules: 100, 300, 400 mg Tablets: 600, 800 mg Oral solution: 250 mg/5 mL
Usual dosages	Initial: 300–900 mg/day. Maintenance: 900–3600 mg/day
Dosing frequency	2 or 3 times/day
Significant drug interactions	Antacids containing aluminium or magnesium hydroxide can reduce gabapentin absorption by about 20%
Serum level monitoring	Not routinely used. Dosage is generally adjusted on the basis of clinical response
Reference range	2–20 mg/L
Common/important adverse effects	Drowsiness, dizziness, ataxia, headache, tremor, diplopia, nausea, vomiting, rhinitis, non-pitting leg oedema, weight gain
Main advantages	Good tolerability and lack of drug interactions
Main disadvantages	Modest efficacy, particularly in severe cases, and spectrum of efficacy restricted to partial epilepsies
Mechanism of action	Modulates neurotransmitter release by binding to the α_2-δ subunit of voltage-gated calcium channels. Additional actions are possible
Oral bioavailability	<65% (decreases with increasing dose)
Time to peak levels	2–3 h
Elimination	Renal excretion in unchanged form
Volume of distribution	0.65–1.04 L/kg
Elimination half-life	5–9 h
Plasma clearance	1.3–1.6 mL/kg/min (after intravenous dosing in non-elderly adults)
Protein binding	Nil
Active metabolites	None
Comment	A well-tolerated drug, the value of which is limited by relatively modest efficacy

Introduction

Gabapentin (1-aminomethyl-cyclohexyl-acetic acid, Neurontin®) is an amino acid derived by the addition of a cyclohexyl group to the backbone of γ-aminobutyric acid (GABA). It was originally synthesized in the 1970s in Freiburg, Germany, at the pharmaceutical company Goedecke A.G., part of Warner-Lambert, which has since been incorporated into Pfizer [1]. The rationale for its development was that the cyclohexyl group would make the inhibitory neurotransmitter GABA more lipophilic, thus helping it penetrate the CNS while maintaining similar pharmacology [2]. At this time, it was believed that gabapentin would act via GABA receptors in

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

a similar manner to baclofen. However, subsequent studies have shown that gabapentin does not act *in vitro* at GABA receptors, but binds a subunit of voltage-sensitive calcium channels.

A US patent was granted in 1977 for the compound and its use in epilepsy. Following clinical trials, FDA approval was granted on 31 December 1993, and although originally available to clinicians as Neurontin® (Pfizer), it is now off patent and a large number of generic versions are available.

Chemistry

Gabapentin is a highly water-soluble bitter-tasting white crystalline substance with a molecular weight of 171.34 (conversion factor 1 μg/mL = 5.84 μmol/L). At 25°C it has two pK_a values at 3.68 and 10.70, and at physiological pH it is a zwitterion – an electrically neutral compound that carries both positive and negative charges on different atoms [3]. This permits absorption from the gut via the L-type amino acid transporter system, which usually carries L-leucine and L-phenylalanine [4].

Pharmacology

Activity in experimental models

There have been many studies of the effect of gabapentin in animal seizure models, with some correspondence to results from subsequent clinical experience (reviewed in ref. 3). Prevention of hind limb extensor response in rats in the maximum electroshock model has been a standard method to identify compounds with the potential to treat generalized tonic–clonic and partial seizures. In this model, gabapentin (ED_{50} = 9.1 mg/kg oral and 2.1 mg/kg intravenous) was found to be about as effective as phenytoin (ED_{50} = 9.5 mg/kg oral). In a partial-seizure model, the lowest effective dose of gabapentin required to block fully kindled hippocampal seizures in rats was 30 mg/kg, but the events were sometimes not completely blocked even with intraperitoneal doses up to 100 mg/kg. Gabapentin was found to be ineffective at preventing flash-induced myoclonic seizures in the photosensitive baboon (*Papio papio*).

Evidence of the non-epileptic uses of gabapentin has been available from animal studies for over a decade (reviewed in ref. 5). Gabapentin has anxiolytic-like effects and can prevent the nociceptive responses from hyperalgesia [6].

Mechanisms of action

Gabapentin was originally synthesized as a derivative of GABA, but whether its actions include a modification of GABAergic transmission is unclear. Whilst some authors have reported that gabapentin acts as a subtype-selective $GABA_B$ receptor agonist *in vitro* [7,8], other groups have not found this [9] and the actions of gabapentin appear not to be affected by $GABA_B$ receptor antagonists or agonists [10]. Although gabapentin has also been reported to elevate whole brain GABA levels in healthy volunteers, both acutely and after 1 month of therapy [11], the majority of evidence suggests that its pharmacology is not related to GABA neurotransmission or metabolism.

The identity of a protein in the brain to which gabapentin appears to bind specifically was discovered in 1996 by column fractionation of pig brain membranes which had been treated with [^{3}H]gabapentin. Fractions that retained radiolabelled gabapentin-binding activity were isolated and sequenced, demonstrating that gabapentin bound a protein which matched the α_2-δ type 1 subunit of voltage-gated calcium channels [12]. This binding site was shown to be present in high density in both brain and skeletal muscle. Subsequently, new α_2-δ subunit genes have been discovered, but it appears that [^{3}H]gabapentin binds only α_2-δ-1 and -2 [13].

Many reports have suggested that gabapentin reduces the cellular influx of calcium via voltage-gated calcium channels, identified by study of synaptosome fractions prepared from brain tissue or by electrophysiological techniques. However, not all researchers have found this, perhaps relating to strain differences in the mice used for the research [2,10]. There are also several studies suggesting that gabapentin, and the closely related compound pregabalin, subtly reduces the release of a wide variety of neurotransmitters including noradrenaline, glutamate, acetylcholine, substance P and calcitonin gene-related peptide, as reviewed recently [10]. The connection between gabapentin binding of the α_2-δ subunit, modulation of calcium currents, the reduction of neurotransmitter release and the subsequent clinical effects on seizures or pain remains to be clarified.

Pharmacokinetics

Absorption

Gabapentin is absorbed from the gastrointestinal tract through an active transport system, the efficiency of which decreases and becomes saturated at higher doses [10]. Absorption and bioavailability of gabapentin vary between patients, such that different doses may be required for therapeutic effect [14]. Peak serum concentrations are attained in 2–3 h. The oral bioavailability of gabapentin is about 60% after a 300-mg dose, but only around 40% following a 600-mg dose and about 35% at a steady-state dose of 1600 mg three times per day [15]. Interestingly, with doses above 3600 mg/day, there appears to be significantly increased oral bioavailability by using four rather than three doses per day [16]. This, of course, must be weighed against the inconvenience of such frequent dosing.

Since the half-life of gabapentin is fairly short (little more than 5 h [17]) it takes only 1–2 days before steady state is achieved with repetitive dosing [3]. Because of dose-dependent bioavailability, the relationship between serum gabapentin concentration and dose is non-linear, with less than proportional increases in serum levels when dosage is increased.

Distribution

Gabapentin has minimal or no binding to plasma proteins [15] and it has a volume of distribution of approximately 60 L, or 0.65–1.04 L/kg [3]. Gabapentin readily crosses the blood–brain barrier via the L-amino acid transport system, which, in animals, appears to be saturable [18]. The concentration found in human cerebrospinal fluid (CSF) is approximately 7–35% of that in plasma [19], with CSF levels continuing to rise for hours after peak plasma levels are achieved.

Elimination

Although in the dog there is considerable formation of *N*-methylgabapentin, no biotransformation of gabapentin has been observed in man [15]. In humans, gabapentin is excreted unchanged in the urine, and has an elimination half-life of 5–9 h in patients with normal renal function [20]. There is no significant effect of gender, but a significant linear decrease in clearance has been observed in patients between the age of 20 and 78 years [21].

The relatively slow absorption of gabapentin from the gut implies that fluctuations in serum drug concentrations at steady state are less marked than expected on the basis of the short half-life [22,23]. This, and the fact that accumulation of gabapentin in the central nervous system (CNS) continues beyond attainment of maximum serum concentrations, may explain its clinical efficacy when administered either two or three times per day [23].

Pharmacokinetics in special groups

Clearance is fastest in young children, and those from 1 month to 5 years of age require approximately 30% higher dosing rates than children aged 5–12 years old [24,25]. In 48 healthy children aged between 1 month and 12 years, peak plasma concentrations occurred 2–3 h after administration [24]. An Italian group [26] studied gabapentin plasma concentrations in a group of 41 patients with refractory epilepsy and confirmed that children may require larger doses of gabapentin than adults to achieve comparable drug plasma concentrations. At the other extreme of age, in the elderly, plasma gabapentin concentrations are higher than in non-elderly adults taking the same dose, presumably due to an ageing-related decrease in renal function [21].

Little is known of the pharmacokinetics of gabapentin in pregnancy. Ohman and colleagues [27] reported on the pharmacokinetics of gabapentin at delivery, and during the neonatal period and lactation. They reported drug accumulation in the fetus, possibly due to function of the L-type amino acid transporter system in the placenta. Transfer of gabapentin to breast milk was found to be extensive, but plasma levels in the breastfed newborn were low (12% of the mother's plasma level). In the newborn period there seemed to be a lower capacity to eliminate gabapentin than in adults.

The elimination half-life of gabapentin is prolonged with renal failure, and the clearance of the drug has been found to be proportional to creatinine clearance [3,20]. Tables to guide dosage in renal impairment are included in the product information sheet.

Drug interactions

There are no interactions between gabapentin and hepatically cleared medications since gabapentin is not metabolized in the liver and does not induce or inhibit cytochrome P450 drug-metabolizing enzyme systems or uridinediphosphoglucuronyl transferase isoenzymes. To date, no significant interactions have been reported between gabapentin and other antiepileptic medications. There is no interaction with a contraceptive regimen of norethindrone acetate and ethinylestradiol [28].

Antacids containing aluminium or magnesium hydroxide can reduce gabapentin absorption by about 20% [3,29], so it is recommended that administration of antacids and gabapentin should be separated by at least 2 h.

Serum level monitoring

Gabapentin should be titrated according to clinical effect. It is generally not helpful to monitor the serum levels of gabapentin, although in difficult individual cases an argument could be made for measurement to document 'therapeutic' drug levels and confirm compliance, or to document that high levels are ineffective [30].

The reference range has been estimated at approximately 2–20 mg/L, a figure derived from the trials of patients treated with therapeutic doses. There is evidence that serum drug concentrations below 2 mg/L are less likely to be effective [31]. Case reports suggest the development of tremor and mild changes in cognition with much higher serum levels (up to 85 mg/L) but a lack of serious toxicity even in overdose [32,33].

Efficacy

The efficacy of gabapentin has been subject to a number of recent reviews [34–36]. It should be highlighted that the dose of gabapentin used in many early trials was relatively low (up to 1800 mg/day), and efficacy may be improved by higher doses up to, and in some cases exceeding, 3600 mg/day [30].

Gabapentin as adjunctive therapy in epilepsy

Refractory partial seizures in adults

There have been four randomized placebo-controlled trials providing class I evidence of the efficacy of gabapentin as adjunctive therapy in adults with refractory partial-onset seizures [31,37–39] (Table 41.1). Each had a treatment phase of approximately 3 months' duration. Overall, these trials indicated that with daily doses of 1200–1800 mg, 23–33% of patients showed a more than 50% reduction in seizure frequency compared with baseline. The discontinuation rate of gabapentin because of adverse events ranged between 3% and 11.5%. In the four placebo-controlled trials, higher doses yielded higher responder rates.

The Study of Titration to Effect Profile of Safety (STEPS) trial used open-label gabapentin as adjunctive treatment in 2216 patients with partial epilepsy, with doses up to 3600 mg/day [40]. An increase was noted in the cumulative percentage of responders and of seizure-free patients as dose increased. In addition, a small observational study of 50 patients provides some evidence of additional benefit with very high doses of gabapentin (up to 6000 mg/day) [41].

Refractory partial seizures in children

Class I evidence of the efficacy of gabapentin as add-on treatment for intractable partial seizures comes from a multicentre double-blind placebo-controlled study of 247 children aged 3–12 years [42]. Gabapentin was titrated to a dose of 23–35 mg/kg/day. Children taking gabapentin had a median reduction in frequency of complex partial seizures of 35% (versus a 12% reduction on placebo), and a reduction in frequency of secondary generalized seizures of 28% (versus a 13% increase on placebo).

The efficacy of gabapentin adjunctive therapy for partial seizures in very young children has been assessed in a study of 76

Table 41.1 Summary of randomized placebo-controlled controlled trials of gabapentin as adjunctive therapy in adults with refractory partial seizures.

	Number of evaluable patients (total)	Number of patients and dose of gabapentin		Responder rate (%)	Median decrease in seizure frequency (%)	Discontinuation rate (%)
		n, evaluable	Daily dose (mg)			
UK gabapentin study [37]	113 (127)	52	1200	25 ($P = 0.04$)	29.2	12

Responder rate = percentage of patients with at least 50% reduction in seizure frequency from baseline to treatment. Responder rate and median decrease in seizure frequency are calculated from the total number of evaluable patients after exclusions. *P*-values are reported where available.
NS, not significant

patients aged between 1 and 36 months [43]. Partial seizures were diagnosed either by electroencephalographic capture of a focal seizure, or by matching clinical semiology to a focal abnormality on EEG or brain imaging. A 40 mg/kg/day dose of gabapentin (intended to be equivalent to 30 mg/kg/day in older children and 1200 mg/day in adults) was compared with placebo. The rate of partial seizures was calculated by a blinded observer during 48 h of video-electroencephalography performed at baseline, and 72 h during the double-blind phase. Gabapentin was well tolerated, but although there was a slight effect on seizure frequency in favour of gabapentin, the result was not significant.

Primary generalized seizures

A double-blind placebo-controlled trial of 129 patients aged 12 years and over assessed the potential value of gabapentin as add-on treatment of refractory generalized seizures in patients with idiopathic or symptomatic generalized epilepsies [44]. Patients were randomized to receive either placebo or gabapentin 1200 mg/day in addition to their usual medication. Although an intention-to-treat and evaluable-patient analysis both showed that gabapentin caused greater reduction in the frequency of generalized tonic–clonic seizures than placebo, the result did not reach significance. This may reflect the low dose of gabapentin chosen. No effect was seen on absence or myoclonic seizures. Results in the subgroup of children included in this study were not reported separately.

Gabapentin as monotherapy in epilepsy

Conversion to monotherapy in patients with refractory partial seizures

In a randomized double-blind study, 275 patients with complex partial or secondary generalized seizures were randomized to receive 600, 1200 or 2400 mg/day gabapentin [45] and then underwent a gradual withdrawal of their baseline antiepileptic drug (AED) therapy. If seizure deterioration occurred during the withdrawal phase, patients were required to exit the study. There was no dose–response relationship in outcome measures including time to exit, completion rate and mean time on monotherapy. Overall, completion rate was only 20%, perhaps reflecting the difficulty in converting from polytherapy to monotherapy. Completion rates were higher among patients who had discontinued one AED (23%) than two AEDs (14%), and higher among patients who were not withdrawn from carbamazepine (27%) than among those who were (16%).

Short-term presurgical assessment in patients with refractory partial seizures

An inpatient double-blind study conducted in the USA compared a daily gabapentin dose of 300 mg versus 3600 mg in 82 patients, all of whom had their usual medication stopped for inpatient recording of their seizures [46]. The outcome variable was median time to exit (due to defined seizure-related endpoints or adverse events) in the course of an 8-day period, which was found to be significantly longer for the higher dose of gabapentin (151 h versus 85 h).

Studies in patients with predominantly newly diagnosed partial seizures

A randomized trial compared outcome in 218 patients treated with gabapentin monotherapy for newly diagnosed partial seizures (300, 900, 1800 mg/day) and 74 patients treated with 600 mg/day carbamazepine [47]. The allocation to carbamazepine or gabapentin was not blinded but the dose of gabapentin was double blind. Patients were required to exit if they experienced three simple or complex partial seizures, one generalized tonic–clonic seizure or status epilepticus. In addition, patients could be withdrawn for lack of efficacy, adverse events or non-compliance. Completion rate was 37% in the carbamazepine group versus 25%, 39% and 38% in the gabapentin groups at 300, 900 and 1800 mg/day respectively.

Although the completion rates for 900 and 1800 mg/day of gabapentin were similar to that of carbamazepine, more patients exited from the gabapentin arms due to seizures (40% and 43% respectively) than from the carbamazepine arm (30%), but more patients withdrew due to adverse events while taking carbamazepine (24%) than gabapentin (4% and 14%).

A subsequent double-blind, randomized, multicentre study of gabapentin versus lamotrigine monotherapy was completed in 309 patients with newly diagnosed partial and/or generalized tonic–clonic seizures [48]. Gabapentin was maintained at 1200–3600 mg/day, and lamotrigine at 100–300 mg/day. Overall, 72% of the gabapentin group and 67% of the lamotrigine group completed the 30-week study, and 76% of patients in both groups were seizure free for the final 12 weeks of treatment, a period shorter than desirable in assessing efficacy in newly diagnosed patients. The number of patients with primarily generalized tonic–clonic seizures in this study was too small for a meaningful subgroup analysis. However, it is of interest that five (16.1%) of the 31 patients with primarily generalized tonic–clonic seizures randomized to gabapentin met exit criteria, while none of the 27 patients with primarily generalized tonic–clonic seizures randomized to lamotrigine met exit criteria.

The recently completed SANAD trial in the UK compared gabapentin with carbamazepine, oxcarbazepine, topiramate and lamotrigine in 1791 patients with mostly (89%) partial epilepsy for whom carbamazepine was considered a preferable choice to valproate [49]. This randomized open-label trial included predominantly (82%) newly diagnosed patients, although patients who had been given earlier suboptimal treatment or had relapsed after withdrawal of effective therapy were not excluded. The study showed that time to treatment failure (defined as stopping the randomly assigned drug due to inadequate seizure control or intolerable side-effects, or the addition of other AEDs) was significantly better with lamotrigine than with gabapentin [hazard ratio 0.65; 95% confidence interval (CI) 0.52–0.80] when prescribed at the usual dose used by the clinician [49]. For the other primary outcome measure, time to 12-month remission, carbamazepine was significantly better than gabapentin [hazard ratio 0.75 (0.63–0.90)].

Newly diagnosed absence seizures

A total of 33 children aged 4–12 years with newly diagnosed absence epilepsy were included in two identical, double-blind, placebo-controlled trials, in which gabapentin was tested at doses of 9.7–19.1 mg/kg/day [50]. A 2-week double-blind treatment phase was followed by a 6-week open-label phase. Gabapentin did not significantly decrease or increase seizure frequency (derived from quantified EEGs) compared with placebo in this study, although the lack of efficacy may relate to the relatively low doses used.

Gabapentin in non-epilepsy indications

Gabapentin has efficacy in a number of non-epilepsy indications (reviewed in ref. 50). In particular, it has shown efficacy in neuropathic pain, particularly postherpetic neuralgia [52] and diabetic neuropathy [53]. It has also been useful in trigeminal neuralgia. The Cochrane group has analysed 15 studies of the use of gabapentin in acute, chronic or cancer pain, including a total of 1468 patients [54]. In chronic pain, the number needed to treat (NNT) was 4.3 (95% CI 3.5–5.7), whereas it was 3.9 in postherpetic neuralgia and 2.9 in diabetic neuropathy. In addition, there are reports that gabapentin may be useful in movement disorders, migraine prophylaxis, perioperative pain and cocaine dependence.

Adverse effects

General overview of the most common adverse effects

The adverse effects of gabapentin tend to be CNS related, mild to moderate in severity, and present primarily in the first 2–3 weeks of treatment [30]. A review of adverse events reported in 1748 patients treated in early trials confirmed the good tolerability of this agent [55] (Table 41.2). Overall, only 7.4% of patients treated with gabapentin withdrew due to an adverse event compared with 3.3% of 485 patients taking at least one AED but prescribed placebo rather than gabapentin. The most common adverse events were somnolence and dizziness.

An open-label French study investigated the use of gabapentin as an add-on drug in 610 patients with partial epilepsy [56]. There was little difference in tolerability when gabapentin was used at doses between 900 and 2400 mg/day. The most common adverse effects were (in decreasing order of incidence) somnolence, asthenia, weight gain, nausea, ataxia and vertigo. A tolerability analysis from the STEPS trial, an open-label study of gabapentin as adjunctive therapy for partial seizures, showed good tolerability up to doses of 3600 mg/day, but beyond that dose there were too few patients to draw meaningful conclusions [57].

A number of studies permit an assessment of tolerability as a function of the starting dose and rate of titration. In a randomized controlled trial of 574 patients with partial seizures, gabapentin initiation at 900 mg/day was more likely to cause dizziness than

Table 41.2 Summary of the adverse events reported in 1748 patients treated with gabapentin in early trials.

Number (%) of patients with one or more adverse events	Controlled studies		All studies
	Placebo (n = 307)	Gabapentin (n = 485)	Gabapentin (n = 1160)
	174 (56.7)	369 (76.1)	944 (81.1)
Adverse events			
Somnolence	30 (9.8)	98 (20.2)	283 (24.4)
Dizziness	24 (7.8)	87 (17.9)	235 (20.3)
Ataxia	16 (5.2)	64 (13.2)	202 (17.4)
Fatigue	15 (4.9)	54 (11.1)	171 (14.7)
Nystagmus	15 (4.9)	45 (9.3)	174 (15.0)
Headache	28 (9.1)	42 (8.7)	176 (15.2)
Tremor	12 (3.9)	35 (7.2)	174 (15.0)
Diplopia	6 (2.0)	31 (6.4)	124 (10.7)
Nausea and/or vomiting	23 (7.5)	29 (6.0)	108 (9.3)
Rhinitis	12 (3.0)	22 (4.5)	101 (8.7)

a 3-day dose titration (10.5% versus 6.4% respectively) [58]. However, there was no significant difference in the incidence of fatigue, ataxia or somnolence, suggesting that rapid initiation is generally well tolerated. It should be stressed that high starting doses of gabapentin are certainly feasible in the acute situation, and starting doses up to 3600 mg/day have been tolerated in some double-blind multicentre trials. In one such study, adverse events were reported in a higher proportion of patients treated with an initial daily dose of 3600 mg than with 300 mg (73% versus 52%), but most of these were of mild to moderate intensity, and the duration of adverse events was shorter in patients receiving the higher dose (mean duration 28 h versus 39 h in those treated with 300 mg/day) [46].

Randomized add-on placebo-controlled clinical trials have shown that increases in partial seizure frequency of at least 50% or at least 75% are *no more* likely with gabapentin than with placebo [37,39]. There are, however, several reports of seizure aggravation by gabapentin, mostly in patients with generalized epilepsies. Most are anecdotal, unquantified and do not involve rechallenge. In one of the most comprehensive reports, based on a review of clinic charts of 104 consecutive patients started on add-on gabapentin, there were 13 cases of subtle myoclonus, which was multifocal in 10 and focal (contralateral to the epileptic focus) in three [59]. Six patients had a severe chronic static encephalopathy, while five had no diagnosis other than seizures. Two patients had an exacerbation of pre-existent myoclonus. An EEG recorded during myoclonus in three patients showed no correlate. Withdrawal of gabapentin resulted in rapid cessation of the myoclonus, although discontinuation of therapy was not deemed necessary in most cases. Patients with renal failure appear to be at special risk of developing a more disabling myoclonus [60].

Less common adverse effects of gabapentin include diplopia, tremor, dystonia, rhinitis and non-pitting leg oedema.

Serious, rare and long-term effects

Serious idiosyncratic reactions with gabapentin are extremely uncommon, and gabapentin has a much lower potential to cause hypersensitivity reactions than many other AEDs, such as carbamazepine and lamotrigine [61].

Prescription event monitoring of 3100 patients in the UK (136 of whom were children) found no previously unrecognized adverse events [62]. Two cases of hyponatraemia were possibly related to gabapentin, three cases of hair loss were reported after at least 6 months' treatment, and there were 17 cases of overdose recorded. A review of serious, rare or long-term adverse events concluded that oedema and myoclonic jerking might be a consequence of high doses of gabapentin, hyponatraemia might be a rare event and hair loss could be a long-term effect of gabapentin treatment. Although cancers and infections were observed in a few patients, they were not positively linked to gabapentin.

A case of rhabdomyolysis considered to be caused by gabapentin in an elderly woman with neuropathic pain was recently reported [63].

Use in pregnancy

Published data from the prospective UK Epilepsy and Pregnancy Register include 31 pregnancies in which the mother was exposed to gabapentin monotherapy. Only one major congenital malformation (a ventricular septal defect) was detected [64]. The Neurontin Pregnancy Registry, which included both prospective and retrospective data, reported no malformations in babies born of 11 mothers taking gabapentin monotherapy throughout pregnancy [65]. In another study, no congenital anomalies were reported in 11 births in which the fetus was exposed to gabapentin in the first trimester [66]. These data are insufficient to determine possible risks associated with gabapentin treatment in pregnancy.

Place in current therapy

Main indications

Gabapentin is effective in focal epilepsies but *may* aggravate generalized epilepsies. Gabapentin is widely perceived to be better tolerated than most other AEDs, but possesses relatively poor efficacy. This perception probably arises, at least in part, from the relatively low doses used in the pivotal clinical trials. Post-marketing open-label studies have demonstrated greater efficacy with higher doses.

A few studies have been performed to compare gabapentin with other AEDs, including carbamazepine [47,49], lamotrigine [48,49], oxcarbazepine [49] and topiramate [49]. Conclusions are limited by methodological issues. In the SANAD study [49], gabapentin was inferior to lamotrigine in time to treatment failure and to carbamazepine in time to 12-month remission.

In another study comparing gabapentin with carbamazepine, carbamazepine demonstrated superior efficacy, but at the expense of more frequent adverse events [47]. Compared with lamotrigine, gabapentin may show inferior effectiveness [49] but it has the advantage of lacking the potential for serious adverse effects, such as cutaneous hypersensitivity [48,49], and can be introduced much more rapidly.

In general, the main advantages of gabapentin are that it is safe and well tolerated, with lack of drug interactions and a wide therapeutic index. Rapid titration is generally well tolerated and is without significant risk of serious adverse effects. It may be an appropriate choice in patients who have demonstrated a low threshold for adverse effects with other AEDs, in those with hepatic failure or in patients in whom drug interactions may have serious consequences.

Gabapentin approval in most countries includes adjunctive and monotherapy use in partial seizures, as well as an indication for neuropathic pain.

Administration and dosage

The current Neurontin® US physician prescribing information states that the starting dose for patients older than 12 years is 300 mg three times per day [67]. In the elderly and in refractory patients on multiple drugs it is usual practice to introduce gabapentin at a slower rate to improve tolerability, for example starting at 300 mg/day and increasing to 600 then 900 mg/day at weeks 2 and 3 respectively. However, if a rapid response is required, starting doses up to 3600 mg/day can be well tolerated. The effective dose of Neurontin® is stated as 900–1800 mg/day, based on double-blind study data [67]. However, post-

marketing experience now supports better antiepileptic effects with higher doses, and many clinicians now routinely raise the dose to 3600 mg/day. There is limited evidence for use of higher doses.

In children 3 to 12 years old, the starting dose can be in the order of 10–15 mg/kg/day in three divided administrations, and may be increased over a period of approximately 3 days to the effective dosage, which is about 40 mg/kg/day in children aged 3 and 4 years, and 25–35 mg/kg/day in children 5–12 years of age. Dosages up to 50 mg/kg/day have been well tolerated.

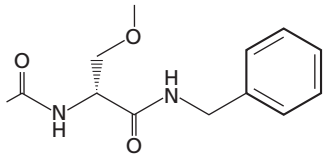
42 Lacosamide

Rajesh Sachdeo
Jersey Shore University Medical Center, Neptune, NJ, USA



Primary indications	Adjunctive therapy of partial-onset seizures with or without secondary generalization in adults with epilepsy
Usual preparation	Tablets: 50 mg, 100 mg, 150 mg, 200 mg Syrup: 15 mg/mL Intravenous solution: 10 mg/mL
Usual dosages	Initial: 100 mg/day. Maintenance: 200–400 mg/day
Dosing frequency	2 times/day
Significant drug interactions	Population pharmacokinetic studies suggest that enzyme-inducing antiepileptic drugs reduce serum lacosamide levels by about 25%
Serum level monitoring	There is insufficient information on the value of monitoring serum lacosamide levels
Reference range	Not clearly defined
Common/important adverse effects (>10%)	Dizziness, headache, nausea, diplopia
Main advantages	Well-documented efficacy, lack of clinically important drug interactions and availability of an intravenous formulation
Main disadvantages	Limited clinical experience, nervous system and gastrointestinal adverse effects
Mechanism of action	Enhances slow inactivation of voltage-gated sodium channels; may interact with collapsin response mediator protein 2 (CRMP-2)
Oral bioavailability	~100%
Time to peak levels	0.5–4 h following oral dosing
Elimination	Partly by excretion in unchanged form in the urine (40% of the administered dose) and partly by metabolism (primarily O-demethylation) followed by excretion
Volume of distribution	0.5–0.8 L/kg
Elimination of half-life	12–16 h
Plasma clearance	No published data
Protein binding	<15%
Active metabolites	None
Comment	A potentially valuable antiepileptic drug, but more data are needed to establish its place in current therapy

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Lacosamide [Vimpat® (SPM 927), formerly known as harkoseride] was specifically synthesized to act as an anticonvulsant, but additional pharmacological properties justifying its evaluation in other indications were subsequently discovered. Studies have been conducted in parallel in patients with epilepsy and in patients with neuropathic pain. Clinical trials completed to date in patients with epilepsy have used lacosamide as adjunctive therapy in refractory partial seizures, but potential usefulness in other epilepsy syndromes is also being investigated.

Lacosamide is unique among existing antiepileptic drugs (AEDs) in that it selectively enhances slow inactivation of voltage-gated sodium channels without affecting fast inactivation. Another unique mechanism which may contribute to its efficacy in epilepsy and neuropathic pain relates to the potential interaction of lacosamide with collapsin response mediator protein 2 (CRMP-2).

Chemistry

Lacosamide is a functionalized amino acid and corresponds chemically to (*R*)-2-acetamido-*N*-benzyl-3-methoxypropionamide. Its chemical formula is $C_{13}H_{18}N_2O_3$. Lacosamide is a white to light-yellow crystalline powder with a molecular weight of 250.30. Its solubility in phosphate-buffered saline (pH 7.5, 25°C) is 20.1 mg/mL.

Pharmacology

Activity profile in experimental models of seizures and epilepsy

Lacosamide shows protective activity against seizures in a variety of experimental models, mostly in the dose range of 1–30 mg/kg intraperitoneally (i.p.) [1]. Models in which anticonvulsant activity has been demonstrated include audiogenic seizures in Frings mice, tonic extension seizures induced by maximal electroshock in mice and rats, and seizures induced by *N*-methyl-D-aspartate (NMDA) administration in mice. Activity has also been demonstrated in the 4-aminopyridine model of epileptiform bursting [2], the 6-Hz psychomotor seizure model of pharmacoresistant epilepsy in mice [1,3], the perforant path model of self-sustained status epilepticus in rats, and the hippocampal-kindled rat model [1,3,4]. Lacosamide effects in the kindling model are not limited to inhibition of kindled seizures, but include a delaying effect on amygdala-kindling acquisition [5].

Lacosamide is ineffective against the clonic seizures induced by pentylenetetrazole and the tonic–clonic seizures induced by picrotoxin and bicuculline in rats and mice. However, lacosamide does increase the threshold for minimal seizures induced by intravenous infusions of pentylenetetrazole in mice [1].

A possible neuroprotective activity of lacosamide against brain damage caused by a variety of experimental insults – including hippocampal damage caused by status epilepticus and infarct size in the rat middle cerebral artery occlusion model of ischemia – has been documented [6].

Activity in models relevant to non-epilepsy indications

Lacosamide is effective in various animal models of chronic pain [1,7].

Mechanisms of action

Enhanced slow inactivation of voltage-gated sodium channels

Unlike other drugs used to treat epilepsy and diabetic neuropathic pain, lacosamide selectively enhances slow inactivation of neuronal voltage-gated sodium channels without affecting fast inactivation (Table 42.1). Depending on the membrane potential and the neuronal activity, voltage-gated sodium channels are in different states. At the resting state, sodium channels are closed and can be opened by depolarization of the cell membrane, allowing sodium ions to enter the cell and thus leading to the initiation of an action potential. The open time of voltage-gated sodium channels is very short (a few milliseconds) and the channel rapidly enters the 'fast inactivated' state (pore occlusion by cytoplasmic domains) from which it cannot be activated. When the membrane potential returns to its baseline (action potential termination), the sodium channel returns to its resting state, from which it may be activated again. Under conditions of slightly prolonged depolarization and sustained neuronal firing activity, the sodium channel can enter the 'slow inactivated' state, which involves the collapse of the inner pore structure. This process happens at a relatively slower rate, taking 1 second to a minute and reduces the long-term availability of voltage-gated sodium channels. Drugs can either block the open channel (e.g. local anaesthetics), enhance fast inactivation (classical sodium channel-blocking AEDs such as carbamazepine or phenytoin) or enhance slow inactivation (lacosamide) [8].

Interaction with CRMP-2

Interaction with CRMP-2 was identified as a second possible mechanism of action for lacosamide. Follow-up experiments suggested a functional interaction of lacosamide with CRMP-2

Table 42.1 Inhibition of sodium current by lacosamide and other antiepileptic drugs with and without removal of fast inactivation.

	Lacosamide	Lamotrigine	Carbamazepine	Phenytoin
% Inhibition of Na^+ current with fast inactivation	32	50	71	48
% Inhibition of Na^+ current after removal of fast inactivation	29	12*	6*	1*

Availability of Na^+ channels was determined in neuroblastoma cells by a 10-msec test pulse to 0 mV from a holding potential of –60 mV. Fast inactivation was removed by a hyperpolarizing pulse to –100 mV (500 msec) prior to the 10-msec test pulse. Concentration of drug was 100 μM for all compounds. *$P < 0.05$ versus % inhibition with fast inactivation.
Data from ref. 1.

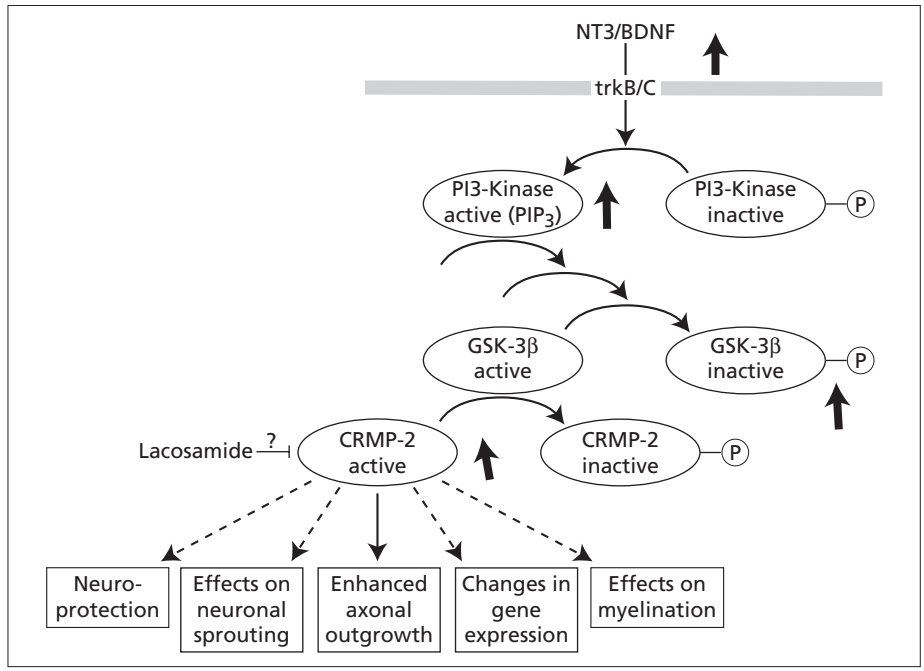


Fig. 42.1 The role of CRMP-2 in the signal transduction cascade of neutrophic factors. From ref. 1 with permission.

in vitro [1]. The confirmation of these initial findings, including more detailed pharmacological investigations, is ongoing.

Neurotrophins such as NT-3 (neurotrophin-3) and BDNF (brain-derived neurotrophic factor) activate their receptors in the plasma membrane, triggering a transduction cascade that regulates the activity of intracellular protein kinases (e.g. PI3 kinase or GSK-3β-glycogen synthase kinase), and results in increased levels of active CRMP-2. Active, non-phosphorylated CRMP-2 has been shown to enhance axonal outgrowth and might also be involved in the induction of other cellular responses (Fig. 42.1). Clinically, an interaction of lacosamide with CRMP-2 may prevent the formation of abnormal neuronal connections in the brain; however, the role of CRMP-2 interaction in seizure control has yet to be determined.

Brain-derived neurotrophic factor is also directly involved in the development of epilepsy [9,10] and neuropathic pain [11,12]. Lacosamide could interfere with these neurotrophin-induced processes and potentially attenuate the development and/or progression of epilepsy and/or neuropathic pain. Neuroprotective effects of lacosamide were observed *in vivo* in animal models, such as following status epilepticus. Bretin *et al*. [13] suggested recently that collapsin response mediator proteins, in addition to their role in neuronal morphogenesis, may contribute to neuronal plasticity. They specifically demonstrated that CRMP-2 is involved in the downregulation of the *N*-methyl-D-aspartate receptor subunit NR2B, a key modulator of pain transmission.

Further experiments to examine the possible interaction between lacosamide and CRMP-2, followed by appropriate clinical trials, should determine whether or not this novel mechanism of action can result in symptomatic and/or disease-modifying effects.

Pharmacokinetics

Key pharmacokinetic features

Lacosamide is rapidly and completely absorbed after oral administration, with negligible first-pass effect [14]. The oral bioavailability is approximately 100%. Peak plasma concentrations occur between 0.5 and 4 h post dose, or immediately following i.v. infusion (i.e. at the end of infusion) [14]. Plasma concentrations are proportional to dose, with low intra- and inter-subject variability. The influence of concomitant food intake on the bioavailability of lacosamide was evaluated in a food interaction study in which lacosamide was given as tablets (three tablets of 100 mg) after a high-fat breakfast or in a fasting state. The results of this study demonstrated that food has no influence on the pharmacokinetics of lacosamide [15].

When administered intravenously over 15 min, the parenteral formulation was shown to be bioequivalent to the tablet formulation with respect to area under the plasma concentration–time curve [$AUC_{(0-tz)}$] but not with respect to C_{max}, which slightly exceeded the upper boundary of the generally accepted bioequivalence range (0.8–1.25) [16]. Bioequivalence was demonstrated with respect to both C_{max} and AUC using 30- and 60-min infusion durations [17]. Bioequivalence has also been shown between two 100-mg tablets of lacosamide (200 mg) and a syrup containing lacosamide 200 mg (10 mg/mL) after oral single-dose administration in healthy subjects.

Lacosamide is negligibly (<15%) bound to plasma proteins and is distributed in total body water, with an apparent volume of distribution of about 0.5–0.8 L/kg.

The half-life of lacosamide is approximately 12–16 h and is not influenced by dose, route of administration (oral or intravenous) or duration of treatment (single versus multiple dosing) [14].

Following twice-daily dosing, steady-state plasma concentrations are achieved after 3 days [18].

Approximately 40% of orally administered lacosamide is excreted unchanged in the urine, and another 30% is recovered in the form of the inactive O-desmethyl-metabolite SPM 12809. SPM 12809 has no known pharmacological activity and its concentration in plasma amounts to approximately 10% of the plasma concentration of the parent compound. The cytochrome P450 isoenzyme CYP2C19 is involved in the formation of SPM 12809, since the plasma concentration of SPM 12809 is reduced in poor CYP2C19 metabolizers and in the presence of CYP2C19 inhibitors; however, the CYP2C19 genotype seems to have no major influence on plasma lacosamide concentrations [19].

Pharmacokinetics in special populations

There are limited data on the influence of age on lacosamide pharmacokinetics. In a study conducted in 23 subjects over 65 years of age (age range not stated), steady-state plasma lacosamide concentrations were 10–35% higher than those recorded in non-elderly adults [18], which may be due to differences in body weight as well as decreased renal function in the elderly.

Since renal excretion contributes significantly to the elimination of lacosamide and SPM 12809, exposure to the parent drug and to its main metabolite increases with increasing degree of renal impairment. Exposure to lacosamide, measured as area under the plasma concentration–time curve during a dosing interval at steady state [$AUC_{(0-\tau)ss}$], in subjects with mild or moderate renal impairment is increased by approximately 30% compared with healthy subjects. In subjects with severe renal impairment, an approximately 60% increase in exposure compared with healthy subjects is seen. Based on the described data, no dose adjustments should be necessary in subjects with mild and moderate impairment of renal function (CLcr >30 mL/min). Subjects with severe renal impairment (CLcr ≤30 mL/min) are expected to have a considerably higher exposure to lacosamide (approximately 60% higher) than subjects with normal renal function. Therefore, the lacosamide dose for subjects with severe and end-stage renal disease should not exceed 250–300 mg/day [20,21].

Lacosamide is cleared by haemodialysis. A dose supplement of up to 50% of the divided daily dose for patients following haemodialysis should be considered [20]. Subjects with hepatic impairment (Child–Pugh score B) showed approximately 50% higher systemic exposure to lacosamide in comparison with healthy subjects, which was attributed, in part, to reduced renal function in these patients. No dosage adjustment is thought to be needed in patients with mild to moderate hepatic insufficiency, but titration should proceed with caution [20]. Patients with severe hepatic impairment have not been studied.

Drug interactions

Overall, lacosamide exhibits a low drug–drug interaction potential, and no dose adjustment is necessary when lacosamide is coadministered with other drugs [22].

Effects of other drugs on lacosamide

In clinical pharmacology studies, concomitant treatment with carbamazepine 400 mg/day or valproic acid 600 mg/day had no influence on plasma lacosamide concentrations [14,19]; however, in a population pharmacokinetic study in subjects with partial-onset seizures, comedication with enzyme-inducing antiepileptic drugs (AEDs) (carbamazepine, phenytoin, phenobarbital) reduced lacosamide exposure by 25% [23].

Digoxin, metformin, omeprazole and a combined oral contraceptive were not found to influence to a clinically significant extent the pharmacokinetics of lacosamide [19].

Effect of lacosamide on other drugs

In human hepatocytes, lacosamide at 100 μM/L (25 μg/mL) showed no potential to induce or inhibit the activity of CYP isoforms 1A2, 2B6, 2C9 and 3A4, but *in vitro* inhibition of CYP2C19 by lacosamide was observed with an IC_{50} of 1797 μM [1]. In subsequent studies with the recombinant human enzymes CYP1A1, 1A2, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4 and 3A5, lacosamide showed no or low inhibitory interactions, suggesting a low risk for inhibition of CYP isoforms *in vivo*. In clinical pharmacology studies, lacosamide plasma concentrations were comparable among both extensive and poor metabolizers of CYP2C19 [22].

In clinical studies, lacosamide was generally well tolerated when administered concomitantly with one to three AEDs. There was no indication that steady-state plasma concentrations of concomitant AEDs [e.g. levetiracetam, carbamazepine, carbamazepine-10,11-epoxide, lamotrigine, topiramate, the oxcarbazepine monohydroxy derivative (MHD), phenytoin, valproic acid, gabapentin and zonisamide] were affected by concomitant intake of lacosamide at any dose [22,24].

Multi-dose drug–drug interaction studies in healthy subjects showed that lacosamide 200 mg twice daily (b.i.d.) had no influence on the pharmacokinetics of digoxin and metformin [22]. Likewise, there was no influence of lacosamide 200 mg b.i.d. on the pharmacokinetics and hormonal effects of an oral contraceptive containing 0.03 mg ethinylestradiol and 0.15 mg levonorgestrel in healthy subjects [19].

Serum level monitoring

There is insufficient information on the value of monitoring lacosamide plasma concentrations, and there is no indication that monitoring lacosamide plasma concentrations may help in individualizing therapy, except for compliance assessment.

Efficacy

Adjunctive treatment with lacosamide was evaluated in a number of phase II and III trials in adults with simple partial-onset seizures and/or complex partial-onset seizures, with or without secondary generalization. Both the oral and parenteral formulations were tested in clinical trials, although the i.v. formulation was studied for safety only. Lacosamide also underwent a parallel clinical development in patients with diabetic

neuropathic pain. Controlled clinical trials in patients with partial-onset seizures have been published or presented as abstracts [24–26].

A first phase II study was performed to define the maximum tolerated dose (MTD) of lacosamide by testing a dose range of 100 mg/day to 600 mg/day [27]. The median MTD for the sample was 300 mg/day, but approximately 50% of subjects had an MTD of 400–600 mg/day. Based on these findings, three lacosamide doses (200 mg, 400 mg and 600 mg/day) were selected for the pivotal trials. Lacosamide 600 mg/day is not an approved dose by either the European Medicines Agency (EMEA) or Food and Drug Administration (FDA).

Placebo-controlled trials in partial-onset seizures

The three randomized placebo-controlled clinical trials in epilepsy patients used a similar double-blind parallel-group design, which involved a titration period in which lacosamide was increased up to the target dose in 100 mg/day weekly increments, followed by a 12-week maintenance period. All three trials demonstrated the efficacy of adjunctive lacosamide therapy in adults with partial-onset seizures compared with placebo.

The primary objective of the first trial was to evaluate the efficacy and safety of lacosamide 200 mg/day, 400 mg/day and 600 mg/day administered on a b.i.d. schedule as adjunctive therapy in adults (18–65 years) with uncontrolled partial-onset seizures currently treated with one or two AEDs [24]. In order to be randomized in the trial, patients had to experience an average of at least four partial-onset seizures per 28 days during an 8-week prospective baseline. Following the baseline period, eligible patients were randomized in a 1:1:1:1 ratio to one of four treatment arms: placebo or lacosamide 200 mg/day (100 mg b.i.d.), 400 mg/day (200 mg b.i.d.) or 600 mg/day (300 mg b.i.d.). The titration period lasted 6 weeks and was followed by a 12-week maintenance period. A single backtitration by 100 mg was allowed at the end of the titration period for patients experiencing significant adverse events. A total of 418 patients were randomized in this trial. These patients were highly refractory as demonstrated by the fact that approximately 50% of patients had tried seven or more AEDs in their lifetime and that the median baseline seizure frequency across all treatment groups was 11 to 13 seizures per 28 days. The primary efficacy variable, median percent reduction in seizure frequency from baseline to maintenance, was 10% in the placebo group and 26%, 39% and 40% in the lacosamide 200 mg/day, 400 mg/day and 600 mg/day groups, respectively. Reductions in seizure frequency over placebo were significant for the lacosamide 400 mg/day (28.4%, $P = 0.0023$) and 600 mg/day (21.3%, $P = 0.0084$) groups. Although there was a statistical trend favouring the lacosamide 200 mg/day group, the median percent reduction in seizure frequency per 28 days over placebo did not reach statistical significance (14.6%, $P = 0.10$). A significant proportion of patients experienced a 50% or greater decrease in seizure frequency during the maintenance period when treated with lacosamide 400 mg/day (41.1%, $P = 0.0038$) and 600 mg/day (38.1%, $P = 0.0141$) compared with placebo (21.9%). A total of 32.7% of 200 mg/day lacosamide-treated patients had a 50% or greater decrease in seizure frequency during the maintenance period ($P = 0.0899$ compared with placebo).

The second placebo-controlled trial was conducted in 485 patients with refractory partial-onset seizures receiving up to three AEDs, and explored lacosamide doses of 200 and 400 mg/day [25]. Significant median percent reductions in seizure frequency of 35% and 36% for lacosamide 200 and 400 mg/day, respectively ($P < 0.05$ vs. placebo for both doses), were observed compared with 21% for placebo. The proportion of patients showing at least a 50% reduction in seizure frequency was 26% in the placebo group, 35% in the 200 mg/day group, and 41% in the 400 mg/day group ($P < 0.01$ for the 400 mg/day group) [14,25].

In the third trial, 405 patients with refractory partial-onset seizures receiving up to three AEDs were randomized to placebo or to target lacosamide doses of 400 or 600 mg/day [26]. A reduction in seizure frequency of at least 50% was recorded in 38.3% of patients treated with 400 mg/day and in 41.2% of patients treated with 600 mg/day lacosamide compared with 18.3% of patients allocated to placebo. The difference versus placebo was statistically significant at both doses.

In conclusion, lacosamide demonstrated clear efficacy in a highly refractory population, with responder rates falling within the range of marketed AEDs [28]. Among the patients who completed the pivotal trials, 3.3% and 4.8% of those taking 400 mg/day and 600 mg/day lacosamide, respectively, were seizure free as compared with 0.9% of the patients in the placebo arm (Fig. 42.2). While these figures seem to be modest, the pivotal lacosamide trials were conducted in a highly refractory population [29].

Long-term efficacy in patients with partial-onset seizures

The long-term efficacy of lacosamide is being evaluated in open-label extension trials, which included patients who had participated in the double-blind studies. In an interim analysis of one of these trials, conducted 30 months after the last subject had entered the trial (exposure up to 5.5 years), the median modal dose was 400 mg/day. In general, the median percent reduction in seizure frequency across all treatment groups was 45.9%. In

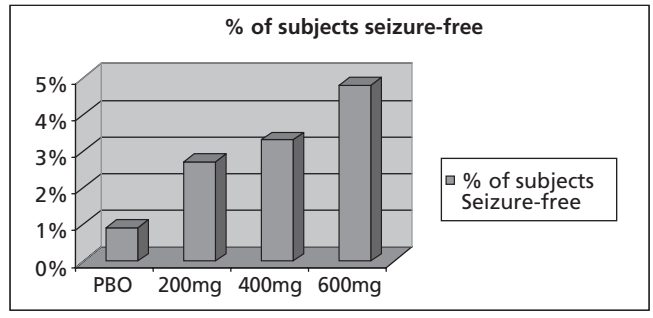

Fig. 42.2 Percentage of subjects who completed the trial and were seizure free during the double-blind maintenance phase in a pooled analysis of the three pivotal randomized placebo (PBO)-controlled adjunctive-therapy trials of lacosamide (200, 400 and 600 mg/day) in adults with refractory partial-onset seizures. From ref 29 with permission.

terms of responder rates, 46.6% of patients had a ≥50% reduction in seizures [30]. Some patients discontinued from the open-label trials due to lack of efficacy (as per protocol), which may have resulted in trends towards better efficacy over time. Therefore, these data should be viewed for descriptive purposes only.

Studies in non-epilepsy indications

A number of randomized placebo-controlled double-blind trials evaluated the potential value of lacosamide in patients with neuropathic pain secondary to distal diabetic neuropathy [31–34]. These studies suggest that lacosamide may be efficacious in attenuating pain in these patients at doses up to 400 mg/day. A dose of 600 mg/day did not appear to confer additional benefit and was less well tolerated.

Adverse effects

Most common adverse events reported in controlled trials

Adverse events observed during the lacosamide clinical programme seem to be consistent with its proposed mechanism of action. AEDs acting through the modulation of sodium currents are associated with dose-related central nervous system (CNS) and gastrointestinal system adverse effects. With lacosamide, dizziness, diplopia and headaches are the most commonly reported CNS adverse events, while nausea and vomiting are the most common gastrointestinal events; all of these events with the exception of headache were dose related (Table 42.2). Of importance, the incidence of somnolence [25] was relatively low, and very few patients treated with lacosamide complained of cognitive difficulties [35].

In the three pivotal, double-blind controlled trials, overall discontinuation rates during the treatment period were 18%, 23% and 38% in the groups assigned to lacosamide doses of 200 mg/day, 400 mg/day and 600 mg/day, compared with 13% among patients randomized to placebo [35]. Dizziness was the most common adverse event leading to premature withdrawal, especially in the 600 mg/day group.

Special safety issues

Lacosamide has been shown to have no effect on QTc interval in a definitive trial which tested doses of 800 mg/day in healthy volunteers [36].

A small, dose-related increase in PR interval was observed with lacosamide treatment. The mean increase from baseline to the end of the maintenance phase was 1.4 ms, 4.4 ms and 6.6 ms for 200, 400 and 600 mg/day lacosamide compared with a 0.3 ms decrease for placebo [34]. In epilepsy patients, the incidence rate of reported treatment-emergent first-degree atrioventricular (AV) block as an adverse event is uncommon (0.4% lacosamide and 0% placebo) [21]. Similar asymptomatic PR prolongations appear to be associated with other AEDs such as carbamazepine [37], lamotrigine [38] and pregabalin [39]. No second- or higher-degree AV block was seen in lacosamide-treated patients with epilepsy. The incidence of syncope was also low and did not differ between lacosamide-treated epilepsy patients (0.1%) and placebo-treated epilepsy patients (0.3%) [20].

In conclusion, the safety profile of lacosamide shows a predominance of dose-related nervous system and gastrointestinal adverse events. PR prolongation and first-degree AV block are being monitored in postmarketing safety studies.

As with all AEDs, suicidality and suicide should be closely monitored especially in the epilepsy population.

Table 42.2 Incidences of treatment emergent adverse events reported by ≥10% of subjects in any lacosamide treatment group, based on a pooled analysis of the three double-blind pivotal lacosamide trials in patients with refractory partial-onset seizures.

Place in current therapy

Lacosamide is a new chemical entity with a novel mode of action, i.e. enhanced slow inactivation of voltage-gated sodium channels and a potential interaction with CRMP-2; however, the precise interaction with CRMP-2 is not fully understood and, at this stage, its implications are rather speculative.

Lacosamide is approved as adjunctive therapy for the treatment of partial-onset seizures in subjects aged ≥16 years in Europe and in subjects ≥17 years in the USA. Lacosamide has a number of advantageous features, including predictable and linear pharmacokinetics with low intra- and inter-patient variability, a half-life compatible with twice-daily dosing, a low potential for drug–drug interactions, and consistent efficacy data when used as adjunctive therapy in adult patients with refractory partial epilepsy. Its potential usefulness in other epilepsy syndromes has not been investigated to date, and its role in the current treatment of epilepsy will be clarified when more extensive data from clinical studies and from postmarketing experience become available. Based on available data, the target dose range appears to be 200–400 mg/day, to be achieved with gradual titration. Although lacosamide 600 mg/day is not an approved dose by either the EMEA or FDA, some patients may benefit from treatment of up to 600 mg/day.

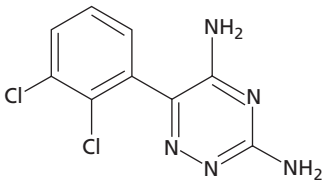
43 Lamotrigine

Fumisuke Matsuo and Awais Riaz

Department of Neurology, University of Utah School of Medicine, Salt Lake City, UT, USA



Primary indications	Adjunctive treatment and monotherapy of partial seizures (with or without secondary generalization) and primary generalized tonic–clonic seizures. Also useful for other generalized epilepsy syndromes, including Lennox–Gastaut syndrome, mostly as adjunctive therapy
Usual preparation	Regular tablets: 25, 50, 100, 150, 200 mg Dispersible tablets: 2, 5, 25, 100 mg Extended-release tablets: in development
Usual dosages	Lamotrigine should be titrated gradually according to pre-established guidelines up to the desired maintenance dose. The following maintenance dosages are often used: Combination therapy without valproic acid and without enzyme-inducing agents: 200–400 mg/day (children 2–12 years of age: 2.5–7.5 mg/kg/day) Initial monotherapy: 100–200 mg/day (over 12 years of age) Combination therapy with valproic acid without enzyme-inducing agents: 100–200 mg/day (children 2–12 years of age: 1–3 mg/kg/day) Combination therapy with enzyme-inducing agents without valproic acid: 300–500 mg/day (children 2–12 years of age: 5–15 mg/kg/day)
Dosing frequency	Once or twice daily, depending on expected half-life in the individual patient and type of formulation
Significant drug interactions	Serum lamotrigine levels are reduced by enzyme-inducing antiepileptic drugs, methsuximide, rifampicin, the lopinavir–ritonavir combination, combined steroid contraceptives and some other oestrogen-containing hormonal preparations. Serum lamotrigine levels are increased by valproic acid. Lamotrigine may reduce the serum levels of levonorgestrel
Serum level monitoring	Dosage is usually individualized based on clinical response. Serum drug level monitoring is particularly useful to guide dosage adjustments in situations associated with changes in lamotrigine pharmacokinetics, such as pregnancy, puerperium and drug–drug interactions
Reference range	2.5–15 mg/L
Common/important adverse effects	Dizziness, diplopia, ataxia, blurred vision, somnolence, insomnia, headache, nausea, asthenia, skin rash (including serious cutaneous reactions) and other hypersensitivity reactions
Main advantages	Relatively broad-spectrum efficacy against multiple seizure types and good tolerability, particularly when used as monotherapy
Main disadvantages	Need for slow-dose escalation. Highly variable pharmacokinetics in relation to physiological factors (e.g. pregnancy) and drug interactions

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Mechanism of action	Blockade of voltage-dependent sodium and calcium channels. Other mechanisms may contribute to antiepileptic efficacy
Oral bioavailability	>95%
Time to peak levels	1–3 h
Elimination	Primarily by conjugation with glucuronic acid
Volume of distribution	1.2 L/kg
Elimination of half-life	Patients on monotherapy, patients on polytherapy receiving neither valproic acid nor enzyme inducers, and patients receiving a combination of valproic acid and enzyme inducers: 25 h Patients receiving valproic acid without enzyme inducers: 60 h Patients receiving enzyme inducers without valproic acid: 13 h The above are mean values and intersubject variability is considerable. Children may have shorter half-lives
Serum clearance	Patients on monotherapy, patients on polytherapy receiving neither valproic acid nor enzyme inducers, and patients receiving a combination of valproic acid and enzyme inducers: 0.50 mL/min/kg Patients receiving valproic acid without enzyme inducers: 0.30 mL/min/kg Patients receiving enzyme inducers without valproic acid: 1.15 mL/min/kg The above are mean values and intersubject variability is considerable. Children have higher clearance values
Protein binding	55%
Active metabolites	None
Comment	A very useful antiepileptic drug which can used as first- or second-line monotherapy, or as adjunctive therapy, in the treatment of partial seizures and in some of the generalized epilepsy syndromes

Introduction

Lamotrigine was initially developed as a folate antagonist after the observation that patients with epilepsy treated with antiepileptic drugs (AEDs) had diminished levels of folic acid [1]. However, no correlation between antifolate effects and AED activity has ever been established, and lamotrigine's antiepileptic acitivity is considered to be mediated by actions other than its weak folate antagonistic properties.

Lamotrigine was introduced for the adjunctive treatment of partial seizures in the UK in 1991, in the USA in 1994, and later worldwide. Its use for initial monotherapy is approved in several countries, but not in the USA, where monotherapy can be attained by successful removal of concurrent AEDs. Its extensive use has also highlighted some unique issues. The manufacturer's product information is regularly updated, and the clinician should refer to the latest version (http://us.gsk.com/products/assets/us_lamictal.pdf).

Chemistry

Lamotrigine [3,5-diamino-6-(2,3-dichlorophenyl)-1,2,4-triazine] has a molecular formula of $C_9H_7N_5Cl_2$, a molecular weight of 256.09 and pK_a of 5.7. It is a white to pale-cream-coloured powder, poorly soluble in water (0.17 mg/mL at 25°C) and slightly soluble in 0.1 M hydrochloric acid (4.1 mg/mL at 25°C).

Pharmacology

Activity in animal models of seizures and epilepsy

A number of electrical, chemical and genetic models of seizures and epilepsy have indicated the therapeutic potential of lamotrigine in the treatment of partial, generalized tonic–clonic and absence seizures [2]. In seizure models, lamotrigine displays an antiepileptic profile broadly similar to that of phenytoin and carbamazepine [3,4]. Lamotrigine was more potent than phenytoin and carbamazepine in these models and in suppressing sound-induced clonic seizures in the genetically epilepsy-prone rat [5]. Compared with other newer AEDs, lamotrigine [intraperitoneal (i.p.) administration] was effective in antagonizing tonic convulsions in the maximal electroshock test, in which gabapentin, tiagabine and vigabatrin had no effect, and was ranked above these agents, in terms of therapeutic index, in the inhibition of sound-induced seizures in DBA/2 mice [6].

Lamotrigine differs from carbamazepine and phenytoin in its effects in some models of absence epilepsy. Even though in

the classic absence model (pentylenetetrazole-induced clonus) lamotrigine, like phenytoin and carbamazepine, failed to show any effect [4,6], in the lethargic mouse model of human absence seizures, i.p. lamotrigine was shown to reduce seizure frequency by 65% compared with vehicle, whereas vigabatrin and tiagabine significantly increased seizure frequency and gabapentin and topiramate had no effect [7].

Lamotrigine produces a dose-dependent suppression of secondary generalized seizures and afterdischarge duration in amygdaloid and hippocampal-kindled seizures in rats (a model of complex partial seizures), with the effect lasting as long as 24 h in some cases [6,8]. This effect was also observed in kindled rats which had previously showed no response to phenytoin. Lamotrigine is thought to produce this effect by increasing afterdischarge threshold, that is by suppression of seizure initiation, not propagation.

Activity in other experimental models

Lamotrigine confers protection against local cerebral ischaemia and reduces kainate-induced neurotoxicity in the rat, presumably by suppressing glutamate release [9–11]. In a rat model of neonatal hypoxic–ischaemic injury, i.p. administration of lamotrigine immediately post insult was shown to significantly decrease neuronal damage in the hippocampus with a concomitant decrease in the tissue levels of glutamate and aspartate and without altering the levels of γ-aminobutyric acid (GABA) [12].

Mechanism of action

Although structurally unrelated to phenytoin and carbamazepine, lamotrigine has been demonstrated to block sodium channels in a voltage-, use- and frequency-dependent manner, preventing propagation of action potentials [13–17] and the release of neurotransmitters, principally glutamate [18–21]. Lamotrigine inhibits voltage-sensitive sodium currents through a preferential interaction with the slow inactivated sodium channel [15], suggesting that it may act selectively against high-frequency epileptiform discharges [13]. In keeping with its cellular actions, lamotrigine suppresses burst firing in cultured rat cortical neurones and sustained repetitive firing in the mammalian spinal cord. Lamotrigine does not affect normal synaptic transmission in hippocampal slices, possibly due to preferential interaction with the slow inactivated sodium channel [22]. Lamotrigine potently inhibits glutamate and aspartate release induced by the sodium channel opener veratrine in rat cerebral cortical slices, and displaces batrachotoxin from its sodium channel-binding site [17,23]. Administration of a subconvulsive dose of *N*-methyl-D-aspartate (NMDA) antagonized the efficacy of lamotrigine in seizures induced by maximal electroshock by increasing its ED_{50} value, and this effect was reversed by simultaneous administration of NMDA receptor antagonists [24].

Lamotrigine has also been shown to modulate the calcium conductance involved in the release of excitatory amino acids in the corticostriatal pathway [21,25–27]. At clinically relevant concentrations, lamotrigine inhibits voltage-activated calcium currents in cortical and striatal neurones, an effect blocked by the N-type calcium channel blocker ω-conotoxin GVIA, but not by nifedipine (a dihydropyridine calcium receptor blocker). This action could inhibit glutamate release presynaptically, as well as prevent calcium overload in neurones through postsynaptic antagonism of voltage-dependent calcium channels [28].

Lamotrigine also appears to affect potassium conductance. In rat neocortical slices, lamotrigine was found to block epileptiform discharges induced by 4-aminopyridine, and in neocortical cell cultures, lamotrigine was shown to potentiate a 4-aminopyridine-sensitive hyperpolarizing potassium current [29].

Lamotrigine lacks any appreciable *in vitro* affinity for dopamine D_1 or D_2, α- or β-adrenergic, adenosine A1 or A2, muscarinic and σ-receptors, but has a weak inhibitory effect on serotonin 5-HT_3 receptors [13,30].

Current research on lamotrigine is also directed at assessing its effects on hippocampal neuronal networks potentially involved in its psychotropic action [31,32]. However, the full impact of data supporting inhibition of neurotransmitter release by lamotrigine should be further examined. Not readily understood is why lamotrigine has a much broader spectrum of clinical activity than either phenytoin or carbamazepine [33]. This difference cannot be easily reconciled by citing the lamotrigine-induced blockade of glutamate neurotransmitter release (an effect secondary to sodium channel blockade) because phenytoin and carbamazepine exhibit similar actions (again, under experimental conditions that may not be clinically relevant). The broader spectrum of activity of lamotrigine in different seizure types may be due to markedly preferential affinities for certain sodium channel subunit combinations, exhibiting differential regional distributions in the brain [34]. Alternatively, there may be an as yet unidentified mechanism of action for lamotrigine that might shed light on this difference.

Kynurenic acid is an endogenous excitatory amino acid receptor antagonist which acts as an antagonist at the glycine binding site on the NMDA receptor (see ref. 35 for review). It has shown antiseizure effect in various animal models. For example, kynurenic acid administration inhibited audiogenic seizures in DBA/2 mice [36]. Co-application of kynurenic acid into the hippocampus was shown to block seizure activity induced by quinolinic acid [37], and local injections of its analogue, 7-chlorokynurenic acid, were shown to delay the development of amygdala-kindled seizures [38]. Lamotrigine, along with other AEDs including phenobarbital, felbamate and phenytoin, was shown to enhance kynurenic acid production in rat cortical slices and to stimulate the activity of kynurenine aminotransferase-1 [39].

Pharmacokinetics

The pharmacokinetic profile of lamotrigine has been studied in the absence and in the presence of other AEDs after single [40–43] and multiple [44,45] doses in paediatric as well as adult patients. The pharmacokinetics of lamotrigine in adults has previously been extensively reviewed [46–49] (Table 43.1), but data in children are more complex (Table 43.2).

Lamotrigine pharmacokinetics is linear, and peak serum concentration (C_{max}) and area under the serum concentration–time curve (AUC) values are directly proportional to dose in the 30–450 mg range in both children and adults with epilepsy [48,50].

Absorption

Lamotrigine is well absorbed following oral administration, displaying an absolute bioavailability of 98% in healthy adult

Table 43.1 Mean[a] pharmacokinetic parameters of lamotrigine in healthy volunteers and in adult patients with epilepsy.

Adult study population	Number of subjects	Time of peak serum concentration (T_{max}) (h)	Half-life (h)	Apparent oral clearance (mL/min/kg)
Healthy volunteers taking no other medications				
Single-dose lamotrigine	179	2.2 (0.25–12.0)	32.8 (14.0–103.0)	0.44 (0.12–1.10)
Multiple-dose lamotrigine	36	1.7 (0.5–4.0)	25.4 (11.6–61.6)	0.58 (0.24–1.15)
Healthy volunteers taking valproic acid				
Single-dose lamotrigine	6	1.8 (1.0–4.0)	48.3 (31.5–88.6)	0.30 (0.14–0.42)
Multiple-dose lamotrigine	18	1.9 (0.5–3.5)	70.3 (41.9–113.5)	0.18 (0.12–0.33)
Patients with epilepsy taking valproic acid only				
Single-dose lamotrigine	4	4.8 (1.8–8.4)	58.8 (30.5–88.8)	0.28 (0.16–0.40)
Patients with epilepsy taking enzyme-inducing AEDs + valproic acid

[a] The majority of parameter means determined in each study had coefficients of variation between 20% and 40% for half-life and apparent oral clearance and between 30% and 70% for T_{max}. The overall mean values were calculated from individual study means that were weighted based on the number of volunteers/patients in each study. The numbers in parentheses below each parameter mean represent the range of individual volunteer/patient values across studies.

[b] Examples of enzyme-inducing AEDs are carbamazepine, phenobarbital, phenytoin and primidone. Methsuximide, oestrogen-containing oral contraceptives, rifampicin and the lopinavir–ritonavir combination have also been shown to increase the clearance of lamotrigine.

Table 43.2 Mean pharmacokinetic parameters of lamotrigine in paediatric patients with epilepsy.

Paediatric study population	Number of subjects	Time to peak serum concentration (T_{max}) (h)	Half-life (h)	Apparent oral clearance (mL/min/kg)
Ages 10 months to 5.3 years				
Patients taking enzyme-inducing AEDs	10	3.0 (1.0–5.9)	7.7 (5.7–11.4)	3.62 (2.44–5.28)
Patients taking AEDs with no known effect on lamotrigine clearance	7	5.2 (2.9–6.1)	19.0 (12.9–27.1)	1.2 (0.75–2.42)
Patients taking valproic acid only	8	2.9 (1.0–6.0)	44.9 (29.5–52.5)	0.47 (0.23–0.77)
Ages 5–11 years				
Patients taking enzyme-inducing AEDs	7	1.6 (1.0–3.0)	7.0 (3.8–9.8)	2.54 (1.35–5.58)
Patients taking enzyme-inducing AEDs plus valproic acid	8	3.3 (1.0–6.4)	19.1 (7.0–31.2)	0.89 (0.39–1.93)
Patients taking valproic acid only[a]	3	4.5 (3.0–6.0)	65.8 (50.7–73.7)	0.24 (0.21–0.26)
Ages 13–18 years

[a] Two subjects were included in the calculation for mean T_{max}.

volunteers. C_{max} occurs at approximately 1–3 h after oral administration in adults [46,48,51], and 1–6 h in children [40,43]. A second peak or plateau may occur at 4–6 h post dose, which is possibly due to enterohepatic recycling of the drug [50]. C_{max} was 1.6 mg/L after a single oral dose of 120 mg in adults, while after a single oral dose of 2 mg/kg a mean C_{max} of 1.48 mg/L was attained in 12 children aged between 6 months and 12 years. Lamotrigine absorption is not appreciably altered by the presence of food.

An extended-release formulation currently in development is associated with a smoother absorption profile, with peak concentrations occurring 4–11 h post dose and reduced fluctuations in serum drug levels during a dosing interval [52].

Distribution

Lamotrigine is approximately 55% bound to plasma proteins *in vitro*. Protein binding is unaffected by therapeutic concentrations of phenytoin, phenobarbital and valproic acid [48].

The volume of distribution was 1.2 L/kg in healthy adult volunteers (range 0.87–1.3 L/kg) [46] and 1.5 L/kg in 12 children with epilepsy receiving single doses of lamotrigine (2 mg/kg) in the absence of other AEDs [40].

Studies in animals show that lamotrigine is widely distributed in all tissues and organs, but little is known of its differential tissue distribution in humans. In 11 adults undergoing neurosurgical intervention, lamotrigine showed good penetration into the brain, with a brain–serum lamotrigine concentration ratio of 2.8 [53,54]. Studies of cerebrospinal fluid (CSF) in children and young adults showed a CSF–serum concentration ratio of 0.43 [41].

Elimination

Lamotrigine is extensively metabolized by the liver, predominantly via N-glucuronidation, which is the rate-limiting step in lamotrigine elimination [46]. Approximately 70% of a single oral dose is recovered in the urine during the first 6 days, of which 80–90% is in the form of the 2-N-glucuronide metabolite, and the remainder in the form of the 5-N-glucuronide and parent drug. About 2% of an oral dose is excreted in the faeces.

The apparent oral clearance of lamotrigine shows great interindividual variation and is significantly influenced by concomitant medication and age [55]. Clearance is increased by 20–170% in children, but not for the first week of life. In comparative studies of lamotrigine monotherapy, apparent oral clearance and volume of distribution values were higher in children (0.038 L/h/kg and 1.5 L/kg) [40] than in adults (0.021–0.035 L/h/kg and 0.9–1.3 L/kg respectively), whereas elimination half-lives were broadly similar in children and in adults (32.3 h in children versus 23–37 h in adults). In the study in children, weight-normalized clearance appeared to be higher in children younger than 6 years (0.05 L/h/kg) than in children aged 6–11 years (0.033 L/h/kg) [40]. Age-related differences in lamotrigine clearance could be attributed to a relative reduction in liver size and hepatic blood flow in adolescents compared with young children [44,56].

In adults, the pharmacokinetics of lamotrigine after multiple dose administration conforms to that predicted from single-dose studies [46], indicating that clinically significant autoinduction does not occur [57]. In keeping with this, lamotrigine does not induce hepatic cytochrome P450 (CYP) enzyme activity after repeated administration [58].

Diminished glucuronidation of lamotrigine accounts for an age-related decline in the clearance of the drug in the elderly [55]. A comparison of the pharmacokinetics of lamotrigine (150-mg oral dose) in healthy young (26–38 years) and elderly (65–76 years) volunteers revealed a 37% lower serum clearance in the elderly, associated with 27% higher C_{max} and 55% higher AUC values [59].

Factors (other than age and co-medication) that affect lamotrigine pharmacokinetics

Pregnancy and lactation

The clearance of lamotrigine increases progressively until 32 weeks of gestation [60,61], a change which is associated with a corresponding lowering of serum lamotrigine concentration [62]. These changes are rapidly reversible after delivery, resulting in a prominent increase in serum lamotrigine concentration during the first few days post partum. The alteration in lamotrigine kinetics during pregnancy is often associated with increased seizure recurrence rates [62,63], and may require lamotrigine dose adjustment. The changes in lamotrigine pharmacokinetics during pregnancy seem to be much less significant in women treated with a combination of lamotrigine and valproic acid [64].

Lamotrigine is excreted in considerable amounts in breast milk, which in combination with slow elimination of the drug in the infants may result in lamotrigine serum concentrations in nursed infants comparable to those observed in patients receiving therapeutic doses [65]. A group of nine mothers (10 infants) were investigated as they delivered and breastfed their infants for 2–3 weeks [66]. At delivery, maternal lamotrigine serum concentrations were similar to those found in cord blood, indicating extensive placental transfer [67]. There was a slow decline in serum concentration in the newborn and, at 72 h post partum, median serum lamotrigine concentrations in the infants were 75% of the cord serum concentration (range 50–100%). The median milk–maternal serum concentration ratio was 0.61 (range 0.47–0.77) 2–3 weeks after delivery, and the nursed infant maintained serum lamotrigine concentrations of approximately 30% of the mother's serum concentration. A similar relationship between serum concentration in nursed infants and maternal lamotrigine concentration was reported at day 10 post partum in another study [68]. Maternal serum concentrations increased during the first 2 weeks post partum, the median increase in serum concentration–dose ratio being 170%. No adverse effects have been reported in the infants.

Gilbert's syndrome

Gilbert's syndrome, a disorder of conjugation characterized by disturbances in bilirubin metabolism and uridine diphosphate glucuronyl transferase (UGT) activity, is associated with a reduced rate of lamotrigine clearance and with prolongation by approximately 35% of lamotrigine half-life. In general, however, lamotrigine half-lives in subjects with Gilbert's syndrome remain within the range reported for healthy subjects [59].

Renal insufficiency

Twelve volunteers with chronic renal failure (mean creatinine clearance 13 mL/min; range 6–23 mL/min) and another six individuals undergoing haemodialysis were each given a single 100-mg dose of lamotrigine [69]. The mean lamotrigine half-lives determined in the study were 42.9 h (chronic renal failure), 13.0 h (during haemodialysis) and 57.4 h (between haemodialysis), compared with 26.2 h in healthy volunteers. On average, approximately 20% (range 5.6–35.1%) of the amount of lamotrigine present in the body was eliminated by haemodialysis during a 4-h session.

Hepatic disease

The pharmacokinetics of lamotrigine following a single 100-mg dose was evaluated in 24 subjects with mild, moderate and severe hepatic dysfunction (Child–Pugh classification system) and compared with that of 12 subjects without hepatic impairment [69]. The patients with severe hepatic impairment were without ascites ($n = 2$) or with ascites ($n = 5$). The mean apparent oral clearance

of lamotrigine in patients with mild (n = 12), moderate (n = 5) and severe liver impairment without ascites (n = 2) and severe liver impairment with ascites (n = 5) was 0.30 ± 0.09, 0.24 ± 0.1, 0.21 ± 0.04 and 0.15 ± 0.09 mL/min/kg, respectively, compared with 0.37 ± 0.1 mL/min/kg in the healthy controls. The mean half-life of lamotrigine in patients with mild, moderate and severe liver impairment without ascites, and severe liver impairment with ascites was 46 ± 20, 72 ± 44, 67 ± 11 and 100 ± 48 h, respectively, compared with 33 ± 7 h in healthy subjects.

Drug interactions

Lamotrigine is most often used in combination with other AEDs, so a clear understanding of possible interactions between lamotrigine and co-administered drugs is important [70–72]. Although lamotrigine has little influence on the pharmacokinetics of other AEDs, the pharmacokinetics of lamotrigine can be markedly influenced by concomitant medications. Pharmacodynamic interactions between lamotrigine and other AEDs also occur.

Effects of co-administered drugs on lamotrigine pharmacokinetics

Other antiepileptic drugs

Co-administration of valproic acid, an inhibitor of glucuronidation, markedly reduces the rate of lamotrigine elimination (Tables 43.1 and 43.2) [73]. As shown in studies in children and adults, the half-life of lamotrigine is approximately doubled (to approximately 45–65 h) in patients receiving concomitant valproic acid compared with values in subjects receiving lamotrigine monotherapy. A study with healthy volunteers employed a single lamotrigine dose of 25 mg and evaluated the alterations of lamotrigine pharmacokinetics at valproic acid doses of 125, 250, 375 and 500 mg/day [74]. A change in the half-life of lamotrigine was demonstrable at a valproic acid dose of 125 mg/day. Maximal inhibition of lamotrigine metabolism is generally achieved at a valproic acid dose of about 500 mg/day. This pharmacokinetic interaction is thought to explain the increased incidence of rash seen after starting add-on lamotrigine in patients receiving valproic acid therapy.

Co-administration of drugs that induce the hepatic drug-metabolizing enzymes, such as phenytoin, carbamazepine and phenobarbital, increases the rate of elimination of lamotrigine, more than halving its half-life (to approximately 7–14 h) in some clinical trials compared with lamotrigine alone. Phenytoin appears to have a slightly greater effect on serum lamotrigine concentrations (decreases steady-state serum lamotrigine concentration by 45–54%) than carbamazepine, phenobarbital or primidone (decreases of approximately 40%). The effect of enzyme-inducing AEDs on lamotrigine appears to be more pronounced in children than in adults. This increased clearance, especially in children aged under 6 years, is likely to result in pronounced peak–trough fluctuations in serum lamotrigine concentrations at steady state [48]. Lamotrigine de-induction was studied by stepwise withdrawal (weekly 20% decrement) of carbamazepine or phenytoin as a part of an active control study [75]. Phenytoin withdrawal was followed by a 160% increase in serum lamotrigine concentration (n = 28), while carbamazepine withdrawal (n = 48) was associated with a 60% increase. Methsuximide has also been reported to decrease markedly serum lamotrigine levels [76].

Lamotrigine half-life is about 4- to 10-fold higher in patients given concomitant valproic acid than in those receiving enzyme-inducing AEDs (Tables 43.1 and 43.2), and steady-state dose-normalized serum lamotrigine concentrations are also increased or decreased accordingly [44,65]. Conversely, patients co-medicated with both valproic acid and enzyme-inducing AEDs have lamotrigine half-lives comparable to those described in subjects on lamotrigine monotherapy.

Because of the interactions described above, lamotrigine dosage must be adjusted according to the type of concomitant medication used. A recent population pharmacokinetic model for children has confirmed the effects of other AEDs on lamotrigine clearance and has been used to develop dose escalation schedules for concomitant therapy [56]. The new guidelines include lower initiation doses and a slower escalation rate, designed to generate average serum concentrations in children close to and not higher than those in adults under the current dosage guidelines [77].

Apart from valproic acid and enzyme-inducing AEDs, other AEDs are not expected to influence lamotrigine pharmacokinetics [71,78]. While some reports have suggested that lamotrigine clearance may be accelerated by oxcarbazepine, a carefully conducted study in healthy volunteers found no evidence of a pharmacokinetic interaction between these drugs [79].

Oral contraceptives and hormone replacement therapy

Addition of combined contraceptive steroids to the therapeutic regimen of women stabilized on lamotrigine results in a prominent drop in serum lamotrigine concentrations, to an average of about one-half the pre-interaction level [80]. The interaction, which appears to be due to stimulation of lamotrigine metabolism by the oestrogen component of the contraceptive, may result in loss of seizure control if lamotrgine dosage is not appropriately adjusted. Conversely, cessation of intake of the contraceptive results in a marked rise in serum lamotrigine levels, with the attendant risk of manifestations of toxicity. It has also been shown that in women stabilized on an oral contraceptive, the interaction follows a cyclic pattern, with a fall in serum lamotrigine levels during the (usually) 21-day period of intake of the contraceptive pill, and a transient increase in lamotrigine levels during the 7-day pill-free interval [80,81]. Interestingly, concomitant intake of valproic acid seems to antagonize the stimulating effects of steroid contraceptives on lamotrigine metabolism, and in women co-medicated with valproic acid serum lamotrigine levels appear to be comparable in the presence and in the absence of contraceptive pill use [64].

Hormone replacement therapy in postmenopausal women also seems to have significant effects on lamotrigine pharmacokinetics. In a randomized placebo controlled trial of hormone replacement therapy in women with epilepsy, two lamotrigine-treated women had a decrease in serum lamotrigine levels of 25–30% following administration of conjugated equine oestrogens 0.625 mg plus medroxyprogesterone acetate 2.5 mg, and in one of these women this was associated with worsening in seizure frequency [82].

Other drugs

Rifampicin and a combination of lopinavir or ritonavir have been found to affect lamotrigine clearance similarly to enzyme-inducing AEDs. Olanzapine causes a modest (about 25%) reduction in serum lamotrigine levels [83]. A slight reduction in serum lamotrigine levels was also noted with co-administration of paracetamol (acetaminophen), 900 mg three times daily, but this effect is unlikely to be of clinical importance [84]. There is anecdotal evidence that sertraline may increase serum lamotrigine levels. Clinical experiences from an expanding range of co-administered medications, including psychoactive drugs [85], are available (Table 43.3).

Table 43.3 Summary of drug interactions with lamotrigine.

Drug	Serum drug concentration with adjunctive lamotrigine[a]	Serum lamotrigine concentration with adjunctive drug[b]

⇌, neutral; –, decrease; +, increase; n/a: not assessed; ?, conflicting data.

[a] From adjunctive clinical trials and volunteer studies.

[b] Net effects were estimated by comparing the mean clearance values obtained in adjunctive clinical trials and volunteers studies.

[c] The effect of other hormonal contraceptive preparations or hormone replacement therapy on the pharmacokinetics of lamotrigine has not been systematically evaluated in clinical trials and the effect may not be similar to that seen with the hormonal products tested.

[d] Modest decrease in levonorgestrel.

[e] Not administered, but an active metabolite of carbamazepine.

[f] Slight decrease, not expected to be clinically relevant.

[g] Not administered, but an active metabolite of oxcarbazepine.

[h] Slight increase not expected to be clinically relevant.

Effects of lamotrigine on the pharmacokinetics of co-administered drugs

Other AEDs

In contrast to many other AEDs, lamotrigine does not appear to inhibit or induce the hepatic CYP drug-metabolizing enzymes [58] or displace other AEDs from serum proteins [46]. Therefore, the pharmacokinetic profiles of most conventional AEDs are not significantly altered when lamotrigine is added or withdrawn [40,86–88] (Table 43.3). In at least one study, however, the addition of lamotrigine to steady-state valproic acid treatment in adult volunteers resulted in a 25% reduction in serum valproic acid concentrations [89].

Oral contraceptives

In a carefully conducted study designed to assess the interaction between lamotrigine and steroid oral contraceptives, lamotrigine (titrated up to 300 mg/day) did not affect the pharmacokinetics of ethinylestradiol in 16 evaluable healthy female volunteers but decreased levonorgestrel moderately, by an average of 19% [80]. Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) concentrations were increased by 4.7-fold and 3.4-fold respectively in the presence of lamotrigine, but serum progesterone concentrations were low, suggesting that suppression of ovulation was maintained. Intermenstrual bleeding was reported by 32% of women during co-administration of lamotrigine and a combined oral contraceptive.

Pharmacodynamic interactions

In addition to pharmacokinetic interactions, pharmacodynamic interactions between lamotrigine and other AEDs have been reported.

Synergistic therapeutic effects, as well as some adverse effects (particularly development of tremor), have been observed [45,90] when combining lamotrigine and valproic acid, an interaction that cannot always be explained by the elevating effect of valproic acid on serum lamotrigine concentration.

On the other hand, an adverse pharmacodynamic interaction between lamotrigine and carbamazepine has been observed. Diplopia, dizziness, nausea, ataxia and nystagmus – classic signs of carbamazepine toxicity – were reported in some adult and child patients when lamotrigine was added to carbamazepine therapy [91,92]. This was originally thought to be attributable to increases in the serum concentrations of the active metabolite carbamazepine-10,11-epoxide. However, the effects of lamotrigine on the serum concentration of carbamazepine-10,11-epoxide are ambiguous. In adults, the addition of lamotrigine to existing carbamazepine therapy has variously been reported to increase serum carbamazepine-10,11-epoxide concentrations by 10–45% [92] or to leave them unaltered [93,94]. In children, the mean serum concentration of carbamazepine-10,11-epoxide decreased significantly when lamotrigine was added to carbamazepine therapy in one study [95]. A pharmacodynamic interaction resulting in reciprocal facilitation of adverse effects has also been reported between lamotrigine and oxcarbazepine [79].

Serum level monitoring

A clear relationship between serum lamotrigine concentrations and clinical response has not been established in clinical trials [96]. A target range of between 1 and 4 mg/L was initially suggested [86,97,98] but children and adults with refractory epilepsy frequently require higher serum concentrations to gain optimum seizure control [99,100]. Although dose-related improvements in seizure control have been observed in children over the serum concentration range of 4–21 mg/L [99], most investigators have not found this [45,78,101]. More recent recommendations for a reference range are 1–13 mg/L [102], 3–14 mg/L [103] and 2.5–15 mg/L [104].

Likewise, there is a variable relationship between serum concentration and incidence of adverse events [45,101,105,106], although some studies do suggest that a useful correlation does exist. In a paediatric study of high-dose lamotrigine therapy, increases in lamotrigine serum concentrations above 21 mg/L were prevented because of the development of unacceptable levels of nausea that did not resolve with reduction of concomitant medications [99]. In a retrospective study of 811 patients, reviewing 3731 lamotrigine serum concentrations [107], the proportion of patients with manifestations of toxicity was 7% at concentrations <5.0 mg/L, 14% at concentrations of 5–10 mg/L, 24% at concentrations from 10 to 15 mg/L, 34% at concentrations from 15 to 20 mg/L and 59% at concentrations >20 mg/L. The correlation between serum lamotrigine levels and tolerability was independent of concurrent medication.

Although lamotrigine dosage is usually individualized on the basis of clinical response, serum drug level monitoring is very useful to guide dosage adjustments in situations associated with changes in lamotrigine pharmacokinetics, such as pregnancy, puerperium and drug–drug interactions.

Efficacy

Pivotal randomized clinical trials of the antiepileptic efficacy of lamotrigine involved adults with refractory partial epilepsies. More recent clinical trials have evaluated lamotrigine in generalized epilepsies, in children, in the elderly, and in monotherapy and long-term use.

Adjunctive therapy studies in refractory partial epilepsy

A large number of short-term randomized double-blind placebo-controlled studies, many with a cross-over design, have confirmed the efficacy of lamotrigine when used as add-on therapy in patients with refractory partial epilepsy [86–88,98,108–116] (Table 43.4). One of the studies has been published in abstract form only [116]. The results of a meta-analysis, incorporating some unpublished data, are also available [117].

In these studies, addition of lamotrigine 50–500 mg/day resulted in a 13–59% reduction in total seizure frequency, with responder rates (proportion of patients experiencing greater than 50% seizure reduction) ranging from 7% to 67%. In the largest of the studies, a multicentre parallel-group trial of 24 weeks' duration [112], lamotrigine 500 mg/day proved to be more effective than lamotrigine 300 mg/day or placebo as add-on therapy, reducing total seizure frequency by 36%, with a responder rate of 34%.

In a large double-blind paediatric multicentre study in the USA [110], a total of 199 patients were randomized to lamotrigine (n = 98) and placebo (n = 101). Over the entire study duration of 18 weeks, a greater than 50% reduction in partial seizures compared with baseline was seen in 42% in lamotrigine-treated patients and 16% of placebo-treated patients.

The most recent double-blind parallel-group study, which allowed a wider range of concomitant AEDs including carbam-

[a] Cross-over design.

[b] Carbamazepine, phenobarbital, phenytoin.

[c] Topiramate, oxcarbazepine, levetiracetam.

azepine, valproic acid, topiramate, oxcarbazepine, phenytoin and levetiracetam (in a decreasing number of patients), employed an extended-release formulation of lamotrigine at three different dosing schedules according to the type of concomitant AEDs: valproic acid, enzyme-inducing AEDs and non-enzyme-inducing AEDs [114]. The patients were 12 years or older, and those implanted with a vagus nerve stimulator were also eligible. Over the entire study of 19 weeks, the median reduction in seizure frequency in the lamotrigine group was 46% (compared with 24% for the placebo group) and a greater than 50% seizure reduction was seen in 42% of patients (compared with 24% for the placebo group).

Conversion to monotherapy studies in refractory epilepsy

A double-blind, short-term active-control study in adolescent and adult patients with refractory partial epilepsy further confirmed the efficacy of lamotrigine in partial epilepsy [118]. A total of 156 patients on monotherapy with carbamazepine or phenytoin were assigned to lamotrigine or valproic acid. While maintaining the concomitant drug at a steady dose level during baseline, the lamotrigine group underwent a dose escalation to the target dose of 500 mg daily while the valproic acid group was escalated to 1000 mg daily, a minimally effective dose. Concomitant medication was gradually tapered, and patients exited the study if seizure deterioration occurred. Overall, 50 and 64 subjects in the lamotrigine and in the valproic acid group, respectively, achieved monotherapy. The lamotrigine group, however, was more successful in completing the 12-week monotherapy phase (56% versus 20%), and the median time to meet escape criteria for seizure deterioration was significantly shorter for the valproic acid group (57 days versus 168 days).

In a complex non-randomized multicentre study, four groups of patients on monotherapy with valproic acid (n = 117), carbamazepine (n = 129), phenytoin (n = 92) and phenobarbital (n = 9) were recruited, and lamotrigine was added to the concomitant AED to the target daily dose of 100 mg for the valproic acid group and 400 mg for the other groups [119]. The concomitant AED was then withdrawn and lamotrigine monotherapy was attained. Lamotrigine dose was adjusted in the valproic acid group as valproic acid was withdrawn. In the remaining groups, serum lamotrigine concentration rose as the concomitant drug was withdrawn. A greater than 50% seizure reduction during the add-on phase was seen in 47% (64% with valproic acid; 41% with carbamazepine; 38% with phenytoin), and the responder rate was higher in patients with 'idiopathic' tonic–clonic seizures (61%) than in those with partial seizures (43%). There were more responders in the valproic acid group, but statistical significance was reached for the partial seizures group only. Although the valproic acid group experienced better seizure control during the add-on phase than the other groups, more patients in the valproic acid group tended to deteriorate during the phase of conversion to lamotrigine monotherapy. These results were interpreted as evidence of synergism between lamotrigine and valproic acid.

A multicentre study from Poland recruited two equal groups of 63 patients with uncontrolled seizures on monotherapy with carbamazepine or valproic acid [120]. The four study phases consisted of (1) 4-week lamotrigine dose escalation; (2) 8-week lamotrigine add-on therapy; (3) 8-week carbamazepine/valproic acid withdrawal if clinically appropriate; and (4) 8-week lamotrigine monotherapy. Of 126 patients, 107 (85%) completed dose escalation and add-on therapy, and 85 (68%) completed the lamotrigine monotherapy phase. A greater than 50% seizure reduction occurred in 50% of patients during add-on therapy and in 53% during lamotrigine monotherapy, and 27% were seizure free during lamotrigine monotherapy. Fakhoury *et al.* [121] reported the US multicentre data from a similar large international open-label conversion to monotherapy study, consisting of two arms (lamotrigine versus carbamazepine and lamotrigine versus valproic acid) in the same four phases. The 144 patients in the carbamazepine arm were randomly assigned to add-on lamotrigine (98 patients) and add-on carbamazepine (46 patients) before withdrawing concomitant medication. Monotherapy was completed (at least 7 weeks) in 56% of lamotrigine patients and 54% of carbamazepine patients. Seizure freedom was attained during the monotherapy phase in 41% of lamotrigine patients and 30% of carbamazepine patients. Neither of these differences was significant. Among the 158 patients in the valproic acid arm (105 assigned to lamotrigine and 53 to valproic acid), monotherapy was completed in 49% of lamotrigine patients and 40% of valproic acid patients. Statistical significance was attained in seizure freedom during the monotherapy phase with 32% versus 11% in favour of lamotrigine.

Monotherapy studies in newly diagnosed (predominantly partial) epilepsy

As monotherapy, lamotrigine is as effective as carbamazepine, phenytoin and gabapentin against partial-onset seizures and secondary generalized tonic–clonic seizures (Table 43.5). Four studies [122–125] enrolled children, while nine [122–130] were conducted in adults, including four trials in the elderly [126–129].

Five randomized trials comparing lamotrigine and carbamazepine required multiple seizures for entry [122,123,126,129,131], and three required a minimum of only one seizure [124,127,128]. One study [122] was exceptional, because eligibility criteria also allowed inclusion of 233 patients between 2 and 12 years of age, and was limited to partial epilepsy. Three studies [126,128,129] recruited elderly patients only (with the oldest being 91 years of age), and other studies included adolescent patients as well. Lamotrigine and carbamazepine were similar in efficacy, when evaluated in a diverse range of patient populations. They differed, however, in tolerability, because withdrawal secondary to treatment-emergent adverse events was more likely with carbamazepine, possibly most significantly in children and the elderly [122,126,128,129]. In the studies for which only one seizure was required for entry [124,127,128], seizure freedom attained tended to be higher for both agents, without statistically significant differences.

In one randomized comparative trial, lamotrigine and phenytoin were similarly effective [132] in terms of time to the first seizure and time to discontinuation. The recruited patients ranged from 14 to 75 years of age, and patients with primary generalized tonic–clonic seizures were eligible. Adverse events led to discontinuation of 13 patients (15%) in the lamotrigine group and 18 (19%) in the phenytoin group.

Table 43.5 Comparative trials of lamotrigine in newly diagnosed patients with epilepsy.

Reference	Number of patients on entry	Dosage (mg/day)	Study duration	Proportion of patients seizure free during final 24 weeks of treatment (%)	Proportion of patients completing study (%)
Versus carbamazepine					
Brodie *et al*. [131]	131	Lamotrigine 100–300 (median 150)	48	39	65
	129	Carbamazepine 300–1400 (median 600)		38	51
Reunamen *et al*. [123]	115	Lamotrigine 100	30	51	62
	111	Lamotrigine 200		60	69
	117	Carbamazepine 600		55	65
Brodie *et al*. [126] (elderly trial)	102	Lamotrigine 75–300 (median 100)	24	38[a]	71
	48	Carbamazepine 200–800 (median 400)		44[a]	42
Nieto-Barrera *et al*. [122] (partly paediatric trial)	417	Lamotrigine 50–300 (median 100)	24	65[b]	81
	201	Carbamazepine 100–1500 (median 400)		73[b]	77
Rowan *et al*. [128][c] (elderly trial)	200	Lamotrigine 150	52	51	56
	198	Carbamazepine 600		64	35
Saetre *et al*. [129] (elderly trial)	93	Lamotrigine 25–400 (median 100)	40	57	68
	91	Carbamazepine sustained-release 100–800 (median 400)		52	61
Steinhoff *et al*. [124][c]	88	Lamotrigine 75–300 (median 200)	24	89[d]	91
	88	Carbamazepine 450–1800 (median 900)		94[d]	81
Gilad *et al*. [127][c]	32	Lamotrigine		72	87
	32	Carbamazepine		44	69
Versus phenytoin					
Steiner *et al*. [132]	86	Lamotrigine 100 or more (mode 150)	48	43	48
	95	Phenytoin 200 or more (mode 300)		36	47
Versus gabapentin					
Brodie *et al*. [130]	143	Lamotrigine 150	24	76	67
	148	Gabapentin 1800		76	72
Rowan *et al*. [128][c] (elderly trial)	200	Lamotrigine 150	52	51	56
	195	Gabapentin 1500		47	49
Versus valproic acid					
Stephen *et al*. [125]	114	Lamotrigine 150–600 (median 200)	104	47	62
	111	Valproic acid 600–3000 (median 1000)		47	50
Steinhoff *et al*. [124][c]	33	Lamotrigine 75–300 (median 150)	24	61[d]	88
	30	Valproic acid 600–2100 (1050 median)		84[d]	97

[a] Data were collected for 16 weeks.
[b] For patients older than 13 years only.
[c] At least one seizure before entry.
[d] Data were derived from the final 8 weeks. Marked seizure freedom difference in the trial versus valproic acid (not statistically significant) was attributed to worse outcome in 10 lamotrigine patients with juvenile myoclonic epilepsy.

Lamotrigine and gabapentin were similar in efficacy in two randomized studies [128,130]. One study recruited the elderly (60 years of age or older) and most of the patients had symptomatic epilepsy [128]. The other included patients 16 years or older (with one exceptional patient at 13 years of age, and the oldest at 78), and patients with primary generalized tonic–clonic seizures were eligible [130].

Lamotrigine was compared with valproic acid in two studies of newly diagnosed patients. One study with 225 patients (aged between 13 and 80 years) consisted of 161 patients with partial epilepsies, 47 with generalized tonic–clonic seizures and 17 with juvenile myclonic epilepsy [125]. Seizure freedom was attained in 47% of patients for both lamotrigine and valproic acid, while more patients withdrew from valproic acid secondary to adverse events, including eight patients with excessive weight gain. In the other study, which required only one seizure (partial or generalized) for entry [124], 63 out of 239 patients (with 33 patients younger than 18) had generalized epilepsies and neither seizure freedom nor withdrawal rates were statistically different between groups However, seizure freedom was more often associated with valproic acid in patients with juvenile myclonic epilepsy – 3 out of 10 in the lamotrigine group versus 3 out of 4 in the valproic acid group.

A randomized parallel-group comparison of lamotrigine with several other AEDs in patients with newly diagnosed epilepsy was conducted recently within the context of the SANAD collaboration [133,134]. This was a UK government-sponsored long-term study of AED efficacy and tolerability, comparing newer AEDs with two recognized first-line AEDs, carbamazepine (arm A, including mostly patients with partial epilepsies) and valproic acid (arm B, including mostly generalized and unclassifiable epilepsies). Neither the prescribing physician nor the patient was blinded, and patients were randomly assigned one of four AEDs, carbamazepine, lamotrigine, gabapentin or topiramate, for arm A ($n = 1721$), and one of three AEDs, valproic acid, lamotrigine or topiramate, for arm B ($n = 716$). Enrolment began in 1999, and data collection was completed in 2006. The study added oxcarbazepine to arm A in 2001 but levetiracetam and zonisamide were not included. AED dosing guidelines were provided, but the prescribing physician controlled AED dosing in order to maximize the benefit of the assigned AED. The primary outcomes were time to treatment failure and time to 12-month remission. The secondary outcomes were time from randomization to a first seizure, time to 2-year remission, the incidence of clinically important adverse events and adverse effects emerging after randomization. For arm A (partial epilepsies), lamotrigine was significantly better than carbamazepine, gabapentin and topiramate for time to treatment failure, but its advantage over oxcarbazepine was not significant [133]. Carbamazepine had a non-significant advantage over lamotrigine, topiramate and oxcarbazepine for time to 12-month remission. A per-protocol analysis supported non-inferiority of lamotrigine compared with carbamazepine. The results for arm B of the study are reported below in the section 'Monotherapy studies in newly diagnosed generalized and unclassifiable epilepsies'.

Adjunctive therapy studies in generalized epilepsy

In a multicentre double-blind cross-over study, a total of 26 patients with various generalized epilepsies, including absence, were randomized to lamotrigine (at a maintenance dose of either 75 or 150 mg daily, depending on the concomitant AED) or placebo, added on to the existing regimen [135]. Twenty-two patients completed the placebo-controlled phase. A greater than 50% seizure reduction occurred in 50% of patients with tonic–clonic seizures, and in 33% of those with absence seizures. In the continuation phase, five patients (25%) remained seizure free.

In a single-centre study employing an innovative design [136], 17 patients (57%) experienced a greater than 50% seizure reduction when lamotrigine was added on in an initial open-label phase. Fifteen of the responders were then assigned, according to a double-blind cross-over design, to lamotrigine or placebo after a washout period, with the two double-blind phases consisting of 12-week periods separated by a 3-week cross-over. With the exception of a single patient, the seizure count was lower during the lamotrigine phase. Of the patients recruited at study initiation, consisting of 30 consecutive patients evaluated at the referral centre, 20 had Lennox–Gastaut syndrome, and the responder group included 11 with Lennox–Gastaut syndrome, yielding a responder rate of 65% associated with this diagnostic group in the initial open-label phase.

In a trial that used a multicentre double-blind parallel-group design, lamotrigine was added on to the existing regimen in 58 patients (age range 2–55 years) with primarily generalized tonic–clonic seizures [137]. A greater than 50% reduction in the frequency of primary generalized tonic–clonic seizures occurred in 72% of patients during the 12-week maintenance phase, while 43% of 59 patients assigned to placebo had a greater than 50% seizure reduction, a statistically significant difference.

The efficacy of lamotrigine in the management of Lennox–Gastaut syndrome was shown in a pivotal double-blind, placebo-controlled add-on study [100]. A total of 169 patients were randomized to 16 weeks of treatment with lamotrigine ($n = 79$) or placebo ($n = 90$). The median monthly frequency of all major seizures decreased in the lamotrigine group from 16.4 to 9.9, compared with a seizure frequency change from 13.5 to 14.2 in the placebo group. A greater than 50% seizure reduction was seen significantly more often in the lamotrigine group (33% versus 16%).

In an uncontrolled study of 15 patients of mixed ages [138], when lamotrigine (1.6–3.0 mg/kg/day for children and 25–50 mg/day for adults) was added to valproic acid and continued for 3 months or longer, a total or near-total control of absence seizures was seen in 63% ($n = 9$).

Monotherapy studies in newly diagnosed absence seizures

The efficacy of lamotrigine monotherapy in patients with newly diagnosed childhood absence epilepsy was demonstrated in two studies.

In the first study, 30 of 42 patients (71%) aged 2 to 16 years became seizure free at a median dose of 5 mg/kg/day during a non-blind dose escalation phase [139]. In the subsequent double-blind, placebo-controlled phase restricted to patients who had responded to open-label treatment, significantly more patients remained seizure free in the group ($n = 15$) randomized to continue lamotrigine than in the group ($n = 14$) switched to placebo (62% versus 21%, respectively).

In the second trial, 38 children (3–13 years of age) were randomly assigned to lamotrigine or valproic acid according to an open-label design [140]. At 3 months, 63% of children taking valproic acid and 37% of those taking lamotrigine were controlled. After 12 months, 68% of children taking valproic acid and 53% taking lamotrigine remained seizure free. Valproic acid produced control of absence seizures faster, but the difference in efficacy at 12 months was not significant, possibly due to the limited sample size.

Monotherapy studies in newly diagnosed generalized and unclassifiable epilepsies

The efficacy and tolerability of lamotrigine, valproic acid and topiramate were compared in arm B of the SANAD study (n = 716), the design of which has been described above [134]. In this arm, which included patients with generalized and unclassifiable epilepsies, there was no significant difference between valproic acid and lamotrigine for time to treatment failure. Valproic acid, however, was better than lamotrigine for time to 12-month remission. Topiramate did not perform as well as the other AEDs in this study, largely due to inferior tolerability.

Meta-analyses of randomized controlled trials

In addition to a meta-analysis addressing the efficacy of adjunctive therapy with lamotrigine in refractory partial epilepsy [117], a pooled analysis of pivotal trial data focusing on seizure freedom indicated that lamotrigine was only infrequently associated with seizure-free outcome when added to an existing AED regimen in refractory epilepsy [141]. A series of meta-analyses also suggested lamotrigine to be possibly less effective than the most recently introduced AEDs in the treatment of refractory partial seizures [142,143]. When all available clinical trial data were utilized to compare lamotrigine with carbamazepine, a better tolerability of lamotrigine was confirmed, but comparison of efficacy data was judged inconclusive [144].

Other studies

A large number of experiential clinical studies have documented the place of lamotrigine in epilepsy treatment [47,99,101,145–158]. In an open study, for example, 21 patients (16–65 years old) with epileptic seizures of frontal lobe origin were maintained on a combination of lamotrigine and valproic acid [159]. At the end of 1 year, 17 patients continued on this combination and 10 had been free of clinical seizure recurrences. In other studies, lamotrigine was added on to existing AED regimens, and outcome measures were seizure remission and successful conversion to lamotrigine monotherapy. Treatment outcome of some epilepsy syndromes was quantitatively evaluated with EEG, particularly when the patient was unable to participate in the assessment [139,147,153,160–162]. Treatment-emergent adverse events were recorded and compared with the patient's treatment history as own control. Retention on lamotrigine suggested its clinical usefulness.

Successful applications of lamotrigine in refractory epilepsy have included conditions associated with underlying progressive neurological conditions, including refractory neonatal seizures [163], infantile spasms [164], Rett's syndrome [165] and juvenile neuronal lipofuscinosis [166].

There have been many studies to determine how long lamotrigine is retained during chronic use, mostly in patients with refractory epilepsies. In one study of longer than 3 years' duration, the proportion of patients retained on lamotrigine treatment was 29%, compared with 30% for topiramate and 10% for gabapentin [167]. Another multicentre study of 6 years' duration, in mostly difficult-to-treat patients, demonstrated a retention rate of somewhat less than 40% [168]. The same study demonstrated that fewer than 4% of the patients remained free of seizure recurrences. There also exists the need to better define the efficacy of lamotrigine in generalized epilepsies [168].

Quality of life assessments

A double-blind study compared lamotrigine and carbamazepine in newly diagnosed epilepsy with health-related quality of life as an outcome measure [169]. The population was identical to that of an already reviewed trial [131] that demonstrated a difference in study completion rate (lamotrigine 65% versus carbamazepine 51%). The modified Side Effect and Life Satisfaction (SEALS) inventory with five subscales (worry, temper, cognition, dysphoria and tiredness: a total of 20 points) was applied at weeks 4, 12, 24 and 48. The SEALS score worsened significantly at 4 weeks in the carbamazepine group, associated with deterioration in the cognition, dysphoria and tiredness subscales. Improvement observed among the carbamazepine group in the temper and worry subscales were smaller than those observed in the lamotrigine group. The SEALS score was better among the completers; worse scores at the baseline tended to predict dropout, and worsening of the SEALS score was actually seen, leading to dropout.

In another study, lamotrigine was added on to the treatment of 196 patients who had been receiving other AEDs, and the Profile of Mood States (POMS) and a 31-item Quality of Life scale (QOLIE-31) were applied at baseline [170]. Addition of lamotrigine was tolerated in 155 patients, and lamotrigine monotherapy was successfully established in 51 patients. The lamotrigine monotherapy group experienced an improvement in mood measures.

Paradoxical effects in myoclonus and myoclonic syndromes

Lamotrigine can aggravate myoclonus [171–175] and even precipitate myoclonic status [173], although improved control has also been reported in some cases [146]. Aggravation of severe myoclonic epilepsy in infancy (Dravet's syndrome) is particularly common with lamotrigine [174]. Myoclonus can represent a new symptom when lamotrigine is initiated in a patient with genetically determined forms of epilepsy [176,177]. The mechanisms involved in the differential exacerbation of myoclonus are unknown. There is a single case report of recurrent absence status epilepticus associated with lamotrigine therapy [178].

Use in non-epilepsy indications

A number of early reports of adverse events from clinical trials of lamotrigine in epilepsy concerned psychiatric symptoms compatible with elevation of mood. Subsequent clinical trials established the indication of lamotrigine in the maintenance treatment of bipolar I disorder and, in particular, bipolar depression [179,180]. A comprehensive review of the rapidly expanding lit-

erature on this topic is beyond the scope of this chapter. Lamotrigine has also been shown to be effective in the management of acute and chronic pain [181].

Adverse effects

Overview of the most common adverse effects

Assessment of the tolerability profile of lamotrigine has been complicated by its frequent use in combination with other AEDs [182,183]. Adverse events necessitated withdrawal of adjunctive lamotrigine therapy in 10.2% of patients participating in premarketing trials (n = 3501) [184]. Of these, skin rash was most frequently cited, and was responsible for discontinuation in 3.8% of patients. The most common adverse events associated with adjunctive lamotrigine use were primarily neurological, gastrointestinal and dermatological. In a placebo-controlled study of add-on lamotrigine (up to 500 mg/day) in 334 adults with partial epilepsy, dizziness (reported by 50% of lamotrigine patients), diplopia (33%), ataxia (24%), blurred vision (23%) and somnolence (14%) occurred significantly more frequently in the lamotrigine group than in the placebo group [185]. Skin rash was reported by 10% of lamotrigine patients, but the difference compared with the placebo group was not significant. Lamotrigine tolerability has been formally tested in maintenance doses up to 700 mg/day [186].

Information concerning the tolerability of lamotrigine alone can be derived from controlled studies of lamotrigine monotherapy. In comparative monotherapy trials in patients with newly diagnosed epilepsy, withdrawal rates were always lower with lamotrigine (4–15%) than with carbamazepine (10–42%), a difference mainly attributable to adverse events rates [122–124,126,128,129,131]. Withdrawal rates did not differ significantly between lamotrigine and gabapentin [128,130]. In two studies comparing lamotrigine and valproic acid in newly diagnosed patients, differences in rates of withdrawal from treatment were opposite in direction [124,125].

Pooled data from 536 patients with newly diagnosed epilepsy treated with lamotrigine monotherapy identified headache (18%), asthenia (15%), rash (11%), nausea (10%), dizziness (9%) and somnolence (8%) as the most frequent adverse events [122,123,126,129,131,132] (Table 43.6). When compared with carbamazepine and phenytoin, lamotrigine showed tolerability advantages in terms of a lower incidence of drowsiness. In fact, insomnia can be an adverse effect of lamotrigine [187]. Tolerability data available from studies comparing lamotrigine with gabapentin or valproic acid are more limited than those available for carbamazepine and phenytoin. When adverse events were compared between lamotrigine and gabapentin, weight gain was significant with gabapentin in both studies [128,130]. Valproic acid was definitely also more frequently associated with weight gain than lamotrigine [124,125].

Table 43.6 Adverse experiences often reported by newly diagnosed patients on lamotrigine monotherapy and active control groups.

Study	Lamotrigine, total [123,129,131,132]	Carbamazepine, total [123,129,131]	Phenytoin [132]
n	536	338	95
Daily dose	100–200 mg	600 or 400 mg	300 mg
Headache	99 (18%)	53 (17%)	18 (19%)
Asthenia	79 (15%)	69 (20%)	28 (29%)
Rash	57 (11%)	47 (14%)	9 (9%)
Nausea	51 (10%)	29 (9%)	4 (4%)
Sleepiness	43 (8%)	58 (17%)	27 (29%)
Dizziness	49 (9%)	43 (13%)	11 (12%)

Cognitive and psychomotor effects

Studies in healthy volunteers and patients with epilepsy have shown that lamotrigine causes fewer adverse psychomotor and cognitive effects than traditional AEDs. In contrast to diazepam (10 mg), carbamazepine (400–600 mg) and phenytoin (1000 mg), lamotrigine (120–300 mg) did not accentuate body sway and did not impair adaptive tracking (a measure of hand-to-eye coordination), smooth visual pursuit (a measure of cortical and cerebellar function) or saccadic eye movement (a measure of parapontine reticular formation function) after single oral doses in healthy volunteers [91,97]. Repeated doses of lamotrigine (mean 7.1 mg/kg/day for 4 weeks) did not affect psychomotor speed, sustained attention, verbal memory, language and mood measures in 17 healthy volunteers; in contrast, topiramate (5.7 mg/kg/day) significantly impaired attention and word fluency [188]. Similar results have been reported in other normal volunteer studies, when lamotrigine was tested against carbamazepine [189], valproic acid [190] and topiramate [191].

The absence of adverse cognitive effects of lamotrigine has been reported uniformly since earlier clinical studies [108,131,160], and these findings were confirmed in more recent controlled trials, when lamotrigine was added to pre-existing AED regimens [192,193]. In fact, one of the studies in healthy volunteers [190] demonstrated positive cognitive effects with lamotrigine.

Neurological and behavioural effects

A nationwide survey of patients in the UK evaluated the association between AED use and acute psychological disorders [194]. In 19 cases (30% of the total reported), the AED was considered to be responsible. Lamotrigine was implicated in three, and all three patients experienced interictal events, consisting of delirium in two and mood disorder in one. Schizophrenia-like psychotic symptoms were reported in six patients receiving lamotrigine for epilepsy [195]. Tourette's symptoms were provoked in a single patient with a bipolar disorder [196]. Additional neurobehavioural adverse experiences include aggression [197] and insomnia [187].

Sporadic reports suggest an association of lamotrigine use with chorea without a family history [198–200]. There is a single case report of downbeat nystagmus [201]. Dysgeusia has also been reported [202].

Neuroendocrine effects

In recent years, there has been increasing concern over the adverse effects of AEDs on neuroendocrine functions. Isojarvi *et al*. [203] were the first to direct attention to a possible contribution of valproic acid in the pathogenesis of polycystic ovarian syndrome.

The data from a double-blind randomized trial comparing lamotrigine with valproic acid monotherapy were analysed [204]. The patients were 12 years or older, consisting of 18 assigned to lamotrigine (doses of 100–500 mg/day) and 20 assigned to valproic acid (doses of 10–60 mg/kg). Among the adolescent patients (12–20 years old), body weight gain was more common in the valproic acid group during the 24 weeks of the maintenance phase, and the difference between the two groups was significant at 10 weeks. In another monotherapy comparison, there was a suggestion of a subclinical increase in the fasting insulin level in the valproic acid group, but only a small number of obese females had a polycystic ovarian syndrome [205]. Patients who had been on lamotrigine ($n = 119$) and valproic acid ($n = 103$) monotherapy for longer than 5 years were compared in an open-label study [206]. More lamotrigine patients (87%) than valproic acid patients (77%) reported regular menstrual cycles at the screening visit. The prevalence of anovulation did not differ between two groups. Mean total serum testosterone and androstenedione levels were significantly higher in the valproic acid group. Mean total insulin levels did not differ significantly.

Patients with epilepsy on AED treatment have been known to suffer impairments of sexual function. A study using a sexual function questionnaire reported improved sexual function when 79 male patients were initiated on lamotrigine monotherapy, or when 62 male patients were switched to lamotrigine because of unsatisfactory seizure control [207]. In another study, three groups of 25 male patients with partial epilepsy treated with phenytoin, carbamazepine and lamotrigine and 10 on no treatment were compared for sexual function scores (S-scores) and serum levels of dehydroepiandrosterone sulphate (DHEAS), bioactive testosterone, bioactive estradiol and bioactive androstenediol [208]. The lamotrigine group and the patients under no treatment were similar in S-scores and bioactive testosterone, and showed a more favourable sexual function profile than the carbamazepine and phenytoin groups.

There is a report of two children treated for diabetes insipidus who experienced an increase in desmopressin requirement when lamotrigine was added to treatment for their epilepsy [209].

Child development

In one study, concern was raised about reduced growth and bone mass in children with epilepsy receiving the combination of lamotrigine and valproic acid [210]. The effects of lamotrigine on physical maturation were evaluated more specifically in a group of 103 children over periods of 6–71 months [211]. The mean age at lamotrigine introduction was 6.7 years (1.6–16.4), and the mean daily lamotrigine dose was 7.4 mg/kg (range, 3.5–14.2 mg/kg). Long-term lamotrigine monotherapy was associated with normal body growth.

Idiosyncratic effects

Cutaneous reactions

Of all the adverse effects of lamotrigine, skin rash is one of the most significant. Many AEDs cause allergic skin rashes and lamotrigine is not unique [212]. Lamotrigine-induced skin rash has the typical characteristics of an allergic drug rash, and its incidence is higher in patients with a history of allergic skin rash in response to some other aromatic AEDs, and lower when a low starting dose and a slow dose escalation rate are used [213,214]. As lamotrigine use increased among paediatric populations, multiple clinical studies suggested that the incidence of lamotrigine-associated skin rash is higher in children than in adults [215–217]. In a retrospective review of 988 outpatient records, a skin rash was recorded in 56 (5.6%) and led to lamotrigine discontinuation in 39 (3.9%) [218]. A history of skin rash attributed to other AEDs increased the risk of a lamotrigine rash to 13.9%, compared with 4.6% in patients who had no such history. A younger age (<13 years) raised the risk from 4.3% to 10.7%. When two risk factors were present in the same patient, the risk of a lamotrigine-induced rash was 18.2%.

While there has been a report of non-maculopapular rash [219], lamotrigine-associated skin rash is typically maculopapular or erythematous, is associated with pruritus and has the characteristics of a delayed hypersensitivity reaction, appearing within the first 4 weeks of initiating treatment and resolving rapidly on drug withdrawal [220]. Rarely, the rash may be more severe (erythema multiforme) and progress to desquamation with involvement of the mucous membranes (Stevens–Johnson syndrome) and possibly to toxic epidermal necrolysis [221,222]. According to the manufacturer's product information [69], the incidence of serious skin rashes, including Stevens–Johnson syndrome, and rashes requiring hospitalization is approximately 8 per 1000 in patients younger than 16 years receiving lamotrigine as adjunctive therapy for epilepsy. In clinical trials of bipolar and other mood disorders, the rate of serious skin rashes was 0.8 per 1000 in adults receiving lamotrigine as initial monotherapy and 1.3 per 1000 in adults receiving lamotrigine as adjunctive therapy.

Apparently, the pathophysiology of serious skin rashes is different from that of common allergic skin rashs, but its understanding must wait further studies [223]. In some patients, rash is accompanied by a flu-like syndrome of fever, malaise, myalgia, lymphadenopathy or eosinophilia, suggesting an immunological mechanism. No consensus exists as to which early dermatological features allow the clinician to differentiate potentially life-threatening from self-limited skin rash [224,225]. Specifically, reports from clinical trials indicated that as many as 1 in 100 to 1 in 50 paediatric patients developed a potentially life-threatening rash [216,226]. Conversely, the lamotrigine group did not differ significantly from the placebo group (9% versus 7%) in the incidence of any skin rash when elaborate dose escalation schedules were employed in a multicentre study of children with Lennox–Gastaut syndrome [100].

It is relevant that the US double-blind placebo-controlled study in children with refractory partial epilepsy [111] was carefully designed in terms of dose escalation schedule, and skin rash was a reason for withdrawal. No statistically significant difference in the incidence of skin rash emerged between the lamotrigine and placebo groups, but isolated cases of more severe skin rash occurred in the lamotrigine group. In a multicentre, non-randomized study, multiple dose escalation schedules included initial doses of 100, 25 and 12.5 mg/day in valproic acid-treated patients, and initial doses of 200 and 50 mg/day in carbamazepine- and phenytoin-treated patients [115]. When withdrawal rates due to skin rash were compared, the effect of a lower initial dose and a slower escalation was statistically significant only for

Table 43.7 Paediatric and adult rash rates with lamotrigine used alone and with different concomitant AEDs in clinical trials. In at least some of the groups included in early studies, rash rates were probably increased by excessively high dose escalation rates.

AED therapy	Total number of patients	All rash (%)	Rash leading to discontinuation (%)	Rash leading to hospitalization or Stevens–Johnson syndrome (%)[a]
Paediatric (younger than 16 years)				
Lamotrigine + enzyme-inducing AEDs	394	9.6	4.1	0.8
Lamotrigine + valproic acid + enzyme-inducing AEDs	155	4.5	0	0
Lamotrigine + valproic acid only	145	20.0	9.0	1.4
Lamotrigine + valproic acid + non-enzyme-inducing AEDs	145	21.4	10.3	1.4
Lamotrigine + other	60	11.7	3.3	0
Lamotrigine monotherapy	192	13.5	3.1	1.6
Adult (older than 16 years)				
Lamotrigine + enzyme-inducing AEDs	2240	6.7	2.0	0.1
Lamotrigine + valproic acid + enzyme-inducing AEDs	303	7.6	3.3	0.7
Lamotrigine + valproic acid only	205	19.5	12.2	2.0
Lamotrigine + valproic acid + non-enzyme-inducing AEDs	10	20.0	10.0	0
Lamotrigine + other	195	10.3	5.1	0.5
Lamotrigine monotherapy	420	14.5	6.0	0

[a] Hospitalization occurred more often for rash other than Stevens–Johnson syndrome.

the valproic acid group, in which 38%, 11% and 8% of patients discontinued treatment due to a rash for initial lamotrigine doses of 100, 25 and 12.5 mg/day respectively. A correlation between serum drug concentration and risk of skin rash at initiation of treatment had previously been noted with other AEDs [227]. More recent epidemiological data further suggested that there has been a reduction in the incidence of lamotrigine-associated serious skin rashes since lower starting doses and slower dose escalation rates were introduced, while the incidence of milder skin rashes has not changed [217,228].

There has been increasing recognition that the risk of skin rash is significantly increased when lamotrigine is initiated in patients already receiving valproic acid [222], but the risk can be reduced by using a slow escalation from a low starting dose [182,220] (Table 43.7).

It has been reported that lamotrigine withdrawal was not necessary in all patients who experienced skin rashes in clinical trials [138], as also suggested by a recent large retrospective review [218]. Some patients experiencing a skin rash at the initial exposure have been rechallenged later without recurrence of a rash [229,230], but any such rechallenges should be very cautious (and use very low starting dosages) to minimize the risk of serious reactions.

Other idiosyncratic reactions

Sporadic cases of multiorgan failure associated with disseminated intravascular coagulation have been reported. Multiorgan failure was initially attributed to status epilepticus [231] and/or concurrent serious systemic illnesses [184], but cases of multiorgan failure attributable to lamotrigine have also been reported [232–236]. Systematic analysis has suggested an overlap between multiorgan failure and a severe hypersensitivity syndrome associated with serious rash and fever [237].

There exist isolated reports of occurrences of pseudolymphoma [238], agranulocytosis [239], neutropenia [240] and hepatotoxicity [241]. The British postmarketing surveillance of adverse events associated with lamotrigine included rare single occurrences of hepatic failure, a severe flare-up of ulcerative colitis, disseminated intravascular coagulation and acute renal failure [167].

Sudden unexpected death in epilepsy

A total of 20 cases of sudden unexpected death in epilepsy (SUDEP) were reported among a cohort of 4700 patients with epilepsy (5747 patient-years of exposure) during the premarketing development of lamotrigine [69]. Retrospective analysis of the lamotrigine database indicated, however, that the risk of sudden death in lamotrigine-treated patients is no greater than that reported for other populations of people with epilepsy [242]. In a British postmarketing study, standardized mortality ratio was slightly higher than reported in the literature [167], but the result was interpreted to reflect the severity of epilepsy in the study population.

A 10-year series of consecutive SUDEP cases implicating lamotrigine as a possible causative factor was reported from one institution [243]. The four cases reported had been on long-term outpatient lamotrigine monotherapy, with serum lamotrigine concentrations between 7.0 and 27.5 mg/L prior to SUDEP.

A single case report of electrocardiographic QRS prolongation may be relevant [244]. The patient had been prescribed 200 mg lamotrigine and 600 mg felbamate, both three times daily, for epilepsy, and visited the emergency department following two clinical seizures. QRS prolongation (108 ms) was found and was immediately reversed to 98 ms with sodium bicarbonate administration. There was no evidence of acute intentional ingestion, and the lamotrigine serum concentration was 14.7 mg/L at presentation. Another single case report attributed QRS prolongation (110 ms) to lamotrigine [245]. Further investigations are needed, because lamotrigine may inhibit the cardiac rapid delayed rectifier potassium ion current, potentially rendering the patient at increased risk for cardiac arrhythmia [246].

Teratogenicity

Lamotrigine did not reveal significant teratogenic potential in preclinical animal testing. The manufacturer established a pregnancy registry and additional data about possible human teratogenicity of lamotrigine have been collected during routine clinical use [247].

As of March 2007, a total of 2622 pregnancies had been prospectively registered, with the pregnancy outcome known for 1741 and pending for 289 [248]. Exposure to lamotrigine monotherapy occurred in the first trimester in 1145 pregnancies. There were 23 live-born infants with major defects, three pregnancy terminations involving major defects and one fetal death with major birth defects, following earliest exposure to lamotrigine in the first-trimester. Following earliest exposure to lamotrigine monotherapy in the second trimester, four infants had major defects (62 total outcomes). There were 148 outcomes following first-trimester exposure to lamotrigine and valproic acid combined. Major birth defects were reported in 13, and there were two induced abortions with major birth defects. The first-trimester exposure to lamotrigine polytherapy without valproic acid was associated with 368 outcomes, eight infants with major birth defects, and one abortion with major birth defects.

While the sample size is still considered insufficient to reach definitive conclusions about the teratogenic risk of lamotrigine, a higher frequency of major malformations was seen in the group exposed to AED combinations including lamotrigine and valproic acid compared with lamotrigine monotherapy or other drug combinations. It is unclear, however, whether the higher frequency of major defects in the group receiving the valproic acid–lamotrigine combination can be ascribed to the independent teratogenic effects of valproic acid, or whether lamotrigine played a contributory role. Comparable results have been reported from a prospective UK Epilepsy and Pregnancy register [249].

Other studies discussing comparative teratogenicity data in women exposed to lamotrgine and other AEDs during pregnancy are discussed in Chapter 25.

Lamotrigine overdose

Sporadic cases of accidental or deliberate overdose of lamotrigine, involving quantities up to 15 g, have been reported, and some have been fatal. Observations from several cases of attempted suicide through ingestion of lamotrigine doses from 1350 to 4500 mg suggest that lamotrigine does not cause respiratory depression [245,250]. Recorded peak serum concentration varied from 18 to 53 mg/L. Reports to US poison centres during 2000 and 2001 included 493 lamotrigine cases, of which 173 (35.1%) were 5 years old or younger [251]. No toxic clinical effects were seen in 52.1%. Drowsiness, vomiting, nausea and ataxia were reported in 20.5%, 11%, 5.1% and 4.9%, respectively. Lamotrigine can induce seizures after acute injection [250,252]. Activated charcoal [245,250] can be used in the treatment of acute lamotrigine overdose.

Place in current therapy

Lamotrigine has been successfully tested as an effective therapeutic agent for a wide range of epilepsy syndromes, and the scope of its use is expected to continue to broaden. Treatment-emergent adverse experiences associated with its use have generally been limited to the period of dose escalation. It may not be the most effective of all AEDs, but it is highly acceptable for long-term use once its efficacy has been demonstrated and a maintenance dose has been determined in the individual patient. Clinicians are encouraged to attain monotherapy. Because of differences in lamotrigine pharmacokinetics related to type of co-medication, the dosing schedule at initiation of lamotrigine treatment depends on whether the patient is currently treated with valproic acid, enzyme-inducing AEDs or non-enzyme-inducing AEDs [182,253]. The flexibility of paediatric initiation and dosing has been appreciably improved by the introduction of lamotrigine in tablet sizes of 5 and 2 mg, and seems to have helped to reduce the incidence of skin rash. The manufacturer recommends the administration of whole tablets only. The dosing interval can be either once or twice daily, the latter being preferred in patients in whom the half-life is expected to be at the lower end of the reported range. An extended-release formulation is being developed to minimize fluctuations in serum lamotrigine concentrations during a dosing interval [52,114]. The manufacturer's updated recommendations for initial lamotrigine dose escalation are available online at http://us.gsk.com/products/assets/us_lamictal.pdf.

Dosing schedules for adjunctive use of lamotrigine in patients with epilepsy are given in Table 43.8 for subjects over 12 years of age and in Table 43.9 for subjects 2 to 12 years of age (with slight modifications from the US manufacturer's prescribing information, dated May 2007). A weight-adjusted dosing scheme for children (2 to 12 years of age) taking valproic acid is provided in Table 43.10. Drug interaction data indicate that in patients co-medicated with both valproic acid and enzyme-inducing AEDs, the opposing effects of these medications on serum lamotrigine levels cancel out virtually completely, resulting in lamotrigine pharmacokinetics comparable to those observed in patients on lamotrigine monotherapy (Table 43.3). It is, therefore, common practice, when the patient is currently receiving polytherapy including valproic acid and at least one enzyme-inducing AED, to employ the initial lamotrigine dosing schedule for 'patients taking AEDs other than carbamazepine, phenytoin, phenobarbital, primidone, or valproate'.

Table 43.11 provides guidance for adjusting lamotrigine dose when converting from adjunctive lamotrigine therapy with valproic acid to lamotrigine monotherapy in patients over 16 years of age.

Initial monotherapy with lamotrigine is currently approved in the UK and many other countries for patients older than 12 years only. The dose titration rate recommendations for initiating lamotrigine monotherapy are identical to those for patients taking AEDs other than enzyme-inducing AEDs or valproic acid (Table 43.8), but seizure freedom in newly diagnosed patients can be maintained at doses appreciably lower than those derived from clinical trials involving refractory patients [254], and consideration of lower dosing for the elderly is appropriate [126,128,129]. In the USA, only conversion to lamotrigine monotherapy is approved.

Because of a faster rate of metabolism in children, children aged 2–6 years may require a maintenance dose at the higher end of the recommended range, especially when concomitant enzyme-

Table 43.8 Escalation regimen for lamotrigine in patients with epilepsy over 12 years of age.

	For patients taking valproic acid without enzyme inducers	For patients taking AEDs other than enzyme-inducing AEDs[a] or valproic acid[b]	For patients taking enzyme-inducing AEDs[a] and not taking valproic acid
Weeks 1 and 2	25 mg every *other* day	25 mg every day	50 mg/day
Weeks 3 and 4	25 mg every day	50 mg/day	100 mg/day (in two divided doses)
Week 5 onwards to maintenance	Increase by 25 to 50 mg/day every 1–2 weeks	Increase by 50 mg/day every 1–2 weeks	Increase by 100 mg/day every 1–2 weeks
Usual maintenance dose[c]	100–200 mg/day (one or two divided doses)	200–400 mg/day (in two divided doses) 100–200 mg/day (in two divided doses) for patients with newly diagnosed epilepsy started on initial monotherapy	300–500 mg/day (in two divided doses)

From ref. 69 with permission.

[a] Methsuximide, rifampicin, the lopinavir–ritonavir combination and oestrogen-containing contraceptive steroids have also been shown to increase the apparent clearance of lamotrigine.

[b] It is common practice to use this regimen also for patients started on lamotrigine monotherapy and for those receiving concomitant therapy with valproic acid plus at least one enzyme-inducing AED. Use for initial monotherapy is not currently approved in the USA.

[c] Lamotrigine maintenance doses were modified from the US manufacturer's prescribing information, which had been derived from the doses employed in placebo-controlled trials in refractory epilepsy.

Table 43.9 Escalation regimen for lamotrigine in patients with epilepsy, 2 to 12 years of age.

	For patients taking valproic acid without enzyme inducers	For patients taking AEDs other than enzyme-inducing AEDs[a] or valproic acid[b]	For patients taking enzyme-inducing AEDs[a] and not taking valproic acid
Weeks 1 and 2	0.15 mg/kg/day in one or two divided doses, rounded down to the nearest whole tablet (see Table 43.10 for weight-based dosing guide)	0.3 mg/kg/day in one or two divided doses, rounded down to the nearest whole tablet	0.6 mg/kg/day in two divided doses, rounded down to the nearest whole tablet
Weeks 3 and 4	0.3 mg/kg/day in one or two divided doses, rounded down to the nearest whole tablet (see Table 43.10 for weight-based dosing guide)	0.6 mg/kg/day in two divided doses, rounded down to the nearest whole tablet	1.2 mg/kg/day in two divided doses, rounded down to the nearest whole tablet
Week 5 onwards to maintenance	The dose should be increased every 1–2 weeks as follows: calculate 0.3 mg/kg/day, round this amount down to the nearest whole tablet, and add this amount to the previously administered daily dose	The dose should be increased every 1–2 weeks as follows: calculate 0.6 mg/kg/day, round this amount down to the nearest whole tablet, and add this amount to the previously administered daily dose	The dose should be increased every 1–2 weeks as follows: calculate 1.2 mg/kg/day, round this amount down to the nearest whole tablet, and add this amount to the previously administered daily dose
Usual maintenance dose	1–3 mg/kg/day (maximum 100 mg/day in one or two divided doses)	2.5 to 7.5 mg/kg/day (maximum 200 mg/day in two divided doses)	5–15 mg/kg/day (maximum 400 mg/day in two divided doses)
Maintenance dose in patients less than 30 kg	May need to be increased by as much as 50%, based on clinical response	May need to be increased by as much as 50%, based on clinical response	May need to be increased by as much as 50%, based on clinical response

[a] Methsuximide, rifampicin, the lopinavir–ritonavir combination and oestrogen-containing contraceptive steroids have also been shown to increase the apparent clearance of lamotrigine.

[b] It is common practice to use this regimen also for patients started on lamotrigine monotherapy (not approved up to 12 years) and for those receiving concomitant therapy with valproic acid plus at least one enzyme-inducing AED.

Table 43.10 Initial weight-based dosing guide for lamotrigine in patients with epilepsy aged 2 to 12 years and taking valproic acid (weeks 1 to 4).

If the patient's weight is . . .		Give this daily dose, using the most appropriate combination of lamotrigine 2-mg and 5-mg tablets	
Greater than	And less than	Weeks 1 and 2	Weeks 3 and 4
6.7 kg	14 kg	2 mg every *other* day	2 mg every day
14.1 kg	27 kg	2 mg every day	4 mg every day
27.1 kg	34 kg	4 mg every day	8 mg every day
34.1 kg	40 kg	5 mg every day	10 mg every day

inducing AEDs are used. The safety and effectiveness of lamotrigine under 2 years of age has not been established and no dosage guidelines are available, but a lamotrigine dosing interval longer than 24 h has been successfully employed in infants prior to the availability of 2-mg tablets [255].

The highest maintenance dose reported in adults is 1900 mg daily [105]. In some patients, serum lamotrigine concentrations above 20 mg/L have been achieved during long-term treatment for epilepsy [107]. Even if rapid resumption of maintenance treatment may be desired in some patients in whom lamotrigine therapy has been stopped, the use of initial dose titration guidelines is recommended if lamotrigine has been discontinued for a

Table 43.11 Conversion from adjunctive lamotrigine therapy with valproic acid to lamotrigine monotherapy in patients with epilepsy ≥16 years of age.

	Lamotrigine	Valproic acid
Step 1	Achieve a dose of 200 mg/day according to guidelines in Table 43.8 (if not already on 200 mg/day)	Maintain previous stable dose
Step 2	Maintain at 200 mg/day	Decrease to 500 mg/day by decrements no greater than 500 mg/day per week and then maintain the dose of 500 mg/day for 1 week
Step 3	Increase to 300 mg/day and maintain for 1 week	Simultaneously decrease to 250 mg/day and maintain for 1 week
Step 4	Increase by 100 mg/day every week to achieve maintenance dose of 500 mg/day	Discontinue

period longer than five half-lives. A mean single oral lamotrigine loading at 6.5 mg/kg was evaluated in 24 patients in epilepsy monitoring units [256]: transient nausea was reported, but the target (maintenance) serum lamotrigine concentration was reached in 1–3 h. Replacement of lamotrigine with valproic acid can be performed by abrupt discontinuation of lamotrigine [257], but rapid lamotrigine withdrawal is not recommended without careful monitoring. Special cautions are recommended in optimizing lamotrigine therapy in patients with renal and hepatic disease [258], and lamotrigine dosing may require adjustment based on the degree of organ dysfunction (see section on Pharmacokinetics).

Routine monitoring of serum lamotrigine levels is not considered necessary [106,259,260] and dosage should be adjusted according to individual clinical response and tolerability. Serum drug level monitoring, however, may be indispensable in maintaining an individually tailored lamotrigine serum concentration through periods of alteration in lamotrigine pharmacokinetics discussed in this chapter, for example during pregnancy and puerperium and when potential interacting drugs are added or removed. While no other laboratory monitoring is recommended during lamotrigine treatment, clinical monitoring for adverse symptoms is important in view of rare reports of adverse systemic reactions.

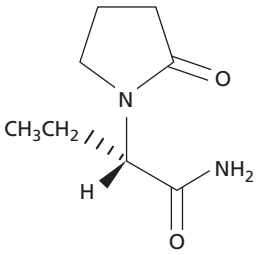
44 Levetiracetam

Jacqueline A. French[1] *and Françoise Tonner*[2]

[1]New York University Comprehensive Epilepsy Center, New York, NY, USA
[2]UCB Pharma S.A., Braine L'Alleud, Belgium



Primary indications	First-line and adjunctive therapy of partial-onset seizures. Adjunctive and, possibly, first-line therapy of generalized tonic–clonic seizures and myoclonic seizures associated with idiopathic generalized epilepsies. May also be valuable in the treatment of other generalized seizure types
Usual preparation	Immediate-release tablets: 250, 500, 750, 1000 mg Extended-release tablets: 500 mg, 750 mg Oral solution: 100 mg/mL Intravenous formulation: 500 mg/5 mL
Usual dosage	Adults: 1000–3000 mg/day. Treatment may be started with 500 or 1000 mg/day and increased to target dose by increments of 500 mg or 1000 mg every 1–2 weeks Children: 20–60 mg/kg/day. Treatment may be started at 10–20 mg/kg/day and adjusted, according to response, by increments of 10–20 mg/kg/day every 2 weeks
Dosing frequency	Twice daily
Significant drug interactions	Enzyme-inducing antiepileptic drugs decrease plasma levetiracetam levels by about 20–30%
Serum level monitoring	Dosage can usually be adjusted on the basis of clinical response. Monitoring serum levetiracetam levels may be useful in selected cases
Reference range	12–46 mg/L
Common/important adverse effects	Somnolence, asthenia, dizziness, ataxia, infection, nervousness, irritability, behavioural and psychiatric disorders
Main advantages	Relatively broad-spectrum activity, good tolerability and lack of clinically significant drug interactions
Main disadvantages	Efficacy in some generalized seizure types and epilepsy syndromes unproven. Behavioural and psychiatric adverse effects
Mechanism of action	Binds to synaptic vesicle 2A (SV2A) protein
Oral bioavailability	Complete
Time to peak levels	0.5–2 h (2–10 h with extended-release tablets)
Elimination	Primarily by urinary excretion in unchanged form. About 24% of the dose undergoes hydrolysis to LO57. Minor oxidized metabolites account for about 3% of urinary recovery
Volume of distribution	0.5–0.7 L/kg
Elimination half-life	6–8 h

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Plasma clearance	0.9–1.3 mL/min/kg (values in the upper range for patients co-medicated with enzyme inducers). Clearance is faster in children and slower in the elderly
Protein binding	<10%
Active metabolites	None known
Comment	A valuable antiepileptic drug for both first-line use and adjunctive therapy

Introduction

The antiepileptic drug (AED) levetiracetam is a pyrrolidine derivative that differs from all other currently approved AEDs in its chemical structure, pharmacological profile and mechanism of action, and as a consequence possesses unique pharmacological properties. Levetiracetam was first approved in the USA in 1999 as adjunctive treatment in patients with partial-onset seizures, and subsequently gained approval for this and other indications in many countries around the world. This chapter will review preclinical data, efficacy, safety and clinical use.

Chemistry

Levetiracetam is a white to off-white crystalline powder that is highly soluble in water (104.0 g/100 mL) and freely soluble in chloroform (65.3 g/100 mL) and in methanol (53.6 g/100 mL). Its chemical name is (–)(*S*)-α-ethyl-2-oxo-1-pyrrolidine-acetamide and its chemical structure can be found in the summary table on the opening page of this chapter. Its molecular weight is 170.21. Levetiracetam is a racemically pure S-enantiomer [1]. The R-enantiomer has been shown to be devoid of anticonvulsant properties in animal models of epilepsy [2].

Pharmacology

Activity in experimental models of seizures and epilepsy

Unlike other AEDs, levetiracetam is not active in standard animal screening models which rely on production of an acute seizure, such as the maximal electroshock and the subcutaneous pentylenetetrazole model [3], which had previously been thought to reliably identify compounds endowed with antiepileptic effects in man. Levetiracetam does not show protective activity in a variety of maximal chemoconvulsive seizure models in mice, including seizures induced by the excitatory amino acids *N*-methyl-D-aspartate (NMDA), kainic acid and α-amino-3-hydroxy-5-methyl-4-isoxazolone propionate (AMPA), as well as bicuculline, picrotoxin and 3-mercaptopropionic acid [4]. However, it is active against seizures induced by pilocarpine and kainic acid in rats, which mimic human partial seizures with secondary generalization. Despite its unusual and mostly inactive profile in acute seizure models, levetiracetam is active in a variety of animal models that are felt to mimic chronic epilepsy, such as the amygdala kindling model in rats and pentylenetetrazole kindling in mice [4]. One study [5] demonstrated that levetiracetam is effective in a subset of amygdala-kindled rats which are resistant to phenytoin, suggesting that levetiracetam might be useful in patients who had been treatment resistant in the past. Levetiracetam is also effective in genetic animal models that resemble human spike–wave conditions, including the Genetic Absence Epilepsy Rat from Strasbourg (GAERS) [6].

Levetiracetam is also effective in delaying the acquisition of amygdala kindling in rats and corneal and pentylenetetrazole kindling in mice [2,7]. This is felt to signal a potential antiepileptogenic effect, which is not present for many standard AEDs. Phenytoin and carbamazepine do not delay acquisition of kindling, although valproic acid and phenobarbital do. However, levetiracetam is the only one of these three drugs that delays acquisition of kindling at doses that are devoid of adverse effects [4].

Some experiments indicate a potential for the development of tolerance in the amygdala-kindled rat model, but no tolerance was observed in a chronic mouse model of epilepsy or in a bicuculline rat model [4,8,9]. Of note, a recent experiment in chronically seizing rats demonstrated that levetiracetam infusion produced complete suppression of seizures in the first 3 days, after which seizures gradually returned to baseline frequency, despite continuously elevated brain concentrations of the drug [10]. A 2-week hiatus in treatment led to a return of effect. The significance of these disparate findings remains to be determined. Levetiracetam is not considered to be a substrate for the P-glycoprotein multidrug transporter [11].

In preclinical safety tests, levetiracetam did not produce motor impairment in the Rotarod test in rats and mice, except at very high levels, and did not cause obvious sedation in the open-field test [3,4]. In both the kindling model and the GAERS model, there was a wide safety margin between the effective dose and the neurotoxic dose. Levetiracetam, in contrast to other AEDs, did not demonstrate an increase in neurotoxicity when used in kindled animals compared with control animals [4]. Levetiracetam did not produce cognitive impairment in the Morris water maze test in rats, whereas carbamazepine, valproic acid and clonazepam did [12].

Mechanisms of action

The mechanism of action of levetiracetam differs from that of other AEDs and appears to be mediated by binding to the synaptic vesicular protein SV2A [13]. The precise mechanism by which this binding produces an anticonvulsant effect is unknown, but it is likely to involve inhibition of neurotransmitter release from end

terminals. There is a strong correlation between binding affinity at this site and anticonvulsant potency as measured in a number of animal models, including the mouse audiogenic seizure model, the mouse corneal kindling model and the GAERS rat [14].

The binding of levetiracetam to SV2A can be displaced by piracetam, ethosuximide and pentylenetetrazole, but not by commonly used AEDs such as phenytoin and carbamazepine [15]. Levetiracetam's action does not involve any of three main mechanisms underlying the effects of classical AEDs (i.e. blockade of sodium and T-type calcium channels and enhancement of GABAergic neurotransmission) [16]. Some studies suggest that levetiracetam moderately inhibits N-type calcium channels and opposes the inhibitory action of zinc on GABA- and glycine-gated currents [16]. It is unclear whether these mechanisms have a role in its antiepileptic action. Levetiracetam inhibits burst firing without affecting normal neuronal excitability [17,18]. This appears to relate to a novel ability to inhibit hypersynchronization of epileptiform activity, which distinguishes levetiracetam from other AEDs [19].

Pharmacokinetics

Levetiracetam shows linear pharmacokinetics. The pharmacokinetic profile of the drug has been studied in healthy adults, in adults and children with epilepsy, in elderly subjects and in subjects with renal and hepatic impairment.

Absorption

Immediate-release tablets

Levetiracetam is rapidly and virtually completely absorbed after oral administration of immediate-release tablets, with an absolute oral bioavailability close to 100%. Peak plasma concentrations (C_{max}) are reached in 0.5–2 h [20,21]. Administration with food does not reduce the extent, but slows the rate of absorption [20]. Administering the immediate-release tablets after crushing and mixing them with apple sauce or enteral nutritional formulas slightly reduced C_{max}, but not significantly so [22].

Oral solution

The pharmacokinetic profile for the 10% oral solution of levetiracetam is essentially identical to that of the tablet formulation. Because the solution is bioequivalent to the tablets, no adjustment in dosage is necessary if a patient is switched from one formulation to another [23].

Extended-release formulation for once-daily administration

An extended-release formulation has been designed to be administered once a day. After administration of levetiracetam extended release under fasting conditions, median time to peak is delayed by approximately 3 h compared with the immediate-release formulation (4 h versus 0.9 h, respectively). At a dosage of 1000 mg/day, the average steady-state plasma concentration was 12.9 mg/L [coefficient of variation (CV) = 13%] with levetiracetam extended release given once daily and 13.6 mg/L (CV = 16%) with immediate-release tablets given twice daily, and the two regimens were bioequivalent [24]. The absorption of the extended-release formulation is not modified by food intake [24].

Intravenous formulation

Levetiracetam is available as an intravenous formulation (100 mg/mL), to be administered as a 15-min infusion. A 1500-mg intravenous infusion is bioequivalent to the oral formulation (three doses of 500-mg tablets) and steady-state conditions are achieved in 48 h with twice-daily intravenous dosing [21]. Pharmacokinetic modelling using adult intravenous and paediatric oral data indicate that a 15-min infusion should also be optimal for paediatric populations [25]. Approval of the intravenous use in children was granted in the European Union on this basis, without formal paediatric trials.

Distribution

The volume of distribution of levetiracetam is similar to intracellular and extracellular water, at 0.5–0.7 L/kg. Despite its water-soluble nature, levetiracetam readily and freely crosses the blood–brain barrier [26]. Levetiracetam also crosses the placenta, and fetal plasma levels approximate maternal levels. Levetiracetam is also excreted in breast milk at concentrations comparable to those in maternal plasma [27,28].

Levetiracetam is <10% bound to plasma proteins [29]. Saliva and plasma concentrations are similar, as shown in children [30] and in adults [31].

Elimination

Overall, 66% of an orally administered dose of levetiracetam is excreted unchanged in the urine. Most of the remainder (24%) is metabolized by enzymatic hydrolysis of the acetamide group to the corresponding carboxylic acid ucb L057 [20], which has no known pharmacological activity. Hydrolysis occurs diffusely in different tissues. Conversion to minor oxidized metabolites accounts for about 3% of urinary recovery.

In healthy volunteers, the apparent total body clearance of levetiracetam across studies is around 70 mL/min (1 mL/min/kg) on average. The half-life of levetiracetam in adults is approximately 6–8 h. However, since the mechanism of action is unclear, this may not necessarily reflect the functional half-life, and indeed there is evidence from studies of the effect on the photoparoxysmal response that the duration of effect (up to 30 h, after single 250- to 750-mg doses) may be much longer than the drug's half-life [32]. It was on this basis that a twice-daily regimen was selected for clinical trials.

Pharmacokinetics in special populations

Ethnic groups

The pharmacokinetics of levetiracetam has been evaluated in Asians of both Chinese and Japanese descent, and appears to be similar to that in whites, when differences in body weight are taken into account [33,34].

Infants and children

Levetiracetam pharmacokinetics has been assessed in infants and children with epilepsy in a variety of studies [30,35–37]. Follow-

ing a single oral dose of 20 mg/kg in 24 children aged 9.4 ± 2.2 years, the average plasma clearance of levetiracetam was 1.43 ± 0.36 mL/min/kg and the average half-life was 6.0 ± 1.1 h [36]. At steady state with 20 mg/kg twice-daily dosing in 14 children aged 10.2 ± 2.2 years, the mean plasma clearance was 1.10 ± 0.16 mL/min/kg and the mean half-life was 4.9 ± 0.4 h [30]. In a third study, 13 infants and young children aged 19.9 ± 14.16 months (range 2.3–46 months) received a single dose of 20 mg/kg, and the mean clearance and half-life were 1.46 ± 0.42 mL/min/kg and 5.3 ± 1.3 h respectively [35]. Overall, these results suggest that levetiracetam clearance, normalized for body weight, is about 20–45% greater in infants and children than in adults.

Population pharmacokinetics was used to analyse pooled data collected from 228 children with epilepsy aged 3 months to 18 years [37]. The main explanatory variables were the influence of age on the absorption rate, of body weight on clearance and on distribution volume, and of enzyme-inducing AEDs on clearance, body weight being the most influential covariate. Concomitant use of enzyme-inducing AEDs lowered the plasma concentrations of levetiracetam by about 20%. Simulations were performed to identify dosing regimens achieving steady-state peak and trough plasma levetiracetam concentrations similar to those attained in adults receiving a dose of 500 mg twice daily, the recommended starting dose for adjunctive therapy in the product information sheet. It was concluded that, to achieve these concentrations, dosing can be carried out with either 10 mg/kg of oral solution twice daily in children weighing <50 kg and a 500-mg tablet twice daily in those weighing >50 kg or, when patients favour a solid formulation, 10 mg/kg of oral solution twice daily in children weighing <20 kg, a 250-mg tablet twice daily in those weighing 20–40 kg, and a 500-mg tablet twice daily in those weighing >40 kg. As in adults, this dose could be adjusted based on the individual efficacy and tolerability within the range of 10–30 mg/kg twice daily.

Pregnancy and perinatal period

The pharmacokinetics of levetiracetam was investigated in women with epilepsy receiving levetiracetam treatment during pregnancy and lactation, as well as in neonates born to these women [27]. In 12 pregnant women, levetiracetam apparent oral clearance was significantly increased from 87 ± 40 mL/min at baseline to 297 ± 147 mL/min during the third trimester, implying that at unchanged doses the plasma concentration of the drug decreases by a mean of about 70% between baseline and the third trimester. At delivery, the concentration of levetiracetam in neonatal cord blood approximated maternal plasma concentration (mean ratio 1.09, range 0.64–2.0). However, neonatal plasma concentrations declined to 20% of maternal levels within 36 h, despite the fact that most infants were breastfed. Neonatal elimination half-life was 18 h [27]. Concentrations of levetiracetam in breast milk were similar to maternal plasma concentrations, and no accumulation was found in the plasma of breastfed infants [27,28]. Plasma concentrations of levetiracetam in these infants were about 13% of those seen in the mothers.

A marked decline in plasma concentration of levetiracetam during pregnancy, followed by a rapid increase after delivery, has been confirmed in another study [38]. In 11 women, the mean plasma concentration–dose ratio in the third trimester of pregnancy was only one-half of the mean concentration–dose ratio at baseline.

Table 44.1 Levetiracetam dosing in patients with renal impairment.

Renal function	Creatinine clearance (mL/min/1.73 m^2)	Dose administered twice daily (mg)
Normal	>80	500–1500
Mild	50–80	500–1000
Moderate	30–50	250–750
Severe	<30	250–500

From ref. 41 with permission.

The elderly

In a study based on therapeutic drug monitoring data, levetiracetam apparent oral clearance was compared in the youngest (16–31 years; $n = 151$) and oldest (55–88 years; $n = 157$) quartile of a population of 629 adult outpatients receiving levetiracetam therapy [39]. On average, clearance was 40% lower in older patients than in younger patients (46.5 versus 78.3 mL/h/kg, respectively). In another study conducted in 16 hospitalized elderly patients, levetiracetam exhibited a prolonged half-life, which could be explained entirely by reduced creatinine clearance [40]. The elimination half-life was approximately 10–11 h, compared with 7.7 h in younger normal subjects [20]. Adjustments in dosage in elderly patients should be made based on estimated creatinine clearance, taking body surface area into account.

Renal impairment

As might be expected, renal impairment reduces the clearance of levetiracetam and its metabolites. Compared with values recorded in subjects with normal renal function, levetiracetam clearance is reduced on average by 40% with a creatinine clearance (CL_{Cr}) of 50–80 mL/min, by 50% with CL_{Cr} of 30–50 mL/min, and by 60% with $CL_{Cr} < 30$% [20,41]. Dose reductions in relation to the degree of renal impairment are recommended, as outlined in Table 44.1. For patients with renal failure on dialysis, a dose of 500–1000 mg/24 h is recommended, with a supplemental dose of 250–500 mg after a dialysis treatment [20].

Hepatic impairment

The disposition of levetiracetam has been investigated in subjects with various stages of hepatic impairment. Mild to moderate (Child–Pugh class A or B) hepatic impairment did not alter the clearance of levetiracetam, and no dosage adjustments are required in these patients. However, levetiracetam clearance was reduced in severe hepatic failure (Child–Pugh class C), most likely due to concomitant renal insufficiency [42]. Adjustments in dose should therefore be made based on renal rather than hepatic function.

Drug interactions

A study using human liver microsomal enzymes revealed no inhibitory effects of levetiracetam on drug-metabolizing enzymes,

including CYP3A4, CYP1A2, CYP2C19, CYP2C9, CYP2E1, CYP2D6, epoxide hydrolase and various uridine glucuronyltransferases [43]. Because the major metabolic pathway of levetiracetam is not cytochrome P450 dependent, and because levetiracetam does not induce or inhibit drug-metabolizing enzymes, interactions between levetiracetam and other drugs are considered unlikely. However, because unpredictable interactions may occur, specific investigations were performed with commonly used agents.

Effect of other drugs on levetiracetam pharmacokinetics

Two population pharmacokinetic analyses conducted in adults [33,44,45] and in children [37] showed that concomitant use of enzyme-inducing AEDs led to an increase of about 20% in levetiracetam clearance. In another study, co-medication with an enzyme-inducing AED, mostly carbamazepine, was associated with a 24% increase in levetiracetam clearance [39]. In a small number of patients who were studied on and off concomitant enzyme-inducing AEDs, however, levetiracetam clearance was 37% higher while enzyme inducers were co-administered [39]. At least for the majority of patients, no adjustments in levetiracetam dosage are expected to be required when enzyme-inducing AEDs are added or withdrawn.

Probenecid increases the plasma levels of the levetiracetam metabolite ucb L057 2.5-fold, by inhibiting renal tubular excretion, but does not affect the pharmacokinetics of the parent drug [20].

Effect of levetiracetam on the pharmacokinetics of other drugs

When up to 2000 mg/day levetiracetam was added on in patients receiving monotherapy with phenytoin (n = 6), carbamazepine (n = 4), valproic acid (n = 6) or a combination of carbamazepine and valproic acid (n = 2), there were no changes in plasma levels of the background drugs [46]. Another small study of 17 refractory epilepsy patients found no effect of levetiracetam on the plasma levels of carbamazepine, phenobarbital, valproic acid, primidone and clobazam [47]. In this study, there was a variable change in plasma phenytoin levels when levetiracetam was added. This potential interaction was specifically investigated in a subsequent study [48]. Tracer doses of deuterium-labelled phenytoin were given intravenously before and 12 weeks after adding on levetiracetam to the regimen of patients initially taking phenytoin as monotherapy. Phenytoin pharmacokinetic parameters did not change after adding levetiracetam. The authors concluded that levetiracetam does not affect phenytoin disposition.

The potential influence of levetiracetam on the pharmacokinetics of other AEDs was also assessed during randomized controlled trials. Plasma levels of concomitant AEDs were not significantly altered in any of the placebo-controlled adjunctive trials of levetiracetam or in a pooled analysis in adults and in children [44–45,49–52].

In interaction studies with oral contraceptives digoxin and warfarin, no evidence of any specific interaction between levetiracetam and these agents could be demonstrated [43].

Serum level monitoring

Plasma or serum concentrations of levetiracetam have been determined using gas chromatography with nitrogen phosphorus detection [29], high-performance liquid chromatography with ultraviolet detection [53] or liquid chromatography with mass spectrometric detection [54].

Levetiracetam exhibits moderate intra- and interindividual variability in pharmacokinetics, compared with other AEDs. However, due to its relatively short half-life, coupled with the common practice of twice-daily administration, plasma concentrations will vary over the course of the day, depending on temporal relationship to the last dose. Thus, if monitoring is performed for the purpose of measuring compliance, it should be done at the same time in relation to dose (usually trough levels). In patients who benefit from levetiracetam therapy, plasma concentrations in the range of 8–40 mg/L have been reported [55,56]. In a recent position paper published by a subcommittee of the International League Against Epilepsy, the reference range for plasma levetiracetam concentrations was set at 12–46 mg/L, although it was emphasized that individual patients may require concentrations outside this range [57].

To date, the clinical utility of monitoring plasma levetiracetam levels has not been established, but there are reasons to expect that concentration measurements may be valuable in selected situations, such as a check for compliance or when clinically important changes in plasma concentrations are expected (e.g. before and during pregnancy, and during puerperium). It is recommended that the blood be centrifuged within a short time frame after sampling, so as to avoid levetiracetam hydrolysis *in vitro* that would result in spuriously lower concentrations being measured [58].

Efficacy

Adjunctive therapy in refractory partial seizures in adults

Studies with the conventional formulation

Levetiracetam has been demonstrated to be effective in reducing the frequency of partial-onset seizures in patients with treatment-resistant epilepsy in three randomized controlled studies [50–52]. The characteristics of these studies can be found in Table 44.2. A total of 904 subjects were randomized to placebo or levetiracetam 1000 mg/day, 2000 mg/day or 3000 mg/day. Results from these studies showed that levetiracetam-treated patients had significantly fewer seizures than placebo-treated patients, as measured by the responder rate (proportion of patients with ≥50% reduction in weekly seizure frequency from baseline) and percent reduction in seizure frequency.

In a fourth study, also summarized in Table 44.2, patients with fewer refractory partial-onset or primary generalized tonic–clonic seizures (eligibility criteria allowed inclusion of patients with low seizure frequency, that is up to four seizures during the 24 weeks prior to enrolment) were randomized to placebo, 2000 mg/day levetiracetam or 4000 mg/day levetiracetam, started without titration [49]. Responder rates were higher

Table 44.2 Randomized placebo-controlled trials of levetiracetam as adjunctive therapy in adults with partial-onset seizures.

Study	*n*	Design	Inclusion criteria	Doses	Treatment duration	Percentage responders (patients with ≥50% seizure reduction). *P*-values refer to each levetiracetam group compared with placebo	Percentage seizure free for full study duration
Shorvon [51]	324	Double-blind randomized parallel	Refractory partial seizures; ≥4 seizures/4 weeks; one or two concomitant AEDs	1000 mg, 2000 mg	12 weeks	Placebo: 10.4% 1000 mg: 22.8%, $P = 0.019$ 2000 mg: 31.6%, $P < 0.001$	Placebo: 9% 1000 mg: 5% 2000 mg: 2%
Ben-Menachem [52]	286	Double-blind randomized parallel group followed by responder-selected	Partial seizures; 2 or more seizures/4 weeks; one concomitant AED	3000 mg	18 weeks (add-on phase only)	Placebo: 16.7% 3000 mg: 42.1%, $P < 0.001$	Placebo: 1.0% 3000 mg: 8.2%
Cereghino [50]	294	Double-blind randomized parallel	Refractory partial seizures; ≥12 seizures/12 weeks; one or two concomitant AEDs	1000 mg, 3000 mg	18 weeks	Placebo: 10.8% 1000 mg: 33.0%, $P < 0.001$ 3000 mg: 39.8%, $P < 0.001$	Placebo: 0.0% All levetiracetam doses: 5.5%
Betts [49]	119	Double-blind randomized parallel group	Refractory partial seizures;[a] ≥4 seizures/24 weeks; one to three concomitant AEDs	2000 mg, 4000 mg[b]	24 weeks	Placebo: 16.1% 2000 mg: 28.6%, $P = 0.01$ 4000 mg: 48.1%, NS	Placebo: 2.5% 2000 mg: 9.5% 4000 mg: 5.2%

[a] Also included patients with primarily generalized tonic–clonic seizures.
[b] No titration was used in this study.

with levetiracetam 2000 mg/day (48.1%, $P < 0.05$, $n = 27$) and 4000 mg/day (28.6%, NS, $n = 28$) than with placebo (16.1%, $n = 31$). When all patients were converted to 4000 mg/day in a non-blinded extension phase, no additional efficacy was gained (46.2% responder rate in patients initially treated with 2000 mg/day versus 39.3% in patients initially treated with 4000 mg/day).

Pharmacological modelling of seizure count data from the four trials led to the conclusion that about three-quarters of patients on levetiracetam exhibited a reduced seizure frequency from baseline [59]. There was a significant relationship between dose and seizure frequency reduction from baseline, characterized by an ED_{50} of 1408 mg/day. Age, gender, body weight, race and number of concomitant AEDs affected neither the percentage of improving patients nor the extent of change in seizure frequency from baseline.

A Cochrane review [60] demonstrated that the overall odds ratio (OR) for levetiracetam versus placebo for responder rates across the four double-blind placebo-controlled studies described above was 3.81 [95% confidence interval (CI) 2.78–5.22]. The review provided clear evidence for levetiracetam's efficacy, with an increase in effect with increasing dose within the 1000–3000 mg/day dose range.

A pooled analysis investigated seizure freedom rates. When seizure freedom was defined as the absence of seizures during the stable dose period, and withdrawals were counted as not seizure free, seizure freedom rates were 0.8%, 4.7%, 6.3% and 8.2% for placebo and levetiracetam 1000 mg/day, 2000 mg/day and 3000 mg/day, respectively [61].

In a retrospective pooled analysis, a fast onset of action was demonstrated within the first weeks of treatment in patients with partial-onset seizures [62]. With respect to long-term efficacy, Zaccara *et al.* [63] reviewed eight open-label long-term studies in adults with refractory, mostly partial-onset, seizures in whom levetiracetam was added to a previous treatment. Selected studies reported or allowed the calculation of the number of patients who achieved seizure freedom for 6 months and/or the number of patients withdrawing for adverse effects and/or the number or percentage of patients continuing treatment after 1 year. The results showed that the total percentage of patients who experienced 6 months' seizure freedom was 13.2% (95% CI 11.8–14.6). After 1 year of treatment, levetiracetam retention rates, a combined estimate of efficacy and safety, ranged from 60% to 75%.

Studies with the extended-release formulation

A double-blind, placebo-controlled study demonstrated the efficacy and tolerability of once-daily dosing with 1000 mg (two doses of 500-mg tablets) levetiracetam extended release as add-on therapy in patients (12–70 years old) with refractory partial-onset seizures uncontrolled on one to three AEDs [64]. After an 8-week prospective baseline, patients were randomized to levetiracetam extended release ($n = 79$) or placebo ($n = 79$) for 12 weeks without titration. The median per cent reduction in partial-onset seizure frequency per week on levetiracetam extended release was 46.1% compared with 33.4% on placebo. The estimated per cent reduction over placebo in seizure frequency per week over the treat-

ment period was 14.4% in the intent-to-treat (ITT) population ($P = 0.038$). Overall, 43% of patients on levetiracetam extended release were responders compared with 29.1% of patients on placebo. Among subjects who completed the 12-week treatment, 8/79 (10.1%) patients on levetiracetam extended release and 1/79 (1.3%) on placebo were free of partial-onset seizures during the treatment period.

Adjunctive therapy in refractory partial seizures in children

A randomized placebo-controlled trial assessed the efficacy of levetiracetam as adjunctive therapy in children (4–16 years of age) with treatment-resistant partial-onset seizures [65]. A total of 198 children were randomized and provided evaluable data. The starting dose of 20 mg/kg/day was up-titrated to a target dose of 60 mg/kg/day. A ≥50% reduction in partial seizure frequency per week was attained in 44.6% of patients (45/101) in the levetiracetam group, compared with 19.6% of patients (19/97) in the placebo group ($P = 0.0002$). Seven (6.9%) levetiracetam-treated patients were seizure free during the entire 14-week double-blind treatment period, compared with one (1.0%) placebo-treated patient. Of 192 patients who completed the short-term phase, 183 entered a long-term phase.

A multicentre, double-blind, randomized, placebo-controlled, parallel-group, adjunctive therapy inpatient study assessed the efficacy and safety of levetiracetam oral solution (20–50 mg/kg/day) in infants and children (1 month to less than 4 years of age) with partial-onset seizures. The study consisted of a 5-day evaluation period that included 1 day's up-titration. The average daily seizure frequency was calculated from a 48-h screening video-EEG assessment over the last 2 days of the evaluation period. Video-EEGs were read by an experienced reader who was blinded to treatment groups. The ITT population included 116 patients randomized, and the modified ITT population included 109 (58 levetiracetam, 51 placebo) patients, representing all ITT subjects who completed the baseline video-EEG and at least 24 h of the evaluation video-EEG, plus any randomized subjects who withdrew before the first 24 h of the evaluation video-EEG for reasons linked to lack or loss of efficacy. The responder rate was significantly greater for levetiracetam (43.1%) than for placebo (19.6%; $P = 0.013$), with consistent results across all age categories (1 month to <1 year; 1 year to <2 years; 2 years to <4 years) [66].

Monotherapy in partial-onset seizures

One double-blind, randomized, placebo-controlled study evaluated levetiracetam as monotherapy after conversion from adjunctive treatment in refractory patients with partial-onset seizures [50]. A total of 286 patients entered an initial double-blind randomized 18-week phase during which they received add-on levetiracetam (3000 mg/day, $n = 181$) or placebo ($n = 105$). The 86 patients who had a ≥50% reduction in seizure frequency (whether on placebo or levetiracetam) during the randomized add-on phase underwent a 12-week gradual taper of their background AED, after which they entered a 12-week monotherapy phase. Patients exited the study if they had worsening of seizures, as measured by pre-established criteria. By the end of the study, 19.9% (36/181) of patients initially randomized to levetiracetam were able to complete the study, compared with 9.5% (10/105) of placebo patients. Nine of the 49 patients who were successfully down-titrated to levetiracetam monotherapy were seizure free.

Another monotherapy study was performed in patients with newly diagnosed epilepsy [67]. In this study, levetiracetam was compared with controlled-release carbamazepine at optimized dosages in a non-inferiority designed trial, which was the first study to comply with European regulations for the evaluation of a new AED in pursuit of a monotherapy indication. Adults with two or more partial-onset or generalized tonic–clonic seizures in the previous year (excluding patients with clinical or EEG evidence suggestive of idiopathic generalized epilepsy) were randomly assigned to levetiracetam (500 mg twice daily, $n = 288$) or controlled-release carbamazepine (200 mg twice daily, $n = 291$). Dosage was adjusted stepwise based on seizure recurrence up to an intermediate (levetiracetam 2000 mg/day; carbamazepine 800 mg/day) or up to the maximum daily dose (levetiracetam 3000 mg/day or carbamazepine 1200 mg/day). Patients achieving the primary endpoint (6 months' seizure freedom) continued on treatment for a further 6-month period. At per-protocol analysis, 73.0% (56.6%) of patients randomized to levetiracetam and 72.8% (58.5%) of those randomized to carbamazepine were seizure free for 6 months (1 year) at the last evaluated dose (adjusted absolute difference for the primary endpoint 0.2%; 95% CI 7.8–8.2%). Because the lower limit of the 95% CI for the adjusted absolute difference for the primary endpoint was above the non-inferiority limit set by the study protocol (–15%), levetiracetam could be considered non-inferior to controlled-release carbamazepine. Of all patients achieving 6-month (1-year) seizure freedom, 80.1% (86.0%) in the levetiracetam group and 85.4% (89.3%) in the carbamazepine group did so at the lowest dose level (levetiracetam 1000 mg/day; carbamazepine 400 mg/day). More than 50% of the patients who were escalated to the intermediate (levetiracetam 2000 mg/day; carbamazepine 800 mg/day) or highest (levetiracetam 3000 mg/day; carbamazepine 1200 mg/day) doses responded to treatment. Levetiracetam and controlled-release carbamazepine produced equivalent seizure freedom rates in newly diagnosed epilepsy at optimal dosing in a setting mimicking clinical practice.

Adjunctive therapy in refractory generalized epilepsies

The first randomized placebo-controlled trial of levetiracetam in patients with idiopathic generalized epilepsy with myoclonic seizures evaluated the efficacy and safety of a 3000 mg/day dose as adjunctive therapy in 120 subjects (12–65 years old) diagnosed with either juvenile myoclonic epilepsy (93.4%) or juvenile absence epilepsy (6.6%) [68]. The response rate during the 16-week treatment period (reduction of ≥50% in the number of days/week with myoclonic seizures) was 58.3% in the levetiracetam group compared with 23.3% in the placebo group ($P < 0.001$). Levetiracetam-treated patients were more likely to respond to treatment than patients receiving placebo (OR 4.77; 95% CI 2.12–10.77; $P < 0.001$). Levetiracetam-treated patients also had higher freedom rates from myoclonic seizures (25.0% versus 5.0%; $P = 0.004$) and from all seizure types (21.7% versus 1.7%; $P < 0.001$) during the 12-week evaluation period.

Another randomized, double-blind, placebo-controlled, parallel-group study enrolled adults and children (4–65 years of age)

with uncontrolled generalized tonic–clonic seizures associated with idiopathic generalized epilepsies [69]. Patients were randomized to levetiracetam (target dose 3000 mg/day for adults; 60 mg/kg/day for children) or placebo as adjunctive therapy. Among the 164 randomized patients (levetiracetam, $n = 80$; placebo, $n = 84$), the percentage who had a ≥50% reduction in the frequency of generalized tonic–clonic seizures per week (responders) during the treatment period was 72.2% for the levetiracetam group and 45.2% for the placebo group ($P < 0.001$; OR 3.28; 95% CI 1.68–6.38). During the 20-week evaluation period, seizure freedom rates were greater on levetiracetam than on placebo for both generalized tonic–clonic seizures (34.2% versus 10.7%; $P < 0.001$) and all seizure types (24.1% versus 8.3%; $P = 0.009$).

The results of these randomized studies demonstrate that levetiracetam is an effective adjunctive treatment for patients with previously uncontrolled idiopathic generalized epilepsy with myoclonic or tonic–clonic seizures, and confirm a spectrum of efficacy for levetiracetam beyond partial-onset seizures.

Suggestive evidence for levetiracetam having broad-spectrum efficacy in generalized seizure types also comes from uncontrolled studies in patients with idiopathic generalized epilepsies [70–73], including juvenile myoclonic epilepsy, eyelid myoclonia with absences [71] and other syndromes associated with absence seizures [74,75], and from studies in non-idiopathic generalized epilepsies [76–78]. In some case series, patients with progressive myoclonic epilepsy experienced dramatic improvements with the addition of levetiracetam to their regimen [77,79], and favourable responses have also been reported in children with severe myoclonic epilepsy of infancy [78]. Because of the nature of these observations, some of which are restricted to case reports, these findings require adequate confirmation in controlled studies.

Impact on patient functioning and health-related quality of life

Results from a double-blind placebo-controlled efficacy study of levetiracetam added to standard therapy in patients with partial-onset seizures [50] showed improvements over placebo in most domains of QOLIE-31 [80], a multidimensional instrument that measures the impact of epilepsy and its treatment on important dimensions of a patient's functioning and health-related quality of life (cognitive functioning, daily activities/social functioning, emotional well-being, overall quality of life, energy/fatigue, seizure worry and medication effects) [81,82]. Specifically, a beneficial impact of levetiracetam over placebo was seen for seizure worry, cognitive function, overall quality of life and total score (P-values < 0.05). Levetiracetam responders (patients with ≥50% seizure reduction) had improvements in all scores, and did better than the placebo responder group. The QOLIE-31 was further assessed in patients who enrolled into a long-term open-label follow-up study [83]. Improvements observed in levetiracetam starters ($n = 66$) were sustained long term (mean follow-up 4.1 years). Placebo starters ($n = 35$) who were converted to levetiracetam in the open-label study reached similar levels of improvement in QOLIE-31 scores to earlier starters in the long term.

In patients with idiopathic generalized epilepsy with myoclonic seizures [68], results from QOLIE-31 assessments indicated improvements in patient functioning and health-related quality of life for levetiracetam-treated patients which were larger than the limited changes reflecting stability for the placebo group (for all scores but daily activities/social functioning). Since starting study medication, more patients receiving levetiracetam than placebo reported an improvement in their overall health-related quality of life (88.3% versus 60.4%). In the study in patients with idiopathic generalized epilepsy with generalized tonic–clonic seizures [69], treatment with levetiracetam resulted in greater improvements in quality of life from the start of study than with placebo (38.3% versus 28.6% important improvement in overall quality of life, respectively), as assessed by the QOLIE-31-P scale.

Adverse effects

The adverse effect profile of levetiracetam has been well characterized during phase I, II and III clinical trials. Collective safety data from 3347 subjects receiving levetiracetam during trials, including 1422 adults and children with epilepsy, 1558 subjects evaluated in studies for other indications (cognitive disorders, anxiety and deep vein thrombosis) and 367 subjects in clinical pharmacology studies, indicated that levetiracetam is well tolerated. Safety data from several double-blinded studies reported that the overall incidence of adverse events with levetiracetam 1000 mg/day (70.8–88.8%), 2000 mg/day (75.5–83.3%) and 3000 mg/day (55–89.1%) was similar to that observed with placebo (53–88.4%) [49–52].

An analysis of withdrawal rates for adverse events has been performed on the four double-blind, placebo-controlled studies [84] and on eight open-label long-term studies [63]. In the double-blind studies overall, 106 (15.8%) of 672 patients in the levetiracetam groups withdrew from treatment, compared with 46 (13.1%) of 351 patients in the placebo groups. The overall Mantel–Haenszel OR (95% CI) for the withdrawal rate was 1.26 (0.86–1.84). Since the confidence interval encompassed unity, withdrawal rates did not differ significantly between the levetiracetam groups and the placebo groups. In the selected prospective open-label long-term studies, 14.5% (95% CI, 13.0–15.9) of patients withdrew due to treatment-emergent adverse events.

Adverse events with adjunctive therapy in adults with partial-onset seizures

Most common adverse events

The most commonly reported treatment-emergent adverse events associated with levetiracetam in randomized adjunctive therapy trials in adults with partial-onset seizures were somnolence and asthenia (>10% of patients). In a pooled analysis, somnolence was recorded in 14.8% of patients treated with levetiracetam versus 8.4% of placebo patients [85]. In the recommended dose range (1000–3000 mg/day), there was no clear dose–response relationship for adverse events [86]. For example, in one study, somnolence occurred in 20.4% of patients at 1000 mg/day levetiracetam versus 18.8% at 3000 mg/day, compared with 13.7% of placebo patients [50]. The overall incidence of asthenia was 14.7% compared with 9.1% of placebo patients, and again was not dose related. Other adverse effects included dizziness and nervousness.

Table 44.3 Overview of adverse events reported more commonly with levetiracetam administered at different dosages than with placebo in the pivotal placebo-controlled as adjunctive therapy in adults with predominantly refractory partial-onset seizures, with or without secondary generalization.

Adverse events	Incidence (% of patients)				
	Placebo	Levetiracetam 1000 mg/day	Levetiracetam 2000 mg/day	Levetiracetam 3000 mg/day	Levetiracetam 4000 mg/day

[a] Levetiracetam was started without titration of the dose.

A summary of adverse events recorded in placebo-controlled trials is given in Table 44.3. In a study where no titration was used, the incidence of somnolence, nausea and dizziness was greater during initiation of the medication and at the higher dose of 2000 mg twice daily [49]. On the other hand, a clear dose-related effect for asthenia and headache was not established. In the Cochrane review [60] based on the four double-blind, placebo-controlled studies, incidence rates for ataxia, dizziness, fatigue, nausea, somnolence, accidental injury, headache and infection were analysed. Dizziness (OR 2.36, 99% CI 1.21–4.61) and infection (OR 1.82, 99% CI 1.05–3.14) were statistically associated with levetiracetam. In contrast, accidental injury was significantly associated with placebo (OR 0.55, 99% CI 0.32 to 0.93). The incidence of ataxia, fatigue and somnolence was higher with levetiracetam than with placebo, while the incidence of headache and nausea did not differ statistically between levetiracetam and placebo. The clinical significance of infections, including upper respiratory tract (rhinitis and pharyngitis) and urinary tract infections, being increased in the levetiracetam group compared with placebo is unclear. There was no association with increases in white blood cell count, and none of the infections led to discontinuation of levetiracetam. Increased infection rates were seen in some studies and not in others, and may have been an artefact related to the terms used to report adverse effects and their coding [87].

Levetiracetam can be associated with behavioural disturbances and irritability. In premarketing studies, the category of behavioural symptoms including agitation, hostility, anxiety, apathy, emotional lability, depersonalization and depression was reported in 12.9% of levetiracetam patients compared with 6.2% of placebo patients ($P < 0.001$) [88]. Furthermore, 0.7% of levetiracetam patients reported psychotic symptoms compared with 0.2% of placebo patients, and suicidal behaviour occurred in 0.5% of levetiracetam patients versus none of the placebo patients [88]. Premarketing studies may not be ideal for assessing behavioural side-effects, because patients on antidepressants and other psychoactive medications are often excluded from clinical trials. Behavioural problems occurred at a lower rate in other populations treated with levetiracetam in early placebo-controlled trials, including patients with anxiety and cognitive disturbances [88]. This suggests that either the epileptic condition or concomitant AED use may increase the potential for behavioural problems associated with levetiracetam. Behavioural problems appear to remit when levetiracetam is discontinued. Paediatric studies have indicated that children may also be at risk for irritability and behavioural problems with levetiracetam. This is discussed below in the section on paediatric adverse effects.

In adjunctive therapy studies, the safety and tolerability of levetiracetam extended release in patients with partial-onset seizures have been similar to, if not better than, those of the immediate-release formulation. In the double-blind, placebo-controlled study conducted with the extended-release formulation, 41 (53.2%) patients randomized to levetiracetam extended release and 43 (54.4%) patients randomized to placebo reported at least one treatment-emergent adverse event. Somnolence and irritability occurred more frequently on levetiracetam extended release than on placebo [64].

Seizure aggravation

Somerville [89] explored the likelihood of seizure aggravation in randomized, placebo-controlled trials of second-generation AEDs. In the levetiracetam trials, some degree of seizure aggravation occurred in 44.8% of patients receiving placebo ($n = 310$), with ≥50% increases in seizure frequency being recorded in 15.2% and a doubling or worse in 5.8%. In the patients randomized to levetiracetam ($n = 589$), an increase in seizure frequency (25.7% for any worsening, 6.6% and 2.5% for ≥50% and ≥100% increases in seizure frequency, respectively) was significantly less likely to occur than in patients taking placebo.

In at least three of the four pivotal placebo-controlled double-blind studies of levetiracetam, exacerbation of seizures was reported among the serious adverse events that eventually led to discontinuation of the drug in a few patients. Five out of 460 epilepsy patients who received levetiracetam in these studies were reported to have had severe seizures [49,50,52]. A case series suggested that possible exacerbation of seizures may occur in a small number of patients at high doses of levetiracetam, especially in those with primary generalized epileptiform EEG discharges [90]. Others have reported that patients may worsen (increase in seizures) at higher doses of levetiracetam, and in these cases a dose reduction may lead to improvement [91]. However, in a pooled analysis, >25% worsening of seizure frequency occurred more frequently during add-on trials in the placebo groups (26%) than in the levetiracetam-treated groups (14%) [89].

Idiosyncratic reactions

Hypersensitivity and skin rash are uncommon adverse effects of levetiracetam. In placebo-controlled epilepsy trials, hypersensitivity reactions led to dose reduction or discontinuation in one patient in the levetiracetam groups, and in six in the placebo groups. There were no reports of Stevens–Johnson syndrome in the clinical trials with levetiracetam.

No clinically significant adverse effects were observed with any dosage of levetiracetam on haematology or blood chemistry tests, ECG assessments or vital signs.

No reports of serious idiosyncratic adverse effects attributable to levetiracetam are available to date. A total of 3347 patients were included in the levetiracetam safety database [92] and, as of 2007, 2 248 260 patient-years of market exposure had been estimated for levetiracetam (UCB, personal communication). Longer experience is needed to draw any conclusions about risks for rare serious idiosyncratic adverse effects, but the absence of such reports to date is reassuring.

Adverse events with monotherapy in adults with partial-onset seizures

In the monotherapy study comparing levetiracetam and controlled-release carbamazepine in newly diagnosed patients with partial epilepsy [67], discontinuation of treatment due to adverse events occurred in fewer patients on levetiracetam (14.4%) than on carbamazepine (19.2%), but the difference was not significant. Overall, there was no substantial difference in reported adverse events between the two treatment groups. However, depression and insomnia were reported significantly more often with levetiracetam, whereas back pain was experienced significantly more frequently with carbamazepine. More patients gained weight (≥7% of baseline) on carbamazepine than on levetiracetam (37/276, 13.4% versus 21/269, 7.8%).

Adverse events with the intravenous formulation

Two studies have been performed to assess the safety profile of the intravenous formulation, one in healthy subjects who received a single infusion either at high doses or at high infusion rates [93] and one in patients who received the infusion within the recommended dose range and with the recommended conditions of administration [94].

A randomized, single-blind, placebo-controlled study in 48 healthy subjects evaluated the safety, tolerability and pharmacokinetics of single doses of levetiracetam administered intravenously at higher doses (2000 mg, 3000 mg or 4000 mg over 15 min) or faster infusion rates (1500 mg, 2000 mg, 2500 mg over 5 min) than currently recommended [93]. Reported adverse events were primarily related to the central nervous system (dizziness, 52.8%; somnolence, 33.3%; fatigue, 11.1%; headache, 8.3%) and were consistent with the safety profile established for the oral formulation. Safety profiles were similar for each dose level of levetiracetam and for all infusion rates.

Among the 25 patients with epilepsy who received levetiracetam as intravenous infusions over a 4-day period [94], a total of 11 (44%) experienced at least one treatment-emergent adverse event. Overall, a 15-min infusion (500–1500 mg, twice daily) was well tolerated in patients with partial-onset seizures. Adverse events were either mild or moderate, and those most frequently reported were headache and fatigue. After the 4-day twice-daily treatment, results of clinical examination and laboratory parameters remained stable, no clinically relevant changes in vital signs or ECGs were observed, and tolerability at the injection site was very good.

The results of these studies suggest a broad tolerability margin of intravenous levetiracetam.

Adverse events with adjunctive therapy in children with partial-onset seizures

In the adjunctive therapy controlled trial performed in children with partial-onset seizures [65], the most common treatment-emergent adverse events that occurred in at least 10% of levetiracetam-treated patients and more frequently than in placebo-treated patients were somnolence, accidental injury, vomiting, anorexia, rhinitis, hostility, increased cough, pharyngitis and nervousness (Table 44.4). The majority of these events were rated as mild to moderate in severity. The incidence of many of the common adverse events, including infection, fever, abdominal pain, nausea, diarrhoea, increased cough, rhinitis and otitis media, that were seen in both the levetiracetam and placebo groups was consistent with the expected incidence for school-age children. Psychiatric and behavioural treatment-emergent adverse events occurring in more than 5% of patients were, in decreasing order of incidence, hostility (11.9% levetiracetam, 6.2% placebo), nervousness (9.9% levetiracetam, 2.1% placebo), personality disorder (7.9% levetiracetam, 7.2% placebo), emotional lability (5.9% levetiracetam, 4.1% placebo) and agitation (5.9% levetiracetam, 1.0% placebo) [65]. The relative risk (RR) of psychiatric/behav-

Table 44.4 Incidence (%) of treatment-emergent adverse events in a double-blind, placebo-controlled adjunctive therapy trial of levetiracetam in subjects 4–16 years of age with partial-onset seizures. Only events with an incidence >5% in the levetiracetam group and greater with levetiracetam than with placebo are reported.

ioural events for children treated with levetiracetam compared with those receiving placebo was estimated for the 198 evaluable patients [95]. Patients were categorized for analysis by prior psychiatric or cognitive history, and by response status, and results were then compared with a similar analysis completed for adults treated with levetiracetam for refractory partial seizures. Although the incidence of psychiatric/behavioural events in children with partial-onset seizures treated with levetiracetam was 38.6% versus 18.6% in adults, there was also a higher incidence of psychiatric/behavioural events in children treated with placebo compared with placebo-treated adults (27.8% versus 10.5%). Therefore, the RR was similar for adults (1.77, 95% CI 1.30–2.42) and for children (1.39, 95% CI 0.93–2.08). The psychiatric adverse event profile in children with refractory partial-onset seizures is similar to that for adults, as indicated in the currently approved product labelling.

A recent randomized, double-blind, placebo-controlled adjunctive therapy study using a non-inferiority design assessed the neurocognitive effects of levetiracetam (target dose 60 mg/kg/day) in children (4–16 years of age) with partial-onset seizures [96]. Memory and attention/concentration were assessed with the Leiter International Performance Scale-Revised Attention and Memory Battery (Leiter-R AM) and the Wide Range Assessment of Memory and Learning-2 (WRAML-2). These scales were rated at baseline and after 8–12 weeks of treatment. The primary analysis was testing the non-inferiority between levetiracetam and placebo on the Leiter-R AM composite score in the per protocol population; superiority between the two groups was tested on the secondary variables. Ninety-nine patients were randomized, with 73 (46 levetiracetam, 27 placebo) in the per protocol population. Mean Leiter-R AM composite scores improved over the evaluation period in both groups. The non-inferiority of levetiracetam versus placebo was demonstrated on the Leiter-R AM in the per-protocol population, with the 90% CI lower boundary for the difference between levetiracetam and placebo on the change from baseline (–4.69) being within the pre-set non-inferiority margin of –9.0. There were no significant differences between groups in WRAML-2 scores. In the same study, the Achenbach Child Behavior Checklist (CBCL) was completed by parents or guardians to assess behavioural and emotional functioning [97]. After 12 weeks' treatment, levetiracetam did not appear to adversely affect competence in social skills, school and total competence scores (no significant difference between groups), and activities scores worsened for placebo and remained stable for levetiracetam (P = 0.0490). CBCL syndrome scores showed no statistically significant difference between groups for anxious/depressed, withdrawn/depressed, somatic complaints, social problems, thought problems, attention problems, rule-breaking behaviour or internalizing syndromes. However, improvement on placebo and worsening for levetiracetam was observed on aggressive behaviour (P = 0.0126), affecting broader scores of externalizing (P = 0.0114) and total problems (P = 0.0203). Most frequently reported treatment-emergent psychiatric events in the ITT population (n = 98) for levetiracetam and placebo, respectively, were aggression (12.5%, 8.8%), abnormal behaviour (7.8%, 0%), altered mood (6.3%, 0%), anxiety (6.3%, 0%) and insomnia (6.3%, 2.9%). In summary, there appeared to be no deleterious neurocognitive effects of levetiracetam used as adjunctive therapy in paediatric patients with partial-onset seizures. Behavioural findings were consistent with the overall safety profile of levetiracetam.

In the study conducted in the population aged 1 month to less than 4 years [66], there was no difference between the percentages of patients who reported treatment-emergent adverse events between the levetiracetam group (55.0%) and the placebo group (44.6%) during the 5-day treatment period. The most frequently reported treatment-emergent adverse events with a higher incidence in the levetiracetam group than in the placebo group were somnolence (levetiracetam 13.3%, placebo 1.8%) and irritability (levetiracetam 11.7%, placebo 0%).

Tolerance

There has been interest in the question of whether levetiracetam treatment is associated with the development of tolerance over time, because of a report of such an occurrence in an animal model [8]. An analysis of patients continuing on levetiracetam after the completion of controlled trials indicated that many

maintained benefits from levetiracetam therapy for up to 5 years [98]. Thirteen per cent of treated patients were seizure free for at least 6 months. A post hoc pooled analysis of three randomized placebo-controlled trials examined seizure-free days over the first 3 months of treatment and found that seizure-free days were highest in the first week of therapy (81%) and fell to 74–76% thereafter. However, after the first week, efficacy was maintained over time and was always greater than in the placebo group [62]. In an interesting case study, a patient with severe epilepsy and multiple seizures per day became initially seizure free with levetiracetam therapy, but the effect was completely lost after the first few weeks of treatment. Subsequently, she was able to regain an effect when levetiracetam was dosed only once per week, and this effect was maintained over years [99].

Teratogenicity

Levetiracetam is currently classified as a pregnancy category C drug. Few pregnancies have been reported in women treated with levetiracetam. As of November 2007, 45 pregnancies were recorded during clinical trials, of which 22 were either terminated or ended in spontaneous abortion or ectopic pregnancy. Of the 23 pregnancies ending in live births, there was one case with syndactyly, one with tetralogy of Fallot, one with heart block and one with dysplasia of the hip, all after exposure to polytherapy. The remaining 19 live births had a normal outcome. UCB Inc. established the Keppra® Pregnancy Registry in January 2005, and the expert panel that reviewed the data through August 2007 concluded that the limited amount of data available is insufficient to draw conclusions about potential risks [100].

Overdosage

Somnolence, agitation, aggression, depressed level of consciousness, respiratory depression and coma were observed with levetiracetam overdoses [41].

Place in current therapy

Levetiracetam has a unique position among AEDs because of its pharmacokinetic properties, which make it easy to use, and because of its broad spectrum of activity. To summarize, levetiracetam is highly water soluble, whereas almost all other AEDs are either only partially soluble or totally insoluble, and one advantage of high water solubility is the availability of an intravenous formulation. The SV2A-related mechanism is unique. Unlike most other AEDs, levetiracetam is not significantly metabolized by cytochrome P450 enzymes. It has linear pharmacokinetics within the recommended dose range, has no potential for autoinduction, and is devoid of major drug–drug interactions inherent to most AEDs. These properties permit easy addition of levetiracetam to other drug therapies without major concerns about drug interactions. Moreover, levetiracetam is well tolerated as add-on therapy, and can be initiated at a therapeutic dose, with rapid onset of action.

Levetiracetam has been approved in Europe and in the USA as adjunctive therapy for partial-onset seizures in adults and children from 4 years of age, as adjunctive therapy for myoclonic seizures in adults and adolescents with juvenile myoclonic epilepsy from 12 years of age, and as adjunctive therapy for primary generalized tonic–clonic seizures in adults and adolescents with idiopathic generalized epilepsy from 12 years of age in Europe and from 6 years of age in the USA [68,69]. Levetiracetam demonstrated non-inferior efficacy to carbamazepine in newly diagnosed patients with partial-onset seizures [67] and it is approved for use as initial monotherapy for adults with partial-onset seizures in Europe. Despite its lack of regulatory approval for this indication in the USA, it is commonly used as monotherapy around the world and it is, in the authors' opinion, a reasonable first choice in selected patients.

Reports suggest that levetiracetam may also be effective in the management of progressive myoclonic epilepsies and other generalized epilepsy syndromes.

The introduction of an intravenous formulation has substantially increased the use of levetiracetam in hospitalized patients. Case reports have suggested its utility in status epilepticus, but this has not been proven in formal trials [101,102]. Levetiracetam is, however, ideal for use in patients hospitalized for medical conditions, due to its low potential for drug interactions and the absence of changes in laboratory safety parameters.

Overall, levetiracetam has become established as an AED with efficacy in different seizure types, and is well tolerated and easy to use. The most frequently reported adverse effects in adults with epilepsy are somnolence, asthenia, nervousness and dizziness, while in children, behavioural and cognitive problems appear to be the most commonly noted adverse events, although the relative risk for such events versus placebo is similar to that in adults. In our experience and in agreement with other reports, levetiracetam tolerability is improved by slower titration [103]. Patients and family members should be alerted to possible behavioural side-effects and encouraged to discuss these with their physician.

The recommended starting dose of levetiracetam is typically 500 mg twice daily, which is a therapeutic dose. Lately, there has been increasing preference for starting some or all patients on 250 mg twice daily, to reduce the likelihood of fatigue and irritability. Further clinical experience will determine whether this practice is beneficial. The dose can be titrated by 500–1000 mg every 1–2 weeks until maximum benefit has been obtained. In a randomized controlled study, patients were initiated on doses of 2000 mg/day or 4000 mg/day without titration [49]. Although dropout rates were not significantly different between the two dose groups and placebo, the high dose was associated with higher rates of somnolence, dizziness and nausea and responder rates did not differ between doses, indicating that, while safe, starting at 4000 mg/day is probably not beneficial. As noted above, very high doses of levetiracetam have not been proven to be more effective, and there is preliminary evidence that such doses may exacerbate seizures in some patients [91]. The seizure-suppressing effects of levetiracetam are seen relatively quickly after initiation. In a pooled analysis of clinical trial data, seizure-free days were significantly increased after the first day of therapy [62].

In children, the elimination of levetiracetam is faster than in adults and, therefore, higher doses per body weight are required. The recommended doses in children range from 20 to 60 mg/kg/

day, which are expected to produce the same plasma concentrations as in adults receiving doses between 1000 and 3000 mg/day. Initial doses in children are typically 10–20 mg/kg/day [104,105]. The characteristics of levetiracetam, particularly its low drug–drug interaction potential, make it potentially suitable for treating elderly patients, particularly those who have other illnesses and are on several other medications.

The need for laboratory monitoring is minimal when using levetiracetam. Liver function tests, electrolytes and blood counts are not expected to change in a clinically meaningful way. It would be prudent to determine serum creatinine, and to assess creatinine clearance prior to using levetiracetam when there is a possibility of renal insufficiency, or in the elderly, to determine proper dosing. Plasma levetiracetam levels are available from some laboratories, but they are likely to be useful only in selected situations.

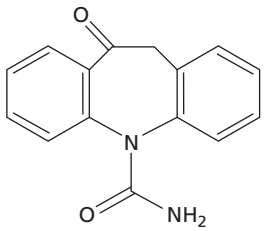
45 Oxcarbazepine

Edward Faught and Nita Limdi
University of Alabama at Birmingham Epilepsy Center, Birmingham, AL, USA



Primary indication	Adjunctive therapy or monotherapy of partial and secondary generalized seizures. Also useful to treat primary generalized tonic–clonic seizures not associated with absence and myoclonic seizures
Usual preparation	Tablets: 150, 300, 600 mg Oral suspension: 60 mg/mL
Usual dosage	Starting dosage in adults: 300 mg/day. Titration rate of 300 mg/week. Usual maintenance adult dose is 900–1800 mg/day. For children, starting dosage can be 4–5 mg/kg/day, increased by 5 mg/kg/day weekly. Usual maintenance dose in children is 20–45 mg/kg/day
Dosing frequency	Twice daily
Significant drug interactions	Enzyme-inducing antiepileptic drugs reduce the serum levels of the active metabolite monohydroxy derivative (MHD). Oxcarbazepine may increase the serum levels of phenytoin and phenobarbital, and reduces the serum levels of steroid contraceptives and felodipine
Serum level monitoring	May be useful in selected cases
Target range	3–35 mg/L
Common/important adverse effects	Dizziness, diplopia, ataxia, somnolence, headache, fatigue, rash, hyponatraemia, gastrointestinal disturbances
Main advantages	Better tolerated and fewer interactions than carbamazepine
Main disadvantages	Efficacy spectrum restricted to partial epilepsies. Higher incidence of hyponatraemia compared with carbamazepine. Interaction with oral contraceptives
Mechanism of action	Blocker of voltage-gated sodium channels and N- and P-type calcium channels
Oral bioavailability	Almost complete (in terms of MHD)
Time to peak levels	4–6 h (MHD)
Elimination	Ketoreduction to MHD, which is then cleared in urine in unchanged form and as a glucuronide conjugate
Volume of distribution	0.7–0.8 L/kg (MHD)
Elimination half-life	7–12 h (MHD)
Plasma clearance	40–50 mL/h/kg (MHD) (with higher values in patients on enzyme-inducing antiepileptic drugs and in children)
Protein binding	≤40% (MHD)
Active metabolites	MHD (monohydroxycarbazepine)
Comment	A useful antiepileptic drug for the treatment of partial and secondarily generalized seizures, with some advantages over carbamazepine

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Carbamazepine and oxcarbazepine were synthesized at the J. R. Geigy AG Laboratories, Basle, Switzerland, in 1957 and 1963 respectively, based on structural similarities to tricyclic antidepressants. Although similar in their primary mechanism of antiseizure action, carbamazepine and oxcarbazepine differ in secondary mechanisms of action, metabolic pathways and propensity for drug interactions, and are therefore not interchangeable in therapeutic use [1].

Clinical trials of oxcarbazepine as an antiepileptic agent began in 1977, and the drug was introduced commercially in Denmark in 1990. Oxcarbazepine has been available throughout the European Union since 1999 and in the USA since 2000. In most countries it is approved for use as monotherapy or add-on treatment of partial seizures with or without secondary generalization for adults and children aged 4 and above [2].

Chemistry

Oxcarbazepine (10,11-dihydro-10-oxo-5H-dibenz[*b*,*f*]azepine-5-carboxamide) is a 10-keto analogue of carbamazepine [2]. It is a highly lipophilic compound with very low water solubility [2]. Oxcarbazepine is rapidly reduced to its 10-monohydroxy derivative (Fig. 45.1), also known as MHD (10,11-dihydro-10-hydroxy-5H-dibenz[*b*,*f*]azepine-5-carboxamide), which is found in serum as a mixture of its enantiomers *R*-(–)-MHD (20%) and *S*-(+)-MHD (80%) [3].

Both oxcarbazepine and MHD are pharmacologically active. However, in humans, oxcarbazepine is almost completely metabolized to MHD [2,3], which is found in serum at concentrations several-fold higher of those of the parent drug and is therefore primarily responsible for the pharmacological effect. MHD has greater water solubility, but no parenteral preparation of either oxcarbazepine or MHD is currently available.

Pharmacology

Carbamazepine, oxcarbazepine and MHD exhibit similar activity in standard animal seizure models. In the maximal electroshock test, which predicts efficacy against partial-onset and generalized tonic–clonic seizures, carbamazepine, phenytoin, oxcarbazepine and MHD were equally potent [2,4]. Carbamazepine, oxcarbazepine and MHD lacked efficacy in seizure models predictive of efficacy against absence seizures (strychnine, pentylenetetrazole and picrotoxin) [2,4].

Oxcarbazepine and MHD modulate voltage-sensitive cationic channels [4]. The mechanism of blockade of sodium channels is similar to that of phenytoin and carbamazepine, but MHD has a greater affinity for the inactivated state of the channel [4]. MHD inhibits N- and P-type calcium channel currents, unlike carbamazepine, which has a greater effect on L-type channels [4]. Elevation of hippocampal dopamine and serotonin levels has also been reported [5].

Pharmacokinetics

Steady-state serum concentrations of MHD are reached in 2–3 days of twice-daily dosing; they are ninefold higher than those of

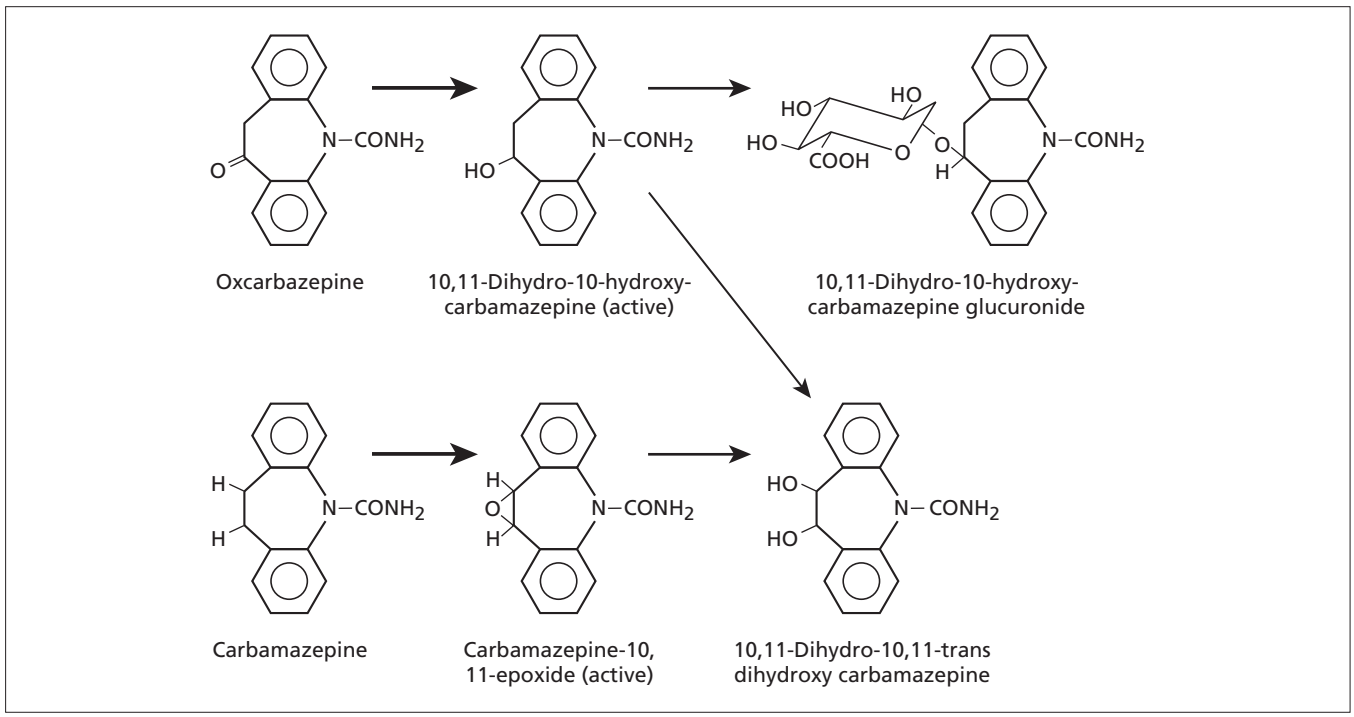


Fig. 45.1 Metabolism of oxcarbazepine and carbamazepine. From refs 10 and 15 with permission.

oxcarbazepine. The dose–concentration relationship is linear across a wide dose range (300–2400 mg/day) [2]. The following relationship between MHD concentration and dose of oxcarbazepine has been described, over the range 300–2700 mg/day [6]:

MHD concentration (mg/L) = 0.93 × oxcarbazepine dose (mg/kg)

Absorption

Oxcarbazepine is rapidly and completely absorbed (>95%). Although its peak concentrations are achieved within 1 h, they are very low because the drug is rapidly reduced to the active 10-monohydroxy derivative (MHD), which reaches peak concentrations in 4–6 h [3]. Oral bioavailability is not significantly affected by food intake, and therefore oxcarbazepine can be given with or without food [2].

Distribution

The volume of distribution of oxcarbazepine is 0.3 L/kg and that of MHD is 0.7–0.8 L/kg, or about 49 L [2], indicating distribution in total body water. As a lipophilic substance, MHD is widely distributed in the body and easily passes the blood–brain barrier. Both oxcarbazepine and MHD exhibit low protein binding (33–38% for MHD and 60–67% for oxcarbazepine), independent of the dose [7]. Therefore, oxcarbazepine does not produce protein-binding interactions with highly protein-bound drugs such as phenytoin and valproic acid.

Biotransformation and elimination

Oxcarbazepine is rapidly eliminated from plasma, and therefore its half-life (1–2.5 h) is of no practical significance. The half-life of MHD is 9.3 ± 1.8 h [2,8]. The elimination is monoexponential and follows linear kinetics in patients with epilepsy on oxcarbazepine monotherapy or polytherapy. Unlike carbamazepine, no autoinduction during early therapy occurs [8].

The metabolic pathways of carbamazepine and oxcarbazepine differ significantly (see Fig. 45.1). Carbamazepine is metabolized by cytochrome P450 (CYP) oxidases with an arene oxide (epoxide) intermediate [8]. Oxcarbazepine is rapidly and extensively metabolized by cytosolic aldo-ketoreductase enzymes in the liver to the active metabolite 10,11-dihydro-10-hydroxycarbamazepine or monohydroxycarbazepine (MHD, 96%). Aldo-ketoreductases are practically non-inducible enzymes. A small fraction of oxcarbazepine (4%) is oxidized to an inactive dihydroxy derivative (DHD). MHD is partly glucuronidated by microsomal uridine-diphosphoglucuronyltransferases (UGTs).

Most of an orally administered oxcarbazepine dose is accounted for in urine as MHD glucuronide (51%) and unchanged MHD (28%). The dihydroxy derivative accounts for 3% of the dose excreted in the urine, with <13% of the drug excreted as minor conjugates of oxcarbazepine and MHD [8].

Pharmacokinetics in special groups

Steady-state MHD concentrations, adjusted for body weight, in older children and adolescents were comparable to those in adults, but areas under the concentration–time curve (AUC) for MHD were 30% lower in children under 8 years of age [9]. Higher mg/kg doses may therefore be required in young children [2]. AUC values for MHD were significantly higher in elderly patients (>60 years of age), suggesting that dosing should be lower in this group. This may be explained by age-related decreases in creatinine clearance [10].

Serum MHD levels have been reported to drop by 28–36% [11] or even more [12] during pregnancy, and to return to baseline values shortly after delivery.

Mild to moderate hepatic dysfunction did not alter the pharmacokinetics of oxcarbazepine or MHD, but the pharmacokinetics of oxcarbazepine has not been evaluated in severe hepatic dysfunction [2,8].

Elimination is little affected by mild to moderate renal dysfunction, but patients with creatinine clearances of <30 mL/min/1.73 m^2 exhibited significant increases in elimination half-life and plasma concentrations of MHD [6].

Drug interactions

In vitro studies indicate that both oxcarbazepine and MHD are competitive inhibitors of cytochrome CYP2C19. High doses of oxcarbazepine may produce clinically significant inhibition of CYP2C19, with consequent elevations of serum concentrations of substrates such as phenobarbital and phenytoin [2,13].

Interactions between antiepileptic drugs (AEDs) and oxcarbazepine are listed in Table 45.1. The addition of oxcarbazepine to existing AED regimens produces increases in serum phenytoin, phenobarbital and carbamazepine-10,11-epoxide concentrations and a decrease in carbamazepine concentrations. When enzyme-inducing AEDs are added to oxcarbazepine, plasma MHD concentrations decrease by 29–40%, which may require an increase in oxcarbazepine dose.

Oxcarbazepine has a weaker enzyme-inducing activity than carbamazepine on CYP enzymes [14]. However, breakthrough bleeding and loss of contraceptive efficacy may occur when oxcarbazepine is added to a stable regimen of oral contraceptives, due to increased metabolism of ethinylestradiol and levonorgestrel [15,16]. Oxcarbazepine may reduce serum felodipine levels, but to a much lesser extent compared with the decrease in serum felodipine levels caused by carbamazepine [14]. A single case report suggested that oxcarbazepine may also reduce ciclosporin

Table 45.1 Summary of interactions between antiepileptic drugs (AEDs) and oxcarbazepine.

Influence of AED on	Influence of oxcarbazepine on	
	AED concentration	MHD concentration
Phenytoin	0–40% increase	29–35% decrease
Phenobarbital	14–15% increase	30–31% decrease
Valproic acid	No influence	0–18% decrease
Carbamazepine	0–22% decrease	40% decrease
Carbamazepine-10,11-epoxide	30% increase	Not studied
Clobazam	Not studied	No influence
Felbamate	Not studied	Not studied
Lamotrigine	No influence or modest decrease	No influence

A levels, but more data are required to confirm this interaction [17]. Unlike carbamazepine, oxcarbazepine does not interact significantly with warfarin, cimetidine, propoxyphene or erythromycin [18].

Because of their differing effects on the CYP enzyme systems, substitution of oxcarbazepine for carbamazepine may result in de-induction and a consequent increase in the serum concentration of inducible concomitant AEDs, such as lamotrigine, valproic acid, topiramate and zonisamide [19].

Serum level monitoring

Since oxcarbazepine is rapidly converted to MHD *in vivo*, only measurement of MHD, usually by high-performance liquid chromatography, is useful. In a group of 214 patients treated with a clinically optimized dose, the mean plasma level of MHD was 15.3 mg/L, but with a wide individual variation between patients [20]. A range of therapeutic concentrations of 3–35 mg/L has been suggested, although variability in response at these concentrations is considerable [17]. Routine monitoring of serum levels is generally not recommended, though it may be helpful to assess compliance, or to gauge dosage in the presence of enzyme-inducing concomitant AEDs. Since MHD levels have been reported to drop by 28–36% during pregnancy [11,12], it is probably worthwhile monitoring MHD levels during pregnancy and in the postpartum period.

Efficacy

The efficacy of oxcarbazepine has been established in many randomized, controlled clinical trials. Oxcarbazepine was compared with carbamazepine [19,21,22], phenytoin [23,24], valproate [25] and levetiracetam [26] in controlled monotherapy trials. Other randomized trials utilized oxcarbazepine monotherapy in comparison with either placebo [27,28] or lower-dose oxcarbazepine [29,30]. Randomized controlled trials of adjunctive therapy for refractory patients have enrolled adults aged 15–65 [31], children aged 3–17 years [32], and infants from 1 month to 4 years of age [33].

All of these trials were designed to evaluate patients with partial-onset seizures with or without secondary generalization, although in some trials patients with primary generalized tonic–clonic seizures were also included. Oxcarbazepine is not indicated for absence, myoclonic and other types of generalized seizures other than tonic–clonic seizures, and indeed may exacerbate them [34].

Efficacy in comparison with carbamazepine

Three controlled trials compared oxcarbazepine with carbamazepine (Table 45.2). In a randomized, double-blind cross-over study, 48 patients taking carbamazepine along with other AEDs had their carbamazepine replaced by oxcarbazepine [21]. Patients took oxcarbazepine and carbamazepine for 12 weeks each, in addition to the titration period. Oxcarbazepine significantly reduced tonic–clonic and tonic seizures in comparison with carbamazepine, but there was no differential effect on complex partial seizures. The possible increases in serum concentration of inducible AEDs during the oxcarbazepine intervals complicates interpretation of these results. Patients taking phenytoin monotherapy were converted to either oxcarbazepine or carbamazepine in another double-blind trial, and no efficacy differences were found [19]. In a trial enrolling 235 patients with newly diagnosed epilepsy [22], patients with previously untreated primary generalized tonic–clonic seizures or partial seizures with or without secondary generalization were begun on either oxcarbazepine 300 mg/day or carbamazepine 200 mg/day with dosage adjustments during a 4–8-week titration period. At the end of the 48-week maintenance phase, carbamazepine patients were taking a mean dose of 685 mg/day, while oxcarbazepine patients were taking 1040 mg/day. Fifty-two per cent of oxcarbazepine patients and 60% of carbamazepine patients were seizure free during this year-long study, not a significant difference.

Oxcarbazepine is equal in efficacy to carbamazepine in head-to-head comparisons. However, it is more effective in certain patients, based on data from monotherapy trials in which some patients were converted from carbamazepine to oxcarbazepine,

Table 45.2 Randomized clinical trials comparing oxcarbazepine with carbamazepine.

Study	Number and type of patients	Trial design	Mean dose per day	Efficacy results	Percentage of dropouts for adverse events
Houtkooper *et al*. [21]	48 adult inpatients on carbamazepine plus one to three drugs	Crossover	Oxcarbazepine: 2628 mg Carbamazepine: 1302 mg	9% seizure reduction on oxcarbazepine (NS)	None on either treatment
Reinikainen *et al*. [19]	40 adults unsatisfactorily treated with phenytoin	Conversion to oxcarbazepine or carbamazepine, parallel group	Oxcarbazepine: 13.1 mg/kg Carbamazepine: 8.3 mg/kg	No difference	None on either treatment
Dam *et al*. [22]	149 adults newly diagnosed with partial or generalized tonic–clonic seizures	Parallel group	Oxcarbazepine: 1040 mg Carbamazepine: 684 mg	Oxcarbazepine: 52% seizure free Carbamazepine: 60% seizure free (NS)	Oxcarbazepine: 14% Carbamazepine: 25% ($P = 0.04$)

NS, not statistically significant.

Table 45.3 Randomized clinical trials comparing oxcarbazepine with phenytoin or valproate. All studies used a parallel group-design.

Study	Number and type of patients	Mean dose per day	Efficacy results (% seizure free)	Percentage of dropouts for adverse events
Bill *et al*. [23]	287 adults with newly diagnosed partial or generalized tonic–clonic seizures	Oxcarbazepine 1028 mg Phenytoin 313 mg	Oxcarbazepine: 59 Phenytoin: 58 (NS)	Oxcarbazepine: 3 Phenytoin: 1 ($P = 0.002$)
Guerreiro *et al*. [24]	193 children (5–18 years) with newly diagnosed partial or generalized tonic–clonic seizures	Oxcarbazepine 672 mg (18.8 mg/kg) Phenytoin 226 mg (5.8 mg/kg)	Oxcarbazepine: 61 Phenytoin: 60 (NS)	Oxcarbazepine: 2.5 Phenytoin: 18 ($P = 0.002$)
Christe *et al*. [25]	249 adults with newly diagnosed partial or generalized tonic–clonic seizures	Oxcarbazepine 1053 mg Valproate 1146 mg	Oxcarbazepine: 57 Valproate: 54 (NS)	Oxcarbazepine: 12 Valproate: 58 (NS)

NS, not statistically significant.

and from open-label experience. Since there are no systematic data on conversion from oxcarbazepine to carbamazepine, the converse may or may not be true.

Efficacy in comparison with other antiepileptic drugs

In patients with newly diagnosed epilepsy, the efficacy of oxcarbazepine is equivalent to that of phenytoin and valproate (Table 45.3). Fifty-nine per cent of patients with a new diagnosis of partial seizures with or without secondary generalized seizures, or generalized tonic–clonic seizures without partial onset, were seizure free while taking oxcarbazepine during a 48-month maintenance treatment period, compared with 58% receiving phenytoin [23]. The mean daily dose at the start of the maintenance period was 1028 mg for oxcarbazepine and 313 mg for phenytoin. A similar result emerged from a study of 193 children aged 5–18 years, who were randomized to oxcarbazepine or phenytoin after a new diagnosis of epilepsy [24]. Sixty per cent of each group was seizure free during the maintenance period. However, in both these studies oxcarbazepine was better tolerated, and phenytoin therapy was more likely to fail because of adverse effects. A study of similar design compared oxcarbazepine with valproate among 249 patients aged 15–65 years [25]. Seizure-free rates were 57% for oxcarbazepine and 54% for valproate, not significantly different. The median daily maintenance dose was 900 mg for each drug.

In a large, randomized, unblinded study (the SANAD trial), oxcarbazepine was compared with carbamazepine, lamotrigine, gabapentin and topiramate for treatment of newly diagnosed partial epilepsy [35]. No significant differences in efficacy between oxcarbazepine and the other drugs emerged, although fewer patients took oxcarbazepine than the other drugs because it was added as a treatment arm later.

Oxcarbazepine was slightly less effective (72% seizure free) than levetiracetam (90% seizure free) in a randomized, open-label trial of 39 children with benign epilepsy with centrotemporal spikes, though the difference was not statistically significant [26].

Monotherapy in refractory patients

The studies demonstrating monotherapy efficacy in newly diagnosed patients [22–25] led to the design of studies to evaluate monotherapy efficacy in patients with refractory partial-onset seizures. All of them led to statistically significant differences in favour of oxcarbazepine, or in favour of high-dose rather than low-dose oxcarbazepine.

Patients removed from therapy for presurgical video-EEG monitoring ($n = 102$) were randomized to resume therapy with either oxcarbazepine 2400 mg/day or placebo while remaining in hospital [27]. Patients exited the trial after completing 10 days of treatment, or after meeting exit criteria suggesting drug failure, such as four partial-onset seizures within this period. Forty-seven per cent in the oxcarbazepine arm and 84% in the placebo arm met one of the exit criteria. This study also demonstrated the feasibility of quick initiation of oxcarbazepine when necessary for inpatients: 1500 mg on the first day, then 2400 mg on subsequent days.

Two outpatient studies have employed a more gradual conversion to oxcarbazepine monotherapy for patients with refractory partial-onset seizures [29,30]. Outpatients aged 12 years or older were converted from one or two baseline AEDs over 14 days to monotherapy with oxcarbazepine 300 mg/day or 2400 mg/day [29]. Patients exited if there was a twofold increase in partial seizure frequency over baseline during any 2-day or 28-day period, if a single tonic–clonic seizure occurred if none had occurred previously in the past 6 months, or if judged necessary by the investigator. During the 112-day maintenance period, 41% of the high-dose group met one of the exit criteria compared with 93% of the low-dose group. The second study used a similar design, but all patients were stabilized on carbamazepine monotherapy before conversion to oxcarbazepine 300 or 2400 mg/day as monotherapy [30]. Fifty-nine per cent of the oxcarbazepine 2400 mg/day group and 89% of the oxcarbazepine 300 mg/day group met one of the exit criteria.

A true placebo control was used in another study of newly diagnosed patients with currently untreated partial seizures, who received a placebo or 1200 mg oxcarbazepine per day during the 90-day double-blind treatment phase [28]. The primary endpoint, median time to the first seizure, was 11.7 days in the oxcarbazepine group and 3.2 days in the placebo group.

Adjunctive therapy versus placebo (or low-dose oxcarbazepine)

Randomized controlled trials in which oxcarbazepine or placebo was added to existing therapy for patients with inadequately

Table 45.4 Randomized clinical trials of adjunctive oxcarbazepine therapy. All studies used a parallel group-design.

Study	Number and type of patients	Mean percentage reduction in seizure frequency (versus baseline)	Percentage of dropouts for adverse events
Barcs *et al*. [31]	694 adults with refractory partial-onset seizures	Placebo: 8 Oxcarbazepine 600 mg: 26 Oxcarbazepine 1200 mg: 40 Oxcarbazepine 2400 mg: 50 ($P = 0.001$, all doses versus placebo)	Placebo: 9 Oxcarbazepine 600 mg: 12 Oxcarbazepine 1200 mg: 36 Oxcarbazepine 2400 mg: 67
Glauser *et al*. [32]	267 children (3–17 years) with refractory partial-onset seizures	Placebo: 9 Oxcarbazepine 30–46 mg/kg: 35 ($P = 0.0001$) (median percentage reduction in seizure frequency)	Placebo: 3 Oxcarbazepine: 10
Pina-Garza *et al*. [33]	128 infants/children (1 month to 4 years) with refractory partial-onset seizures	Oxcarbazepine 10 mg/kg: 46 Oxcarbazepine 60 mg/kg: 83 ($P = 0.05$) (median percentage reduction in seizure frequency of electrographic seizures with a behavioural correlate per 24 h, assessed with a 72-h video-EEG recording)	Oxcarbazepine 10 mg/kg: 2 Oxcarbazepine 60 mg/kg: 3

controlled partial-onset seizures are listed in Table 45.4. The results of all these studies demonstrated statistically significant reductions in seizures for oxcarbazepine over placebo or for high-dose over low-dose oxcarbazepine.

A dose-ranging trial enrolled 694 patients aged 15–65 years in a parallel comparison of placebo and three doses of oxcarbazepine [31]. A linear dose–response association was found, with median percentage reductions of 8%, 26%, 40% and 50% for placebo and 600, 1200 and 2400 mg/day oxcarbazepine respectively. However, discontinuation rates for adverse events also increased with increasing dosage, with 66.7% of patients discontinuing treatment in the highest dose group. Among the 75% of patients who were taking carbamazepine as one of their baseline drugs, the improvement in seizure frequency after adding oxcarbazepine was virtually identical to that achieved in the entire study group. Although the patients in this study taking carbamazepine were presumably being treated with an optimal dose, the results do not fully answer the question of whether the addition of oxcarbazepine to carbamazepine produces a qualitatively different effect on seizure frequency or merely an additive one, i.e. whether the same effect could have been achieved by simply adding more carbamazepine.

In another adjunctive therapy study, children aged 3–17 years with inadequately controlled partial-onset seizures taking one or two baseline drugs were assigned to oxcarbazepine 30–46 mg/kg/day or to placebo for a 112-day double-blind treatment phase, after a 56-day baseline [32]. The primary endpoint, percentage change in seizure frequency from baseline, was 35% for oxcarbazepine and 9% for placebo.

Infants and young children aged 1 month to <4 years with uncontrolled seizures were randomized to have either oxcarbazepine 10 mg/kg or 60 mg/kg per day added to one or two baseline drugs [33]. Seizures confirmed by both clinical and EEG evidence were reduced 46% by the low dose and 83% by the high dose.

Other studies in epilepsy

Oxcarbazepine was reported to be effective in the treatment of eight children with nocturnal frontal lobe epilepsy [36].

A quality of life measure (QOLIE-31) improved significantly when patients were converted to oxcarbazepine monotherapy from any of three previous monotherapies: carbamazepine ($n = 121$), phenytoin ($n = 65$) or valproate ($n = 45$) [37]. Results from several open-label patient series suggest that retention on oxcarbazepine therapy is relatively high. For example, in a group of 175 patients, after 1 year 91% of those on initial oxcarbazepine monotherapy and 71% of those converted to oxcarbazepine as their second monotherapy continued to take the drug [38]. It is difficult to define tolerance to antiepileptic efficacy, but these large experiences suggest that tolerance to oxcarbazepine is not a greater problem than with other AEDs.

Non-epilepsy indications

Oxcarbazepine has been used to treat neuropathic pain [39] and there have been some reports suggestive of efficacy in acute mania and, as add-on use, in acute bipolar depression and bipolar depression prophylaxis. A randomized controlled trial, however, demonstrated no benefit over placebo for bipolar affective disorders in children and adolescents [40].

Adverse effects

Central nervous system effects

The most common adverse effects seen early in treatment and those which most often lead to oxcarbazepine discontinuation affect the central nervous system (CNS) (Table 45.5). Adverse effect rates are best assessed in comparison with placebo in monotherapy studies. In these studies, the most common CNS side-effects were headache, somnolence and dizziness [1]. Ataxia, fatigue and diplopia or visual blurring were uncommon during monotherapy, though present much more often than with placebo in adjunctive therapy trials. This adverse effect profile is qualitatively similar to that seen with carbamazepine.

In the oxcarbazepine monotherapy trials, the rate of adverse effects judged as 'severe' by the investigators did not differ from

Table 45.5 Percentage of patients experiencing the five most common central nervous system adverse effects in oxcarbazepine trials.

Adverse effect	Initial monotherapy trials		Adjunctive trials[a]	
	Oxcarbazepine (n = 440)	Placebo (n = 66)	Oxcarbazepine (n = 705)	Placebo (n = 302)
Headache	37	12	26	21
Somnolence	22	6	26	12
Dizziness	20	4	30	11
Ataxia	2	0	17	5
Diplopia	0.5	0	24	3

[a] Combined adult [31] and paediatric [32] data.

placebo, valproate, phenytoin and carbamazepine, ranging from 5.8% to 8.2% [22–25]. In these direct comparative trials, discontinuation rates were significantly lower for oxcarbazepine in comparison with carbamazepine (14% versus 26%) [22] and phenytoin [23,24], but not in comparison with valproate [25]. Discontinuation rates are, as expected, higher in adjunctive therapy trials, mostly because of adverse effects. Among adults, 9% of patients taking placebo and concomitant medications stopped treatment because of adverse effects, in comparison with 12%, 36% and 67% for patients taking oxcarbazepine 600, 1200 and 2400 mg/day, respectively [31]. In an adjunctive study in children [32], there was a 10% dropout rate in the oxcarbazepine treatment group, versus 3% in the placebo group. These clinical trials employed rather rapid titration rates. Dropout rates due to adverse effects may be lower with more gradual introduction.

Except for early, dose initiation CNS effects such as somnolence, cognitive effects appear to be relatively benign. Small studies have reported no difference in cognitive function tests between oxcarbazepine and phenytoin [41], and before and 4 months after initiation of oxcarbazepine [42]. In an open-label, 6-month trial enrolling 112 children randomized to oxcarbazepine, carbamazepine or valproate, none of the three drugs adversely affected the results of cognitive function tests [43].

Gastrointestinal effects

The incidence of nausea was higher than with placebo only during adjunctive oxcarbazepine therapy: 22.5% for all oxcarbazepine doses compared with 8.1% for placebo [31]. Nausea was the most common reason for dropout among children in an adjunctive therapy study [32]. Among infants aged 4 months to <4 years, gastrointestinal effects and somnolence were the two most common side-effects of adjunctive oxcarbazepine, and were much more common at the high dose (60 mg/kg/day) than at the low dose (10 mg/kg/day).

Rash

Oxcarbazepine is less likely to cause a skin rash than carbamazepine. 'Allergy' resulted in medication withdrawal in 10% of oxcarbazepine-treated and 16% of carbamazepine-treated patients in a comparative study [22]. Data from all clinical trials suggest that there is a 3% incidence of rash with oxcarbazepine compared with 7% with carbamazepine [2]. Cross-reactivity with carbamazepine has been reported, with 25.5% of patients who had a history of skin rashes on carbamazepine also developing a rash when they were converted to oxcarbazepine [44]. A few cases of Stevens–Johnson syndrome have been reported [2,45].

Hyponatraemia

The only side-effect of oxcarbazepine which is clearly more common than with carbamazepine is hyponatraemia. This is usually asymptomatic, but could cause an increase in seizures and other adverse effects when serum levels fall below 125 mEq/L. Among 97 oxcarbazepine-treated patients, the incidence of sodium <134 mEq/L was 29.9% compared with 13.5% among 451 carbamazepine-treated patients [46]. The incidence of hyponatraemia varies directly with age, with sodium levels below 135 mEq/l occurring at least once in 0.2% of children, 3.6% of adults aged 17–64 years and 7.3% of those 65 years or older in a database maintained by the manufacturer [47]. Patients prone to hyponatraemia for other reasons, such as those taking natriuretic diuretics, may be at higher risk. The fall in serum sodium usually occurs within the first 3 months of therapy, but may happen later if the dose is increased [48]. Hyponatraemia due to oxcarbazepine was unrelated to altered antidiuretic hormone (ADH) levels in one study, but may have been caused by increased renal tubular sensitivity to ADH [47].

Bone and other systems

Long-term effects on bone health are unknown. In a single study, both carbamazepine and oxcarbazepine reduced serum vitamin D levels [49]. The authors suggest that these drugs may produce a secondary hypoparathyroidism and that patients may need surveillance of bone density or replacement therapy. No significant adverse effects on liver, blood, pancreas or other organs have been reported thus far [2].

Special populations

Types and rates of adverse effects among children [24,32], and among patients with intellectual disability [50], are generally similar to those seen in adult populations. Although hyponatraemia is more common in the elderly [47], discontinuation rates due to adverse effects among elderly adults are the same as among younger adults [51]. The most common adverse effects among 52 patients aged 65 or older were vomiting (19%), dizziness (17%), nausea (17%) and somnolence (15%) [51].

Teratogenicity

When given to pregnant rats in intermediate and high doses, oxcarbazepine was associated with an increased incidence of craniofacial, skeletal and cardiovascular malformations, decreased fetal body weights and increased rates of fetal death [2]. In a retrospective database review, six congenital malformations occurred among 248 infants born to women who had received oxcarbazepine monotherapy during pregnancy (2.4%), suggesting that it is relatively safe in comparison with other AEDs [52]. However, there are no well-controlled studies of oxcarbazepine in pregnant women, and the drug should be used only if the benefits outweigh the risk to the fetus (Food and Drug Administration pregnancy category C) [2].

Current place in therapy

Oxcarbazepine is an effective drug for the treatment of partial-onset seizures and for primary or secondary generalized tonic–clonic seizures, when used as either monotherapy or adjunctive therapy. Its efficacy in the monotherapy of newly diagnosed patients is comparable to that of carbamazepine, phenytoin and valproate, but it is often better tolerated than carbamazepine and phenytoin. Its efficacy as adjunctive therapy for refractory partial-onset seizures is comparable to that of the other AEDs tested in controlled studies of similar design, although meta-analytical comparisons between different clinical trials are scientifically tenuous. Oxcarbazepine tolerability as an adjunctive drug is good for children treated with 30–46 mg/kg/day [40] and for adults treated with 600–1200 mg/day, but tolerability is considerably worse for adults treated with 1800–2400 mg/day [39]. As carbamazepine and oxcarbazepine side-effects are often similar and additive, the tolerability of oxcarbazepine as an adjunct to carbamazepine is likely to be much better in clinical practice if concomitant carbamazepine dosage is reduced as oxcarbazepine is added.

Dose initiation

The manufacturer recommends beginning oxcarbazepine at 600 mg/day in two divided doses, with increases of 600 mg/day at weekly intervals to a recommended daily dose of 1200 mg [1]. Clinical experience suggests, however, that for most outpatients a slower titration schedule is better tolerated. An advisory board of UK physicians has recommended oxcarbazepine monotherapy initiation at 300 mg/day, beginning with 150 mg at bedtime on the first day and then 150 mg twice daily thereafter [53]. Other authorities also suggest beginning with lower doses, such as 300 mg/day in two divided doses, or even 150 mg/day with increases of 150 mg/day every 2 days [54]. A simple schedule which can be used for most adults for monotherapy initiation, adjunctive therapy or substitution for carbamazepine is oxcarbazepine 300 mg at bedtime for 1 week, with weekly increases of 300 mg/day, adhering to a twice-daily schedule.

Oxcarbazepine can be titrated more quickly when this is desirable, and rather rapidly if necessary. There were surprisingly few dropouts because of side-effects (only 3 of 51) in the inpatient trial in which a 2400-mg dose was reached on the second day of treatment [27]. Outpatients needing rapid attainment of an effective dose can be started at 600 mg/day in two divided doses, and inpatients can be started at 900–1200 mg/day in two or three divided doses. Oxcarbazepine has been used successfully for inpatient prophylaxis of early postoperative seizures in brain tumour patients without problematic hyponatraemia [55].

For children aged 4–16 years, the recommended starting dose is 8–10 mg/kg/day [1], but 4–5 mg/kg/day, not over 300 mg/day, may be better tolerated, adhering to a twice-daily schedule. Weekly increases of about 5 mg/kg/day are appropriate.

Conversion from carbamazepine

Conversion from carbamazepine to oxcarbazepine may be considered for patients who have dose-limiting side-effects of carbamazepine, or problems with drug interactions. For example, it is often difficult to achieve adequate serum valproic acid concentrations in patients taking carbamazepine. Overnight conversion is usually well tolerated [56], especially for patients taking carbamazepine doses of 800 mg/day or less [51], but many physicians favour a more gradual approach. A conversion ratio of carbamazepine to oxcarbazepine of 1 : 1.5 is reasonable for initial carbamazepine doses of 800 mg/day or less, but a ratio of 1 : 1 or 1 : 1.25 is often better tolerated for higher initial carbamazepine doses.

Maintenance treatment

For adults with new-onset epilepsy, oxcarbazepine daily dosages of 900–1200 mg/day have been shown to be effective and well tolerated [22,23,25]. For smaller adults and the elderly, 900 mg/day is a good target for initial therapy.

A reasonable dose for children, based on a childhood new-onset monotherapy study [24], is 20 mg/kg/day. If no significant reduction in seizures is achieved, even without clinical toxicity, at 1800 mg/day in adults or 45 mg/kg/day in children, then further increases are unlikely to be very productive.

The elimination half-life of MHD (about 10 h) suggests that three daily doses would be optimal, but most of the clinical trials utilized two daily doses. No difference in efficacy nor in incidence of adverse effects was found in a study comparing twice-daily with three times daily dosing [54]. An occasional patient may tolerate three daily doses better than two because of fewer peak-dose side-effects.

Monitoring of serum sodium

The manufacturer states that measurement of serum sodium levels should be considered, particularly for susceptible patients (e.g. those taking diuretics), or if symptoms possibly indicating hyponatraemia develop, such as nausea, malaise, headache, lethargy, confusion or obtundation [2]. Assessment of serum sodium at baseline, after 1–2 months of therapy, and after large dose increases, will detect most significant drops in serum sodium, although this procedure is not mandatory. Elderly patients are more susceptible, children less [47].

Withdrawal

As with all AEDs, it is prudent to withdraw oxcarbazepine gradually. Patients withdrawn from oxcarbazepine for seizure monitoring were more likely to have generalized tonic–clonic seizures by the second day than those withdrawn from phenytoin; the authors of this paper suggested that a rebound phenomenon may exist [57].

Advantages and disadvantages of oxcarbazepine

The efficacy of oxcarbazepine for partial-onset and generalized tonic–clonic seizures, as both monotherapy and adjunctive therapy, has been thoroughly established by the results of many well-controlled studies involving all ages of patients. During nearly 20 years of clinical use, there has been a remarkably good safety record, with few dangerous side-effects. The rate for both minor and serious skin rashes is low, and definitely lower than for carbamazepine. Drug interactions are fewer than with most older generation AEDs, including carbamazepine.

However, there is no clear population advantage in efficacy for oxcarbazepine over carbamazepine or other first-line drugs;

oxcarbazepine is more expensive than older AEDs in most countries, and it is more likely than carbamazepine to produce hyponatraemia. It is not effective for, and may exacerbate, absence and myoclonic seizures. It is not completely free of drug interactions, and can reduce the efficacy of birth control pills. Safety for use during pregnancy has not been established conclusively, and pregnancy may reduce oxcarbazepine serum levels.

On balance, oxcarbazepine is a useful first-line agent suitable for partial-onset seizures in children and adults, and is better tolerated than carbamazepine and phenytoin for most patients. It compares favourably in terms of efficacy, safety and tolerability with other newer drugs for epilepsy, although few well-controlled comparisons among newer agents are available.

46 Phenobarbital, Primidone and Other Barbiturates

Roberto Michelucci[1], *Elena Pasini*[1] *and Carlo Alberto Tassinari*[2]

[1]Bellaria Hospital, Bologna, Italy
[2]University of Bologna, Bologna, Italy

	Phenobarbital	Primidone
Primary indication	Adjunctive or first-line therapy for partial and generalized seizures (including myoclonus). Also for status epilepticus and neonatal seizures. Ineffective in absences	Adjunctive or first-line therapy for partial and generalized seizures (including myoclonus). Ineffective in absences
Usual preparations	Tablets: 15, 30, 50, 60 and 100 mg Elixir: 15 mg/5 mL Injection: 200 mg/mL	Tablets: 250 mg Suspension: 50 mg/mL
Usual dosage	*Oral*. Initial: 30 or 50 mg/day in adults and 3 mg/kg in children. Maintenance: 30–200 mg/day (adults); 3–8 mg/kg/day (children); 3–4 mg/kg/day (neonates). *Intravenous (status epilepticus)*. Adults: 10 mg/kg infused over 10 min or more (50–75 mg/min). Children and neonates 15–20 mg/kg at a rate of 100 mg/min. These doses may be followed by a maintenance daily dose of 1–4 mg/kg (adults) or 3–4 mg/kg (children and neonates)	*Adults and children > 9 years*. Initial: 62.5 mg at bedtime, to be increased gradually. Maintenance: 500–1000 mg/day. *Children < 9 years*. Initial: 50 mg at bedtime, to be increased gradually. Maintenance: 10–25 mg/kg/day
Dosing frequency	1–2 times/day	2–3 times/day
Significant drug interactions	Phenobarbital is an enzyme inducer and stimulates the metabolism of many other antiepileptic drugs and other drugs. Serum phenobarbital levels are increased by co-administration of valproic acid and some other drugs	Primidone is converted to phenobarbital and therefore interactions described with phenobarbital also apply to primidone. Enzyme-inducing drugs increase the phenobarbital–primidone ratio in serum. Isoniazid and nicotinamide increase serum primidone levels
Serum level monitoring	Although phenobarbital therapy can be adjusted solely on the basis of clinical response, measurement of serum drug concentrations may aid in selected cases	The target range for unchanged primidone has a merely indicative value. In most cases it is sufficient to monitor the serum concentration of metabolically derived phenobarbital

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

	Phenobarbital	Primidone
Reference range	10–40 mg/L	3–12 mg/L
Common/important adverse effects	Sedation, ataxia, dizziness, insomnia, hyperkinesis (children), mood changes (especially depression), aggressiveness, cognitive dysfunction, impotence, reduced libido, folate deficiency, vitamin K and vitamin D deficiency, osteomalacia, Dupuytren's contracture, frozen shoulder, rash, other idiosyncratic reactions	Sedation, ataxia, dizziness, insomnia, hyperkinesis (children), mood changes (especially depression), aggressiveness, cognitive dysfunction, impotence, reduced libido, folate deficiency, vitamin K and vitamin D deficiency, osteomalacia, Dupuytren's contracture, frozen shoulder, rash, other idiosyncratic reactions
Main advantages	Broad-spectrum efficacy against many seizure types, feasibility of once-daily dosing and low cost	Broad-spectrum efficacy against many seizure types
Main disadvantages	Central nervous system adverse effects, enzyme induction	Central nervous system adverse effects, enzyme induction
Mechanism of action	Enhances chloride conductance at the $GABA_A$–benzodiazepine–chloride channel complex, depresses glutamate excitability, affects sodium, potassium and calcium conductance	Although primidone itself has anticonvulsant activity, much of its effect can be ascribed to metabolically derived phenobarbital. A possible contribution of phenylethylmalonamide to clinical effects has not been ascertained
Bioavailability	>95%	>90%
Time to peak levels after single dose	0.5–4 h	2.5–4 h
Main routes of elimination	About 25% of the dose is excreted unchanged in urine. The remainder is cleared by glucosidation and oxidation followed by conjugation	Partly excreted unchanged in urine and partly converted to phenylethylmalonamide (PEMA) and phenobarbital. Because phenobarbital has a much lower clearance, it accumulates
Volume of distribution	0.42–0.73 L/kg	0.64–0.72 L/kg
Elimination half-life	70–130 h (in adults; varies with age in children)	5–20 h (shortest values in children and in patients co-medicated with enzyme inducers)
Plasma clearance	2.1 to 4.9 mL/kg/h (in adults; varies with age in children)	35–52 mL/kg/h (adults, with highest values in patients co-medicated with enzyme inducers)
Protein binding	45–60%	10%
Active metabolites	None	Phenobarbital and phenylethylmalonamide (PEMA)
Comment	Highly effective antiepileptic drug, used as first-line therapy in many parts of the world because of its low cost. Because of its inferior tolerability to other drugs, particularly in children, it is rarely used as first line when cost is not the primary consideration	Because of its inferior tolerability to other drugs (particularly in children), primidone is rarely used as a first-line drug. However, it may be a useful third-line agent, particularly in patients with generalized seizures

Introduction

Barbiturates are a group of derivatives of barbituric acid, a compound synthesized from condensation of malonic acid and urea in 1864. Initially believed to have only sedative properties, barbiturates have been recognized as antiepileptic agents since 1912, when Hauptmann discovered serendipitously a dramatic reduction of seizure frequency in patients with bromide-resistant epilepsy treated with phenobarbital (phenobarbitone) [1]. Phenobarbital is the oldest antiepileptic drug (AED) still in use. Despite the development of successive generations of AEDs, phenobarbital has retained a unique role in the therapeutic armamentarium and is still the most commonly prescribed AED in the world. Because of its efficacy and low cost, it is recommended by the World Health Organization as first line for partial and tonic–clonic seizures in developing countries in all age groups [2]. Despite its sedative and behavioural effects, phenobarbital also remains a relatively commonly prescribed drug in many developed countries [3].

Over the years, attempts have been made to modify phenobarbital's molecular structure in order to identify agents with greater efficacy and lesser toxicity. Primidone was introduced into clinical practice in 1952 and is still relatively widely used. However, its effects can be attributed largely to metabolically derived phenobarbital. Additionally, two *N*-methyl derivatives of barbituric acid, methylphenobarbital (or mephobarbital) and metharbital, possess antiepileptic properties and were introduced into therapeutics in 1932 and 1948, respectively; neither drug, however, achieved widespread use. Barbexaclone, the propylhexedrine salt of phenobarbital, was marketed with the aim of decreasing the sedation associated with phenobarbital.

In this chapter, the comprehensive features of phenobarbital, primidone and other barbiturates will be outlined. A number of excellent reviews devoted to this subject are already available [4–14].

Phenobarbital

Chemistry

Phenobarbital (5-ethyl-5-phenylbarbituric acid) is a substituted barbituric acid with more potent anticonvulsant than sedative properties. Indeed, the presence of a phenyl group at the C-5 position confers relatively selective antiepileptic activity (Fig. 46.1). Phenobarbital has a molecular weight of 232.23; the free acid of phenobarbital is a white crystalline substance, soluble in non-polar solvents such as chloroform, ethyl ether, ethanol and propylene glycol, but relatively insoluble in water. In contrast, the sodium salt is freely soluble in water. Phenobarbital is a weak acid with a pK_a of 7.3, similar to the physiological pH of plasma. Changes in pH, which may occur in active epilepsy, can alter the ratio of ionized to non-ionized phenobarbital, resulting in significant modifications of its distribution and excretion [7].

Activity in animal models and mechanisms of action

In experimental models of epilepsy, phenobarbital seems to act in a relatively non-selective manner. It protects against maximal electroshock convulsions, subcutaneous pentylenetetrazole-induced clonic seizures and electrically kindled seizures [5]. It also appears to prevent seizures induced by a variety of chemicals (such as strychnine, thiosemicarbazide and bicuculline) and photic seizures in the baboon [15]. In contrast, phenobarbital worsens spike–wave discharges in animal models of absence seizures, such as γ-butyrolactone-induced spike–wave seizures and the lethargic (lh/lh) mutant mouse [16]. This pattern of activity in various anticonvulsant tests, and particularly its ability to limit the spread of seizure activity and to elevate seizure threshold, suggests utility in generalized tonic–clonic seizures and partial seizures in humans. This is borne out in clinical practice, and phenobarbital has proven value in controlling generalized tonic–clonic seizures, other generalized seizure types (but not absence seizures) and partial seizures.

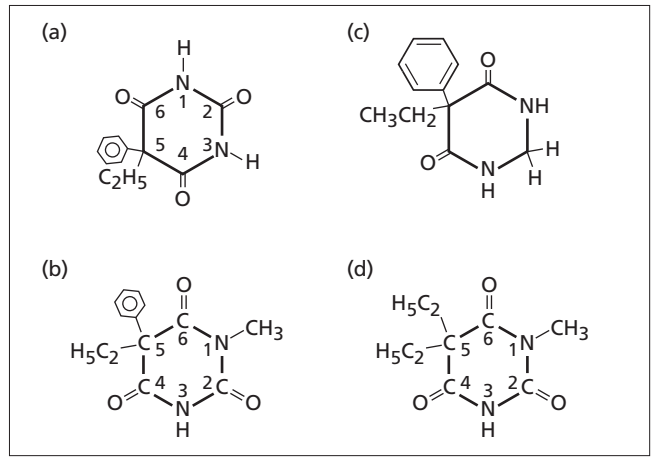

Fig. 46.1 Structural formulae of (a) phenobarbital, (b) methylphenobarbital, (c) primidone and (d) metharbital.

The possible mechanisms of action of phenobarbital are still not completely elucidated. Different effects are noted at different serum concentrations [4]. At high concentrations – such as those achieved in patients during treatment of status epilepticus – phenobarbital limits high-frequency repetitive firing of action potentials, possibly by interacting with Na^+ and K^+ transmembrane transport and conductance, and reduces cellular metabolism at the level of mitochondria or membrane ion gradients [17]. Phenobarbital also decreases the Ca^{2+} influx in presynaptic nerve endings, which could result in decreased release of excitatory neurotransmitters, such as glutamate and aspartate. However, these effects on ion transport appear to be more related to its sedative and/or anaesthetic properties than to its anticonvulsant action. At 'therapeutic' concentrations, phenobarbital produces modest changes in membrane conductance, but exerts its anticonvulsant action mainly by increasing postsynaptic γ-aminobutyric acid (GABA)-ergic inhibition [6].

Phenobarbital interacts with the $GABA_A$ receptor, which is a macromolecular complex containing binding sites for GABA, picrotoxin, neurosteroids, barbiturates and benzodiazepines and a chloride ion-selective channel [18]. GABA binds to $GABA_A$ receptors to regulate gating (opening and closing) of the chloride ion channel [18]. Studies indicate that phenobarbital acts mainly by increasing the mean channel open duration without affecting

channel conductances or opening frequency [19]; in contrast, the binding of a benzodiazepine to its allosterically coupled $GABA_A$ binding site increases opening frequency without affecting open or burst duration [19]. Interestingly, while benzodiazepines do not directly activate channels but only modify the GABA binding affinity, phenobarbital can directly promote channel opening in the presence and in the absence of GABA [20]. These small differences in mode of action can result in different effects: for example, phenobarbital could indiscriminately enhance all $GABA_A$ receptors, whereas benzodiazepines could exert a selective action on those with heavy firing activity, as occurs during a seizure [6]. A molecular basis for differential regulation of GABA receptor currents by barbiturates and benzodiazepines has also been established by studying $GABA_A$ receptor subunits [21]. In particular, it has been observed that $GABA_A$ receptors formed from α_1–β_1 subunits are sensitive to barbiturates but insensitive to benzodiazepines, whereas the transient co-expression of the γ_2, α_1 and β_1 subunits results in sensitivity to both benzodiazepines and phenobarbital [21]. This differential expression and assembly of various subunit subtypes in various cerebral regions – which is genetically determined [22] – could explain differences in the clinical profile between barbiturates and benzodiazepines.

Pharmacokinetics

Absorption

Phenobarbital can be administered by the intravenous, intramuscular and oral routes. Because free acid phenobarbital is poorly water soluble, formulations for intravenous and intramuscular administration are prepared from the sodium salt in slightly alkaline solutions.

Phenobarbital is readily absorbed after oral or intramuscular administration (Fig. 46.2) and peak plasma levels are linearly related to dose within a wide range of doses [7,23]. Times to peak plasma concentrations range between 0.5–4 h after oral dosing and 2–8 h after intramuscular injection [7,23–25]. As a whole, the differences between oral and intramuscular absorption are not statistically significant. In newborns (<6 weeks old) and premature babies, however, the absorption of orally administered phenobarbital is delayed and incomplete when compared with the intramuscular route. Jalling [26] found that 90% of the peak plasma concentration of phenobarbital was achieved within 4 h in 8 of 10 neonates following intramuscular injection, but in only 3 of 6 newborns after oral administration.

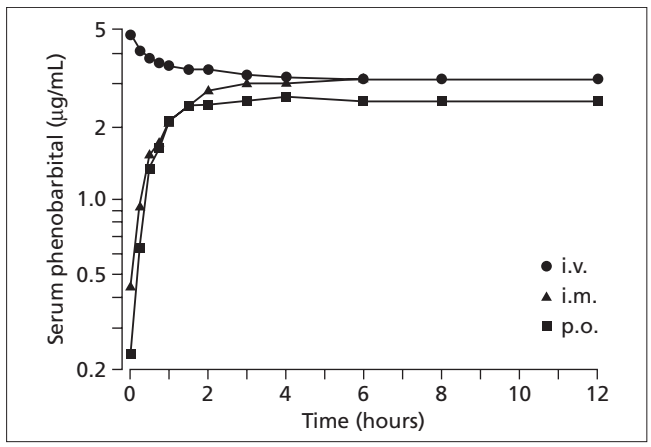

Fig. 46.2 Mean serum phenobarbital levels in six healthy volunteers after single intravenous and intramuscular injections of phenobarbital sodium 130 mg and single oral doses of phenobarbital acid 100 mg. Doses were given at least 1 month apart. From ref. 25 with permission.

The rate and extent of gastrointestinal absorption after oral dosing may also be influenced by other factors [7]. In the acid environment of the stomach, phenobarbital is largely non-ionized and diffusible. The bulk of orally administered phenobarbital, however, is absorbed in the small intestine, where the non-ionized fraction is smaller but intraluminal dwell time is longer. Characteristics of the preparation administered (e.g. free acid or salt, crystal size), gastric blood flow, gastric emptying time, gastric acidity, presence of food and neutralizing agents, and small intestine disorders may all alter phenobarbital absorption. Phenobarbital has a nearly complete bioavailability in humans, usually greater than 95% with a range from 80% to 100%, whether administered by the oral or intramuscular route [7,24,25].

Distribution

Phenobarbital distributes rapidly to all body tissues. Since its pK_a is similar to the physiological plasma pH, distribution processes are very sensitive to variations in the plasma pH. Acidosis results in a higher percentage of non-ionized phenobarbital, enhancing its diffusion from plasma to tissues. On the other hand, alkalosis causes an increased transfer of phenobarbital from tissues to plasma.

In infants, children and adults, phenobarbital is 45–60% bound to plasma proteins [27]. Binding in newborns is lower (36–43%) [26]. Changes in the extent of phenobarbital binding, as they may occur due to hypoalbuminaemia or displacement by other agents, are small and have little effect on unbound phenobarbital levels. The concentrations of phenobarbital in cerebrospinal fluid are 43–60% (in adults) and 48–83% (in infants) of plasma concentrations and correlate well with the unbound phenobarbital levels in plasma [7]. They also provide a reliable index of the phenobarbital concentration in brain. The brain to plasma concentration ratios in human epileptic brain specimens vary widely, ranging from 0.35 to 1.13 [7]. Phenobarbital concentrations are higher in cerebrospinal fluid than in saliva, and saliva to total plasma concentration ratios in infants range from 0.21 to 0.52 [7].

Phenobarbital rapidly crosses the placenta, so that maternally derived plasma phenobarbital concentrations in neonates are similar to those in the mother. Phenobarbital is also secreted in breast milk, in which its concentrations are about 40% of those in plasma [7,28].

After intravenous administration, phenobarbital distribution into body tissues is biphasic. In a first phase, the drug distributes rapidly into highly perfused organs including liver, kidney and heart, but not into the brain. During the second phase, phenobarbital achieves a fairly uniform distribution throughout the body except the fat tissue. This pattern of relatively slow entry into brain (12–60 min) and late exclusion from fat is related to phenobarbital's low lipid solubility; however, in status epilepticus, because of focal acidosis and increased cerebral

blood flow, the transfer of phenobarbital to the brain is much faster [7].

In adults, the volume of distribution of phenobarbital ranges from 0.36 to 0.73 L/kg [7]. The volume of distribution is larger in newborns, in whom it ranges from 0.39 to 2.25 L/kg after intravenous or intramuscular injection [29].

In some animal models, phenobarbital has been found to be a substrate of the efflux drug transporter P-glycoprotein, which is expressed at the cerebral capillary endothelium. The clinical relevance of this remains to be determined, but growing evidence seems to suggest that, by extruding AEDs from their intended site of action in the brain, overexpression of P-glycoprotein could play an important role in pharmacological intractability [30]. Expression of P-glycoprotein seems to be partly determined by genetic polymorphism of the encoding gene *ABCB1*, and the C3435T polymorphism of the *ABCB1* gene has been reported to influence the penetration of phenobarbital across the blood–brain barrier in patients with generalized epilepsy [31].

Elimination

Elimination of phenobarbital by all routes is slow and the average elimination half-life after single doses is between 70 and 130 h, the longest amongst frequently used AEDs [7,25]. Under usual circumstances, the plasma clearance of phenobarbital ranges from 2.1 to 4.9 mL/kg/h in adults [7,24,25,32]. Phenobarbital elimination follows first-order kinetics and thus is independent of concentration [33]. Several factors, however, contribute to variation in rate of elimination, including urinary pH and flow, age, nutritional state, drug interactions and hepatic or renal disease [7].

Phenobarbital is eliminated partly unchanged and partly as inactive metabolites. There is considerable inter- and intrasubject variability in the amount of phenobarbital excreted unchanged; however, single dose and steady-state studies have shown that excretion as unchanged drug accounts for approximately 20–25% of the total clearance (range, 7–55%) [7]. Urinary pH influences the passive reabsorption of phenobarbital from the distal tubule, which favours the transport of non-ionized compounds. Alkalinization of urine converts more drug to the ionized, non-diffusible form, thereby resulting in increased phenobarbital excretion. The opposite occurs with acidification of urine. Raising urinary pH to 8.0, with a corresponding plasma pH of 7.55, increases the fraction of ionized phenobarbital in renal tubular fluid from 69% to 86%. Renal clearance of phenobarbital is also enhanced by diuresis. These findings are the basis for the use of forced diuresis and urine alkalinization in overdose patients.

The majority of a phenobarbital dose is eliminated by hepatic metabolism. A major route of biotransformation is hydroxylation of the phenyl ring (aromatic hydroxylation) by cytochrome P450 (CYP) enzymes to produce *p*-hydroxyphenobarbital. This metabolite is excreted in urine partly in free form and partly conjugated with glucuronic acid. The sum of the free and conjugated metabolite accounts for 8–34% of the administered dose, with high intersubject variability. Hydroxylation is catalysed primarily by the isozyme CYP2C9, with minor contributions from CYP2C19 and CYP2E1. Genetic polymorphism of CYP enzymes affects their expression, and an influence of genetic polymorphisms of CYP2C9 and CYP2C19 on the clearance of phenobarbital has been reported in Japanese patients [34–36]. *N*-glucosidation is a more recently identified metabolic pathway, leading to the formation of a phenobarbital *N*-glucoside metabolite. The *N*-glucosidation pathway is not active at birth but becomes effective only after 2 weeks of life. This may be the main reason for the long phenobarbital half-life in newborns. Phenobarbital *N*-glucoside accounts for clearance of 6–30% of the dose. It has been suggested that phenobarbital *N*-glucoside undergoes significant breakdown to as yet unidentified derivatives; therefore, *N*-glucosidation could be a more important metabolic pathway than originally thought [7]. Other less important routes of biotransformation are epoxidation, aliphatic hydroxylation and hydrolysis [7]. Enterohepatic circulation and faecal excretion probably are not important contributors to phenobarbital disposition under usual circumstances. Oral administration of activated charcoal, however, increases the intestinal elimination of phenobarbital and may be used in phenobarbital overdose [37]. Although phenobarbital is a well-known inducer of hepatic metabolism, it does not induce its own metabolism in humans. In animals, however, considerable autoinduction has been observed.

Pharmacokinetics in special groups

Phenobarbital half-life varies with age. Whereas premature and full-term newborns have the longest phenobarbital half-lives (ranging from 59 to 400 h), infants aged 6 weeks to 12 months have the shortest. Pitlick *et al.* [29] observed that the half-life diminishes from an average of 115 h to 67 h between birth and the first month of life. Half-lives of 37–133 h were found in 33 infants older than 6 months after single doses in one study [38] and even shorter values (21–75 h) were reported in other studies [7]. Total clearance ranged between 5.3 and 14.1 mL/kg/h in nine children aged 8 months to 4 years [39].

The clearance of phenobarbital is moderately reduced in the elderly, but interindividual variation is considerable. Average clearance values were 2.5 mL/kg/h in a group of patients >40 years old compared with 4.9 mL/kg/h in patients 15–40 years old [40]. A more recent study showed that phenobarbital clearance declined from 4.1 mL/kg/h in adults aged 20–50 to 3.2 mL/kg/h in those over 65 years [41].

The half-life of phenobarbital was prolonged in a group of patients with liver cirrhosis (130 ± 15 h) compared with healthy subjects (86 ± 3 h) [42]. Phenobarbital clearance is increased in children with protein–energy malnutrition [7].

Drug interactions

There are no well-documented clinically significant pharmacodynamic interactions between phenobarbital and other drugs, except perhaps for the reciprocal potentiation of central nervous system (CNS) depressant effects between barbiturates, benzodiazepines and other CNS depressants. However, there are many pharmacokinetic interactions [8].

Effects of phenobarbital on the pharmacokinetics of other drugs

Phenobarbital is a potent inducer of various microsomal enzymes including the CYP isoforms CYP1A2, CYP2B6, CYP2C9,

CYP2C19 and CYP3A4, as well as glucuronyl transferases and epoxide hydrolase [43]. Induction of CYP enzymes by phenobarbital results from altered transcriptional regulation mediated by orphan nuclear receptors, including the pregnane X receptor and constitutive androstane receptors [8,44]. Most clinically relevant drug–drug interactions involving phenobarbital are the result of enzyme induction [8]. Enzyme induction is influenced to some extent by environmental factors (e.g. tobacco smoking, alcohol), age and genetic factors, as demonstrated by studies in mono- and dizygotic twins [45]. Because of these influences, the magnitude of induction caused by phenobarbital in individual patients is largely unpredictable.

Because microsomal enzymes are involved in the biotransformation of most therapeutic agents, patients taking phenobarbital metabolize at a faster rate a wide range of concomitantly administered medications. These include, amongst others, a number of analgesics (antipyrine, amidopyrine, paracetamol, meperidine and methadone), antiasthma agents (theophylline), calcium channel blockers (verapamil, nimodipine, felodipine, nisoldipine, nifedipine), antimicrobials (chloramphenicol, doxicycline, griseofulvin, metronidazole, some antiretroviral drugs), anticoagulants (bishydroxycoumarin and warfarin), antiulcer agents (cimetidine), immunosuppressants (ciclosporin), antineoplastic agents (taxanes, vinca alkaloids, cyclophosphamide, methotrexate, nitrosureas, teniposide, irinotecan), psychotropic drugs (chlorpromazine, haloperidol, clozapine, desipramine, nortriptyline, benzodiazepines), corticosteroids (cortisol, dexamethasone, methylprednisolone, hydrocortisone) and steroid oral contraceptives [8].

The metabolism of other AEDs is also stimulated by phenobarbital. Phenobarbital decreases the plasma concentrations of brivaracetam, carisbamate, ethosuximide, felbamate, lacosamide, lamotrigine, levetiracetam, monohydroxycarbazepine, primidone, rufinamide, stiripentol, tiagabine, topiramate, valproic acid and zonisamide [8,46]. The clinical significance of these interactions is often limited, because the partial loss of efficacy resulting from the decreased serum concentration of the affected drug tends to be compensated for by the antiepileptic effect of the phenobarbital added on [43]. However, in some patients, failure to achieve sufficient plasma concentrations of the affected drug may lead to inadequate seizure control. Phenobarbital may also cause a decline of plasma carbamazepine levels in some patients [8], but the effect is variable. The effect of phenobarbital on plasma phenytoin levels is complex: in particular, phenobarbital may simultaneously induce and inhibit phenytoin metabolism, and the prevailing effect in the individual patient is unpredictable [8].

Induction of drug metabolism by phenobarbital does not always result in a reduction of the effects of other drugs. There are instances in which the induction of metabolism causes an increased production of toxic metabolites of the affected drug, leading to increased toxicity. This is the case for acetophenitidin, whose induction of metabolism by phenobarbital may be responsible for methaemoglobin formation by increasing the production of a toxic intermediary metabolite (2-hydroxyphenetidin), particularly in patients with genetically determined metabolic deficiencies [47]. It has also been suggested that induction of the formation of toxic metabolites of valproic acid by phenobarbital may predispose to valproic acid hepatotoxicity [48].

Effects of other drugs on the pharmacokinetics of phenobarbital

Valproic acid, felbamate, clobazam, sulthiame, dextropropoxyphene, chloramphenicol and, to a lesser extent, phenytoin may inhibit phenobarbital metabolism, leading to elevation of phenobarbital levels. Accumulation of phenobarbital caused by valproic acid is the most constant, predictable and clinically important interaction in this group. The clinical manifestations include increasing somnolence, sometimes resulting in coma (an outcome for which a pharmacodynamic interaction may contribute), within days or weeks after the initiation of valproic acid administration. The increase in serum phenobarbital concentrations appears to be greater in paediatric patients (112.5%) than in adults (50.9%). Although the rate and magnitude of this interaction vary among individuals, phenobarbital dosage reductions are necessary in up to 80% of patients started on valproic acid comedication. The primary mechanism of this interaction involves decreased biotransformation to *p*-hydroxyphenobarbital by inhibition of CYP2C9 and/or CYP2C19 [49]. Furthermore, toxic signs may be precipitated by elevated blood ammonia levels, because the magnitude of valproic acid-induced hyperammonaemia is increased in patients co-medicated with phenobarbital.

The use of vigabatrin in combination with phenobarbital has sometimes been associated with a small but significant decrease in serum phenobarbital concentration. The mechanism of this interaction is unknown [8].

Serum level monitoring

Although phenobarbital dosage can often be individualized on the basis of clinical response alone, monitoring the serum concentration of the drug may be useful in selected indications (Chapter 9).

A therapeutic range of serum phenobarbital concentrations was first suggested by Buchthal *et al.* [50], who described 11 previously untreated patients with frequent seizures in whom phenobarbital was administered in small and gradually increased doses. The average level at which EEG and clinical response occurred was 10 mg/L. By pooling the data from four studies (three retrospective and one prospective) [51–54] in a total of 568 patients, Booker [10] found that 84% of the subjects who were controlled had plasma phenobarbital levels between 10 and 40 mg/L (Table 46.1). Some patients, however, experience good seizure control above or below this limit. As the plasma level increases above 40 mg/L, potential benefits must be weighed against the potential for adverse effects. Because of variable development of tolerance to some of the CNS adverse effects of phenobarbital, the upper limit of the therapeutic range is not well defined and varies among individuals.

The optimal plasma phenobarbital concentration also varies with seizure type. In a study of 78 patients with various seizure types, Schmidt *et al.* [55] reported that the plasma concentrations of phenobarbital required to produce complete control of simple or complex partial seizures were significantly higher than those required to control tonic–clonic seizures alone (38 ± 6 mg/L versus 18 ± 10 mg/L).

Table 46.1 Plasma phenobarbital levels versus seizure control. Pooled analysis of four studies (one prospective [51] and three retrospective [52–54]) in a total of 568 patients of different ages and with different seizure types who had achieved seizure freedom, mostly on monotherapy. The table shows the total number of subjects and the number controlled for each range of plasma levels as well as a cumulative percentage of the number of subjects who were controlled at progressively higher plasma levels.

Plasma phenobarbital level (mg/L)	Total number of subjects	Number of subjects controlled	Cumulative percentage of controlled subjects
<10	50	14	6.5
10–14	92	23	17.2
15–19	115	50	40.6
20–24	93	50	64.0
25–29	87	29	77.6
30–34	43	12	83.2
35–39	35	16	90.7
≥40	53	20	100.0

Efficacy

As is the case with other drugs marketed so long ago, phenobarbital efficacy is mainly documented by uncontrolled studies and case series, and information from controlled studies is relatively limited. There are, overall, extensive data indicating the value of phenobarbital in the treatment of both adult and childhood epilepsies. In controlled studies, efficacy has been demonstrated most clearly against partial and generalized tonic–clonic seizures [56], but there is general consensus that phenobarbital can be effective in controlling other generalized seizure types except for absence seizures.

Neonatal seizures and status epilepticus are two other well-established indications for the use of phenobarbital.

Adults and children with partial and generalized seizures

The most authoritative randomized double-blind controlled trial of phenobarbital in adults with epilepsy is the Veterans Administration (VA) Cooperative Study conducted by Mattson *et al*. [57] in the USA. In this study, the efficacy and tolerability of four drugs (phenobarbital, primidone, carbamazepine and phenytoin) were assessed in 622 adults with previously untreated or undertreated partial and secondary generalized tonic–clonic seizures. Phenobarbital, primidone, carbamazepine and phenytoin produced similar rates of overall seizure control (with percentages of 36%, 35%, 47% and 38%, respectively). While the prognosis for complete control of tonic–clonic seizures with the four drugs was also similar, carbamazepine provided significantly better total control of partial seizures (43%) than phenobarbital (16%) or primidone (15%), whereas phenytoin provided intermediate control (26%). These data were confirmed at every 6-month point during the 36 months of follow-up. To some extent, the lower response rates in patients with partial seizures randomized to phenobarbital or primidone could be explained by more patients in these groups exiting the trial because of adverse effects. In keeping with the data from this study, other open studies have shown phenobarbital to be as effective as carbamazepine and phenytoin in the treatment of predominantly tonic–clonic seizures, but with a higher failure rate in the management of partial seizures [55,58].

Two subsequent prospective randomized trials, one conducted in adults and one in children, have compared the efficacy and toxicity of phenobarbital, phenytoin, carbamazepine and valproic acid in newly diagnosed epilepsy in the UK. Patients entered the trial with a minimum of two previously untreated tonic–clonic seizures or partial seizures with or without secondary generalization. In the adult trial, which enrolled 243 patients, the overall outcome with all four drugs was good, with 27% remaining seizure free from the beginning and 75% entering 1 year of remission by 3 years of follow-up [59]. There were no significant differences in efficacy between the four drugs in either time to first seizure recurrence or time to achieve 1-year remission from all seizures. In the paediatric trial, which enrolled 167 children (aged 3–16 years), overall 20% of the patients remained seizure free and 73% achieved 1-year remission by 3 years of follow-up [60]. Although the authors claimed that there was no difference in efficacy between the drugs for either measure of efficacy at 1, 2 or 3 years of follow-up, only 10 children were allocated to phenobarbital because an excess of adverse effects precluded further recruitment of children in this arm of the study. The two UK studies included a larger proportion of patients with tonic–clonic seizures (including primary generalized) than with partial seizures alone, which explains their relatively good outcome in terms of seizure control. There has also been a number of other studies, either randomized or observational, performed in resource-restricted countries, confirming a substantial equivalence of effect of phenobarbital, carbamazepine and phenytoin in adults [9,61] and children [62,63], mostly with generalized tonic–clonic or partial seizures. These studies are described in some detail in the section discussing adverse effects.

The studies reviewed above indicate that phenobarbital is useful in the treatment of partial seizures (with and without secondary generalization) and primary generalized tonic–clonic seizures. The effects of phenobarbital in generalized seizures occurring within the spectrum of idiopathic generalized epilepsies have been also investigated. Phenobarbital has been shown to be effective in the treatment of idiopathic generalized epilepsy with tonic–clonic seizures [9,55,58,64,65]. Phenobarbital is also effective against other generalized seizure types, including myoclonic, clonic, atonic and tonic seizures, although evidence from well-designed randomized studies in these seizure types is lacking. Based on scattered reports and clinical experience, phenobarbital is ineffective against absence seizures and may even aggravate them [56].

Oral phenobarbital has also been used successfully to treat high-frequency tonic spasms in early infantile epileptic encephalopathy with suppression bursts [66]. It is also currently used in the treatment of progressive myoclonus epilepsies, mostly with the aim of suppressing motor seizures [67].

Neonatal seizures

Phenobarbital is traditionally considered the drug of choice for the treatment of neonatal seizures. This is primarily due to years of familiarity and experience with phenobarbital in children and adults. However, controlled evidence of its efficacy or superiority

Table 46.2 Phenobarbital efficacy in neonatal seizures.

Study	Number of patients	Response rate (%)	Loading dose (mg/kg)[a]
Lockman *et al*. [51]	39	32	15–20
VanOrman and Darrvish [68]	81	33	15–20
Painter *et al*. [69]	77	36	15–20
Gal *et al*. [70]	71	85	up to 40

Modified from ref. 71.
[a] Phenobarbital was given intravenously.

over other drugs is scanty. Moreover, neonatal seizures are a rather heterogeneous group of paroxysmal events and EEG confirmation of the diagnosis was remarkably absent in most studies.

Three case series show very close agreement on the efficacy of phenobarbital as the initial agent in the treatment of neonatal seizures [51,68,69]. In these open trials, involving a total of 197 neonates and utilizing intravenous loading doses of 15–20 mg/kg, seizure control was obtained in 32–36% of cases. Gal *et al*. [70], however, reported efficacy in 85% of 71 neonates in whom phenobarbital administered intravenously was used as monotherapy, at doses as high as 40 mg/kg to achieve or exceed plasma concentrations of 40 mg/L (Table 46.2). The lack of specific seizure definition, electrically or clinically, in all of these series makes the differences in outcome difficult to interpret [71].

Painter *et al*. [72] performed a randomized trial to assess the relative efficacy of phenobarbital and phenytoin in the treatment of seizures in neonates, using EEG criteria for diagnosis and to determine efficacy. Fifty-nine neonates with EEG-confirmed seizures mostly caused by asphyxia, or cerebral haemorrhage or infarction, were randomly assigned to receive either phenobarbital or phenytoin intravenously; the doses were sufficient to achieve free plasma concentrations of 25 mg/L for phenobarbital and 3 mg/L for phenytoin. Seizures were controlled in 43% of neonates assigned to receive phenobarbital and in 45% of neonates assigned to phenytoin. In refractory cases, the administration of phenobarbital and phenytoin in combination allowed control of seizures to be achieved in 32% of cases. Interestingly, the severity of seizures was a stronger predictor of the success of treatment than the assigned treatment.

High-dose phenobarbital therapy in newborns at term with severe perinatal asphyxia has been shown to improve neurological outcome. In a randomized prospective study with a 3-year follow-up, phenobarbital administered at a dose of 40 mg/kg intravenously was associated with a 27% reduction in the incidence of seizures and a significant improvement in neurological outcomes at 3 years of age [73].

Status epilepticus

Phenobarbital is efficacious in established status, of both tonic–clonic and partial type. For this indication, it can be given intravenously in adults at a loading dose of 10 mg/kg at a rate of 50–75 mg/min, and in children and neonates at a dose of 15–20 mg/kg at a rate of 100 mg/min. These doses may be followed by a maintenance daily dose of 1–4 mg/kg (adults) or 3–4 mg/kg (children and neonates).

Although current trends for the first-line treatment of status epilepticus favour the use of lorazepam (or diazepam), followed, if required, by phenytoin, several studies have shown that phenobarbital can be as effective as other options. In a randomized, non-blinded clinical trial, 36 consecutive patients with convulsive status epilepticus were treated either with a combination of diazepam and phenytoin or with phenobarbital [74]. Phenobarbital was administered intravenously at a rate of 100 mg/min until a dose of 10 mg/kg was achieved. Diazepam (10 mg) was infused at 2 mg/min intravenously and phenytoin (18 mg/kg) was administered simultaneously at a rate of 40 mg/min. There were 18 episodes of status epilepticus in each group. The cumulative convulsion time was shorter for the phenobarbital group than for the phenytoin/diazepam group (median, 5 versus 9 min, $P < 0.06$) and the response latency was also shorter for the phenobarbital group (median, 5.5 versus 15 min, $P < 0.10$). This finding is in keeping with experimental data demonstrating that, although maximum brain to plasma concentration ratios of phenobarbital may not be achieved 60 min after administration, effective brain phenobarbital concentrations are achieved within 3 min [75].

The best evidence for the efficacy of phenobarbital in generalized convulsive status epilepticus stems from a 5-year, randomized, double-blind, multicentre trial which compared four intravenous regimens: diazepam (0.15 mg/kg) followed by phenytoin (18 mg/kg), lorazepam (0.1 mg/kg), phenobarbital (15 mg/kg) and phenytoin (18 mg/kg) [76]. The study included 518 patients with either overt generalized convulsive status epilepticus or subtle status epilepticus. In the group of overt generalized convulsive status epilepticus (386 patients), lorazepam was successful in 64.9% of cases, phenobarbital in 58.2%, diazepam plus phenytoin in 55.8% and phenytoin in 43.6%. In the group of subtle status (134 patients), no significant differences among the treatments were detected. Despite a trend in favour of lorazepam, in an intention-to-treat analysis, the differences among treatment groups were not statistically significant in terms of either efficacy or tolerability, even on a 12-h and 30-day analysis after the status. These data indicate that phenobarbital can be a valuable option as initial intravenous treatment of tonic–clonic status, its major disadvantage being respiratory depression and the frequent need for intubation.

Special indications

Phenobarbital has been extensively used in the past for prophylaxis against recurrence of febrile seizures; however, the potential adverse effects associated with continuous anticonvulsant treatment in children outweigh the relatively minor risks associated with simple febrile seizures, and this has led to a decline in the use of phenobarbital for this indication. Long-term pharmacological prophylaxis is now currently considered in only a minority of cases of febrile seizures occurring in children with pre-existing neurological abnormalities, or manifesting as prolonged or focal attacks, associated with transient or permanent neurological deficits [9]. If phenobarbital is chosen for prophylaxis, it should not be utilized intermittently, but must be administered daily. Faero *et al*. [77] compared 59 patients, all younger than 3 years, with

72 untreated children, and found that the recurrence rate of febrile convulsions was 13% in the phenobarbital group compared with 20% in the control group. However, the risk of recurrence decreased to 4% in those children whose plasma phenobarbital levels were maintained between 16 and 30 mg/L. In a meta-analysis of the efficacy of various medications in the prevention of recurrent febrile seizures, the risk of recurrence was significantly lower in children receiving continuous phenobarbital therapy than in those receiving placebo [78].

Phenobarbital has also been used in the treatment of seizures complicating cerebral malaria. In a randomized study performed in Kenya, 340 children were assigned to receive either a single intramuscular dose of phenobarbital (20 mg/kg) or an identical placebo [79]. Seizure frequency was significantly lower in the phenobarbital group than in the placebo group (11% versus 27%), but mortality was doubled (18% versus 8% deaths) in the phenobarbital group. Mortality due to respiratory arrest was greatly increased in children who received phenobarbital plus three or more doses of diazepam. The authors concluded that 20 mg/kg phenobarbital as a single intramuscular dose should not be recommended in this population because of an unacceptable risk of mortality, but this conclusion has not been shared by other investigators [80].

Adverse effects

After almost a century of worldwide use, phenobarbital is considered a relatively safe drug, particularly because it causes relatively few systemic or idiosyncratic adverse effects. However, its adverse effects on cognition and behaviour represent a common problem in daily practice. Overdose is also a specific concern with phenobarbital. A summary of the adverse effects of phenobarbital is given in Table 46.3.

Table 46.3 Adverse effects of phenobarbital.

Neurotoxicity
Sedation
Behavioural changes
Depression
Cognitive impairment
Decreased libido and potency
Dysarthria, ataxia, nystagmus[a]
Overdose[b]
Dependence and withdrawal symptoms[c]
Connective tissue disorders
Dupuytren's contracture
Frozen shoulder
Shoulder–hand syndrome
Metabolic bone disorders
Hypocalcaemia
Rickets and osteomalacia[d]
Miscellaneous
Folate deficiency
Megaloblastic anaemia
Vitamin K deficiency[e]
Hypersensitivity reactions
Hepatotoxicity
Exacerbation of porphyria
Teratogenicity

[a] These symptoms appear more commonly at serum levels >40 mg/L.
[b] Overdose may result in coma and death.
[c] Typical in neonates born to mothers who received phenobarbital during pregnancy.
[d] May lead to higher incidence of bone fractures.
[e] May cause a coagulation defect in neonates born to mothers exposed to phenobarbital.

Central nervous system effects

Most of the adverse effects causing discontinuation of treatment with phenobarbital (or impacting negatively on quality of life) involve the CNS. Sedation, in particular, is the most common adverse effect associated with phenobarbital, particularly at the onset of treatment. In the VA Cooperative Study, two of three patients complained of sedation at one or more visits in the first year; acute sedation, however, was not more frequent with phenobarbital than with other drugs (i.e. primidone, carbamazepine or phenytoin), probably because of a cautious dose titration (32 mg as starting dose) [57]. In the study of Heller *et al*. [59] comparing the effects of four drugs (phenobarbital, carbamazepine, phenytoin and valproic acid) as monotherapies in adults with newly diagnosed epilepsy, phenobarbital was more likely to be withdrawn because of adverse effects. Drowsiness and lethargy were the main reasons for early withdrawal, but the initial dose was higher (60 mg/day) than in the VA study.

Some tolerance to sedation may develop, particularly if the drug is introduced and up-titrated gradually. A subgroup of 58 patients taking phenobarbital in the VA Cooperative Study was examined at every visit for the first 3 months (1, 2, 4, 8, 12 weeks) to assess the incidence of acute adverse effects and development of tolerance. Of the subgroup studied for tolerance, 33% of patients started on phenobarbital reported initial sedation, declining significantly to 24% by 12 weeks ($P < 0.04$). Evidence of tolerance was shown by decreasing sedation despite increasing phenobarbital concentrations from a mean of 18 mg/L at 2 weeks to 24 mg/L at 12 weeks [57].

Instead of sedation, which is common in adults, insomnia and hyperkinetic activity may occur in children and, less commonly, in elderly subjects, as a paradoxical effect. In a study by Wolf and Forsythe [81], of 109 children treated continuously with phenobarbital following their first febrile seizure, 42% developed behavioural disorders, primarily hyperactivity. The disturbance was not correlated with plasma phenobarbital concentrations. Hyperactivity improved in all children when phenobarbital was discontinued, and disappeared entirely in 73%. Behavioural disturbances associated with phenobarbital were more likely to occur in the presence of organic brain disease or deficits [82,83]. In another study, when compared with phenytoin, carbamazepine and valproic acid in newly diagnosed children with epilepsy, phenobarbital was associated with the highest withdrawal rate, behavioural problems being the main cause [60]. Interestingly, although several studies in developed countries have shown a high rate of behavioural effects with phenobarbital, studies in countries with limited resources suggest that phenobarbital may not be associated with excess behavioural problems, for example when compared with carbamazepine [14,61,63,84]. The overall tolerability profile which emerged from studies conducted in less developed countries is discussed below.

Problems with memory or compromised work and school performance can develop even in the absence of sedation and hyperkinetic activity, although these factors may play a contributory role. Changes in cognitive function have been measured by various standardized neuropsychological tests. A decrease in verbal and performance intelligence quotient (IQ) scores has been observed in children treated with phenobarbital compared with normal control subjects [82,85] or patients receiving valproic acid [85] or carbamazepine [82]. Memory and concentration scores, visuomotor performance and spatial memory, and short-term memory can also be significantly impaired in phenobarbital-treated subjects, especially children. Performance on vigilance tests requiring sustained effort may also be impaired, even after tolerance has developed [82].

Alteration of affect, particularly depression, has been associated with the use of phenobarbital in children [82]. Complex symptoms, including depression, apathy, impotence, decreased libido and sluggishness, are sometimes observed in adults [4]. In the VA Cooperative Study, decreased libido and/or potency was found to be more common in patients treated with phenobarbital or primidone than in those receiving carbamazepine or phenytoin [57].

During chronic therapy, dysarthria, incoordination, ataxia, dizziness and nystagmus may appear if serum levels exceed 40 mg/L. Dyskinesia and peripheral neuropathy are very rare effects induced by phenobarbital [4]. Worsening [56] or *de novo* appearance of absence seizures [86] have been reported with phenobarbital use in epileptic patients.

Central nervous system tolerability in studies conducted in resource-restricted countries

Three randomized clinical trials and several observational studies investigated the effects of phenobarbital in the treatment of epilepsy in resource-restricted countries.

Pal *et al.* [63] found no between-group difference in efficacy and tolerability (particularly in behaviour rating scores) among 94 children from rural areas of India randomized to phenytoin or phenobarbital. In a large study performed in rural Kenya in which 302 untreated paediatric and adult patients were randomized to receive phenobarbital or carbamazepine, the investigators also found no difference in the proportion of patients remaining seizure free after a 6- and 12-month follow-up period, and tolerability did not differ significantly between groups [61]. Banu *et al.* [87] performed a double-blind randomized controlled trial comparing the adverse effects of phenobarbital and carbamazepine in 108 children with generalized tonic–clonic or partial seizures in a Bangladesh clinic. The authors observed comparable efficacy and tolerability between the two drugs, and there was no excess of behavioural side-effects with phenobarbital.

An increasing number of observational studies performed in resource-restricted countries [88–92], reviewed by Kwan and Brodie in 2004 [14], seem to confirm a relatively good tolerability profile of phenobarbital when used in these settings. In general, these trials included largely unselected, untreated patients with a wide range of seizure types across all ages. A study published more recently was conducted in six rural areas of China and tested a model for the treatment of convulsive forms of epilepsy at primary health-care level [93]. The study included 2455 patients with 'generalized' tonic–clonic seizures who were given treatment with phenobarbital. Overall, 72% of patients who completed the 24-month treatment had a reduction in seizure frequency of at least 50% as compared with a 6-month baseline, with one-third (31.3%) having their seizure frequencies decreased by 75% and one-quarter (26.2%) being seizure free. It is unclear whether the relatively low proportion of seizure-free patients might reflect suboptimal compliance. Mild adverse effects were reported by 26.1% of patients, whereas severe adverse effects were present in only 0.3%. Only 1% of patients discontinued medication because of adverse effects. A detailed cost-effectiveness analysis in a sample of patients enrolled in this project demonstrated that use of phenobarbital was associated with a significant decrease in health-care costs, along with a marked clinical improvement [94].

Overall, the above data indicate that, at variance with the relatively high discontinuation rates for adverse effects reported in randomized clinical trials performed in developed countries, phenobarbital appears to be not only efficacious but also fairly well tolerated when used in resource-restricted countries. This discrepancy may be explained by a number of factors, such as methodological weaknesses of many of the studies (variable length of follow-up, problems with seizure classification, open-label designs), cultural differences in reporting adverse drug effects, and greater acceptability of adverse effects due to lack of alternative AEDs. A more favourable tolerability profile in resource-restricted countries might be also related to the use of lower doses than in trials conducted in developed countries [14,95]. These factors clearly need to be investigated in future studies.

Drug dependence and withdrawal symptoms

Prolonged use of phenobarbital is associated with physical dependence, with the appearance of withdrawal symptoms following abrupt discontinuation. A withdrawal syndrome may also be observed in neonates born to mothers who received phenobarbital during pregnancy. This includes hyperexcitability, tremor, irritability and gastrointestinal upset, and can last for days or even weeks.

An increase in seizure frequency, or seizure recurrence in previously controlled patients, may occur during or after phenobarbital discontinuation, and some evidence suggests that these events may not always be due to the underlying epilepsy, but may involve a drug withdrawal manifestation [82]. In these cases, generalized tonic–clonic seizures may occur even when the patient had previously experienced only partial seizures. Therefore, if a decision is made to stop phenobarbital therapy, the drug should be tapered gradually to avoid convulsive withdrawal seizures and, more importantly, convulsive status epilepticus.

Overdose

Among 27 deaths associated with barbiturate poisoning in Ontario from 1955 to 1964, phenobarbital levels detected in postmortem blood ranged between 23 and 189 mg/L [96]. Clinically, excessively high doses of phenobarbital first produce ataxia, dysarthria, nystagmus, incoordination and uncontrollable sleepiness. As the serum levels rise, these effects progress to stupor and coma (Fig. 46.3). Death is due to depression of cardiorespiratory function.

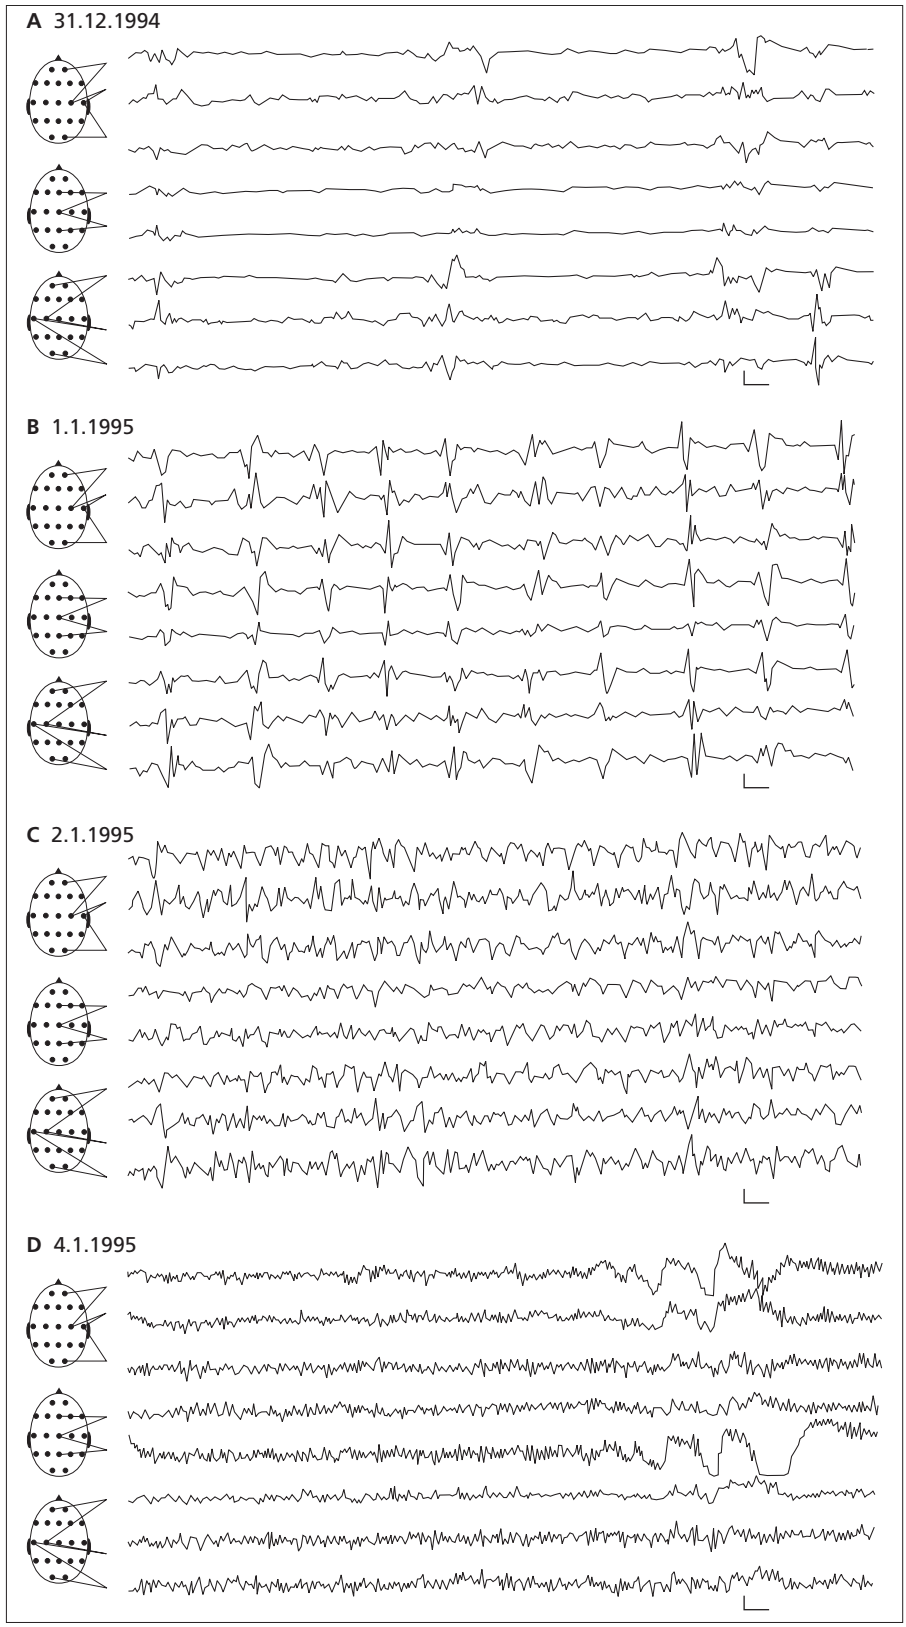

Fig. 46.3 Phenobarbital overdose in a 47-year-old woman with a 34-year history of focal motor and secondarily generalized seizures, on chronic treatment with phenobarbital 100 mg daily (usual plasma levels around 14 mg/L). There was no apparent aetiology for epilepsy. The patient was found comatose in her bed; on admission to the hospital, she was in deep coma and required assisted ventilation; the EEG showed a burst-suppression pattern (A). The plasma phenobarbital level was 82 mg/L. On the subsequent day, there was some improvement of the EEG, with shortening of the 'inter-burst' flattenings (B). The corresponding plasma level was 60 mg/L. Progressive improvement of the EEG (C), with a normal tracing on the fifth day (D) after overdose. When awake, the patient admitted to have taken 'many' pills to attempt suicide (R. Michelucci, personal observation).

The severity of CNS depression is much greater in drug-naive patients, in whom a level of 80 mg/L is considered potentially fatal [97]. Because of tolerance, some chronically treated patients do not report significant drowsiness or sedation even at serum levels that might cause coma in naive individuals. Concentrations above 70 mg/L, however, may compromise the level of consciousness in almost all individuals.

The EEG features of phenobarbital overdose reflect the clinical severity, evolving from burst suppression (Fig. 46.3) to electrical silence in fatal cases. In acute overdose patients, therapy includes maintenance of vital functions with assisted ventilation as well as enhancement of phenobarbital elimination with urine alkalinization and forced diuresis. Charcoal, ion exchange resins and haemodialysis have also been used [82,97,98].

Folate, vitamin D and vitamin deficiencies

Folate deficiency is relatively common in polymedicated patients, and phenobarbital monotherapy can also cause decreased folate levels and macrocytosis. Megaloblastic anaemia is rare, however, and the clinical significance of mild to moderate folate deficiency is uncertain.

Phenobarbital can affect calcium and bone metabolism, by inducing the catabolism of vitamin D. This usually causes decreased calcium absorption, low calcium levels and, sometimes, secondary hyperparathyroidism, rickets and osteomalacia, resulting in higher tendency to bone fractures [99]. Regular measurements of bone density and calcium and vitamin D supplements may be needed, particularly in high-risk populations such as people with poor exposure to sunlight, people with diets poor in vitamin D content and the elderly.

A severe coagulation defect has been reported in neonates born to mothers taking phenobarbital [100]. The coagulation defect is similar to that observed in vitamin K deficiency. Supplementation of vitamin K administered to mothers prepartum or to newborns at birth will prevent this complication [100].

Connective tissue disorders

Chronic phenobarbital treatment is associated with a higher incidence of Dupuytren's contracture with palmar nodules, frozen shoulder, plantar fibromatosis, Peyronie's disease, heel and knuckle pads and generalized joint pain. The incidence of barbiturate-related connective tissue disorders ranges from 5% to 38% depending on the population studied. Shoulder–hand syndrome was observed in 28% of 126 neurosurgical patients treated with barbiturates, but in none of 108 control patients receiving carbamazepine or phenytoin [101]. The condition can be reversible following early discontinuation of the barbiturate.

Exceptionally, phenobarbital has been associated with gingival hyperplasia [102].

Hypersensitivity reactions

Mild skin reactions, usually maculopapular, morbilliform or scarlatiniform rashes, occur in 1–3% of all patients receiving phenobarbital. Serious skin reactions, such as exfoliative dermatitis, erythema multiforme, Stevens–Johnson syndrome or toxic epidermal necrolysis, are rare. Although more common with phenytoin, instances of Stevens–Johnson syndrome or toxic epidermal necrolysis in patients taking phenobarbital while undergoing radiotherapy have been reported [103,104].

A barbiturate hypersensitivity syndrome, characterized by rash, eosinophilia and fever, is infrequent. Signs of hepatic injury (eosinophilic or granulomatous inflammation) may co-exist. Cases of bone marrow aplasia have also been reported, but they are very rare [105].

Systemic lupus erythematosus and acute intermittent porphyria may be unmasked or precipitated by phenobarbital [82].

Teratogenicity

Most studies of fetal outcome after prenatal AED exposure do not clarify the relative role of drugs, epilepsy, genetic and environmental factors. Overall, available studies indicate that intake of phenobarbital during pregnancy, as with other AEDs, is associated with an increased risk of malformations in the offspring. The risk is greater if phenobarbital is used in combination with other AEDs [106,107]. Data from the North American AED Pregnancy Registry showed that 6.5% of 77 children exposed to phenobarbital were born with major malformations, including cardiac defects (coarctation of the aorta with abnormal valves, tetralogy of Fallot, pulmonary atresia) and cleft lip and palate, suggesting a greater risk with phenobarbital exposure compared with exposures to different AEDs other than valproate [108]. Previous studies, however, yielded contradictory results, showing either no differences in fetal malformation rates with phenobarbital compared with other AEDs or even a possibly lower teratogenic profile [109]. Ongoing large prospective registries will hopefully better clarify the teratogenic risk of phenobarbital in the near future. More information on risks associated with the use of specific AEDs during pregnancy can be found in Chapter 25.

Place in current therapy

Phenobarbital has been marketed as either the acid or the sodium salt in 15-, 30-, 50-, 60- and 100-mg tablets, although not all strengths are available in all countries. Oral solutions (elixirs) are also available, as well as parenteral solutions, usually containing 100 or 200 mg of the sodium salt.

Initiation of therapy with phenobarbital should be gradual, with a starting dose in adults of 30 or 50 mg/day. The dose can be titrated by 30- to 50-mg increments every 1 or 2 weeks, according to tolerability. The usual maintenance dose ranges between 60 and 200 mg/day, but in most adults it is within the 90–120 mg/day range. Once-daily dosing is the most convenient mode of administration, particularly in adults.

In children, the starting dose is 3 mg/kg/day, which is titrated up to a maintenance dose of 3–8 mg/kg/day. Sometimes, a twice-daily dosing may be necessary due to the shorter half-life in children. Phenobarbital dosages in status epilepticus and neonatal seizures are discussed in Chapters 18 and 13, respectively.

Though not usually considered a first-line agent when cost is not a primary consideration, phenobarbital still plays a significant role in therapeutic practice. Clear advantages are low cost, ease of use, once-daily dosing, availability of different routes of administration (oral, intramuscular, intravenous), low risk of idiosyncratic reactions and efficacy against most seizure types. These characteristics render phenobarbital an important agent, particularly suitable for resource-restricted countries. Because of its long

half-life, phenobarbital can be suitable for specific categories of patients, such as those who are prone to short periods of non-compliance. Its main disadvantage consists in its potential to cause CNS adverse effects, particularly sedation in adults and behavioural changes in children. While its sedative effects may be minimized by slow titration and development of tolerance, behavioural changes need close monitoring. The enzyme-inducing effects of phenobarbital are also disadvantageous, particularly in patients requiring co-medications. Phenobarbital shows good efficacy in controlling tonic–clonic seizures, either primary or secondary generalized, and is also efficacious in other generalized seizure types, though it is ineffective against absence seizures. It is also efficacious against partial seizures, though to a lesser extent than carbamazepine. Neonatal seizures and status epilepticus are two other valuable indications. Aside from epilepsy, phenobarbital is also used at times in the management of increased intracranial pressure following severe brain injury, although it may not affect overall outcome in these patients [110].

Primidone

Chemistry

Primidone [5-ethyldihydro-5-phenyl-4,6-(1H,5H)-pyrimidinedione] is a deoxybarbiturate which differs from phenobarbital in lacking the carbonyl group in position 2 of the pyrimidine ring (Fig. 46.1). Primidone has a molecular weight of 218.25. It is an odourless crystalline white powder, with a slightly bitter taste and a melting point of 218–282°C. It is almost insoluble in water and organic solvents, but is somewhat soluble in ethanol [11,12].

Activity in animal models and mechanisms of action

Primidone's actions are largely mediated by its metabolite phenobarbital. Another active metabolite, phenylethylmalonamide (PEMA), might also play a role in the activity of primidone in animal models, though its contribution to clinical effects is unclear. Primidone itself, in any case, has independent anticonvulsant activity. Indeed, a single dose of primidone has been shown to protect rats against experimentally induced seizures before active metabolites become detectable in blood [111]. Similar protection has been demonstrated in mice when the biotransformation of primidone was delayed by pre-administration of a metabolic inhibitor [112].

Primidone is effective in preventing seizures induced by maximal electroshock, but is virtually inactive against seizures induced by pentylenetrazole or bicuculline [112]. The activity profile of primidone in some animal models resembles that of carbamazepine and phenytoin more than that of phenobarbital, which is active against both maximal electroshock- and pentylenetrazole-induced seizures [112]. Primidone and phenobarbital differ pharmacodynamically not only in anticonvulsant spectrum, but also in protective or therapeutic index. In terms of brain concentrations in mice, primidone was found to be 2.5 times less neurotoxic than phenobarbital, with a correspondingly higher therapeutic index [112].

In cultured mouse neurones, primidone had no effect on GABA and glutamate responses at concentrations up to 50 mg/L, but showed a synergistic action with phenobarbital to reduce sustained high-frequency repetitive firing [113].

Pharmacokinetics

Absorption

Primidone can only be administered orally, because its low solubility prevents parenteral administration. Time to peak plasma concentrations of primidone after oral ingestion of tablets ranged between 2.7 and 3.2 h in adults [11,12,114] and between 4 and 6 h in children [11,12]. The oral bioavailability of primidone seems to be virtually complete because approximately 92% of the daily dose was recovered in the urine as unchanged primidone or as metabolites in children.

Distribution

Primidone distributes throughout body tissues and fluids in a similar pattern and to the same extent as phenobarbital. In humans, variable brain to blood concentration ratios of primidone have been reported, ranging from 40% to 87% [11,12]; these discrepancies may be due to the timing of specimen collections. Primidone does not bind significantly to plasma proteins: the bound fraction ranges from 0% to 20% [11,12]. The volume of distribution of primidone has been estimated to be in the order of 0.64–0.72 L/kg in adults with epilepsy [11,12].

Elimination

Although the majority of an administered dose is excreted in the urine unchanged, primidone undergoes significant biotransformation. The primary and most relevant metabolic pathways involve (a) formation of PEMA by cleavage of the pyrimidine ring and (b) formation of phenobarbital by oxidation of the methylene group. Phenobarbital in turn is further metabolized, as previously discussed in this chapter. Other metabolites of primidone have been identified (i.e. α-phenylbutyramide, *p*-hydroxyprimidone and α-phenyl-*p*-butyrolactone), but they have no practical significance because of their low concentrations and lack of pharmacological activity. The time-course of appearance in plasma of the metabolites is different for PEMA and phenobarbital. After a first dose of primidone, PEMA was detected in blood within a few hours, whereas phenobarbital was often not measurable during the first 24 h [114].

Numerous clinical studies have addressed the quantitative aspects of the biotransformation of primidone to phenobarbital and PEMA. By comparing the level to dose ratios for phenobarbital and primidone in patients who had taken either drug for at least 6 months, Olesen and Dam [115] concluded that, on average, 24.5% of primidone administered was converted to phenobarbital. This finding was in keeping with the observation that, in order to achieve the same serum phenobarbital levels, the primidone dose (in mg/kg) has to be about five times higher than the corresponding dose of phenobarbital. Other studies, however, suggested that the proportion of a primidone dose converted to phenobarbital is lower. The biotransformation of primidone is influenced by enzyme-inducing AEDs such as phenytoin and carbamazepine, which increase the rate of conversion of primidone to phenobarbital (Table 46.4).

The elimination half-life of primidone is variable and may range from 3.3 to 22.4 h, with factors such as age and concomitant therapy accounting for much of the variability [11,12]. In

Table 46.4 Ratios of serum levels of primidone (PRM), phenobarbital (PB) and phenylethylmalonamide (PEMA) to primidone dose, and ratios of serum levels of primidone, phenobarbital and PEMA at steady state. All blood samples were drawn before the first morning dose in hospitalized patients.

	n	Ratios of serum levels to PRM dose[a]			Ratios of serum levels[a]	
		PRM	PB	PEMA	PB/PRM	PEMA/PRM
Monotherapy	10	0.78 ± 0.25	1.47 ± 0.53	0.64 ± 0.39	1.65 ± 0.74	0.70 ± 0.36
Co-medication[b]	53	0.40 ± 0.15	2.40 ± 0.98	0.75 ± 0.42	5.83 ± 2.62	1.71 ± 0.75

From ref. 11 with permission.

[a] Mean ± SD; primidone dose in mg/kg/day, serum levels in mg/L.

[b] Co-medication consisted of phenytoin, carbamazepine or both.

adults co-medicated with enzyme-inducing AEDs, half-life values are generally in the range of 3.3–11 h [11,12,114]. The ability of newborns to metabolize primidone to phenobarbital appears to be very limited, and in neonates the half-life of primidone has been found to be 23 h on average, with a range of 8–30 h [11,12].

Drug interactions

Since primidone is metabolized to phenobarbital, interactions described for phenobarbital also apply to phenobarbital derived from primidone. In addition, primidone itself is the cause as well as the target of numerous pharmacokinetic interactions. In particular, the conversion of primidone to phenobarbital and PEMA may be induced and inhibited by other drugs.

A marked increase in the rate of biotransformation of primidone is caused by phenytoin [116]. Carbamazepine also accelerates the biotransformation of primidone, but to a lesser extent. Bourgeois [11] reviewed the effects of co-medication with phenytoin, carbamazepine or both on the concentration to dose ratio and on the ratios between the concentrations of primidone, phenobarbital and PEMA (Table 46.4). Compared with primidone monotherapy, morning trough levels of primidone were reduced by about 50% and, conversely, phenobarbital levels were raised by a factor of 1.6 in patients co-medicated with phenytoin and/or carbamazepine. Thus, when patients are taking phenytoin or carbamazepine, the average primidone dose required to achieve a given phenobarbital concentration is 1.6 times lower than with primidone monotherapy. In addition, the morning trough serum concentration ratio of phenobarbital to primidone is more than three times higher in co-medicated patients. This implies that the serum levels of phenobarbital may increase from 'therapeutic' to 'toxic' levels if phenytoin or carbamazepine is added to pre-existing primidone therapy.

Valproic acid may increase the levels of metabolically derived phenobarbital by inhibiting phenobarbital metabolism, and it may cause transient elevations of primidone levels. Isoniazid and nicotinamide have been shown to inhibit the conversion of primidone to phenobarbital, resulting in high levels of primidone.

The effects of primidone on the pharmacokinetics of other drugs are similar to those described for phenobarbital.

Serum level monitoring

There is a poor correlation between the oral dose of primidone and the plasma levels of primidone itself and its metabolite phenobarbital. The VA Cooperative Study [57] suggested that optimal plasma primidone levels are on average in the order of 12 mg/L with an associated phenobarbital level of 15 mg/L, which corresponds to a primidone to phenobarbital ratio of 0.8. However, a large variability occurs between patients, and co-medication with enzyme-inducing agents invariably lowers the primidone to phenobarbital ratio. Although a therapeutic range of about 3–12 mg/L has been suggested for primidone, monitoring primidone levels have very limited clinical value, and monitoring the levels of metabolically derived phenobarbital is more useful in guiding therapy.

Efficacy

Because primidone is metabolized to phenobarbital, there has long been a controversy as to whether primidone is simply a prodrug of phenobarbital or whether it conveys added advantages. Primidone generally has the same indications as phenobarbital.

A number of comparative open-label clinical studies of primidone and other AEDs (usually phenobarbital, phenytoin and carbamazepine) have been performed in patients with partial and secondary generalized seizures, mostly showing no significant differences in efficacy [11,12]. In one cross-over study, primidone and phenobarbital were compared sequentially in 21 patients at the Chalfont Centre for Epilepsy in the UK [117]. Similar phenobarbital levels were maintained during both therapies, and primidone treatment was found to be slightly more effective against generalized tonic–clonic seizures than phenobarbital treatment [117]. In the authoritative double-blind VA study which compared primidone, phenobarbital, carbamazepine and phenytoin in previously untreated or undertreated adults with partial and secondary generalized tonic–clonic seizures, primidone controlled tonic–clonic seizures similarly to phenobarbital, phenytoin and carbamazepine, but was less effective in controlling partial seizures than carbamazepine and had, overall, a poorer tolerability than the other drugs [57].

Primidone has been used as a first-line agent in the treatment of juvenile myoclonic epilepsy [118], but has been largely replaced by valproic acid and other AEDs for this indication. Owing to its ability to shorten the QT interval, primidone has been proposed as an agent of choice for epilepsy patients with QT prolongation [119].

Adverse effects

As for antiepileptic effects, it is difficult to separate the adverse effects of primidone from those of phenobarbital. It is usually

stated that primidone shares all the adverse effects of phenobarbital, both in adults and in children [11,12]. The same also applies to idiosyncratic adverse effects and potential teratogenicity. Birth defects described in the offspring of women who took primidone during pregnancy are not specific and include ventricular septal defects, microcephaly and poor somatic development [120].

What clearly distinguishes primidone from phenobarbital is the occurrence of acute, mostly transient, initial intolerance. Marked adverse effects, including drowsiness, dizziness, ataxia, nausea and vomiting, can occur in some individuals even after a single low initial dose of primidone, and may lead to early discontinuation of treatment. Early adverse events were responsible for the higher rate of treatment failures reported with primidone as compared with phenobarbital, phenytoin and carbamazepine in the VA Cooperative Study [57]. Since acute toxicity has been shown to occur before phenobarbital and PEMA are detected in blood, it must be caused by primidone itself. Tolerance to these adverse effects of primidone develops rapidly, however, in a matter of hours to days. There is also some evidence that phenobarbital produces a cross-tolerance to acute primidone toxicity, as patients on long-term phenobarbital therapy are less prone to experience the same degree of intolerance when first exposed to primidone [11].

Overdose

Primidone overdose causes signs of CNS depression, hypotonia, reduced deep tendon reflexes and marked crystalluria. Symptoms of CNS depression seem to correlate better with plasma and cerebrospinal fluid primidone levels than with phenobarbital or PEMA levels.

Place in current therapy

Because of the potential for initial acute adverse reactions, it is important to start primidone treatment with a small dose and to up-titrate it slowly. An average starting dose for an adult would be 62.5 or 125 mg at night, with increments every 3 days (or longer) up to a final daily maintenance dose of 10–20 mg/kg. Because of the relatively short half-life of primidone, it is recommended to divide the daily dose into three administrations, although the need for this has never been documented.

Primidone is an intriguing drug because of its metabolic profile. It is an AED in its own right, and also a phenobarbital prodrug. Most experts believe, as does the author, that the main antiepileptic action of primidone is due to metabolically derived phenobarbital. The contribution of primidone itself or PEMA to antiepileptic effects is controversial, but is likely to be minor. The efficacy and tolerability profiles of primidone do not differ significantly from those of phenobarbital, and there is little reason to prescribe primidone instead of phenobarbital. When used, primidone has the same indications as phenobarbital. Aside from epilepsy, the main indication of primidone is essential tremor, in which primidone produces greater therapeutic benefit than phenobarbital. Eight double-blind placebo-controlled studies reviewed by Koller *et al.* [121] have provided consistent evidence of efficacy of primidone (at doses ranging from 50 to 1000 mg/day), with tremor relief comparable to that achieved with β-adrenergic blockers.

Other barbiturates

Metharbital

Metharbital or 5,5-diethyl-1-methylbarbituric acid (Fig. 46.1) is less polar than phenobarbital and more lipid soluble. There has been little interest in this drug for many years. There are no consistent published data on its pharmacokinetics, clinical use and toxicity. Whether it has a role in contemporary therapeutic practice is debatable.

Methylphenobarbital (or mephobarbital)

Methylphenobarbital (5-ethyl-1-methyl-5-phenylbarbituric acid) is the *N*-methylated analogue of phenobarbital (Fig. 46.1). It is used as a racemic mixture containing equal parts of the R(–) and S(+) enantiomers, it has somewhat more lipophilic properties than phenobarbital, and it has a pK_a value of 7.8.

Methylphenobarbital is well absorbed from the gastrointestinal tract but it undergoes appreciable presystemic metabolism and its oral bioavailability is about 75% [122]. Methylphenobarbital has a mean apparent volume of distribution of about 2 L/kg in adults, which is higher than that of phenobarbital and correlates with the greater lipophilicity of the compound, favouring extensive distribution into tissues [5,13]. In human plasma, about 70% of the R-enantiomer and 60% of the S-enantiomer is protein bound.

In adults not being treated with other drugs, the half-life of racemic methylphenobarbital after the first oral dose averages 49 ± 18.8 h, but is significantly shortened (19.6 ± 5 h) in patients co-medicated with enzyme-inducing agents [5,13]. The two enantiomers have different half-lives, 7.50 ± 1.7 h for the R-enantiomer and 69.8 ± 14.8 h for the S-enantiomer after a single oral dose. These differences reflect different clearance values, which are in the order of 0.4 ± 0.18 L/kg/h for the R-enantiomer and 0.017 ± 0.001 L/kg/h for the S-enantiomer. Methylphenobarbital is cleared almost entirely by biotransformation, and only 1.5–3% of an orally administered dose is excreted unchanged in urine [13]. Biotransformation is stereoselective. The R-enantiomer is metabolized mainly by CYP2C19-mediated aromatic hydroxylation leading to the formation of phenolic, diol and O-methylcatechol derivatives, and to a lesser extent is converted by other enzymes to phenobarbital. On the other hand, the S-enantiomer is mainly dealkylated to phenobarbital, though a small amount of hydroxylation also occurs. In subjects with genetically determined CYP2C19 deficiency, the fraction of the R-enantiomer converted to phenobarbital increases substantially, leading to more extensive phenobarbital accumulation.

The therapeutic and adverse effects of methylphenobarbital appear to be mediated largely by metabolically derived phenobarbital, the plasma concentrations of which at steady state are 3–10 times higher than those of the parent drug. Enzyme-inducing AEDs stimulate the conversion of methylphenobarbital to phenobarbital. Otherwise, drug interactions with methylphenobarbital are likely to reflect those observed with phenobarbital. Methylphenobarbital also has the same indications as phenobarbital and, in nearly all clinical situations, phenobarbital and methylphenobarbital may be considered interchangeable. The tolerability profile of methylphenobarbital is also substantially indistinguishable from that of phenobarbital.

Methylphenobarbital has been marketed as 30-, 60- and 200-mg tablets. Considerations concerning dose titration, daily dosing and optimal plasma concentrations are the same as for phenobarbital, except that, to obtain equivalent phenobarbital levels, 1.7–2.0 mg of methylphenobarbital should be prescribed for each milligram of phenobarbital. The higher dosage requirement is due to the need to compensate for the rapid elimination of *R*-methylphenobarbital.

Although phenobarbital and methylphenobarbital are virtually interchangeable, an argument has been raised for preferring methylphenobarbital to phenobarbital. Within the range of plasma concentrations of phenobarbital encountered therapeutically, the relationship between steady-state plasma concentrations of phenobarbital and methylphenobarbital dose is linear, whereas at times some deviations from linearity can be observed in the relation between plasma phenobarbital levels and phenobarbital dose [123]. Therefore, plasma concentrations of phenobarbital might be adjusted more predictably in patients taking mehylphenobarbital than in those taking phenobarbital itself.

Barbexaclone

Barbexaclone is the propylhexedrine salt of phenobarbital. These two ingredients are contained in the proportions of 60% and 40%, respectively. Propylhexedrine is intended to act as a CNS stimulant in order to antagonize the sedative properties of the barbiturate.

The pharmacokinetics of phenonobarbital were compared after oral administration of equimolar doses of the drug as the acid or as the propylhexedrine salt in healthy volunteers. Absorption and elimination parameters were very similar and it was concluded that propylhexedrine does not affect the pharmacokinetics of phenobarbital given as barbexaclone [124].

There has been a considerable interest in the use of barbexaclone, mostly in the Italian and Spanish literature. Several reports, mostly based on small series of patients receiving barbexaclone as add-on or first-line agent, or after switching from phenobarbital therapy, have claimed that barbexaclone is at least as effective as phenobarbital but better tolerated, with less sedative properties in both adults and children. The more favourable tolerability profile was attributed to the psychostimulant effect of propylhexedrine. These promising results, however, were mostly published in the 1970s and 1980s, and still await confirmation in controlled trials.

Barbexaclone is available as 25- and 100-mg tablets. Considerations concerning dose titration, daily dosing and optimal plasma concentrations are the same as for phenobarbital, except that, to obtain equivalent phenobarbital levels, 100 mg of barbexaclone is equivalent to 60 mg of phenobarbital.

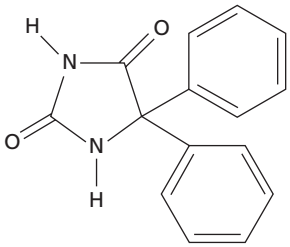
47 Phenytoin

Mervyn J. Eadie
University of Queensland, Brisbane, Australia



Primary indications	First-line or adjunctive therapy for partial and generalized seizures (except for myoclonic and absence seizures) and convulsive status epilepticus
Usual preparations	Capsules and tablets: 25, 30, 50, 100, 200 mg; chewtabs: 50 mg; liquid suspension: 30 mg/5 mL, 100 mg/5 mL; injection: 250 mg/5 mL
Usual dosages	Orally: 5 mg/kg/day (adults), 10 mg/kg/day (children); lower or higher maintenance doses may be needed, guided by serum level monitoring and clinical response
Dosing frequency	1–2 times/day
Significant drug interactions	Phenytoin is an enzyme inducer and may reduce the serum levels and clinical effect of many other drugs. Numerous drugs may interfere with phenytoin absorption, plasma protein binding, and metabolic elimination
Serum level monitoring	Useful
Target range	Total serum concentration: 10–20 mg/L (40–80 μmol/L). Unbound serum concentration (1–2 mg/L (4–8 μmol/L)
Common/important side-effects	Ataxia, dizziness, lethargy, sedation, headache, cognitive dysfunction, dyskinesia, acute encephalopathy, cutaneous and systemic hypersensitivity reactions (including fever, lymphadenopathy, liver toxicity, blood dyscrasias, vasculitis), gingival hyperplasia, folate deficiency, megaloblastic anaemia, vitamin K deficiency, decreased immunoglobulins, mood changes, depression, coarsened facies, hirsutism, acne, peripheral neuropathy, osteomalacia, hypocalcaemia, hormonal dysfunction, loss of libido, connective tissue alterations, pseudolymphoma, myopathy, teratogenic effects
Main advantages	Highly effective and inexpensive
Main disadvantages	Central nervous system and systemic adverse effects; non-linear elimination kinetics
Mechanisms of action	Blockade of voltage-dependent sodium channels
Oral bioavailability	95%
Time to peak levels	4–12 h
Elimination	Hepatic oxidation and hydroxylation, then conjugation
Volume of distribution	0.5–0.8 L/kg
Elimination half-life	7–80 h, dependent on serum level (mean, 20 h at 10–20 mg/L)
Plasma clearance	0.003–0.02 L/kg/h in adults (dependent on serum level), higher in children

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Michaelis constant (K_m)	~6 mg/L (24 μmol)
Maximum velocity of elimination (V_{max})	Adults 6–16 mg/kg/day; children higher
Protein binding	~90%
Active metabolites	None
Comment	Well-established first-line therapy. Its adverse effects profile and non-linear kinetics may make it a less desirable first-line therapy than other drugs in most patients

Introduction

Phenytoin was the first effective antiepileptic substance developed from systematic scientifically based screening, rather than from chance discovery. The molecule was synthesized early in the 20th century but, being less sedative than the bromides and phenobarbital, was not considered for an antiepileptic role until Putnam and Merritt, in the late 1930s, sought from various chemical suppliers substances with molecular structural resemblances to phenobarbital and which also contained phenyl substituents. It was then thought that an aromatic ring substituent probably enhanced any antiepileptic properties present in members of a family of molecules, as was the case for the barbiturates [1]. The substances supplied were tested in an animal model of convulsive epileptic seizures where phenytoin proved to combine antiseizure efficacy with a relative lack of sedation. Almost two-thirds of a century after its introduction into therapeutics, the drug remains extensively used worldwide, and has served as the paradigm for the development of many of the antiepileptic drugs (AEDs) which have subsequently been marketed. Several accounts of the discovery of phenytoin are available [1,2].

Chemistry

Phenytoin (5,5′-diphenylhydantoin) is usually supplied for therapeutic use as the free acid (molecular weight 252.3) or, more often, as the sodium salt (molecular weight 274.3). It is a white crystalline, relatively poorly water-soluble acidic substance (pK_a ~ 8.4). The sodium salt is more water soluble than the free acid, and is usually supplied in capsules or as a parenteral injection (pH ~ 12). The corresponding free acid is available in tablets or an oral suspension. Milligram for milligram, sodium phenytoin preparations contain about 8% less active substance than preparations containing phenytoin as the free acid.

There are many methods for measuring phenytoin at therapeutic concentrations in humans. The early methods were chemical or spectrophotometric, but, currently, phenytoin concentrations are usually measured by various immunoassays or, if other AEDs are to be measured simultaneously, by chromatographic methods, mainly high-performance liquid chromatography. Electrokinetic assays also exist.

Pharmacology

Anticonvulsant activity in experimental models

Phenytoin prevents or reduces the severity of induced seizures in various animal models of convulsive epileptic seizures (notably in the maximal electroshock model). It is also effective in models of partial (localization related) epileptic seizures, for instance electrically or chemically induced kindled focal seizures in rats [3]. It is relatively ineffective against generalized seizures induced by systemically administered chemical convulsants and in what were previously considered animal models of absence seizures (e.g. pentylenetetrazole-induced seizures) but which are now probably better regarded as models of myoclonic seizures. The drug is also ineffective in more recently developed and more realistic animal models of absence seizure, for instance the lethargic mouse and the Genetic Absence Epileptic Rat of Strasbourg (GAERS) [3].

Mechanisms of action

The antiepileptic effect of phenytoin at therapeutic relevant concentrations is thought to depend on its capacity to bind to, and prolong the inactivation of, mammalian, voltage-dependent sodium channels in neuronal cell membranes [4]. This effect is greater when the cell membrane is depolarized than when it is hyperpolarized. With repeated depolarizations, the ion channel block becomes use dependent. Phenytoin binds to the same site on the outer surface of the sodium channel as carbamazepine and lamotrigine [5]. However, phenytoin and carbamazepine have different binding site affinities and quantitatively, though not qualitatively, possess somewhat different actions [4]. Inactivation of voltage- and frequency-dependent sodium channels makes partly depolarized axons less capable of transmitting rapid trains of action potentials (as occur in epileptic discharges), but interferes less with axonal lower impulse frequency action potential traffic.

Phenytoin at high concentrations may also inhibit axonal and nerve terminal calcium channels. This action could stabilize axonal cell membranes and diminish neurotransmitter release at axon terminals in response to action potentials. The drug has no effect on T-type calcium channels in the thalamus, important in the genesis of absence seizures [4]. At high concentrations, phenytoin inhibits calcium/calmodulin-mediated protein phosphorylations [6]. The drug increases chloride conductances at

$GABA_A$ receptors, though whether this process contributes to its antiepileptic effects is unclear. Phenytoin is a weak dopamine antagonist.

Phenytoin's inhibition of axonal fast action potential traffic results in various well-documented electrophysiological effects, for example preventing post-tetanic potentiation of synaptic transmission in experimental preparations [7] and tending to prevent spike discharges spreading rather than suppressing their formation at experimental epileptic foci.

Pharmacokinetics

In recent times, little has been added to the knowledge of the pharmacokinetics of phenytoin that was available a decade or more ago [8–10]. Therefore, in the following account, references are cited mainly for more recently established facts.

Absorption

The absorption rate of phenytoin from different oral preparations may vary, but the absorption is not affected by food. Phenytoin bioavailability was reviewed in some detail by Neuvonen [11]. The importance of formulation was demonstrated 40 years ago when the oral bioavailability of phenytoin in the market leader's capsule formulation in Australasia was compromised due to an interaction between the drug in the capsule and the excipient calcium sulphate. Since then, the usual branded preparation has a lactose excipient. In this formulation, phenytoin has a consistent and complete, or nearly complete (~95%), oral bioavailability. Nonetheless, there are still reports of generic phenytoin tablets whose oral bioavailabilities appear incomplete and, to an extent, inconsistent [12]. Storage of phenytoin capsules under conditions of high temperature and humidity may reduce the oral bioavailability of the drug. Earlier reports suggested that the bioavailability of orally administered phenytoin was impaired during pregnancy, but subsequent studies showed that this was not so [13]. Variations in bioavailability should be unimportant clinically, provided the same preparation of the drug is always used by each patient. At least in the elderly, however, it has been suggested that day-to-day variation in phenytoin bioavailability may contribute to unexplained interindividual variability in serum phenytoin levels in patients stabilized on a constant dosage [14].

Phenytoin is absorbed very slowly and inconsistently from intramuscular injection sites, making this route of administration unsatisfactory in clinical practice. Fosphenytoin, a phenytoin prodrug which is water soluble and well absorbed after intramuscular administration, may be more conveniently used if the intramuscular route is needed [15]. Intravenous phenytoin is fully bioavailable, but the highly alkaline pH of the solution, and its content of polyethylene glycol, require very slow administration to minimize unwanted effects. The drug may crystallize out if injected into an intravenous fluid reservoir containing a solution at a more physiological pH. Fosphenytoin does not need to be dissolved in alkaline organic solvents, and offers some tolerability advantages over phenytoin for intravenous use [15].

The rectal bioavailability of phenytoin is low, around 24% ± 3%.

Distribution

After absorption, phenytoin is distributed throughout total body water, with relatively little selective regional concentration. Published values for the drug's apparent volume of distribution in humans have usually been in the range of 0.5–0.8 L/kg. In the brain, phenytoin achieves a slightly higher concentration than in serum. At steady state, it is present at a higher concentration in white than in grey matter, though soon after administration its concentration is temporarily higher in grey matter. Phenytoin is transported out of the brain by a P-glycoprotein mechanism, the increased activity of which may cause treatment resistance [16].

In whole blood, the phenytoin concentration in red cells is lower than in serum. Therefore, whole blood phenytoin concentrations are lower than simultaneously measured serum (or plasma) phenytoin concentrations. Some 90% of the drug in plasma is bound to plasma proteins, mainly albumin. The unbound fraction of the drug in plasma is higher in the neonate than in the adult, and increases a little with advanced age, in late pregnancy, and in the presence of hypoalbuminaemia (as occurs in malnutrition, liver disease, nephrotic or uraemic states, AIDS) and with high levels of glycated albumin, as in diabetics. Phenytoin concentrations in cerebrospinal fluid and routinely collected saliva, tears and sweat are very similar to the unbound phenytoin concentrations in plasma. However, the saliva phenytoin concentration varies with saliva flow rate and gum disease [17]. Certain acidic drugs, for example salicylates, valproic acid and various endogenous substances (fatty acids, bilirubin), can displace phenytoin from its plasma protein binding sites. Such displacements are rarely important clinically, but they must be kept in mind when total serum phenytoin concentrations are used as a guide to dosage adjustments. In fact, in the presence of an increased unbound fraction, therapeutic and toxic effects will occur at total phenytoin concentrations that are lower than usual.

Phenytoin concentrations in maternal milk are lower (~19%) than those simultaneously present in whole plasma, and vary to an extent with the fat and protein content of the milk. A breast-fed infant is unlikely to receive enough phenytoin from breast milk to experience adverse effects, unless the mother is very substantially overdosed with the drug.

Elimination

Less than 5% of a phenytoin dose is excreted in urine unmetabolized. The main known metabolic pathways for the drug are indicated in Figures 47.1 and 47.2. Nearly all of the body's metabolism of the drug appears to occur in the liver, though some conversion of phenytoin to its major metabolite, *p*-hydroxyphenytoin, occurs in the gums and perhaps in other peripheral tissues, for example neutrophil leucocytes and skin.

The major metabolite of phenytoin found in urine, *p*-hydroxyphenytoin (5-phenyl,5′-*p*-hydroxyphenylhydantoin, HPPH), present mainly in the form of its O-glucuronide conjugate, accounts for some 60–80% of usual doses of the drug. The glucuronidation is catalysed by UDP glucuronosyl transferase 1A isoforms [18]. *p*-Hydroxyphenytoin is formed via a postulated short-lived arene oxide intermediate in a reaction catalysed by the CYP450 (CYP) isoforms CYP2C9 and CYP2C19 (Fig. 47.1), and in the skin, possibly by CYP2C18 [19]. At conventional dosages, CYP2C9 activity accounts for some 90% of the hydroxylation of

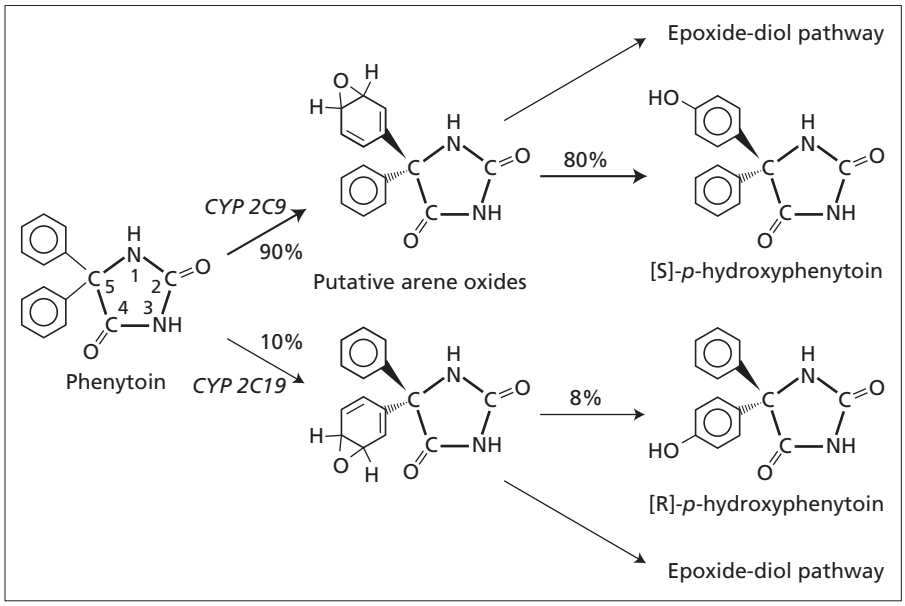


Fig. 47.1 Formulae for phenytoin and its known and putative stereoisomeric metabolites along the drug's major biotransformation pathway to *p*-hydroxyphenytoin.

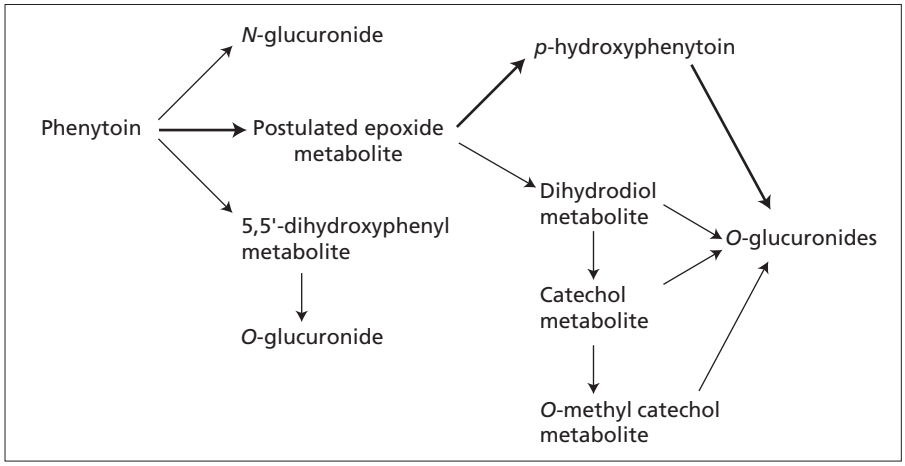

Fig. 47.2 Known metabolic pathways for phenytoin.

phenytoin in humans, the [S]-isomer being formed preferentially. The [R]-isomer of *p*-hydroxyphenytoin is formed via activity of CYP2C19. The glucuronide conjugate of the [S]-isomer of *p*-hydroxyphenytoin constitutes 75–95% of the total phenytoin metabolites in human urine. Neither *p*-hydroxyphenytoin isomer possesses known biological activity, or is likely to achieve a high enough concentration in the serum of patients with intact renal function to exert feedback inhibition on phenytoin biotransformation. There are suggestions that the postulated arene oxide intermediate and also postulated epoxide products of phenytoin metabolism may interact with various tissue proteins, leading to some idiosyncratic effects of the drug. Poor metabolizers of mephenytoin (methoin) form relatively little [R]-*p*-hydroxyphenytoin [20]. About 1 in 500 of the Japanese population is a slow hydroxylator of phenytoin [21], and hereditary poor metabolizers of the drug occur in other populations, related mainly to CYP2C9 and CYP2C19 functional polymorphisms. Various minor metabolites of phenytoin are known (Fig. 47.2), mostly additional derivatives of the arene oxide pathway, for example *m*-hydroxyphenytoin (possibly an analytical artefact), dihydrodiol, catechol, *O*-methyl catechol derivatives, and a molecule para-hydroxylated on each aromatic ring. A possible hydantoin ring-opened product and a *N*-glucuronide conjugate of the drug have also been described. Dickinson *et al.* [22] showed that, early in the course of repeated administration, there can be a degree of self-limited autoinduction of phenytoin metabolism, via the *p*-hydroxyphenytoin pathway and involving CYP2C19 more than CYP2C9.

Unlike most drugs, at clinical dosages phenytoin exhibits Michaelis–Menten rather than linear kinetics. The Michaelis constant of phenytoin is around 6 mg/L (24 μmol), lower than the usual serum concentration occurring clinically. Half-lives and clearances can be calculated for phenytoin, but the values are not constant in the individual, varying with the phenytoin concentration range over which they have been measured. The half-life is longer, and the clearance lower, at higher serum drug concentrations than at lower ones. The occurrence of Michaelis–Menten kinetics results in a non-linear relationship beteween serum phenytoin concentration and dose, with small dose increments

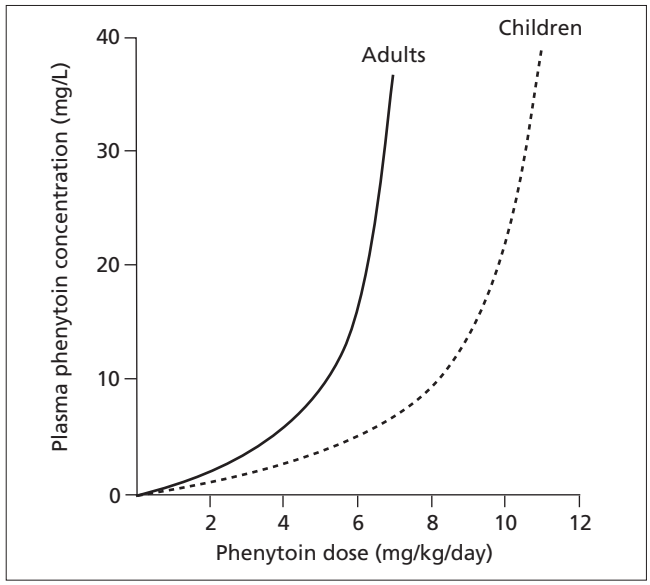

Fig. 47.3 Plot of mean steady-state plasma phenytoin concentration against dose in 21 adults and in 15 children younger than 15 years, generated from the data of ref. 69 (mean K_m for adults 5.8 mg/L and for children 5.3 mg/L; mean V_{max} for adults 8.1 mg/kg/day, and for children 12.5 mg/kg/day).

causing disproportionately large increases in serum concentrations. Typical dose–concentration curves in the individual are shown in Fig. 47.3. A representative published value for the drug's half-life over the concentration range likely to be encountered in human therapeutics is 22 ± 9 h, with a clearance value for adults of 0.02 L/kg/h, and for children below 5 years of age of 0.06 L/kg/h. Most published values of the K_m have been in the range of 3–30 mg/L, with the mean around 6 mg/L (24 μmol). The maximum velocity of phenytoin elimination (V_{max}) has been in the range 6–16 mg/kg/day, and is higher in young children than in adults [23].

The pharmacokinetic parameters of phenytoin are summarized in the table on pp. 605–606.

Drug interactions

Numerous interactions between phenytoin and endogenous substances and co-administered drugs have been reported [24–26]. A few of these interactions are pharmacodynamic in nature, mainly involving additional sedative effects when other drugs with sedative properties are also taken, and hoped for enhanced antiseizure effects when another AED is added to therapy. The great majority of phenytoin's interactions are pharmacokinetic and almost all involve altered rates of metabolism of one or both drugs (see Tables 47.1 to 47.3). The individual interactions that have been described are now too numerous for detailed discussion in this chapter. The outcomes of many of them are listed in Table 47.3. Their possible mechanisms are discussed below, though some of the interactions have unknown or uncertain mechanisms. Some interactions occur inconsistently, possibly because they involve multiple mechanisms which produce mutually antagonistic effects. The final outcome of a given interaction can be the sum of two opposing processes, each of which may vary from person to person, and also vary in extent depending on the concentrations of the interacting substances.

Table 47.1 Interactions which alter phenytoin absorption.

Substances which may decrease the oral bioavailability of phenytoin
Antacids
Calcium sulphate (within phenytoin capsules)
Charcoal (activated)
Protein hydrolysates for enteric feeding
Sucralfate
Theophylline

Table 47.2 Interactions which alter phenytoin distribution.

Substances causing phenytoin displacement from plasma protein binding sites
Acetazolamide
Ceftriaxone
Diazoxide
Heparin
Ibuprofen
Nafacillin
Oxacillin
Primidone
Salicylates
Sulphamethoxazole
Tolbutamide
Valproic acid

Interactions affecting phenytoin absorption

Examples of interactions affecting phenytoin absorption (Table 47.1) include the interaction between phenytoin and the calcium sulphate excipient which led to an Australasian outbreak of phenytoin intoxication and to that excipient being replaced by lactose. When phenytoin in solution is given via a gastrointestinal feeding tube at more or less the same time as certain protein hydrolysates used to provide enteral nutrition, the drug seems not to be fully absorbed. Studies in volunteers have sometimes failed to reproduce this effect, and have also failed to elucidate its chemical mechanism. It has been found that the problem can be avoided by administering the drug to patients several hours before, or after, the protein hydrolysate. Certain antacids, for example aluminium hydroxide, sucralfate and activated charcoal, are also reported to impair oral phenytoin absorption.

Interactions affecting phenytoin distribution

Certain endogenous substances and various acidic drugs (e.g. salicylates, valproic acid, heparin) displace phenytoin from its plasma protein binding sites (Table 47.2). *In vivo*, these potential interactions are unlikely to be of clinical importance in most instances, because the displaced drug is cleared more rapidly and the overall result of the interaction is usually a decrease in total drug concentration without any significant change in the concentration of unbound, pharmacologically active drug. However, these interactions must taken into consideration when total plasma phenytoin concentrations are used as a guide to dosage

Table 47.3 Metabolic interactions involving phenytoin. The level of evidence for these interactions varies across substances, and not all potential interactions occur consistently in all subjects.

Interacting substances causing raised phenytoin concentrations

Allopurinol, amiodarone[a], amphotericin, azapropazone[a], brivaracetam, bupropion, carbamazepine[b], chloramphenicol, chlordiazepoxide, chlorpromazine, cimetidine[b], clinafloxacin, clobazam, clofibrate, co-trimoxazole[a], dexamethasone, dextropropoxyphene[a], diazepam[b], dicoumarol, diltiazem, disulfiram, erythromycin, ethanol (acute intake), ethosuximide, famotidine, felbamate[b], fluconazole[a], flucytosine, 5-fluorouracil, fluvoxamine[a,b], fluoxetine[b], halothane, 10-hydroxyoxcarbazepine, imipramine[b], isoniazid[a], itraconazole, ketoconazole[b], losartan[a], methsuximide, methoin[b], methylphenidate, methylphenobarbital[b], metronidazole[a], miconidazole[a], nafimidone, nifedipine, nor-diazepam[b], omeprazole[b], paroxetine[a], phenylacetylurea, pheneturide, phenylbutazone[a], phenyramidol, pindolol, prochlorperazine, progabide, proguanyl[b], propoxyphene, propranolol[b], ranitidine, remacemide, sertraline[a], stiripentol[a], sulphaphenazole[a], sulthiame, tacrolimus, thioridazine, ticlopidine[a,b], tolbutamide[a], topiramate[b], torsemide[a], trazodone, trimethoprim[a], troxidone, valproic acid, verapamil, viloxazine, voriconazole, [*S*]-warfarin[a]

Interacting substances causing lowered phenytoin concentrations

Aciclovir, aspirin, bleomycin, carbamazepine[d], carmustine, ciprofloxacin, cisplatin, dexamethasone, diazepam, diazoxide, dichloralphenazone, doxycycline, evening primrose oil, ethanol (chronic intake), folate, methotrexate, nelfinavir, nitrofurantoin, oxacillin, phenobarbital, pyridoxine, reserpine, rifampicin[c,d], salicylates, theophylline, tolbutamide, vigabatrin, vinblastine

Phenytoin causing raised concentrations of other substances

Chloramphenicol, phenobarbital, tirilazad, warfarin

Phenytoin causing lowered concentrations of other substances

Albendazole, antipyrine, atorvastatin, bromphenac, campothecin, carisbamate, carbamazepine, chloramphenicol, cisactracurium, clobazam, clonazepam, clozapine, ciclosporin, cyclophosphamide, dexamethasone, dicoumarol, digoxin, disopyramide, doxycycline, efavirenz, ethosuximide, felbamate, felodipine, flunarazine, haloperidol, 10-hydroxycarbazepine, irinotecan, itraconazole, lamotrigine, lidocaine, losartan, methadone, methotrexate, metyrapone, mexiletine, midazolam, mirtazepine, misonidazole, nimodipine, nisoldipine, nortriptyline, oral contraceptives, oxazepam, paracetamol, pethidine, phenobarbital, prednisolone, primidone, praziquantel, quetiapine, quinidine, retigabine, all-*trans*- and ±-*cis*-retinoic acid, simvastatin, sirolimus, tacrolimus, taxanes, teniposide, theophylline, thiotepa, tirilazad, topiramate, topotecan, tricyclic antidepressants, valproic acid, vecuronium, vinca alkaloids, voriconazole, warfarin, zonisamide

Data from refs 28–30 and miscellaneous sources. [a]known substrate and/or inhibitor of CYP2C9; [b]known inhibitor and/or substrate of CYP2C19; [c]known inducer of CYP2C9; [d]known inducer of CYP2C19.

adjustments. In fact, in the presence of an increased unbound fraction, as may occur in the presence of a displacing agent, therapeutic and toxic effects will occur at total phenytoin concentrations that are lower than usual.

Interactions altering phenytoin metabolism

Phenytoin is eliminated from the body mainly by virtue of CYP2C9- and CYP2C19-catalysed oxidations to *p*-hydroxyphenytoin (Table 47.3). Co-administered drugs which induce the activity of either or both of these CYP isoenzymes are likely to cause increased phenytoin elimination, and hence lowered serum concentrations of the drug. Conversely, drugs which competitively inhibit either or both of these CYP isoforms tend to raise serum phenytoin concentrations. Despite these known interaction mechanisms, the metabolic basis of many of the interactions involving altered phenytoin concentrations remains uncertain.

Inhibition of phenytoin metabolism occurs with the CYP2C9 substrates/inhibitors sulphaphenazole, phenylbutazole, fluconazole, azapropazone, disulfiram, metronidazole and stiripentol, and with the CYP2C19 substrates/inhibitors felbamate, omeprazole, cimetidine, fluoxetine and imipramine. Ethosuximide, felbamate, methsuximide, oxcarbazepine or sulthiame may also increase serum phenytoin levels. Because of the Michaelis–Menten elimination kinetics of phenytoin, a small degree of inhibition of the drug's metabolism can produce a disproportionately large increase in serum phenytoin concentrations and possibly drug toxicity.

Interactions involving induction of the drug's metabolism, which reduce its serum concentrations, are far less common and are more likely to go unnoticed, unless serum phenytoin concentrations are monitored, or seizure control deteriorates. Serum phenytoin levels often decrease when primidone, vigabatrin, carbamazepine or phenobarbital is added as co-medication, though sometimes the opposite effect occurs if carbamazepine or phenobarbital is added. The effects of valproic acid on serum phenytoin levels vary. Valproic acid, in fact, may inhibit phenytoin metabolism, and this mechanism may cause an increase in plasma unbound phenytoin concentration. Because at the same time valproic acid displaces phenytoin from plasma protein binding sites, however, the total plasma phenytoin concentration may show little change, or may even be decreased.

Phenytoin affecting other substances

Phenytoin can alter the body's elimination of other substances by (a) inducing the synthesis of the CYP isoenzymes responsible for their metabolism, not only CYP2C isoforms but also CYP3A4 (which catalyses the oxidation of many drugs) and CYP1A1/2, and also by inducing the synthesis of certain glucuronyl transferases involved in drug conjugation; or (b) serving as a competitive inhibitor of the metabolism of other CYP2C9 or CYP2C19 eliminated drugs. It is not yet known how important other mechanisms are. As mentioned above, both induction and inhibition can occur simultaneously, with clinical effects that are difficult to predict.

In most situations, the consequences of enzyme induction prevail. As a result, the concentrations of carbamazepine, clobazam, clonazepam, felbamate, lamotrigine, primidone, tiagabine, topiramate, valproic acid, ethosuximide and zonisamide can fall when phenytoin is added as co-medication. The effect of phenytoin on phenobarbital concentrations varies, with levels rising or falling. By causing enzyme induction, phenytoin can also decrease the serum levels and clinical effectiveness of many cardiovascular

agents, chemotherapeutic agents, hormonal agents, psychotropic agents and many other substances (Table 47.3).

Serum level monitoring

Within limits, increasing phenytoin doses and the consequent increases in serum phenytoin concentrations correlate with increasing degrees of seizure control in types of epilepsy responsive to the drug. Since the publications of Kutt *et al*. in 1964 [27], it has become widely accepted that serum phenytoin concentrations in the range of 10–20 mg/L (40–80 μmol) are usually associated with the best chance of achieving seizure control without producing drug overdosage manifestations. This concentration range is usually considered the 'therapeutic' or 'target' range for the drug. However, certain authors (e.g. Loiseau [28]) have set the lower limit of the range at around 7 mg/L (28 μmol), and the upper limit at 25 mg/L (100 μmol). Everyday clinical experience suggests that these wider limits are valid, and that some patients may even do best at concentrations higher or lower than this range [29].

There is evidence that generalized tonic–clonic seizures may be fully controlled once serum phenytoin levels exceed 6–8 mg/L, but much higher levels may be needed for partial seizure control. Schmidt *et al*. [30] found that a mean serum phenytoin concentration of 14 mg/L (56 μmol) was associated with control of generalized tonic–clonic seizures, but a mean concentration of 23 mg/L (92 μmol) was needed for control of partial seizures. The therapeutic range values for the drug in plasma water (unbound plasma concentration) or saliva are approximately one-tenth of those in whole plasma (serum). In theory, it would be better always to measure the drug's concentration in plasma water, as this would obviate the effects of variation in the plasma protein binding of the drug in disease, in certain physiological states and in the presence of displacing co-medications. In practice, the unbound (free) drug concentrations are more expensive to measure, and less accurate. They are rarely needed unless there is good reason to suspect altered plasma protein binding of the drug.

In practice, with serum phenytoin concentrations in the so-called 'therapeutic' or 'target' range of 10–20 mg/L (40–80 μmol), new steady-state conditions should apply 4–8 days after a phenytoin dosage change, though at higher concentrations the period required to reach steady state may be longer (up to about 2 weeks). Under steady-state conditions in the therapeutic drug concentration range, the peak-to-trough fluctuation in serum phenytoin concentration in adults is likely to be of the order of ± 10% over a 12-h dosage interval, but greater fluctuations occur in children. At lower phenytoin concentrations, under steady-state conditions, the interdosage fluctuations are also likely to be proportionately wider.

There are wide interindividual variations in steady-state serum phenytoin concentrations at conventional doses of the drug (300 or 400 mg/day), and an appreciable proportion of the values fall outside the therapeutic range. The correlation between dose and level is better if phenytoin dosage is expressed relative to body weight. As already mentioned, the maximum velocity of phenytoin biotransformation (or the clearance value) is higher in children than in adults [23]. A daily phenytoin dose of 5 mg/kg will yield a mean mid-therapeutic range steady-state serum phenytoin concentration of 15 mg/L (60 μmol) in adults. However, prepubertal children will need a mean daily phenytoin dose of 11 mg/kg to achieve a similar mean serum drug concentration. The mean dose required is lower in neonates and in children in the first few months of life. It also tends to be slightly lower in the elderly than in younger adults.

The pregnant woman's capacity to eliminate phenytoin begins to increase progressively after the first few weeks of pregnancy so that serum phenytoin concentrations, relative to drug dose, begin to fall [31]. The drug concentration returns to prepregnancy values over a few weeks after childbirth, if the drug dosage remains unchanged. This sequence of changes needs to be kept in mind if it is considered desirable to maintain serum phenytoin concentrations at their prepregnancy values throughout pregnancy, and afterwards. However, if this is done, the reduced serum protein binding of the drug in the third trimester of pregnancy should be taken into consideration. The altered disposition of the drug during pregnancy appears to be a consequence of increased drug metabolism. When Michaelis–Menten parameters of phenytoin during pregnancy were determined after intravenous administration of stable isotope-labelled drug, and compared with those determined after parturition in the same women, Dickinson *et al*. [32] found that mean V_{max} was significantly higher during pregnancy than post partum (1170 ± 600 mg/day versus 780 ± 470 mg/day). Likewise, K_m was also higher during pregnancy than post partum, for values calculated both in whole plasma (18.2 ± 8.4 versus 10.2 ± 7.4 mg/L) and in plasma water (2.50 ± 0.85 mg/L versus 1.16 ± 0.65 mg/L), the latter change being statistically significant. There may also be a premenstrual and menstrual fall in serum (and saliva) phenytoin concentrations in some women. This may correlate with the occurrence of breakthrough seizures, that is catamenial epilepsy.

In clinical practice, a patient's initial or continuing phenytoin dosage may have to be adjusted to achieve a steady-state serum phenytoin concentration within a desired range. Because of the Michaelis–Menten elimination kinetics of the drug, steady-state serum phenytoin concentrations will increase out of proportion to the relative size of an increase in phenytoin dosage [33] (Fig. 47.3). Failure to realize this, and prescribing phenytoin dosage increments in the expectation that the drug's serum concentrations and effects will increase in proportion to the dosage increase, often results in phenytoin intoxication. This phenomenon makes phenytoin dosage adjustment hazardous in the hands of the uninformed.

In patients with severe liver and renal disease, the reduced serum protein binding capacity for phenytoin needs to be taken into consideration when interpreting total serum phenytoin concentrations. In such circumstances, measurement of unbound serum phenytoin, or salivary phenytoin concentrations, is likely to provide more reliable information. There may be a temporary fall in serum phenytoin levels in the 24 h after craniotomy.

Efficacy

Merritt and Putnam [34] first demonstrated in 1938 the efficacy of phenytoin against major seizures in the more common epilep-

Table 47.4 Details of published studies comparing phenytoin with other antiepileptic drugs (AEDs) in monotherapy.

Drug compared	Author	Number of studies	Patients studied	Seizure disorder		Outcome
				Generalized tonic–clonic	Partial	
Phenobarbital	Taylor [55][a]	4	599	Yes	Yes	No difference; phenobarbital more likely to be withdrawn
	Painter [61]	1	59	Neonatal seizures	Drugs equally but incompletely effective	
Carbamazepine	Tudur Smith [56][a]	3	551	Yes	Yes	No difference
	Callaghan [62]	1	117	Yes	Yes	Phenytoin more effective for generalized tonic–clonic seizures
	Thilotammal [63]	1	103	Yes – children		No difference; more frequent side-effects with phenytoin
Oxcarbazepine	Muller [57][a]	2	480	Primary generalized	Yes	No difference for generalized seizures; oxcarbazepine better for time to withdrawal in partial seizures
Valproic acid	Tudur Smith [58][a]	5	669	Primary generalized	Yes	No difference for generalized seizures; no result for partial seizures
	Shakir [64]	1	33	Epilepsy		Reasonably similar efficacies
	Wilder [65]	1	87	Yes	Yes	No difference
	Callaghan [62]	1	122	Yes	Yes	No difference
	Thilotammal [63]	1	100	Yes – children		No difference
	Beenen [66]	1	100	Post-craniotomy prophylaxis		No difference
Lamotrigine	Steiner [67]	1	181	Yes	Yes	No difference
Clobazam	Canadian Study Group [68]	1	76	Yes – resistant cases	Yes – resistant cases	No difference in efficacy
Magnesium sulphate	Duley [59][a]	6	897	Eclampsia		Magnesium sulphate substantially better

No difference: no statistically significant difference.

tic syndromes. They gave the drug for 2–11 months to 142 patients with seizure disorders not controlled by phenobarbital and bromides. Bromides were withdrawn but phenobarbital was continued and phenytoin commenced. In 118 patients with frequent 'grand mal' seizures, 'complete relief' was obtained in 58%, with a 'marked decrease' in seizures in another 32%. The corresponding figures for 74 patients with 'petit mal' (some of whom would now be classified as having complex partial seizures) were 35% and 49% respectively, and for the six with 'psychomotor seizures', 67% and 33%. By modern standards, the study design was rather inadequate. The follow-up was short, background therapy varied between patients, there was no placebo-treated control group, and seizure disorder classification sometimes appeared uncertain. Nonetheless, the study's conclusions were borne out in subsequent routine practice and later clinical investigations. Thus, in newly diagnosed cases of generalized convulsive or partial epilepsy, Shorvon *et al*. [35] found that after 2 years of phenytoin monotherapy there was 78% full seizure control.

Several publications are now available that review the efficacy of phenytoin relative to other, mainly newer, AEDs used in monotherapy in patients with epilepsy, including two studies [36,37] and five Cochrane reviews [38–42]. Table 47.4 summarizes the nature of the material studied and the outcomes of the Cochrane reviews and certain other relevant studies in which the methodology may not have been identical with the Cochrane reviews, but which do add further information. Basically, for varieties of frequently occurring epileptic disorders expected to be responsive to phenytoin, the efficacy and tolerability of the drug seems not to differ appreciably from that of other commonly used and usually more expensive contemporary AEDs.

In addition to showing efficacy in patients with generalized tonic–clonic seizures and partial seizures, phenytoin has been found to be useful in the prevention of acute symptomatic seizures shortly after craniotomy or traumatic brain injury [43]. However, it is ineffective in preventing the occurrence of late seizures or the development of post-craniotomy or post-traumatic epilepsy in these patients [43,44]. Experience has also established that phenytoin is ineffective for treating myoclonic seizures (irrespective of their age of onset), absence and atonic seizures of primary generalized epilepsy, infantile spasms and seizures in the Lennox–Gastaut syndrome. The drug has also proved ineffective in two reasonably common varieties of situation-related seizures, namely

febrile convulsions of infancy and eclamptic seizures of pregnancy toxaemia.

Intravenous phenytoin has been successful in treating neonatal seizures and convulsive status epilepticus. These indications are discussed in Chapters 13 and 18, respectively.

Adverse effects

Phenytoin has been widely used for nearly 70 years, and numerous adverse effects of the drug are known (Table 47.5). Some of these are clearly related to the drug's concentration in the body, many representing what would be regarded as overdosage effects. Some unwanted effects are hypersensitivity reactions, possibly related to immune-mediated interactions involving chemical adducts formed between various tissue proteins, for instance liver microsomal membrane proteins [45], and the postulated arene oxide intermediate derivative of phenytoin hydroxylation, or the drug's catechol metabolite. Adduct formation itself may also alter the composition of various body tissue elements and produce structural change in tissues. However, the mechanisms of some unwanted effects are currently unexplained. The common or otherwise important reported adverse effects of phenytoin are listed in Table 47.5.

Effects on the nervous system

Phenytoin overdosage tends to produce vestibulo-cerebellar disturbances. The earliest manifestation may be a horizontal nystagmus which typically occurs at serum concentrations above 20 mg/L (80 μmol). At concentrations above 30 mg/L (120 μmol) ataxia of gait and double vision occur, and at concentrations above 40 mg/L (160 μmol) drowsiness, sometimes with nausea and vomiting [27]. Coma develops if the drug concentration becomes high enough. However, there are large individual differences, and in some patients unwanted effects occur at serum levels above or below the usual optimal range. Conversely, in other patients, adverse effects may be absent at levels above 30 mg/L (120 μmol).

Dizziness and headache are additional possible adverse effects of phenytoin therapy. Occasional patients may experience mood disorders, mainly depression, as the dose of the drug is increased, but the risk of depression is small. At therapeutic concentrations, phenytoin has been reported to decrease performance in various tests of cognitive function. However, this has been only inconsistently demonstrated, and may be partly an artefact of the drug's interference with motor coordination [46]. Despite the earlier suggestion that carbamazepine caused less interference with cognitive function than phenytoin, the literature review of Kalviainen *et al*. [47] suggested that, at therapeutic concentrations, there was little real difference between the two drugs in this regard.

Seizure control may worsen in some patients as serum levels of phenytoin become 'supratherapeutic', or when phenytoin is prescribed inappropriately in syndromes known to be associated with absence or myoclonic seizures.

Occasionally, phenytoin overdosage results in various dyskinetic and dystonic involuntary movements, asterixis or ophthalmoplegia. There are also reports of the drug causing subclinical and occasionally overt peripheral neuropathy. Shorvon and Reynolds [48] found mild abnormalities of peripheral nerve conduction in 18% of a series of patients (with non-toxic phenytoin levels) who had no clinically detectable evidence of peripheral neuropathy. At toxic levels, a more severe reversible demyelinating neuropathy may occur.

Phenytoin overdosage may cause decreased colour vision discrimination. Cerebellar atrophy has been reported in persons with long-standing phenytoin overdosage [49]. In one individual, cerebellar atrophy was reported after a severe acute phenytoin overdose.

Table 47.5 More common and/or more serious adverse effects of phenytoin.

Nervous system	Nystagmus, gait ataxia, diplopia, dyskinesias, dizziness, headache, mood and cognitive changes, sedation, diplopia, depressed consciousness, cerebellar degeneration
Skin	Morbilliform rash in 5–10%, Stevens–Johnson syndrome, exfoliative dermatitis, toxic epidermal necrolysis, hirsutism, acne
Gums	Hypertrophy
Bone	Osteomalacia
Haematological	Lymphadenopathy (pseudolymphoma), megaloblastic anaemia, suppression of individual blood cell lines
Other hypersensitivity reactions	Aromatic anticonvulsant hypersensitivity syndrome, systemic lupus erythematosus
Cardiovascular	Cardiac conduction defects, arrhythmias, hypotension (intravenous therapy), cardiac depression
Biochemical alterations	Increased: γ-glutamyl transpeptidase, alkaline phosphatase, sex hormone-binding globulin Reduced: folate, thyroid hormones, sex hormones
Teratogenesis	Various malformations – the risk is moderately raised in monotherapy but is higher if other antiepileptic drugs are co-administered Fetal hydantoin syndrome (?)

Effects on the skin

Some 5–10% of patients given phenytoin develop a measles-like rash which usually first appears on the trunk, mostly in the second week of drug intake. If treatment with the drug is not ceased at that stage, more extensive skin and internal organ involvement can develop. Other cutaneous reactions, for example Stevens–Johnson syndrome, systemic lupus erythematosus, exfoliative dermatitis and toxic epidermal necrolysis, are less common. The incidence of phenytoin-related rashes appears to be higher in patients who developed rashes from other aromatic AEDs and in those receiving radiotherapy for intracranial tumours [50]. Phenytoin should be discontinued immediately if a rash appears.

The typical acute phenytoin morbilliform rash described above may merge into the various expressions of the aromatic anticonvulsant hypersensitivity syndrome. In this condition the rash becomes more extensive whilst remaining erythematous, mucosal involvement with ulceration may develop, skin exfoliation may occur and eosinophilia, hepatitis and other evidence of systemic organ involvement may appear. Cross-sensitivity with other drugs is common, and 60% of affected persons experience similar

reactions if subsequently exposed to carbamazepine or phenobarbital. The syndrome is thought to depend on an autoimmune response to adducts formed between phenytoin metabolites and various tissue protein components (e.g. microsomal proteins) [45].

Phenytoin may cause an overgrowth of body hair, particularly in dark-haired females, acne and coarsening of facial features. These effects can be cosmetically important.

Intravenous administration of phenytoin may lead to a 'purple glove' syndrome involving the hand and forearm distal to the administration site, with local progressive skin discoloration, oedema and pain. This phenomenon occurred in 5.9% of one series of 152 patients given the drug intravenously [51], although clinical experience suggests a much lower rate. Thrombophlebitis may develop in the vein into which the drug has been administered. The incidence of these adverse effects appears to be lower when intravenous fosphenytoin is used in place of phenytoin [15].

Effects on the gums

The association between gum hyperplasia and phenytoin intake has long been recognized. The subject has been reviewed on a number of occasions [52]. Estimates of frequency have varied between 13% and 40%. Most authors have noted a correlation between the degree of gum hyperplasia and the serum phenytoin level. Poor dental hygiene makes the hypertrophy more noticeable. The causal mechanisms are unclear. Reduced immunoglobulin A (IgA) concentrations in saliva were originally considered relevant. More recently, the recognition that phenytoin is metabolized in gum tissue to *p*-hydroxyphenytoin has led to the hypothesis that the resulting arene oxide metabolic intermediate forms adducts with various tissue proteins in the gums, leading to gum overgrowth. However, the degree of gum hypertrophy seemed unrelated to the salivary *p*-hydroxyphenytoin concentration [53]. Serum concentrations of basic fibroblast growth factor increase in the presence of phenytoin intake, and these concentrations seem to correlate with the degree of gum hyperplasia [54].

Effects on bone

Patients receiving long-term phenytoin therapy, with or without other older AEDs, can develop reduced bone mineral densities and overt osteomalacia related to increased bone turnover. Serum calcium levels may fall and alkaline phosphatase levels rise. Serum 25-hydroxycholecalciferol concentrations are reduced. The risk of osteomalacia is highest in circumstances where diet is poor in vitamin D content and there is little exposure to sunlight. Osteomalacia is probably due to induction of vitamin D metabolism and possibly impaired intestinal absorption of dietary calcium.

Effects on lymphoid tissue

Rarely, chronic phenytoin intake has been associated with the development of widespread lymphadenopathy which disappears when intake of the drug is ceased. The histological appearance of the affected lymph glands is reminiscent of that of Hodgkin's disease, and the entity is referred to as a pseudolymphoma syndrome. Even more uncommonly, instances of true lymphoma have been reported in association with phenytoin intake.

Effects on folates

Phenytoin intake causes a reduction in serum and red blood cell folate levels. The mechanisms of this effect have not been fully elucidated. The extent of the reduction is proportional to the serum phenytoin concentration. There have been suggestions that this fall in folate concentration plays a role in the slowing of intellectual performance. Folate deficiency occasionally results in megaloblastic anaemia in patients receiving long-term phenytoin therapy.

Cardiovascular effects

Oral phenytoin therapy in usual dosages very rarely causes cardiovascular disturbances. Intravenous administration of phenytoin is potentially hazardous, especially if the rate of administration exceeds 50 mg/min in adults or 1–3 mg/min/kg in children, or if the dose exceeds the recommended levels. Hypotension, cardiovascular collapse and central nervous system depression can then occur. Severe cardiotoxic reactions and fatalities have been reported with atrial and ventricular conduction depression and ventricular fibrillation. Hypotension usually occurs when the intravenous drug is administered rapidly. However, even at slower infusion rates, problems occasionally arise. Severe cardiovascular complications are more common in elderly or gravely ill patients.

Other effects

Phenytoin intake can precipitate attacks of porphyria in sufferers from the disorder.

If the nature of paroxysmal hypoglycaemic symptoms is unrecognized and these symptoms are misdiagnosed as epileptic in nature, prescription of phenytoin can delay the diagnosis of an insulinoma, since phenytoin can diminish pancreatic insulin secretion.

Rarely, phenytoin has caused hepatitis, vasculitis, interstitial lung infiltration, interstitial nephritis, myopathy, thyroiditis, arthritis and the suppression of the formation of particular lines of blood cell. The teratogenic effects of phenytoin are discussed below.

Phenytoin intake can produce a range of biochemical effects, which are often asymptomatic. They include raised serum or plasma levels of γ-glutamyl transpeptidase, alkaline phosphatase, high-density lipoprotein (HDL) cholesterol, caeruloplasmin, copper, prolactin and sex hormone-binding globulin. Phenytoin use has also been associated with reduced serum concentrations of folate (discussed above), IgA, IgG, IgE, IgM, fibrinogen, thyroxine, tri-iodothyronine (but not free T_4 and T_3), protein-bound iodine, vitamin K, vitamin E, vitamin D metabolites (mentioned above), cortisol, oestrogens, progesterone, free testosterone, pyridoxal phosphate, tryptophan and thiamine. The disturbances affecting sex hormone metabolism may result in reduced libido and other sexual disturbances.

In the neonate exposed to phenytoin during pregnancy, blood coagulation defects, probably due to a relative deficiency of vitamin K-catalysed clotting factors, may cause bleeding on the fifth neonatal day unless the mother receives vitamin K before delivery and/or the baby receives prophylactic vitamin K immediately after birth. Presumably phenytoin induces the metabolism of the vitamin to inactive derivatives.

Teratogenicity

For almost 40 years, since the publication of Meadow [55], it has been known that there is an approximate doubling or trebling in the rate of malformed infants born to pregnant women taking AEDs, including phenytoin. The role of phenytoin has been difficult to interpret, because (1) the teratogenicity of AEDs has tended to be treated as a class effect; (2) a distinction has not been made between phenytoin used as monotherapy and when combined with other AEDs (the fetal malformation risk is higher with polytherapy exposure) and (3) optimal control data collected simultaneously and in a similar manner to the phenytoin-exposed pregnancies have not been obtained.

In addition to comprehensive reviews of AED teratogenesis [56], there are now several published studies reporting fetal malformation rate data for pregnancies exposed to phenytoin monotherapy. In five of these, the treated and control pregnancies were collected and evaluated simultaneously and similarly. These five studies have involved 390 phenytoin-treated and 676 AED-unexposed control pregnancies in women with epilepsy. The relative risk of fetal malformations has ranged between 1.0 and 3.0, and the increase was not statistically significant in any individual series. Malformation rates in the five series ranged between 2.4% and 16.0% in the phenytoin-exposed pregnancies and between 0.8% and 5.3% in the controls [57].

Various phenytoin-associated malformations have been reported. The more severe include facial clefts, diaphragmatic hernias, hip dysplasias and congenital heart abnormalities. A 'fetal hydantoin' syndrome has been described [58], involving what is claimed to be a characteristic facies with wide-spaced eyes, together with deformities of the fingernails, slender and shortened terminal phalanges, mild mental retardation and poor infantile growth and development. Many of these minor abnormalities become unrecognizable within the first few years of life. Partial rather than full syndromes are more common. There is some controversy in the literature as to whether or not the fetal hydantoin syndrome is a genuine entity and, if it is, whether or not it is specific to fetal exposure to phenytoin in pregnancy, or is also associated with exposure to other AEDs.

A good deal of experimental embryological work has been undertaken to explore the mechanisms of phenytoin-associated fetal malformations. Fetal maldevelopment may possibly result from reactive phenytoin metabolic free radical intermediates, for example arene oxide derivatives, which form adducts with fetal tissue proteins. If they are not inactivated by glutathione [59], free radical intermediates produced by the activity of tissue peroxidases which metabolize phenytoin to hydroxyl radicals may oxidize various fetal macromolecules. Arene oxide adducts would be more likely to occur at higher concentrations if the activity of the enzyme epoxide hydrolase (which catalyses the further metabolism of arene oxides and epoxides) was deficient. There is evidence that low levels of the enzyme epoxide hydrolase in amniocytes and fetal fibroblasts were associated with the fetal hydantoin syndrome. It has also been proposed that phenytoin-induced bradycardia may make the embryo hypoxic [60] and cause the formation of toxic reactive oxygen species [61]. *p*-Hydroxyphenytoin itself may be embryotoxic [62].

Overall, it seems likely that intrauterine phenytoin exposure may cause fetal malformations, but the risk is not high if phenytoin is taken as monotherapy. Phenytoin appears less likely to cause serious spinal malformations than carbamazepine or valproic acid. The comparative teratogenic risks of available AEDs are discussed in greater detail in Chapter 25.

Place in current therapy

The studies discussed above provide consistent evidence that phenytoin is as effective as other widely used established AEDs in suppressing seizures in common varieties of epilepsy. Its adverse effect profile, and its ease of use, may differ in some ways from other agents with established similar antiepileptic efficacy. A consensus appears to have emerged, at least in Europe, that carbamazepine or a newer generation AED is preferable to phenytoin for the first-line treatment of epilepsies with generalized tonic–clonic seizures, or with simple or complex partial seizures. This view is based on the superior tolerability profile of these drugs and greater ease of use (the latter probably in non-expert hands). Brodie and Kwan [63] attempted to make a comparison of AEDs in a quantitative basis by developing a simple scoring system involving a number of criteria (a 'star' system). Phenytoin scored less well than other AEDs, but the scientific basis for this scheme is arguable. Overall, phenytoin remains a satisfactory agent for treating patients with partial seizures, with or without secondary generalization, and patients with primary generalized tonic–clonic seizures. The choice of phenytoin has greater justification when the drug is used by those familiar with its pharmacokinetics and adverse effect profile. It also has the advantages of very low cost and of availability in parenteral formulations.

Phenytoin has also had some use in tic douloureux, certain cardiac arrhythmias, various neurogenic pain syndromes, as a prophylactic in occasional varieties of migraine, and in paroxysmal choreoathetosis and myotonia, though other agents are probably more efficient for many of these disorders. It is sometimes applied locally to promote skin healing.

A reasonable initial daily phenytoin dose is 5 mg/kg in adults, and 10 mg/kg in prepubertal children. These doses offer a good chance of obtaining a steady-state serum phenytoin concentration in the range of 10–20 mg/L (40–80 μmol) within 1 week, and are unlikely to cause overdosage effects. The full anticipated daily dose can be used from the commencement of therapy. Pharmacokinetic considerations suggest that once-daily intake should be satisfactory, and it often proves so in practice. However, twice-daily intake does not appear to increase compliance problems, and allows greater security against the consequences of missed doses. Twice-daily intake is often preferable in children, as the half-life of phenytoin is shorter in children than in adults.

The serum (or plasma) phenytoin concentration should be measured once there has been time for steady-state conditions to apply. If, in light of the measurement and clinical response, it appears clinically desirable to adjust the drug dose, the non-linear relationship between steady-state serum phenytoin concentrations and dosage should be kept in mind in determining the magnitude of the dose change. Nomograms have been devised in an attempt to predict precise phenytoin dosage adjustments needed to yield particular serum phenytoin concentrations. However, in practice, the size of the available dosage units

(generally 30, 50 and 100 mg) tends to determine the dosage adjustment that will be made. In most adults, a dose increment of 100 mg is unlikely to lead to overdosage manifestations if the patient's steady-state serum phenytoin concentration is below 10 mg/L (40 μmol), and a dose increment of 30 or 50 mg is likely to be tolerated if the serum phenytoin level is between 10 and 15 mg/L (40 and 60 μmol). In children, smaller-sized increments are necessary.

The therapeutic range of serum phenytoin concentrations is usually considered to be 10–20 mg/L (40–80 μmol). However, as mentioned earlier, some patients achieve seizure control at serum phenytoin concentrations as low as 7 mg/L (28 μmol) and even lower, whilst others require, and tolerate, levels of 25 mg/L (100 μmol) or higher before seizures cease. The latter is particularly the case for partial seizures, whilst in the same patient lower concentrations of the drug may allow control of tonic–clonic convulsive seizures [30]. In patients in whom the natural history of epilepsy is not known, or when it is expected that seizures will recur only at long intervals, it is reasonable to try to achieve an initial steady-state serum phenytoin concentration in the range of 7–20 mg/L (28–80 μmol). Thereafter, further dosage adjustment depends on the clinical response. In varieties of epilepsy in which seizures occur frequently from the outset, the clinical response provides the better guide to phenytoin dosage. Achieving serum phenytoin concentrations within the quoted therapeutic range guarantees neither the optimal possible control of seizures nor the absence of adverse effects. Once a satisfactory phenytoin dosage regimen has been achieved in a particular patient, it will rarely be necessary to alter that regimen over many years, unless non-compliance occurs, the epilepsy is associated with progressive brain disease, late-stage adverse effects of prolonged phenytoin intake occur, or another drug is prescribed which interacts with the phenytoin. Phenytoin dosage may need to be reduced in the presence of severe liver disease, though often not in the presence of renal failure. However, the reduced serum albumin concentrations in patients with severe liver or renal disease may confound the interpretation of serum phenytoin concentrations, and make measurement of the unbound drug concentration, or of salivary concentrations, desirable as a guide to therapy.

Intravenous phenytoin often provides effective therapy for convulsive status epilepticus. However, intravenous therapy carries a risk of cardiovascular complications, which is minimized by keeping the rate of administration below 50 mg/min in adults and 1–3 mg/min/kg in neonates or children. Even in patients not previously receiving phenytoin, a total loading dose of 20 mg/kg should not be exceeded. Continuous monitoring of the ECG and blood pressure is strongly recommended. The parenteral formulation of phenytoin should be injected slowly into a large vein, through a large-gauge needle or intravenous catheter. An injection of intravenous phenytoin should be followed by a 'flushing' injection of sterile saline through the same needle or catheter to avoid local venous irritation. Fosphenytoin may offer some advantages in minimizing the complications of intravenous therapy. Prolonged infusions of phenytoin should be avoided. Intravenous phenytoin therapy requires close medical supervision. The treatment of status epilepticus and acute seizures is dealt with in more detail in Chapter 18.

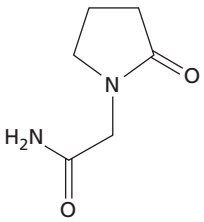
48 Piracetam

Simon D. Shorvon
UCL Institute of Neurology, London, UK



Primary indications	Monotherapy or adjunctive therapy for myoclonus
Usual preparations	Tablets or capsules: 400, 800, 1200 mg; solution: 20, 33%
Usual dosages	Initial: 7.2 g/day. Maintenance: up to 24–32 g/day
Dosing frequency	2–3 times/day
Significant drug interactions	None
Serum level monitoring	Not routinely done
Target range	Not applicable
Common/important adverse effects	Dizziness, insomnia, nausea, gastrointestinal discomfort, hyperkinesis, weight gain, tremulousness, agitation, drowsiness, rash
Main advantages	Well tolerated and very effective in some resistant cases
Main disadvantages	Not effective in many cases
Mechanisms of action	Unclear
Oral bioavailability	Close to 100%
Time to peak levels	30–40 min
Metabolism and excretion	Renal excretion without known metabolism
Volume of distribution	0.5–0.75 L/kg
Elimination half-life	4–5 h
Plasma clearance	–
Protein binding	None
Active metabolites	None
Comment	Useful drug for some patients with refractory myoclonus

Introduction

The pyrrolidone (2-oxo-pyrrolidine) derivatives are a family of compounds which have unique properties of potential value in various neurological settings [1]. Over 12 000 compounds in this chemical group have been synthesized in the past three decades, and over 900 compounds have undergone primary and secondary screening for anticonvulsant activity at UCB Pharma and other pharmaceutical companies. Experimental and clinical work on the pyrrolidones was focused initially on the so-called nootropic effect [1–3], then on potential neuroprotection after stroke, and most recently on their antiepileptic and antimyoclonic effects.

Piracetam was the first drug of the class to be developed, following pioneering research by Giurgea and Salama [2,3], working in the UCB laboratories. It was Giurgea who coined the term nootropic to mean (a) enhancement of learning and memory, (b) facilitation of cross-hemispheric information flow, (c) neuroprotection and (d) lack of other psychopharmacological actions (e.g. sedation, analgesia, or motor or behavioural changes). These effects distinguish this class of compounds from other psychoactive drugs. The clinical value of piracetam as a nootropic is contentious, and the findings are not considered conclusive enough currently to allow licensing for this indication in the USA or the UK. However, piracetam has been, and continues to be, widely used for this indication in many other countries, particularly in the developing world, with over 1 000 000 people worldwide reported to be receiving the drug. There are notable geographical differences in the use of this drug class, with expanding programmes of clinical studies particularly in Japan and Asia. Whilst

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

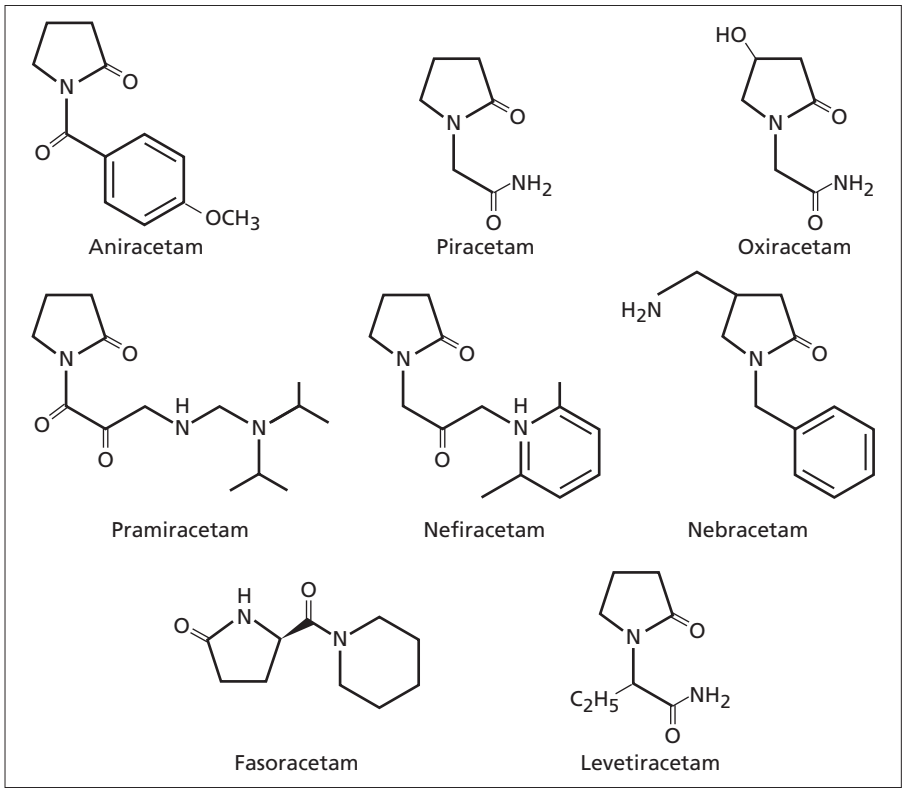


Fig. 48.1 Structure of piracetam and seven other pyrrolidone drugs which are either licensed or in clinical development.

the geographical differences are likely to be due to cultural and regulatory factors, it remains at least possible that there are racial differences in drug response for the class as a whole, although these have been investigated in relation to the antiepileptic effects of levetiracetam without striking differences observed.

In the field of epilepsy, the newer pyrrolidone derivative, levetiracetam, has in the last few years occupied centre stage and, in parallel, interest in piracetam has diminished. It is clear that levetiracetam's antiepileptic effects greatly exceed those of piracetam. However, piracetam does have a marked antimyoclonic effect, which is the main focus of this chapter.

The remarkable antimyoclonic effect of piracetam was first reported in 1978 in a case of post-anoxic myoclonus after cardiac arrest [4], and in the past decade the effectiveness of this drug in cortical myoclonus of various aetiologies has been confirmed. Its use in epilepsy is confined to this indication.

A striking pharmacological feature of pyrrolidone derivatives is their stereospecificity [5]. Minor changes in structure result in remarkable differences in pharmacological activity (Fig. 48.1). Levetiracetam, which is closely related to piracetam, exhibits quite different cerebral binding and broad-spectrum antiepileptic properties (see Chapter 44). Levetiracetam also has an antimyoclonic effect, although it is not clear whether this differs from that of piracetam. Other drugs in this class (e.g. nefiracetam, brivaracetam and seletracetam) also have antimyoclonic and antiepileptic properties, and are in various stages of development.

A notable aspect of the whole class is their relatively good tolerability. This has been an important impetus to further study, and remains one of the primary attractions of this drug class.

Chemistry and mechanism of action

Piracetam, 2-oxo-1-pyrrolidine acetamide, is a white, almost odourless crystalline powder. It is closely related to levetiracetam (which is the ethyl ester of the laevo isomer of piracetam). Since the launch of levetiracetam, there has been major experimental effort designed to elucidate the antiepileptic effect of this drug and, by extension, of the whole drug class. These agents do not, like some antiepileptic drugs, bind to the $GABA_A$–benzodiazepine receptor complex, do not inhibit voltage-gated Na^+ channels and do not inhibit low voltage-gated T-type Ca^{2+} channels. Levetiracetam and its derivatives have been found to bind to the SV2A protein [6], which is one of the three isoforms of the SV2 protein, and the isoform most widely distributed in brain (levetiracetam does not bind to the other two isoforms). The SV2A protein is present in the membrane of synaptic vesicles at the presynaptic terminal. Its role in synaptic transmission is not clear, but it is hypothesized to modulate maturation and/or fusion of vesicles with the plasma membrane of the presynaptic terminal, and to control vesicle exocytosis. There is a strong correlation between affinity of pyrrolidone derivatives for the SV2A binding site and seizure protection in animal models of seizures and epilepsy (Fig. 48.2) [6]. There are no published studies of the molecular mechanisms of action of piracetam, but it is possible that the antimyoclonic actions are related to its weak binding to the SV2 protein.

Piracetam has also been shown to enhance oxidative glycolysis, to have anticholinergic effects, positive effects of the cerebral microcirculation under certain conditions with an increase in cerebral blood flow, effects on membrane physics and also rheo-

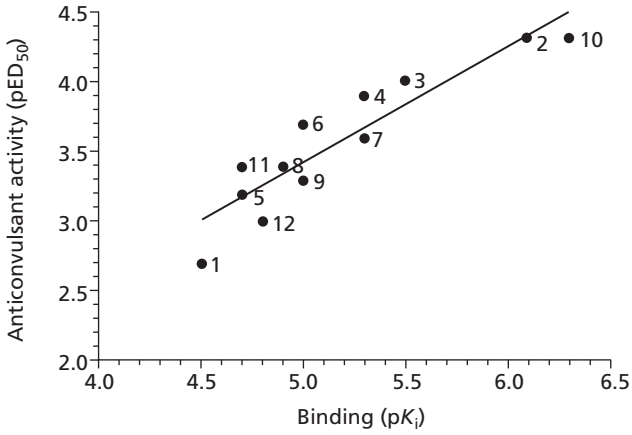

Fig. 48.2 Piracetam has weak binding to the SV2A binding site compared with levetiracetam. Here is shown a comparison between the affinity of (S)homologues of levetiracetam at the [^{3}H]levetiracetam binding site with the anticonvulsant activity of these compounds in the audiogenic mouse test. r^2 = 0.84, $P < 0.0001$, $n = 12$. 1, piracetam; 2, levetiracetam. Reproduced with permission from ref. 48.

logical properties, including reduction of platelet aggregation and changes in erythrocyte properties [1,7–10]. Piracetam may also affect mitrochondrial function. Whether any of these properties contribute to the suppression of myoclonus is quite unclear. Although disturbances of serotonergic and GABAergic function may be implicated in cortical myoclonus, piracetam does not seem to modify GABAergic activity, or affect cerebral serotonin or dopamine levels.

Pharmacokinetics

The pharmacokinetics of piracetam has been relatively extensively characterized in humans, and found to be linear (Fig. 48.3) [11,12].

Absorption

Studies in healthy volunteers have shown rapid and complete absorption after oral administration, with peak plasma concentrations (C_{max}) occurring at between 30 and 50 min. C_{max} values are 15–37 mg/L after a single dose of 800 mg, and 30–54 mg/L after a dose of 1600 mg.

Distribution

The volume of distribution of piracetam is 0.5–0.75 L/kg, and there is no significant binding to plasma proteins. Piracetam crosses the blood–brain barrier with a delayed peak, and the mean half-life in cerebrospinal fluid is 7.7 h after intravenous injection in healthy volunteers. The drug crosses the placental barrier freely. The distribution of the molecule has been investigated in the rat with radioactive labelled drug, with some evidence of preferential concentration in brain.

Metabolism and excretion

Piracetam does not undergo any known metabolism, although Hitzenberger *et al.* [11] postulate that some degree of metabolism must occur. The drug is largely excreted unchanged through the kidneys, with renal excretion accounting for 65–100% of the dose in various studies, after both acute and chronic administration (Fig. 48.4). After oral administration of single doses between 800 and 1200 mg, an elimination half-life of 4–5 h is found, and similar findings have been reported in the elderly.

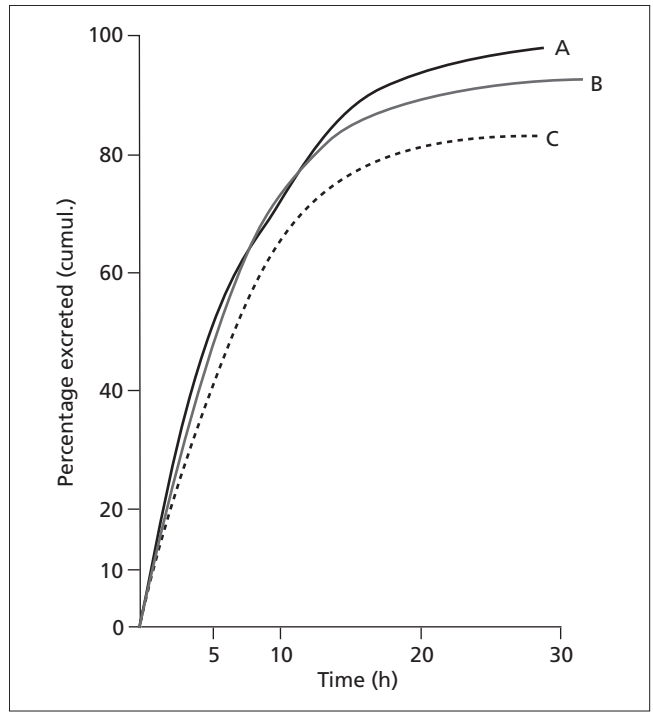

Fig. 48.3 Urinary excretion of radiolabelled piracetam in three subjects following a single oral dose of 2 g. From the manufacturer's literature.

Drug interactions

No drug interactions have been recorded, and none indeed would be expected in view of the lack of metabolism or protein binding and its mode of elimination. Over the years, the studies of potential interaction have included co-medication with antibiotics, antiepileptic drugs, muscle relaxants, corticosteroids, antifibrinolytic drugs, antidepressants, antihypertensive drugs and hormone replacement therapy.

Serum level monitoring

No adequate data on the potential usefulness of serum drug level monitoring are available.

Efficacy

An *n*-of-1 clinical trial can provide compelling evidence of efficacy in myoclonus, as the jerks are often so frequent and so intrusive that the effectiveness of therapy can be immediately apparent. So

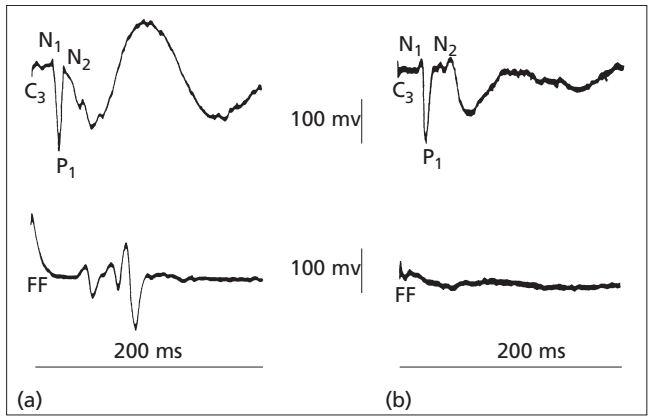

Fig. 48.4 Giant cortical somatosensory evoked potential to electrical stimulation of the forefinger and the reflex EMG discharge recorded from the finger flexor (FF) muscles of the right arm in a patient with stimulus-sensitive cortical action myoclonus. (a) Prior to treatment with piracetam, and (b) following treatment, showing the abolition of the reflex myoclonus after treatment with oral piracetam (8 g/day). From ref. 23 with permission.

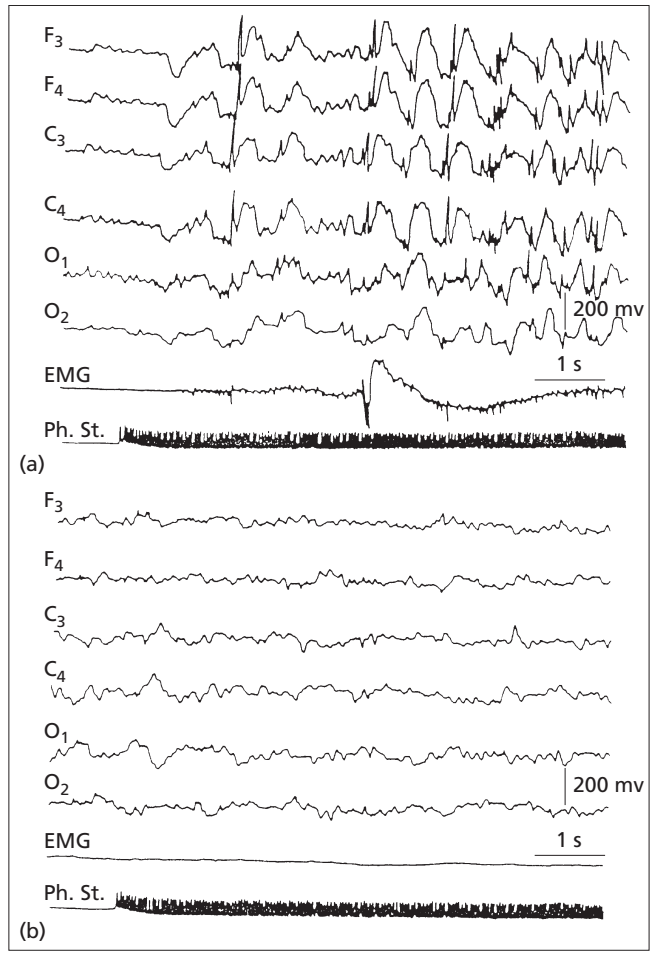

Fig. 48.5 EEG from a patient with stimulus-sensitive cortical action myoclonus (a) before and (b) after piracetam treatment. The pretreatment EEG shows spike-and-wave activity associated with generalized muscle jerks, induced by photic stimulation at 18 flashes/s. The post-treatment EEG shows a complete suppression of the spike–wave bursts and also the reflex myoclonic jerking after oral treatment with piracetam on 9 g/day for 7 days. From ref. 23 with permission.

was the case with piracetam: the first case report demonstrating an unequivocal antimyoclonic effect [4] relates to a patient with severe post-anoxic myoclonus who showed a dramatic acute effect after serendipitous administration of piracetam for another purpose. Subsequent uncontrolled reports in small numbers of patients confirmed this action [13–19]. Following these early anecdotal reports, Obeso *et al*. published a series of studies [20–25] exploring the effects of piracetam in myoclonus more systematically (Figs 48.4 and 48.5). These studies included a series of 40 patients with myoclonus, with differing clinical and electrophysiological features [24], and subsequently a further report of 10 patients extensively studied and treated with up to 18 g/day of piracetam [25]. In 1993, a placebo-controlled double-blind cross-over trial was reported by David Marsden's group, confirming the undoubted effectiveness of the drug in myoclonus [26]. The drug was then licensed for use in myoclonus in the UK and elsewhere.

The 40 patients reported by Obeso *et al*. [24] were heterogeneous. The myoclonus was secondary to anoxia in 12 cases, associated with the Ramsay–Hunt syndrome in five cases, multisystem atrophy in four, torsion dystonia in seven, birth anoxia in three, Creutzfeldt–Jakob disease in two, and occurred in single cases of Alzheimer's disease, herpes encephalitis, Lafora body disease and essential myoclonus. In three cases, the cause was unknown. Piracetam was given as short-term monotherapy to six patients and to the rest in combination therapy (doses used were between 18 and 24 g/day). Of these monotherapy-treated patients, two with cortical myoclonus showed electrophysiological improvement, but none of the four with electrophysiological evidence of subcortical myoclonus improved. Thirty-six patients had piracetam added to existing antimyoclonic therapy, and in 16 there was improvement. A dramatic response was seen in a woman on clonazepam who was bedbound with severe post-anoxic action myoclonus. When piracetam was added she could walk, dress and feed herself; within 2 days of withdrawal of piracetam she was again bedbound. Five out of eight other patients with post-anoxic myoclonus also improved, but less dramatically. All of the 16 patients who showed improvement had cortical myoclonus, and the aetiology underlying the cases varied. Five other patients with cortical myoclonus did not improve, nor did any of the patients with subcortical myoclonus.

The study of Brown *et al*. [26] was a well-conducted double-blind placebo-controlled cross-over trial in 21 patients. All patients had cortical myoclonus and received piracetam up to a maximum dose of 16.8 g per day or placebo for 14-day trial periods, in addition to their routine antimyoclonic therapy. Patients were rated on scales of stimulus sensitivity, motor skills, writing ability, functional disability, and were also scored on global assessments and visual analogue scales. Ten of the 21 patients failed to complete the placebo phase due to a severe exacerbation of their myoclonus, and none during the piracetam phase. Significant improvements were noted in all the scales on piracetam, and there was a median 22% improvement on piracetam on the global rating scale. There were also more seizures of

other types during the placebo phase than during the piracetam phase. These results are impressive and confirm that piracetam can have a marked effect on cortical myoclonus. The study also showed that abrupt withdrawal of piracetam may lead to a marked exacerbation of myoclonus and withdrawal seizures. Longer-term follow-up of some of the patients in these trials has confirmed the effect of piracetam, and in at least one of the cases (treated by the author), the effect was profound and maintained without evidence of tolerance. This 21-year-old patient was under my care with myoclonus and occasional generalized epileptic seizures of unknown aetiology, and was bedbound and dependent prior to piracetam therapy. There was an immediate response to piracetam, and immediate relapse on the three occasions that the drug had been withdrawn. After 12 years of piracetam montherapy (at a daily dose of 21 g) she is still almost entirely free of myoclonus, has completed a university education, produced two healthy babies and lives a normal life. Peuvot [27] reported the effect of piracetam in 13 patients (12 with post-anoxic myoclonus), of whom five were 'cured' and all except one improved. It was also noted that temporary withdrawal of piracetam led to a 'spectacular reappearance of myoclonus'.

A more recent double-blind cross-over study in Finland compared placebo and three dosage regimens of piracetam (each for 2 weeks) in 20 patients with Unverricht–Lundborg disease [28]. A daily dose of 24 g piracetam produced significant and clinically relevant improvement in the primary outcome measures of motor impairment, functional disability, and in global assessments by both investigator and patient. Significant improvement in functional disability was also found with daily doses of 9.6 g and 16.8 g. The dose–effect relation was linear and significant. Piracetam was well tolerated and adverse effects were few, mild and transient. This study confirmed the strong effect of piracetam in this condition and also its tolerability and safety, even at massive doses.

Piracetam is used relatively widely in the Far East and an open Japanese study of 60 patients reported very positive antimyoclonic effects in both monotherapy and polytherapy. Piracetam therapy was also associated with benefits on gait ataxia and convulsions, and with improvements in psychological function such as improved motivation, less sleep disturbance, better attention and less depression. No correlation was found between clinical and electrophysiological improvement [28].

Other reports of effectiveness against myoclonus, often dramatic, have been published in three patients with progressive myoclonic epilepsy [29], in myoclonus due to carbon monoxide poisoning [30], in two sisters with myoclonus due to sialidosis type 1 [31], in six cases of dyssynergia cerebellis myoclonica [32], in post-electrocution myoclonus [33], in three patients with Huntington's disease and myoclonus [34] and in myoclonus of the trunk [35]. A recent Russian publication reports a very positive effects on *epilepsia partialis continua* in six children with Kozhevnikov epilepsy given piracetam by daily intravenous infusions, up to a dose of 35 g/day, for 30 days. On this regime, three children improved by 75% or more and three became free of myoclonus. There was also an improvement in other seizures and in the severity of the hemiparesis. The clinical improvement was said to persist for up to 2 months after the cessation of the infusion [36].

Cortical myoclonus, with or without additional epilepsy, can result in profound disability. The jerks are often exacerbated by action, and the patients may be bedbound and immobile, unable to move without severe myoclonic jerking disrupting all motor responses. In some cases, piracetam can have a truly remarkable effect, suppressing the myoclonus, and reversing completely even severe disability. In such patients, the drug is nearer to a 'magic bullet' than any other of which I have experience.

The comparative effectiveness of piracetam and levetiracetam has not been formally assessed, although this would be an important and interesting study. Anecdotally, I have a patient with non-epileptic myoclonus who responded to piracetam but not levetiracetam, but other cases of idiopathic generalized epilepsy in whom levetiracetam had a greater antimyoclonic effect than piracetam. Indeed, there are no systematic studies of piracetam in the myoclonus of idiopathic generalized epilepsy (e.g. in juvenile myoclonic epilepsy), nor comparative trials of piracetam and levetiracetam, although these would be of interest given the efficacy of levetiracetam in idiopathic epilepsy, which has been clearly demonstrated in a randomized controlled study [37]. The effect of piracetam on other types of seizures has not been studied in a controlled fashion, although anecdotal experience is disappointing.

There does not appear to be tolerance to the antimyoclonic effect, but withdrawal of medication will often return the patient to the pretreatment state within a few days [38]. Whether or not the effects are confined to cortical myoclonus is uncertain, and I have personal cases with myoclonus, controlled by piracetam, which were more likely to be subcortical in origin. Not all patients with cortical myoclonus respond to the drug, and what differentiates these cases from others is unclear. It has been said that the drug works best in combination, for example with clonazepam, although personal and anecdotal experience shows that piracetam monotherapy can be highly efficacious.

Adverse effects

Because of piracetam's extensive use as a cognitive enhancer, there is considerable experience of its clinical tolerability, at least at low dosages. The drug seems well tolerated, and even in placebo-controlled trials, adverse effects were often reported at a greater frequency with placebo than with the active drug [26]. In these studies, the most commonly reported adverse effects include dizziness, insomnia, nausea, gastrointestinal discomfort, hyperkinesis, weight gain and agitation (all reported at a frequency of less than 10%). Rash occurs in less than 1% of patients, and there have been no serious idiosyncratic reactions. In the placebo-controlled double-blind cross-over study of Brown *et al*. [26], the only adverse events were sore throat and headache in one patient, and single seizures in two; these effects may not have been treatment related. In the routine treatment of myoclonus, it is not uncommon to use daily doses of up to 24 g or more, and the adverse effect profile at these doses is much less well studied. Anecdotal clinical evidence suggests that most patients tolerate even these high doses well, and that adverse effects are rarely a serious problem. In controlled trials there have been no significant effects on haematological or biochemical parameters, although

anecdotal cases of haematological disturbances are reported [28].

Place in current therapy

Piracetam is available in 800- and 1200-mg white tablets or as a solution of 200 mg/mL or 333.3 mg/mL. In myoclonus, early clinical series used doses which were high by previous standards, but modest by current standards: Terwinghe *et al*. [4] used 4.8 g/day in the first reported case, and other studies used doses of 6.4 g/day [36], 8–9 g/day [16,21,24] and 10 g/day [13,29,32,35]. More recently, higher doses have been used – up to 16.8 g/day [27] or up to 18 g/day [26]. In my personal clinical practice, doses of up to 32 g/day are not uncommonly used, and occasionally even higher doses. The optimal dosage is therefore unclear, but it would seem sensible to recommend initial doses of between 4.8 and 8.0 g/day, and to progressively increase the dose to up to 24 g/day, guided by clinical response, and then to higher doses if required. The drug can be given in two or three divided doses, its major drawback at higher doses being the number of tablets taken and their bulk. For other indications, lower doses are used.

It is usual to reserve piracetam therapy as a third line for patients resistant to treatment with valproate or benzodiazepines and, more recently, levetiracetam. However, some authorities recommended it as first-line therapy in myoclonus [37,39], and its effectiveness in some patients, combined with its almost complete lack of adverse effects, give the drug a special place in antimyoclonic therapy. The recent licensing and greater convenience of levetiracetam, however, may well usurp the place of piracetam. However, there are no comparative studies and the role for piracetam in relation to levetiracetam has not been defined.

As mentioned earlier, piracetam has been widely used clinically for other indications. Its cognitive-enhancing properties have been the subject of numerous open studies but most were uncontrolled and do not meet modern assessment standards. About 50 controlled studies exist, with some showing modest benefits, but others are negative. A Cochrane meta-analysis in 1998 concluded that evidence of effects on cognition and other measures was inconclusive [40]. There are ongoing studies of piracetam in the syndrome of mild cognitive impairment. A distinctive neuroprotective function, separate from cognitive enhancement, has been demonstrated experimentally. Both properties clearly carry promise for use after stroke to limit functional impairment and for rehabilitation. Initial uncontrolled clinical evidence, as well as experimental evidence, in acute stroke had been encouraging [41–47], but a major controlled trial of 927 patients randomized to placebo or piracetam (12 g intravenous, followed by 12 g daily for 4 weeks and 4.8 g daily for 8 weeks) showed no difference in the primary or secondary endpoints (neurological outcome after 4 weeks or functional outcome after 12 weeks) [47]. It is possible that earlier treatment confers more benefit, and also that those with more severe symptoms following stroke do better than those with mild symptoms, and also those with aphasia [46,47].

There is little experience of piracetam in pregnancy, but as the drug readily crosses the placenta and into breast milk, it should probably be avoided in pregnancy and lactation. As piracetam is almost exclusively excreted by the kidneys, the dose should be lowered in patients with renal impairment. Recommended adjustments are a 50% reduction in dose at creatinine clearances of 40–60 mL/min (serum creatinine of 112–153 μmol/L) and a 75% reduction at creatinine clearances of 20–40 mL/min (serum creatinine of 153–270 μmol/L). The drug is contraindicated in patients with creatinine clearances below 20 mL/min, and in those with severe hepatic impairment. There is little published experience of the drug in children.

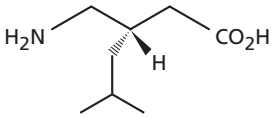
49 Pregabalin

Sylvain Rheims and Philippe Ryvlin
Hospices Civils de Lyon, Lyon, France



Primary indications	Adjunctive therapy for partial seizures with or without secondary generalization
Usual preparation	Capsules: 25, 50, 75, 100, 150, 200, 300 mg
Usual dosages	Initial: 150 mg/day. Maintenance: 150–600 mg/day
Dosing frequency	2 or 3 times/day
Significant drug interactions	Pregabalin may potentiate the effects of other CNS depressants on cognition and motor coordination
Serum level monitoring	Not routinely used. Dosage is generally adjusted on the basis of clinical response
Reference range	Not established
Common/important adverse effects	Dizziness, somnolence, ataxia, asthenia, weight gain, visual disturbances, difficulty concentrating, tremor, peripheral oedema
Main advantages	Robust efficacy, predictable pharmacokinetics, lack of drug interactions and activity in neuropathic pain, fibromyalgia and generalized anxiety disorder
Main disadvantages	Spectrum of efficacy restricted to partial epilepsies. CNS adverse effects and propensity to cause weight gain
Mechanism of action	Modulates neurotransmitter release by binding to the α_2-δ subunit of voltage-gated calcium channels
Oral bioavailability	>90%
Time to peak levels	1–2 h
Elimination	Renal excretion in unchanged form
Volume of distribution	Approximately 0.5 L/kg
Elimination of half-life	5–7 h
Plasma clearance	0.7–1.0 mL/min/kg
Protein binding	Nil
Active metabolites	None
Comment	A useful antiepileptic drug for the management of refractory partial-onset seizures

Introduction

Pregabalin is one of the latest agents introduced for the management of partial epilepsy in adults. Marketing authorization was granted by the European Medicines Agency (EMEA) in July 2004, and by the US Food and Drug Administration (FDA) in June 2005, for use as add-on therapy for the treatment of partial seizures with or without secondary generalization. Pregabalin is also used, or proposed for, the treatment of neuropathic pain [1], fibromyalgia [2] and generalized anxiety disorder [3].

Chemistry

Pregabalin, also known as *S*-(+)-3-isobutyl-GABA, is a structural analogue of γ-aminobutyric acid (GABA) and corresponds chemically to (*S*)-3-(aminomethyl)-5-methylhexanoic acid. Its molecular formula is $C_8H_{17}NO_2$ and its molecular weight is 159.23.

Pregabalin has a pK_{a1} of 4.2 and a pK_{a2} of 10.6. It is a white to off-white crystalline powder, freely soluble in water and in basic and acidic aqueous solutions. The log of the partition coefficient (*n*-octanol/0.05 M phosphate buffer) at pH 7.4 is –1.35.

Pharmacology

Activity in animal models of epilepsy and other indications

In all animal models of seizures and epilepsy tested, pregabalin has a similar activity profile to gabapentin, but it is consistently three- to sixfold more potent on a mg/kg dose basis than gabapentin [4]. Thus, pregabalin has been shown to be effective against seizures in a wide range of experimental animal models, exhibiting potent activity against seizures induced by maximal electroshock, pentylenetetrazole, bicuculline and picrotoxin [5–7]. Pregabalin is also effective in preventing seizures in kindled rats, and audiogenic seizures in genetically susceptible (DBA/2) mice, although it is ineffective in genetic animal models of absence seizures such as the Genetic Absence Epileptic Rat of Strasbourg.

Pregabalin also exhibits activity in preclinical models predictive of activity against anxiety and neuropathic pain.

Mechanism of action

The pharmacological effects of pregabalin are believed to result from its binding to the α_2-δ subunit of P-, Q- and N-type voltage-gated calcium channels, resulting in allosteric modulation of the channels, decreased depolarization-induced calcium influx at nerve terminals, and reduced excitatory neurotransmitter release [5,6,8–10].

Although pregabalin is structurally related to GABA, it does not appear to act via the GABAergic system, being inactive at $GABA_A$, $GABA_B$ and benzodiazepine receptors, not converted metabolically into GABA or a GABA agonist, and having no effect on GABA uptake or degradation [5,11].

Pharmacokinetics

Key pharmacokinetic features

In clinical pharmacology studies, pregabalin demonstrated predictable linear pharmacokinetics following oral dosing, with low intersubject variability.

Absorption is rapid, with maximal serum concentrations (T_{max}) occurring approximately 1 h after single or multiple oral doses. Although pregabalin's passage across the gastrointestinal mucosa is mediated by an active transport system which is the same as that responsible for the absorption of gabapentin, within the clinically occurring pregabalin dose range the system does not become saturated and therefore oral bioavailability is virtually complete [5,6]. Steady-state conditions are achieved within 24–48 h following repeated administration [5].

Pregabalin does not bind to plasma proteins, is not significantly metabolized and is excreted virtually entirely in unchanged form by the kidney [5]. The elimination half-life is in the order of 5–7 h and the apparent plasma clearance is in the order of 0.7–1.0 mL/min/kg following oral administration.

Pharmacokinetics in special groups

Since pregabalin is excreted virtually unchanged by the kidney, its clearance is decreased in subjects with renal impairment, proportionally to the reduction in creatinine clearance (CL_{Cr}) [12,13]. Based on pharmacokinetic calculations, a 50% reduction in pregabalin daily dose is recommended for patients with CL_{Cr} between 30 and 60 mL/min compared with those with $CL_{Cr} > 60$ mL/min, and daily doses should be further reduced by approximately 50% for each additional 50% decrease in CL_{Cr}.

Randinitis *et al.* [13] have shown that pregabalin is extensively cleared by haemodialysis. Therefore, supplemental doses may be required for patients on chronic haemodialysis after each dialysis session to maintain unaltered serum pregabalin concentrations.

The influence of age on pregabalin pharmacokinetics does not appear to have been formally investigated. However, since renal function declines physiologically in old age, pregabalin clearance is expected to be reduced in elderly patients in proportion with the reduction in CL_{Cr}. Preliminary data support this prediction [12].

There are no data on pregabalin disposition during pregnancy. Since pregnancy is associated with an increase in glomerular filtration rate, the possibility of a increase in pregabalin clearance during gestation can be anticipated [14].

Drug interactions

Pregabalin is devoid of enzyme-inducing or -inhibiting activity on drug-metabolizing enzymes, and it is not itself significantly metabolized. Therefore, drug–drug interactions are considered unlikely with pregabalin.

Formal drug interaction studies have shown that pregabalin does not affect the serum concentrations of concomitantly administered antiepileptic drugs (AEDs), including carbamazepine, phenytoin, lamotrigine and valproic acid [5,6,15,16]. Serum pregabalin concentrations also do not appear to be affected by concomitant AEDs [15], even though in one study a moderate decrease in pregabalin concentrations (20–30%) was reported in patients co-medicated with enzyme-inducing AEDs [12].

Post hoc population analysis of pharmacokinetic studies has revealed no significant interactions between pregabalin and oral contraceptives, insulin, diuretics or oral hypoglycaemic agents [5,6,15,16]. Additive effects of pregabalin on the impairment of cognitive and gross motor function caused by oxycodone, and potentiation of the effects of ethanol and lorazepam, have been observed (Pfizer, data on file). However, co-administration of multiple oral doses of pregabalin with oxycodone, lorazepam or ethanol did not result in clinically important effects on respiration.

Serum level monitoring

The relationship between serum pregabalin concentrations and clinical effects has not been adequately investigated, and serum pregabalin levels are not routinely monitored during pregabalin therapy [17].

Efficacy in epilepsy

Pregabalin efficacy has been evaluated as add-on therapy in adults with refractory partial epilepsy in short-term randomized controlled trials and in long-term open-label studies. A monotherapy clinical development programme in adult patients with partial epilepsy is currently under way.

Short-term randomized controlled trials

Study designs

The efficacy and safety of pregabalin as add-on therapy in partial seizures with or without secondary generalization has been studied in four randomized, double-blind, placebo-controlled short-term multicentre trials involving 1396 patients with uncontrolled seizures [6,18–24] (Table 49.1).

Three of these studies [18,19,22] (n = 1052) were designed to investigate dose–response relationships by using fixed-dose regimens (Table 49.1). The data from these three trials were then used to define a minimum effective dose and an approved dosing regimen as required by regulatory authorities. In the first of these studies [22], 453 patients (≥12 years old) in Canada and the USA were randomized to receive placebo or 50, 150, 300 or 600 mg/day pregabalin administered as two divided doses, with no titration period. In the second international study [18], 287 patients (≥18 years old) received placebo or 150 or 600 mg/day pregabalin administered in a three times daily regimen, with up to 1 week of titration. The third fixed-dose study [19] involved 312 patients (≥18 years old) randomized to receive placebo, pregabalin 600 mg/day twice daily or pregabalin 600 mg/day three times daily, each with up to 1 week of titration.

The fourth study was a 12-week placebo-controlled trial [21], which differed from the earlier trials in that it was designed to more closely represent pregabalin's potential use in real-world management settings by comparing a flexible dose regimen with a high-dose fixed-dose regimen, both given in two divided daily doses. In total, 341 patients aged 18 years and above were randomized to receive adjunctive twice-daily dosing with either placebo, a fixed pregabalin dose of 600 mg/day, or a flexible pregabalin dose of 150–600 mg/day (Table 49.1 and Fig. 49.1). Patients randomized to the pregabalin fixed-dose group received 600 mg/day for the entire double-blind treatment period. Patients randomized to the pregabalin flexible-dose group started on 150 mg/day pregabalin for the first 2 weeks, and then increased

Table 49.1 Characteristics of short-term randomized placebo-controlled adjunctive therapy trials of pregabalin in patients with partial seizures.

Study	Pregabalin dose	Trial duration (weeks)			Number of patients (intent to treat)			Gender (%)		Baseline seizure frequency (median/month)	Location

[a] Given in two divided doses.
[b] Given in three divided doses.

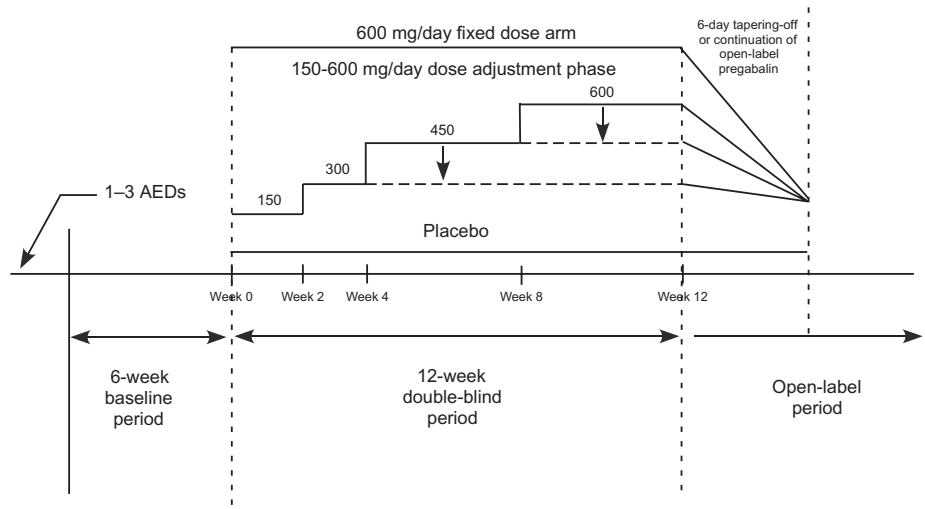

Fig. 49.1 Design of the trial comparing pregabalin at flexible doses (150–600 mg/day) with a fixed dose (600 mg/day) as adjunctive therapy in refractory partial epilepsy. From ref. 21 with permission.

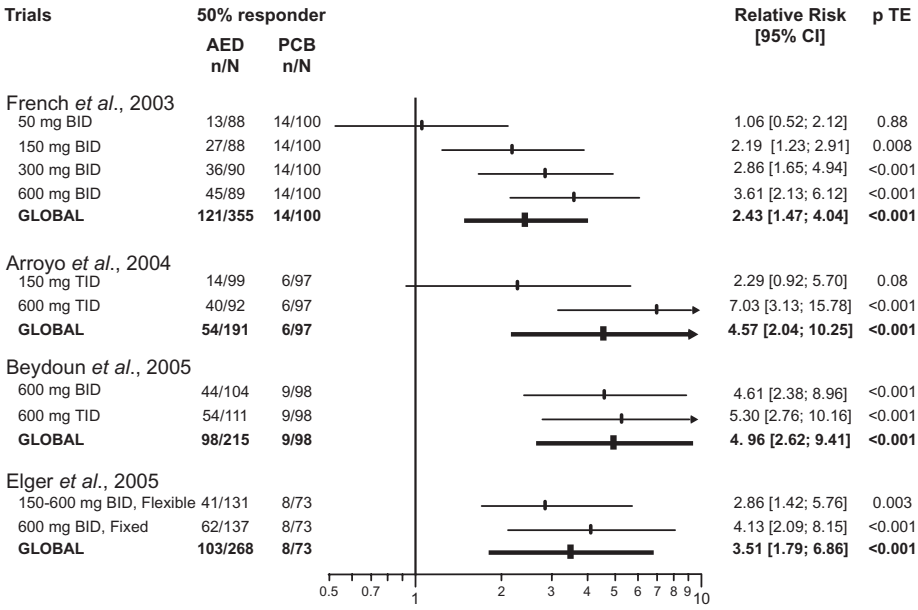

Fig. 49.2 Proportions of patients achieving at least 50% seizure reduction (50% responder rates) in short-term randomized adjunctive therapy trials of pregabalin in refractory partial epilepsy. Relative risks and 95% confidence intervals (CIs) for responder rates are also shown. Indicated doses are total daily doses (BID and TID indicate that the specified dose was divided into two or three daily administrations, respectively). AED, pregabalin; PCB, placebo, pTE, *P*-value for the treatment effect. Adapted from ref. 40.

to 300 mg/day for the next 2 weeks. Patients who were seizure free then remained on 300 mg/day for the remainder of the study as directed by the investigator, whilst those still having seizures increased their dose to 450 mg/day for the next 4 weeks. Similarly, at week 8, seizure-free patients remained on 450 mg/day, whilst those still having seizures increased their dose to 600 mg/day. At any point after the first 4 weeks, patients who experienced intolerable adverse events could reduce their daily dose to the previous level for the remainder of the treatment period. Thus, after the first few weeks, these patients received a pregabalin dose that was optimized both for efficacy in reducing seizure frequency and for tolerability.

All the patients enrolled in each of these four studies were highly refractory to treatment. Patients entering the three fixed-dose studies were required to have a history of failing two or more AEDs at maximally tolerated doses and to experience six or more partial seizures and no 4-week seizure-free period during the 8-week baseline phase [18,19,22]. For the fourth flexible-dose study, patients were required to have four or more partial seizures and no 4-week seizure-free period during the 6-week baseline [21].

Efficacy in the fixed-dose trials

Enrolled patients in fixed-dose trials had a mean duration of epilepsy of 25 years and were highly refractory to treatment, with a mean baseline seizure rate of 24.4 seizures per month (median 11.2 per month) and with 73% of them taking at least two AEDs [20,24].

In each of the three fixed-dose studies, add-on therapy with pregabalin (dosed twice and/or three times daily) was found to be effective against refractory partial seizures [18,19,22]. In particular, doses of 150, 300 and 600 mg/day were significantly superior to placebo in reducing seizure frequency, whilst the 50 mg/day dose was not effective [18,20,22,24]. Thus, the minimum effective dose was established as 150 mg/day, and this was shown to be statistically different from placebo given as either two or three divided doses. A statistically significant dose–response relationship for seizure reduction was also demonstrated in both of the dose-finding studies ($P < 0.0001$ for each study). Twice-daily and three times daily dosing regimens displayed similar efficacy in terms of seizure reduction.

Responder rates (proportions of patients with ≥50% reduction from baseline seizure frequency) across the effective pregabalin doses (150–600 mg/day) ranged from 14% to 51% (Fig. 49.2), and also demonstrated a clear and significant dose–response relationship. The number of background AEDs or the baseline seizure frequency had no influence on the responder rate.

Pooled data for the proportion of seizure-free patients on each study day across the three fixed-dose studies indicated that pregabalin has a rapid onset of action. For the effective pregabalin doses (150–600 mg/day), a significant reduction in seizure activity compared with placebo was observable by day 2, and this persisted throughout the 12-week evaluation period [25]. Between 3% and 17% of patients receiving effective pregabalin doses in each of the three fixed-dose trials were free from seizures during their last 28 days of treatment (compared with between 0% and 1% of those receiving placebo), with seizure-free rates tending to increase with increasing dose [20]. Furthermore, in two separate studies, seizure freedom rates in patients receiving pregabalin 600 mg/day in three divided doses were statistically significant compared with those in placebo-treated patients [18; Pfizer, data on file]. When the seizure-free period was extended to include the entire double-blind treatment period for the modified intent-to-treat (ITT) population, pregabalin doses of 300 or 600 mg/day were each significantly more effective than placebo, with seizure-free rates of 8% for the 300 mg/day dose (one study) and between 7% and 19% for the 600 mg/day dose (three studies). Furthermore, in the two dose-finding studies, seizure-free rates for the double-blind treatment period tended to increase with dose. Seizure-free rates for the entire double-blind period for patients

who completed the study ranged between 1% and 5% for the 600 mg/day dose.

Overall, these three short-term trials provided proof of efficacy for adjunctive pregabalin using several different endpoints (seizure reduction, responder rate and seizure-free rate), and also provided some valuable dosing-related data. The minimum effective dose in these studies was 150 mg/day, which was effective when given as either two or three divided doses. An effect of pregabalin was detectable as early as day 2, so patients would be expected to obtain benefit soon after starting treatment. These studies have also demonstrated a clear and significant dose–response relationship for pregabalin in this patient population, meaning that escalating the dose should provide additional efficacy for patients who can tolerate pregabalin and whose seizures are not effectively controlled by the starting dose.

Efficacy in the flexible-dose trial

In the study that compared a fixed dose (600 mg/day) with a flexible-dose regimen (150–600 mg/day) in patients with partial seizures, both dosing regimens were found to be significantly more effective than placebo in reducing seizure frequency. Seizure frequency reductions from baseline were 35.4% in the flexible-dose group ($P = 0.0091$) and 49.3% in the fixed-dose group ($P = 0.0001$), compared with 10.6% in the placebo group [21]. Responder rates were also significantly greater in both the fixed-dose (45.3%, $P < 0.001$) and flexible-dose (31.3%, $P < 0.001$) groups than in the placebo group (11.0%) [21]. During the last 28 days of treatment, 12.2% of patients in the pregabalin flexible-dose group, 12.4% in the fixed-dose group and 8.2% in the placebo group were completely free of seizures.

Responder rates in this study compare well with those observed in the three fixed-dose studies (Fig. 49.2), and provide further support for the efficacy of pregabalin as add-on therapy for partial seizures.

Long-term studies

The long-term efficacy of adjunctive therapy with pregabalin at doses ranging from 75 to 600 mg/day has been evaluated in four long-term, open-label, extension studies. An interim analysis obtained whilst the four studies were still ongoing has been published [6,24]. Since then, all four trials have been completed, and data from the final analysis of the full data set are presented below (Pfizer, data on file).

In total, these trials included 1480 patients with an overall exposure to pregabalin of 3150 patient-years. Prior to participating, most patients ($n = 968$) had previously completed one of the double-blind, randomized, fixed-dose pregabalin trials or an inpatient monotherapy study. Three of the open-label studies also allowed *de novo* entry of patients ($n = 512$). Approximately 2–3.5 years after the open-label studies began, the FDA requested that continuing participation in the studies at US sites be restricted to patients refractory to other AEDs who were responding to pregabalin (i.e. having at least a 30% reduction in seizure frequency compared with baseline). This requalification somewhat complicates the interpretation of the efficacy data, because it creates a bias in favour of pregabalin when assessing patients continuing on long-term treatment. For this reason, seizure data collected after requalification have not been included in the analyses of efficacy, with the exception of seizure freedom data. Seizure freedom analyses have been performed both on data collected prior to initial requalification and on all open-label data for the ITT patients.

By the completion dates of the studies, 77% of patients had received at least 24 weeks of pregabalin treatment whilst 59% had received at least 1 year of treatment, and 35% had received at least 2 years. Approximately 20% of the patients had been studied for at least 5 years. A total of 71% of pregabalin exposures in terms of total patient-years was at doses of 450 mg/day or greater and 48% of pregabalin exposures occurred at the 600 mg/day dose. Approximately half of the patients were taking two other AEDs at the start of the open-label period. In total, 188 patients had to withdraw because of failure to meet the requalification criteria (13% of 1480 enrolled, 44% of the 431 assessed for requalification).

When seizure freedom data for the whole ITT population were analysed, there was an increase in the mean number of seizure-free days per 28 days, from 18.3 days at baseline to 21.5 days during open-label treatment, which represents a mean improvement of 41.6% in seizure-free days for individual patients. In patients who took treatment for at least 6 months or 1 year, 9.2% (103/1119) were seizure free for the last 6 months, and 8.1% (71/877) for the last 12 months, respectively (Fig. 49.3). As discussed previously, the requirement for a response to pregabalin in the US requalification process means that data for the whole population may be biased in favour of pregabalin. Thus, seizure freedom parameters were also analysed by excluding all data collected after requalification, in an attempt to remove any such bias. In this analysis, there was a similar increase in the mean number of seizure-free days/28 days, from 18.3 days at baseline to 21.6 days during open-label treatment. This represents a mean improvement of 39.2% for individual patients. Seizure-free rates were slightly lower in this analysis, with 7.7% (69/892) of patients remaining seizure free over their last 6 months of pregabalin treatment and 3.7% (26/710) being seizure free over the last year. The number of patients remaining seizure free for at least 6

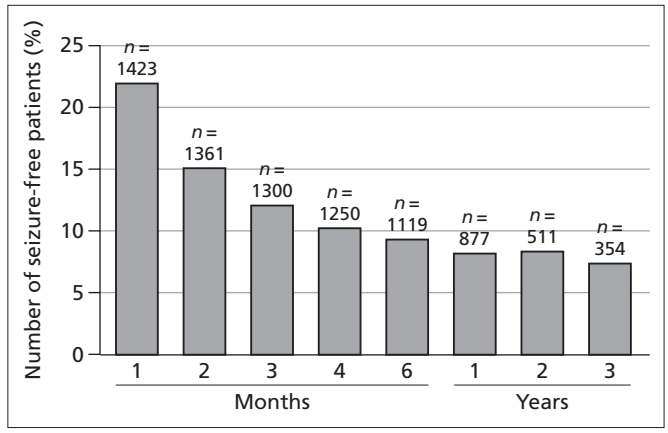

Fig. 49.3 Seizure freedom rates in patients treated with long-term pregabalin in the pooled data set from four open-label trials (entire intent-to-treat population). Numbers in bars indicate duration of seizure freedom in the period preceding the last study visit.

months, or at least 1 year, are particularly encouraging for long-term management, since in many countries these are the seizure-free periods needed to receive a driving licence.

During the initial 12-week period of open-label treatment, the 50% responder rate for the evaluable population who had previously completed one of the three short-term fixed-dose studies was 37%. At subsequent intervals (up to 4 years of open-label treatment), responder rates among patients still treated with pregabalin ranged between 41% and 66%. In the subset of patients who had remained in the study for 2 years, the responder rate during the initial 12-week period of open label was 52%, with responder rates at subsequent intervals remaining at between 50% and 58%. A similar pattern was observed for cohorts of patients who had remained in the study for 6 months or for 1 year. Though these observations might suggest that little or no tolerance to pregabalin develops with long-term exposure, they must be interpreted with caution due to the important number of patients who discontinued treatment, with responders more likely to remain in the study than non-responders. In addition, changes in co-medication often occurred during these long-term studies, and might also play a role in the apparent stability of seizure control over time.

Efficacy in other indications

There is evidence from placebo-controlled randomized trials that pregabalin is effective in the treatment of neuropathic pain syndromes [1,26–28], particularly postherpetic neuralgia and painful diabetic neuropathy [26,27]. Pregabalin is also effective in the treatment of fibromyalgia and other chronic musculoskeletal pain [2,29–31] and in the treatment of generalized anxiety disorder or social anxiety disorder [3,32].

Adverse effects

Tolerability data from short-term fixed-dose placebo-controlled studies

The most frequently reported adverse events in pregabalin-treated patients in double-blind trials were central nervous system (CNS) related (Table 49.2). These events were usually mild or moderate in intensity, generally self-limiting and clearly increased in frequency with increasing dose. Dizziness and somnolence were reported in 28.9% and 20.8% of pregabalin patients, and caused discontinuation in 5.3% and 3.3% of all patients, respectively. Complaints of imbalance, reported in 9.6% of all patients, were significantly increased in pregabalin-treated patients in comparison with placebo-treated patients, with a relative risk of 3.14 [95% confidence interval (CI) 1.37–7.19] for all doses and 5.26 (2.24–12.38) for the highest doses [33]. In general, these adverse events occurred during the first 2 weeks of treatment and then resolved with continued treatment [25]. Overall, withdrawal rates due to adverse events were 15.3% for pregabalin-treated patients and 6.1% for placebo-treated patients [20,24], and few patients (≤5% in any treatment group) discontinued due to lack of efficacy. The relative risk of withdrawal (pregabalin versus placebo) due to adverse events was 2.47 (1.80–4.17) [23]. Most patients (86.6%) elected to enter the open-label extension studies.

There was a strong relation between the occurrence of adverse events and the pregabalin dosage (Table 49.2). In addition, subgroup analyses assessing treatment withdrawal for adverse events with differing doses of pregabalin suggested a higher withdrawal rate with higher doses [23]. Thus, in patients receiving doses of 50 mg or 150 mg/day, the withdrawal rate for adverse events did not significantly differ between placebo and treatment arms. By contrast, the relative risk of withdrawal (pregabalin versus placebo) due to adverse events was 2.89 (1.07–7.78) with a dose of 300 mg/day and 3.74 (2.44–5.74) with a dose of 600 mg/day [23].

Weight gain was reported as a common adverse event, and was spontaneously reported in 10.4% of pregabalin-treated patients compared with 1.4% of placebo-treated patients. In these studies, body weight was also measured at baseline and at last observation, and considered clinically significant if ≥7% over baseline. Eighteen per cent of patients treated with pregabalin and 2.1% of patients treated with placebo presented such significant weight gain, with the majority of patients not gaining more than 10%. Overall, pregabalin-treated patients in these studies gained a mean of 2.1 kg, whereas there was no change in the weight of placebo-treated patients. In those patients who did gain weight with pregabalin, the weight gain appeared to be dose related.

Table 49.2 Most common adverse events (frequency, %) in short-term fixed-dose clinical trials of pregabalin as adjunctive therapy.

	Pregabalin daily dose					Placebo [18,19,21,22] (*n* = 294)
	50 mg [22] (*n* = 88)	150 mg [18,22] (*n* = 187)	300 mg [22] (*n* = 90)	600 mg [18,19,21,22] (*n* = 533)	Flexible, 150–600 mg [21] (*n* = 131)	
Dizziness	9.1	17.6	31.1	33.8	24.4	10.5
Somnolence	10.2	11.2	17.8	25.5	19.1	10.9
Ataxia	3.4	5.9	10	19.9	9.2	4.1
Fatigue	5.7	10.7	12.2	18	16.8	8.2
Headache	6.7	7.5	5.6	10.1	13.7	11.6
Weight gain[a]	1.1	4.8	6.7	17.1	19.1	1.4
Withdrawal for adverse events	6.9	5.9	14.4	24.2	12.2	6.3

Pooled data from four studies [18,19,21,22]. Some patients reported more than one adverse event.
[a]Weight gain spontaneously reported as an adverse event by patient.

There was, however, no apparent association between weight change and changes in blood lipids or loss of glycaemic control. Very few patients (0.4% and 0.0% of pregabalin- and placebo-treated patients, respectively) discontinued during the double-blind phase as a result of weight gain.

There were no deaths during the double-blind periods of these short-term controlled trials.

Tolerability data from the flexible-dose placebo-controlled trial

Fixed-dose trials identified an adjunctive dose of 150 mg/day as an effective starting dose capable of reducing seizure frequency in a significant proportion of patients. In practice, however, it is likely that many patients will require higher maintenance doses to achieve optimal seizure control, and these doses have been associated with a higher incidence of adverse effects in short-term trials. Clinical experience has shown that adverse effects associated with some other commonly used AEDs may be avoided with gradual slow dose escalation [34]. Thus, one of the later pregabalin trials [21] explored whether a flexible dose-escalation regimen (from 150 mg/day up to a maximum of 600 mg/day) would enhance the tolerability of pregabalin while maintaining efficacy compared with a 600 mg/day dose given without titration (for a description of trial design, see Fig. 49.1 and the subsection 'Study designs' in the 'Efficacy' section).

As in short-term fixed-dose trials, the most common adverse events experienced by the fixed-dose group in this trial were dizziness, ataxia and weight gain (43.1%, 21.2% and 20.4%, respectively), while those reported by the flexible-dose group were dizziness, somnolence and weight gain (24.4%, 19.1% and 19.1%, respectively) [21]. As expected, there was a tolerability advantage with flexible dose adjustment, with lower overall rates of discontinuation due to adverse events in the flexible-dose group than in the fixed-dose group (12.3% versus 32.8%). Kaplan–Meier plots estimating the time to exit due to adverse events revealed that patients in the fixed-dose group withdrew from the study sooner and at a greater rate than those in the flexible-dose group ($P = 0.0001$). Only 3% of patients in the flexible dose group and none in the placebo group withdrew due to adverse events in the first week of treatment, compared with 24% of patients in the pregabalin fixed-dose group.

The results from this study suggest that a flexible stepwise dose escalation from a starting dose of 150 mg/day may help to improve tolerability in patients who would ultimately benefit from a higher dose, and can also encourage patients to continue taking medication. It is worth noting, however, that the discontinuation data from this study indicate that most of the patients in the fixed-dose group (over 60%) could actually tolerate the maximum 600 mg/day dose from initiation, and so this could also be a realistic option for patients who may need immediate high doses to attain rapid seizure control.

Long-term tolerability and safety data in patients with epilepsy

In total, 1480 patients with an overall exposure to pregabalin of 3150 patient-years were assessed in four long-term open-label studies (for more information on duration of exposure and dosing in long term studies, see the 'Efficacy' section). Overall, the experience of adverse events and tolerability in these long-term studies was consistent with that observed in short-term placebo-controlled trials. In total, 193 patients (13%) withdrew due to adverse events, and these were considered to be treatment related in 160 patients (11%).

Again, the most frequently reported adverse events were CNS related, with symptoms experienced by ≥5% of all pregabalin-treated patients, including dizziness, somnolence, ataxia, thinking abnormal (a coded term used to indicate difficulties with concentration), tremor, amnesia, depression, insomnia, nervousness, anxiety and confusion. Other frequent adverse events related to the body as a whole included accidental injury, infection, headache, asthenia and pain, although these were not judged to be treatment related. Amblyopia and diplopia were the most frequently reported vision-related adverse events. Painful gynaecomastia and lower extremity pain in association with pregabalin therapy have been reported [35]. A case series of five patients from a single centre suggested that erectile dysfunction and impotence may be an adverse effect of pregabalin [36]. Focal myoclonus has also been reported as a possible adverse effect [37].

Overall, in the open-label extension studies the four most commonly reported adverse events were dizziness, accidental injury, somnolence and weight gain, although very few patients (0.3–2%) reported these events as a reason for withdrawal. Most adverse events were mild or moderate in intensity and usually resolved with continued treatment.

Weight gain was reported as an adverse event overall by 24% of patients. All patients in the four studies were also objectively assessed for body weight changes at their last study visit and at follow-up. The mean weight gain between baseline and study termination was approximately 5 kg, with 44% of patients experiencing a 7% or greater weight increase. Similarly, in a 6-month study which had as primary outcome the assessment of weight gain in patients treated with less than 300–450 mg/day pregabalin, the median body weight gain was 4.0 kg, and 41% of patients who completed the study had a body weight increase of more than 5 kg [38]. Although short-term trials suggested a relation between weight gain and pregabalin dosage (see Table 49.2), long-term studies did not show any correlation of weight gain with absolute dosage (mg/day), relative dosage (mg/kg/day) or categorized dosage (more or less than 300 mg/day) of pregabalin [38]. Conversely, weight gain significantly correlated with the number of AEDs [38]. Finally, this side-effect could not be prevented by extended patient counselling within a standard clinical setting [38].

Serious adverse events were experienced by 246 (17%) open-label patients, although in only 15 patients (1.0%) were these considered by the investigator to be related to pregabalin treatment. Twenty-three patients died during or after the open-label studies; five of these deaths were related to seizures. None of the deaths was considered by the investigator to be causally related to pregabalin treatment.

Tolerability and safety data in other indications

The adverse effects of pregabalin in studies conducted in other indications are similar to those recorded in patients with epilepsy, with the exception of peripheral oedema, which appears to occur more commonly in patients with neuropathic pain than in patients

with epilepsy. In a review of seven randomized controlled trials in painful diabetic neuropathy, the most common treatment-emergent adverse events were dizziness, somnolence and peripheral oedema [26].

In the USA, pregabalin has been designated as a Schedule V controlled substance because of its potential for abuse and dependence, although clinical evidence for such a potential is scarce and this is not a significant consideration when prescribing pregabalin for epilepsy.

Teratogenicity

No adequate information is available on the effects of pregabalin treatment during pregnancy in women with epilepsy. Pregabalin is not teratogenic in mice or rabbits, but teratogenicity was observed in rats at very high doses of 1250–2500 mg/kg, which are much higher than the upper end of the human recommended dose range (Pfizer, data on file).

Place in current therapy

The indications of pregabalin in epilepsy are currently limited to the add-on treatment of adults with drug-resistant partial seizures, with or without secondary generalization. Clinical trials evaluating pregabalin as monotherapy in adults with partial epilepsy, as well as adjunctive therapy trials in children with partial epilepsy, are under way. There is no experience of pregabalin in idiopathic generalized epilepsies, but the potential for seizure aggravation observed with gabapentin is most likely to apply to pregabalin. Thus, pregabalin should not be used in these conditions.

The responder rates observed for pregabalin in short-term randomized controlled trials compare favourably with those seen for other AEDs tested as add-on therapy in refractory populations [39,40]. In a systematic review of all randomized controlled trials performed in adult patients with drug-resistant partial epilepsy, pregabalin was ranked second in efficacy among the 10 most recently developed AEDs [40]. After excluding ineffective dosages from the analysis, pregabalin was associated with the highest relative risk for responder rates, being followed in decreasing order of response by levetiracetam, topiramate, oxcarbazepine, tiagabine, zonisamide, vigabatrin, gabapentin and lamotrigine [40]. However, the confidence intervals of relative risk for all AEDs overlapped, indicating lack of significant differences between the majority of drugs. This is more likely to reflect lack of power of the available data rather than true equivalence between AEDs.

According to its efficacy profile, pregabalin is an appropriate option in the majority of patients with drug-resistant partial epilepsy, including possible use as a first-line add-on therapy. Prior failure to respond to gabapentin does not seem to decrease the chance of responding to pregabalin. There is also no indication of a synergistic action between pregabalin and any other AED that would favour its prescription over that of another drug, as a function of the baseline antiepileptic treatment.

Conversely, the patient's co-morbidities and prior drug-related adverse events may influence the decision on whether pregabalin should be prescribed. In particular, pregabalin is probably not a preferred choice in overweight patients, patients with a past history of AED-triggered weight gain or intolerance to gabapentin, and those with renal dysfunction. In contrast, pregabalin may be considered more appropriate for patients suffering from co-morbid generalized anxiety, insomnia or neuropathic pain. It must be stressed, however, that there is no firm demonstration of beneficial effects of pregabalin in treating such co-morbidities in the specific population of patients with epilepsy.

An effective starting dose for pregabalin is 150 mg/day, which can be given as two divided doses. In patients prone to develop AED-related CNS side-effects, a starting dose of 50 mg/day or 75 mg/day might also be considered, with a 2- to 4-week titration up to 150 mg/day. If needed for additional efficacy, higher doses of 300 mg/day, 450 mg/day, and 600 mg/day may be used, increasing dosage by maximal steps of 150 mg/day over a minimum period of 2 weeks.

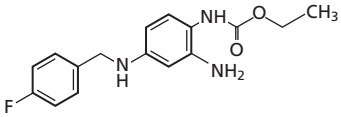
50 Retigabine

Harry Mansbach[1] *and Michel Baulac*[2]

[1] Valeant Pharmaceuticals International, Aliso Viejo, CA, USA
[2] Hopital de la Pitie-Salpetriere, Paris, France



Primary indications	Adjunctive therapy of refractory partial-onset seizures
Usual preparation	Tablets: 50, 100, 200, 300 and 400 mg
Usual dosages	600–1200 mg/day. Treatment may be started with 300 mg/day and increased at weekly intervals by 150 mg/day up to the desired target dose
Dosing frequency	3 times/day
Significant drug interactions	Retigabine decreases serum lamotrigine levels by about 20%. One study suggested that carbamazepine and phenytoin may reduce serum retigabine levels by about 30%, but these interactions were not confirmed in a more comprehensive analysis based on population pharmacokinetics
Serum level monitoring	There is insufficient information on the value of monitoring serum retigabine levels
Reference range	Not clearly defined
Common/important adverse effects	Dizziness, somnolence, fatigue, confusion, dysarthria, ataxia, tremor, blurred vision, nausea, urinary hesitancy/retention
Main advantages	Clearly defined dose-related efficacy in controlled studies, low interaction potential and unique mode of action
Main disadvantages	Need for gradual titration and for three times daily dosing, central nervous system adverse effects and limited clinical experience
Mechanism of action	Activation of voltage-gated neuronal potassium [KCNQ (Kv7)] channels, resulting in enhanced M-current, and thereby stabilization of resting membrane potentials
Oral bioavailability	About 60%
Time to peak levels	0.6–1.5 h
Elimination	Partly by excretion in unchanged form (20–30% of administered dose) and partly by metabolism (50–65% of the dose), including *N*-acetylation and glucuronide conjugation
Volume of distribution	2–3 L/kg (at steady state, as determined with intravenous dosing)
Elimination of half-life	8–10 h
Plasma clearance (CL/*F*)	0.5–0.7 L/h/kg
Protein binding	About 80%
Active metabolites	*N*-acetyl-retigabine (weakly active)
Comment	A potentially valuable drug for the adjunctive treatment of refractory partial-onset seizures. Studies are required to assess potential efficacy in other seizure types

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Retigabine is a novel antiepileptic drug (AED) which exhibits unique pharmacological features in that its primary mode of action involves direct activation of the voltage-gated potassium [KCNQ (Kv7)] channels that conduct the M-current, a critical regulator of neuronal excitability. Double-blind, placebo-controlled studies have demonstrated its efficacy as adjunctive therapy in adults with refractory partial-onset seizures. Retigabine is currently in phase III clinical development.

Chemistry

Retigabine corresponds chemically to *N*-[2-amino-4-(4-fluorobenzylamino)-phenyl] carbamic acid ethyl ester and it is structurally related to the centrally acting analgesic flupirtine. It is a white to slightly coloured substance with a molecular weight of 303.3 and a pK_a of 3.7 (calculated as free base), poorly soluble in water and soluble in organic solvents.

Pharmacology

Activity in experimental models of seizures and epilepsy

Retigabine exhibits antiseizure effects in an array of *in vivo* seizure/epilepsy models. Rats and mice given retigabine were protected from acute seizures induced by maximal electroshock (MES), low-intensity corneal stimulation (6 Hz; 22, 32 and 44 mA), subcutaneous pentylenetetrazole or picrotoxin, and intracerebroventricular *N*-methyl-D-aspartate (NMDA) [1]. Audiogenic seizures in mice (Frings and DBA/2) and rats (GEPR-3 and -9) were blocked by retigabine [1–3]. In fully kindled rats, retigabine given intraperitoneally (i.p.) raised the afterdischarge threshold (0.01 mg/kg) and reduced behavioural seizure severity (2.5 mg/kg), seizure duration (5 mg/kg) and afterdischarge duration (5 mg/kg) [4]. Effective anticonvulsant doses were widely separated from neurotoxic doses (protective index, 13–14 in the MES threshold test) [1]. The antiseizure effects of retigabine were dose-dependently attenuated by the neuronal KCNQ antagonist XE-991 in the MES model, supporting *in vitro* electrophysiological evidence that activation of neuronal KCNQ M-current is critical to the anticonvulsant activity of retigabine.

Retigabine is active in several models in which seizures do not respond to other AEDs. Specifically, retigabine (20–30 mg/kg i.p.) suppresses seizures in the 6-Hz psychomotor mouse stimulated at either 32 mA or 44 mA [1], although these seizures are resistant to non-toxic doses of lamotrigine, topiramate and carbamazepine (32 and 44 mA), as well as phenytoin, tiagabine and felbamate (44 mA) [5]. In the amygdala-kindling model, the presence of sodium channel blockers carbamazepine [6] or lamotrigine [7] during kindling stimulations rendered post-kindling seizures resistant to carbamazepine, lamotrigine and other AEDs such as phenytoin and topiramate [8]. However, retigabine (20 mg/kg i.p.) was effective against pharmacoresistant post-kindling seizures when lamotrigine was administered during amygdala kindling in rats [9]. The activity of retigabine in models resistant to other AEDs is consistent with retigabine acting at a novel and distinct molecular target.

The amygdala-kindling model has been used to distinguish anticonvulsant activity of AEDs from potential antiepileptogenic effects. Retigabine was not only effective against post-kindling seizures [4], but in several studies it was also found to interfere with kindling-induced increases in seizure susceptibility. When administered before amygdala-kindling stimulations, retigabine (5 mg/kg/day i.p.) retarded kindling acquisition in adult rats [10]. In developing animals, retigabine (2.5 or 5 mg/kg) treatment during the kindling procedure inhibited kindling acquisition in an age-dependent manner [11]. Effects on seizure susceptibility were most prominent at an age corresponding to post-neonatal development in humans, and were also observed at an age corresponding to early childhood but not in more mature ('adolescent') animals.

Activity in experimental models relevant for non-epilepsy indications

Loss-of-function mutations in *KCNQ2/3* genes are associated not only with seizure disorders (benign neonatal familial convulsions) but also with peripheral nerve hyperexcitability (neuromyotonia, neuromyokymia) [12,13]. These channelopathies and the distribution of KCNQ/M-current channels in areas prominently involved in pain signalling (dorsal horn, dorsal root ganglia, afferent peripheral nerves), mood regulation (amygdala) and movement (striatum) underscore the spectrum of disorders beyond epilepsy that may be amenable to treatment with neuronal KCNQ channel openers such as retigabine [14–16].

Although retigabine, an analogue of the analgesic flupirtine, had no consistent effects in acute pain models, it was broadly active in chronic and neuropathic pain models, including capsaicin-induced visceral pain in mice [17], acid-induced muscle allodynia in rats [18], mechanical allodynia and thermal hyperalgesia in nerve-ligated rats [15,19], and pinprick hypersensitivity in the chronic constriction injury and spared-nerve models in rats [20]. The effective doses of retigabine in pain are similar to those in seizure models, ranging from 5 to 20 mg/kg orally (rats) and up to 10 mg/kg i.p. (rats and mice). The M-channel blockers linopirdine and XE-991 reversed the effects of retigabine on chronic/neuropathic pain [15,19,21].

As with various other AEDs, potential therapeutic uses of retigabine may extend to psychiatric and neuromuscular disorders. Unconditioned anxiety in the marble-burying and elevated zero maze tests showed dose-dependent anxiolytic properties of retigabine (3–10 mg/kg i.p.) in mice [22]. Retigabine (1–4 mg/kg i.p.) also dose-dependently attenuated hyperactivity in the amphetamine and chlordiazepoxide rat model of mania [23]. When administered to rats in combination with addictive psychostimulants, retigabine (1–10 mg/kg i.p.) blocked hyperlocomotion and neuronal activation in key dopaminergic systems, suggesting that it may interfere with the reinforcing effects of these drugs and be possibly useful in counteracting addiction [24]. In rodent models of primary paroxysmal dystonia and levodopa-induced dyskinesia after striatal dopamine depletion, retigabine and flupirtine dose-dependently reduced dystonia and dyskinesia, effects that were blocked by XE-991 [25,26].

Mechanisms of action

Early investigations showed that retigabine activated a voltage-sensitive, neuronal-specific outward potassium current that was later identified as the M-current that is mediated by KCNQ (Kv7) channels [27,28]. The M-current is characterized by slow activation at low thresholds (–40 to 50 mV), slow deactivation and lack of inactivation [29]. Upon activation by excitatory input, the M-current opposes subsequent depolarizing inputs, precluding escalation of a single spike to a sustained burst discharge [30,31]. The importance of the M-current in regulating neuronal excitability is underscored by the proconvulsant effects of the M-current blocker linopirdine [32] and the association between benign familial neonatal convulsions and loss-of-function mutations in *KCNQ2* and *KCNQ3* genes [33].

The M-current and KCNQ2, KCNQ3, KCNQ4 and KCNQ5 potassium channel subunits are found throughout the nervous system, and they are enriched in areas associated with oscillation and synchronization [34]. KCNQ channel subunits comprise six transmembrane domains and a large intracellular C-terminus (Fig. 50.1) [35]. An association domain in the C-terminus directs four subunits to co-assemble, forming a pore lined by the fifth and sixth transmembrane segments of each subunit. Functional channels can be formed by homomeric KCNQ2, KCNQ4 and KCNQ5, although they preferentially form higher-conducting heteromers in the presence of KCNQ3 [27,29,36]. The classical M-current in sympathetic neurones most closely resembles the current through heteromers of KCNQ2 and KCNQ3 subunits (KCNQ2/3) [29], while the M-currents in sensory outer hair cells of the cochlea [37] and in axons of large myelinated fibres of the sciatic nerve [38] are apparently carried by homomers of KCNQ4 and KCNQ2, respectively. Subunits KCNQ2, KCNQ3 and sometimes KCNQ5 are co-localized in many areas of the central nervous system (CNS) [16,36]. The precise nature of M-currents in many neuronal populations has yet to be elucidated.

In the presence of retigabine, the M-current activates at a lower threshold, closer to the resting membrane potential, and its amplitude is augmented at negative potentials [27,28,39]. Retigabine enhances the M-current by increasing the channel open probability, accelerating activation and slowing deactivation, without altering single-channel conductance or channel density [40,41]. A putative high-affinity binding site has been identified in the ion pore region that requires at least a tryptophan on the fifth transmembrane segment and a glycine on the sixth transmembrane segment [42,43]. Binding of retigabine to this site appears to alter the channel gating mechanism, lowering the energy required for channel opening (Fig. 50.2).

Enhancement of the M-current by retigabine is voltage and concentration dependent and specific for subunits KCNQ2–5 [40,44]. At concentrations as low as 0.1 μmol/L, retigabine shifts the voltage-dependent activity of KCNQ2–5 channels expressed in cultured cells to more negative potentials; maximal enhancement is achieved with 10 μmol/L retigabine [41]. In contrast, retigabine is a weak inhibitor (IC_{50} = 100 μmol/L) of the predominantly cardiac KCNQ1 channels. Homomeric KCNQ3 channels, although weakly expressed on the cell surface and probably not responsible for endogenous M-current, show the greatest responsiveness to retigabine (EC_{50} = 0.9 μmol/L), followed by KCNQ2/3 (EC_{50} = 1.9 μmol/L) and KCNQ2 (EC_{50} = 2.5 μmol/L) [40]. Retigabine has comparable potency at KCNQ3/5 heteromers, but has less pronounced effects on KCNQ4 [40,44]. Consistent with the potency of retigabine in exogenously expressed KCNQ channels, 0.1–10 μmol/L retigabine activates endogenous M-currents, as

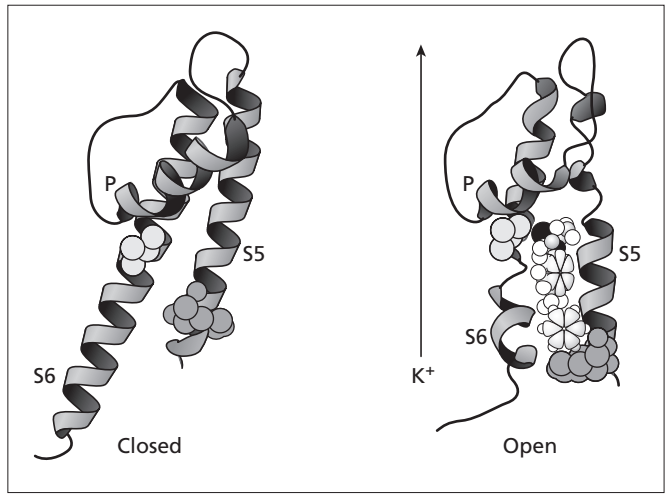


Fig. 50.2 Ribbon schematic of KCNQ2 channel subunit fifth (S5) and sixth (S6) transmembrane domains and P-loop (P), comprising the selectivity filter, pore and gate. Retigabine binds near the gate, favouring channel opening and the outward flow of potassium ions. Adapted from ref. 42.

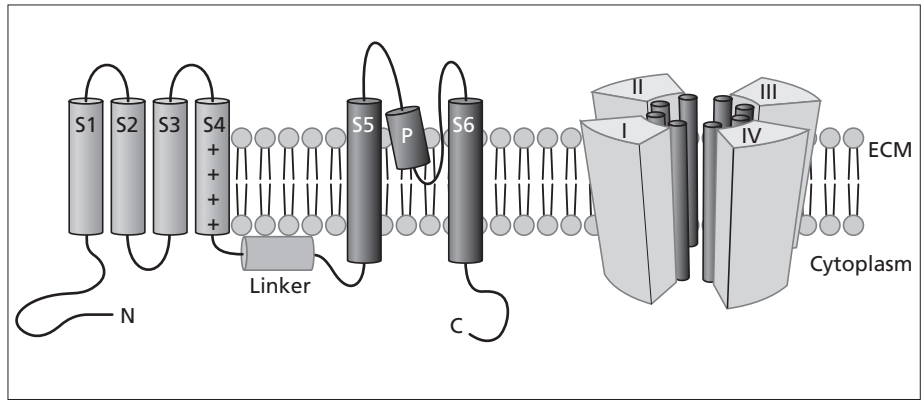

Fig. 50.1 Schematic illustration of a KCNQ2–5 channel subunit (left) comprising six transmembrane domains (S1–6), a P-loop (P), and intracellular termini. S4 detects voltage, S5–P–S6 line the pore. Functional channels are formed by the interaction of four subunits (right). Adapted from ref. 35.

demonstrated in neurones dissociated from sympathetic ganglia [45] and hippocampus [46], dopaminergic neurones in midbrain slices [47], and CA1 pyramidal neurones in hippocampal slices [31,48,49]. Importantly, initial firing of action potentials is not affected by retigabine in these neurones, but subsequent bursting is strongly attenuated (Fig. 50.3). Thus, epileptiform activity induced by electrical stimulation [50] or various bath manipulations (4-aminopyridine [51,52], low Ca^{2+} [19], or low Mg^{2+} [53,54]) in brain slices is suppressed in the presence of 1–100 μmol/L retigabine.

The dampening of neuronal hyperexcitability by retigabine is reversed by antibodies against KCNQ2 channels [55], and by the direct M-current antagonists linopirdine and/or XE-991 [47,48,56,57], arguing for a primary role of M-current enhancement in the pharmacological activity of retigabine.

No retigabine binding interactions were observed in a broad panel screen of known modulator sites on neural receptors, enzymes or second-messenger systems [2]. At concentrations up to 100 μmol/L, retigabine did not interact with the benzodiazepine and GABA binding sites on the $GABA_A$ receptor, or the glutamate, glycine and ion channel binding sites of the NMDA receptor complex. Likewise, currents through NMDA, AMPA or kainate glutamate receptors are not directly affected by retigabine. Early suggestions that retigabine could alter the synthesis of excitatory amino acids [58] or GABA [59] have not been substantiated [34]. At concentrations (≥10 μmol/L) exceeding those achieved with therapeutic dosages (2–6 μmol/L with 600–1200 mg/day), retigabine potentiated GABA-evoked chloride currents at a non-benzodiazepine site in cultured neocortical neurones [60] and isolated $GABA_A$ receptor complexes [61]. However, a GABAergic effect was lacking in limbic slices [50] or isolated $GABA_A$ receptors from hippocampal pyramidal neurones [62], obscuring the contribution of GABA to the seizure-suppressing action of retigabine.

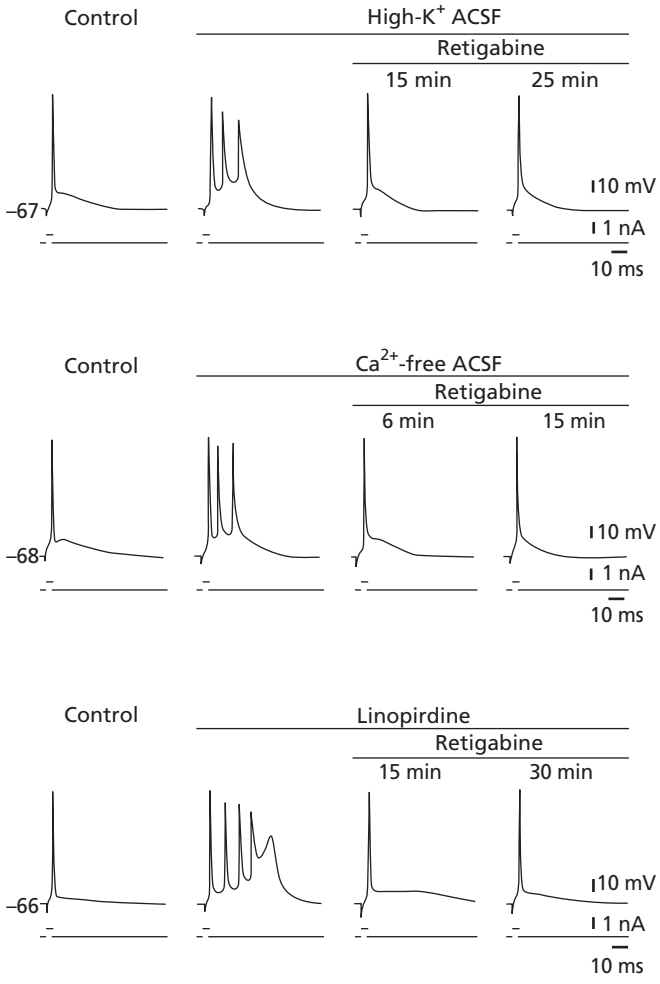

Fig. 50.3 Under excitatory bath conditions, CA1 neurones in hippocampal slices respond to stimulation with bursts of action potentials. Treatment with 10 μmol/L retigabine blocks bursting without affecting the initial spike. Adapted from ref. 31.

Toxicology data

In general, the across-species acute toxicity of retigabine was limited to CNS effects, such as hyperkinesia, hypokinesia, disturbed coordination, stilted gait, tremor and convulsions [2]. In repeated-dose studies in rodents and, to a lesser extent, in dogs, retigabine administration was associated with bladder and minor renal changes. These may have reflected inhibition of bladder contractility and urinary retention secondary to the effects of retigabine on KCNQ channels in the muscle of the bladder [63]. Retigabine did not prolong QTc interval in isolated guinea pig hearts and had no effect on ECG parameters monitored continuously in dogs receiving oral doses of up to 38 mg/kg for 7 days.

No retigabine-related effects on reproductive function were observed in male or female rats [2]. No teratogenic effects of retigabine were detected in rats and rabbits at a dose of 60.0 mg/kg orally. Perinatal/postnatal administration of retigabine to mated female rats was not associated with developmental toxicity in offspring except delayed growth at the highest dose level (61.9 mg/kg orally). Evaluation of retigabine safety in juvenile rats is ongoing. Retigabine is not mutagenic or carcinogenic [2].

Pharmacokinetics

Absorption

Retigabine is rapidly absorbed from the gastrointestinal tract, with peak serum concentrations (C_{max}) achieved within 0.6–1.5 h following single (25–600 mg) or multiple doses (100–300 mg twice daily) in healthy volunteers [64]. A similar profile is observed at steady state in patients with epilepsy receiving 100–1200 mg/day (twice or three times daily administration), with exposure (area under the plasma concentration–time curve) increasing in proportion to retigabine dose. Over the therapeutic dosage range of 600–1200 mg/day, the average retigabine concentration with three times daily administration is 0.6–1.2 μg/mL, fluctuating from a peak (C_{max}) of 0.8–2.0 μg/mL to trough concentrations of 0.5–1.0 μg/mL.

The bioavailability (F) of orally administered retigabine is about 60% compared with an intravenous dose, primarily due to first-pass metabolism [2]. When retigabine is taken with a high-fat

meal, C_{max} is modestly increased compared with administration in the fasted state, but exposure is not changed, demonstrating that retigabine can be taken without regard to food [2].

Distribution

The volume of distribution at steady state of retigabine, calculated after intravenous dosing, is about 2–3 L/kg.

The binding of retigabine to plasma proteins is about 80%. Plasma protein binding is reversible and independent of plasma concentration (0.1–2.0 μg/mL).

Metabolism and elimination

Retigabine is cleared partly by renal excretion in unchanged form and partly by metabolic elimination. About 20–30% of an orally administered radiolabelled dose is recovered in the urine as unchanged parent drug, and another 50–65% as metabolites.

Retigabine does not appear to be a substrate of oxidative cytochrome P450 (CYP) isozymes. Metabolism is almost exclusively by hydrolysis/*N*-acetylation and glucuronidation [65]. A major metabolite in humans is an *N*-acetyl derivative that has weak pharmacological effects and inconsistent antiseizure activity in preclinical models. Uridine diphosphate glucuronosyltransferase isozymes (UGT1A1, A3, A4, A9) metabolize retigabine and the *N*-acetyl metabolite by glucuronidation at the *N*2 and *N*4 amino groups [66,67].

The half-life of retigabine and its *N*-acetyl metabolite is about 8–10 h on average [64]. The apparent oral clearance (CL/*F*) is in the order of 0.5–0.7 L/h/kg. Retigabine does not induce or inhibit its own metabolism and pharmacokinetic profiles after multiple dose (15 days) can be predicted from single-dose pharmacokinetics.

Pharmacokinetics in special populations

Several *in vitro* and *in vivo* studies have examined the effects of impaired glucuronidation and/or impaired acetylation on retigabine metabolism. Preparations of kidney microsomes, which lack UGT1A1, and hepatic microsomes with a loss-of-function mutation in the *UGT1A* gene (sampled from individuals with Crigler–Najjar type II syndrome) still produced glucuronide conjugates of retigabine [66]. In individuals with genetic polymorphisms in drug-metabolizing enzymes, the pharmacokinetics of retigabine was not altered by polymorphisms that impair UGT1A1 glucuronidation (Gilbert's syndrome) or result in slow acetylation by *N*-acetyltransferase 2 (NAT2) [68]. Taken together, these studies suggest the existence of alternative routes of retigabine metabolism and glucuronidation that may involve other UGT1 or UGT2 isozymes, as well as extrahepatic metabolism. Dose adjustments are not required in individuals who are slow acetylators or have glucuronidation polymorphisms.

A study in healthy young volunteers (18–40 years) and older subjects (66–81 years) evaluated the effect of old age and gender on the pharmacokinetics of retigabine administered as a single 200-mg dose [69]. Weight-normalized clearance did not differ according to gender. However, retigabine was eliminated more slowly in older than in younger subjects, resulting in 42% higher mean exposure and 30% longer half-life. Based on a pharmacokinetic study showing that retigabine clearance and exposure are influenced by renal impairment, age-related differences in clearance are likely to reflect at least in part age-related differences in renal function.

Relative to healthy individuals, retigabine exposure increased by about 30% in patients with mild renal impairment (creatinine clearance, 50–80 mL/min) and by about 100% in patients with moderate (30 to < 50 mL/min) to severe (<30 mL/min) renal impairment or end-stage renal disease requiring dialysis [2].

Retigabine exposure is also increased in individuals with moderate (Child–Pugh score, 7–9) or severe (Child–Pugh score >9) hepatic impairment. Whereas mild hepatic impairment did not alter the pharmacokinetics of a single 100-mg dose of retigabine, moderate and severe hepatic impairment resulted in 50% and 100% higher exposure, respectively [2].

Population pharmacokinetic analysis of data from healthy volunteers and patients with epilepsy identified body surface area, age and creatinine clearance as co-variates having meaningful effects on retigabine pharmacokinetics.

Drug interactions

Effect of other drugs on retigabine pharmacokinetics

Studies *in vitro*

In human liver microsomal assays, neither lamotrigine nor imipramine affected retigabine glucuronidation by human liver microsomes, even at very high concentrations [66]. Because valproic acid inhibited retigabine glucuronidation with K_i values of ≥3.5 mmol/L, which are five or more times the therapeutic concentrations of valproic acid, a clinically relevant effect of valproic acid on retigabine pharmacokinetics was considered unlikely.

Studies *in vivo*

In healthy volunteers (n = 15), phenobarbital (90 mg/day for 28 days) did not alter the pharmacokinetics of retigabine (200 mg three times a day) [70] even though phenobarbital induces UGT1A1 and increases the clearance of other AEDs metabolized by *N*′-glucuronidation, such as lamotrigine.

In a separate study in healthy volunteers (n = 14), administration of a very low dose of lamotrigine (25 mg/day for 6 days) did not affect the pharmacokinetics of a single 200-mg dose of retigabine [71].

In a study designed to evaluate pharmacokinetics of retigabine as adjunctive therapy and as monotherapy in patients with epilepsy, retigabine clearance (CL/*F*) was increased by 36% and 27%, respectively, in patients co-medicated with the enzyme-inducing AEDs phenytoin (n = 9) and carbamazepine (n = 8). Neither valproic acid (n = 4) nor topiramate (n = 5) significantly altered retigabine pharmacokinetics. In contrast, population pharmacokinetic analysis of data from all clinical studies involving more than 800 patients did not identify any effect of enzyme-inducing AEDs or clinically meaningful effects of non-enzyme-inducing AEDs on retigabine pharmacokinetics.

Effect of retigabine on pharmacokinetics of other drugs

Studies *in vitro*

In human liver microsome preparations, retigabine had only a modest potential to inhibit the CYP isozyme CYP2A6 (IC_{50} = 7.6 μg/mL), and low or no potential to inhibit other tested CYP isoforms (CYP1A2, CYP2C8, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4/5, CYP4A9/11; IC_{50} > 33 μg/mL) at concentrations expected to reflect C_{max} in patients receiving therapeutic doses (up to 2.0 μg/mL). Based on these findings, it was considered unlikely that retigabine can alter the pharmacokinetics of drugs that are metabolized by CYP isozymes.

Studies *in vivo*

In a study conducted in 15 healthy volunteers, treatment with retigabine at a dosage of 600 mg/day for 15 days was associated with a mean 22% increase in the clearance (CL/*F*) of a single 200-mg dose of lamotrigine [71].

In phase III studies, retigabine co-administration was not associated with clinically meaningful changes in the trough concentrations of concomitant AEDs, with the exception of a 20% reduction in trough lamotrigine concentrations, as in the study conducted in healthy subjects. Because of its modest magnitude, the interaction of retigabine with lamotrigine is unlikely to be clinically significant in the majority of patients.

The potential for an interaction between retigabine (750 mg/day for 19 days after a 9-day titration period) and an oral contraceptive preparation (0.035 mg ethinylestradiol + 1 mg norethindrone) has been evaluated in healthy female volunteers. No change in ethinylestradiol exposure was observed, whereas norethindrone exposure was increased by 28%. These findings suggest no potential for reduced contraceptive efficacy when retigabine is added on to oral contraceptive hormones. Although the study was not designed to assess the effect of oral contraceptives on retigabine, retigabine exposure was similar to that in other studies, suggesting that contraceptive hormones do not markedly alter retigabine pharmacokinetics.

Serum level monitoring

There is insufficient information on the value of monitoring serum retigabine levels, and there is no indication that monitoring serum retigabine concentrations may help in individualizing therapy, except for compliance assessment.

Efficacy

Studies in patients with epilepsy

In initial exploratory, open-label studies, adjunctive therapy with retigabine (300–1200 mg/day) in patients with inadequately controlled seizures was associated with a median reduction in seizure frequency by approximately 40%. These early clinical observations have been confirmed in a series of randomized double-blind, placebo-controlled trials and long-term open-label extension studies in adults with partial-onset seizures.

The first such study was a dose-ranging trial (Study 205 [72]) evaluating 600, 900 and 1200 mg/day retigabine administered three times a day versus placebo as adjunctive therapy. The intent-to-treat (ITT) study population comprised 396 adults of 16–70 years of age with a baseline monthly seizure frequency of four or more partial-onset seizures, with or without secondary generalization, despite stable therapy with one or two AEDs. After an 8-week prospective observation to document baseline seizure frequency, patients were randomized to placebo or 600, 900 or 1200 mg/day retigabine for the 16-week double-blind treatment period. The starting dose was 300 mg/day (100 mg three times a day), and titration proceeded with weekly dose increments of 150 mg/day (50 mg three times a day) over 6 weeks to the assigned target dosage. Only two 100-mg dose decrements were allowed during weeks 7 and 8; minimum dosages during the 8-week maintenance phase were 400, 700 and 1000 mg/day.

Patients in Study 205 were on average 35–38 years of age, their mean duration of epilepsy was approximately 20 years, and their median baseline seizure frequency was 8 to 10 seizures per month. In the majority (70%) of patients, retigabine was added to two other AEDs. Median seizure frequency was reduced by 23%, 29% and 35% from baseline in the groups assigned to 600, 900 and 1200 mg/day retigabine, respectively, compared with a 13% reduction in the placebo group ($P < 0.001$ for dose-dependent response across treatment arms). Responder rates (proportions of patients with ≥50% seizure reduction) were 16% with placebo and 23%, 32% and 33% with 600, 900 and 1200 mg/day retigabine, respectively (900 and 1200 mg/day versus placebo, $P < 0.05$). Of patients completing double-blind treatment, 80% (222/279) enrolled in a long-term open-label extension. During the blinded transition, patients in the placebo and 600-mg retigabine arms were up-titrated and those in the 1200-mg arm were down-titrated to a target dosage of 900 mg/day. Patients initially assigned to the 900-mg group remained at the dosage administered during the double-blind maintenance phase. During the long-term extension, dosages of retigabine and concomitant AEDs could be adjusted according to clinical need. Of those entering the open-label extension (mean duration of follow-up, 353 days), 26% discontinued due to inadequate seizure control and 9% discontinued due to adverse events [2]. The 1-year retention rate was 55%. At the end of open-label treatment, 78% were receiving ≤900 mg/day and the optimized dose was ≥1200 mg/day in only 10% of patients (maximum dosage, 1500 mg/day). During open-label treatment, seizure control improved in the groups initially assigned to the placebo or 600-mg retigabine arms and was maintained in those initially assigned to the 900- or 1200-mg retigabine arms. The overall responder rate was 46%. The 6-month and 12-month seizure-free rates were 9% and 6%, respectively. No additional AEDs were added in those who were seizure free.

The results of the dose-ranging trial have been validated by two separate double-blind, placebo-controlled adjunctive therapy studies that evaluated three retigabine dosages (1200 mg/day in RESTORE 1/Study 301; 600 or 900 mg/day in RESTORE 2/Study 302). In both studies, the starting dosage of 300 mg/day was increased weekly in 150 mg/day increments and the maintenance period was 12 weeks. Treatments were administered three times a day in both studies. Dosage reductions were not allowed

in Study 302. In Study 301, dosage could be reduced to 1050 mg/day at week 7 and continued for the remainder of the maintenance phase. Patients who could not achieve target dosages were withdrawn. Patients were adults (18–75 years of age) with documented refractory partial-onset seizures, refractoriness being defined as ≥2 years since epilepsy diagnosis and past failure of two or more approved AEDs, alone or together, in adequate doses for a sufficient period of time to evaluate clinical response. Patients were required to have four or more seizures per month during the 8-week prospective baseline.

Patient characteristics at baseline were very similar across the two studies. Patients had been diagnosed with epilepsy 22–24 years before study entry, had failed three to four (median) AEDs in the 3 years prior to study entry, and were having 11 to 12 (median) seizures per month. More than 75% of patients were receiving two or three AEDs. Mean age was 37–38 years and 52–54% were female. The ITT populations comprised 538 patients in RESTORE 2/Study 302 (placebo, $n = 179$; 600 mg, $n = 181$; 900 mg, $n = 178$) and 305 patients in RESTORE 1/Study 301 (placebo, $n = 152$; 1200 mg, $n = 153$). During double-blind treatment, retigabine at all three doses significantly reduced median seizure frequency compared with placebo (Table 50.1). Efficacy was clearly dose related in terms of both seizure frequency reduction and responder rate, as well as in the proportion of patients seizure free once the target doses were achieved. In patients completing titration, 3% (5/158) in the 600-mg group, 5% (7/149) in the 900-mg group, and 8% (9/119) in the 1200-mg group were seizure free during the 12-week maintenance period, compared with 1% (4/301) in the placebo group. Improved seizure control favouring retigabine over placebo emerged within the first 2 weeks of titration, and within 3 weeks of initiating retigabine therapy, the difference was statistically significant ($P = 0.002$).

Patients completing double-blind treatment in Studies 301 and 302 were eligible for continued retigabine treatment in open-label extensions, which are ongoing. Interim analysis suggests that efficacy is being maintained at the levels achieved during the maintenance phase of the initial double-blind studies.

Table 50.1 Efficacy results from phase III double-blind placebo-controlled adjunctive therapy trials of 600, 900 and 1200 mg/day retigabine in patients with refractory partial-onset seizures. Results refer to ITT analysis from ref. 2.

Studies in patients with other disorders

To date, retigabine has been evaluated clinically in two disorders other than epilepsy. One pilot open-label study ($n = 10$) reported positive effects of retigabine monotherapy (600–1200 mg/day) in some patients with prolonged mania who had not responded to antipsychotic or mood-stabilizing drugs [73]. In addition, a double-blind, placebo-controlled proof-of-concept study has been initiated in patients with postherpetic neuralgia.

Adverse effects

Consistent with AEDs as a class, the most common adverse events associated with retigabine are non-specific CNS effects such as dizziness, somnolence and fatigue (Table 50.2), which are usually mild to moderate in nature. The temporal pattern of these events suggests that peak-dose effects may contribute to the tolerability profile. Among non-CNS events, a small increased incidence of bladder-related adverse events (e.g. urinary hesitancy) relative to placebo was observed with retigabine. Significant urinary retention was observed rarely and occurred at similar frequencies in the retigabine and placebo groups. Bladder ultrasound revealed a small increase in mean post-void residual volume at the 1200-mg dose but not at lower doses, a finding that is of uncertain clinical significance. Other clinical and laboratory monitoring, including ECG, urinalysis and vital signs, showed no clinically significant changes related to retigabine administration during double-blind, placebo-controlled trials or long-term, open-label treatment, with the exception of occasional transient transaminase elevations and modest, dose-related weight gain that generally reached a plateau during open-label treatment [2].

Based on double-blind, placebo-controlled trials, which featured forced titration and very little dosing flexibility to reduce

Table 50.2 Most common (>10% in any treatment group) adverse events (%) recorded in phase III double-blind placebo-controlled adjunctive therapy trials of 600, 900 and 1200 mg/day retigabine in patients with refractory partial-onset seizures.

	Placebo ($n = 331$)	Retigabine (mg/day)		
		600 ($n = 181$)	900 ($n = 178$)	1200 ($n = 153$)
Dizziness	9	17	26	40
Somnolence	13	14	26	31
Fatigue	5	17	15	16
Confusion	1	2	5	14
Dysarthria	1	5	2	12
Headache	16	11	17	12
Ataxia/gait disturbance	4	3	5	12
Urinary tract infection	5	1	2	12
Tremor	3	2	8	11
Vision blurred	2	1	5	11
Nausea	5	6	7	11

From ref. 2 with permission.

common treatment-emergent adverse events, the tolerability of retigabine is primarily dose related and influenced by titration or dose management. In phase III trials, discontinuation rates due to adverse events were 14% at 600 mg/day, 26% at 900 mg/day, and 27% at 1200 mg/day, compared with 8% among patients assigned to placebo. More than two-thirds of discontinuations occurred during forced titration. The most common adverse events associated with retigabine discontinuation were dizziness (6%), fatigue (4%), somnolence (4%) and confusion (3%).

Therapeutic potential

Clinical studies have documented the efficacy of retigabine as adjunctive therapy in adults with refractory partial-onset seizures. Because retigabine is unique among AEDs in targeting M-current KCNQ channels and thereby dampening neuronal excitability, its therapeutic potential may extend more broadly to use in relatively early stages of the medical management of localization-related epilepsies, for example when sodium channel blockers (such as carbamazepine) have failed. Although the possibility exists that retigabine may also be of value in the treatment of generalized epilepsies, and preclinical data suggest a potential for efficacy in non-epilepsy disorders such as pain and mood disorders, such therapeutic uses have not yet been validated in controlled clinical studies.

Double-blind, placebo-controlled studies as well as open-label, long-term studies suggest that the optimal dosage for many patients will be 600–900 mg/day. Based on open-label studies when dosages of retigabine could be adjusted according to clinical response, perhaps 20% of patients will require dosages up to 1200 mg/day. Due to reduction in retigabine clearance in individuals with renal impairment or moderate to severe hepatic impairment, clinicians should be cautious with dose escalation and target doses in these patients.

The tolerability of retigabine is influenced by titration rate and by dose frequency. Dose management techniques applied to other AEDs may be useful in the management of patients receiving retigabine. In particular, retigabine should be initiated gradually, for example with a starting dose of 300 mg/day, which can be increased weekly in 150-mg increments. In clinical trials, retigabine was administered in three divided doses to help reduce peak-dose effects (e.g. dizziness) similar to those seen with immediate-release formulations of other AEDs with relatively short half-lives.

Because retigabine is associated with a relatively low potential for pharmacokinetic interactions with other commonly administered drugs, dosage adjustments of other AEDs are not required when retigabine is added, although clinicians should be aware that lamotrigine levels may decrease by about 20% on average. However, increasing the number of AEDs in a therapeutic regimen increases the potential for pharmacodynamic interactions that may adversely affect tolerability. If adverse effects emerge with the addition of retigabine, consideration should be given to reducing the dosages of concomitant AEDs.

Safety of retigabine during pregnancy or lactation in humans has not been established. As with all AEDs, retigabine should be used during pregnancy or by nursing women only if the potential benefit outweighs the potential risk for the fetus or the infant. Retigabine does not alter the pharmacokinetics of contraceptive hormones.

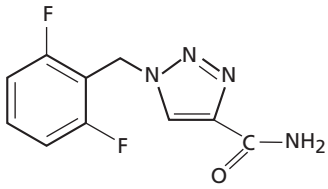
51 Rufinamide

Victor Biton
Arkansas Epilepsy Program, Little Rock, AR, USA



Primary indications	Adjunctive therapy of Lennox–Gastaut syndrome (>4 years of age) and partial-onset seizures
Usual preparation	Tablets: 100, 200 and 400 mg
Usual dosages	Patients weighing <30 kg: 200–1000 mg/day (200–600 with valproic acid co-medication); 400–1800 mg/day, 400–2400 mg/day and 400–3200 mg/day for patients weighing 30–50 kg, >50–70 kg and >70 kg, respectively. Higher doses have been used, up to 4800 mg/day
Dosing frequency	Twice daily
Significant drug interactions	Phenobarbital, carbamazepine, phenytoin, primidone and vigabatrin may cause a slight to moderate decrease in serum rufinamide levels. Valproic acid increases serum rufinamide levels. Rufinamide may slightly decrease the serum levels of carbamazepine and lamotrigine, and increase slightly those of phenytoin and phenobarbital. Rufinamide decreases the serum levels of oral contraceptive steroids and triazolam
Serum level monitoring	There is insufficient information on the value of monitoring serum rufinamide levels
Target range	Not clearly defined
Common/important side-effects	Dizziness, headache, nausea, somnolence, diplopia, blurred vision, fatigue and ataxia
Main advantages	Robust efficacy in the Lennox–Gastaut syndrome trial
Main disadvantages	Modest efficacy in partial-onset seizures
Mechanism of action	Limits excessive firing of sodium channel-dependent action potentials
Oral bioavailability	Up to 85% in the fed state, but decreases with increasing dosage within the clinically used dose range. Bioavailability increases by about 40% when the drug is taken with food
Time to peak levels	4–6 h
Elimination	Primarily by hydrolysis of the carboxamide group
Volume of distribution	0.8 L/kg at 3200 mg/day, assuming complete oral bioavailability. Increases with increasing dosage, because actual bioavailability decreases as dose is increased
Elimination of half-life	8–12 h (shorter in patients co-medicated with enzyme inducers)
Plasma clearance	About 90 mL/h/kg in adults, at a dosage of 45 mg/kg. Increases with increasing dosage, and is higher in children than in adults
Protein binding	30%
Active metabolites	None
Comment	A potentially valuable drug, but more data are needed to define its role in current therapy

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Rufinamide is a novel antiepileptic drug (AED) that is structurally unrelated to any currently marketed anticonvulsant. The European Medicines Agency (EMEA) approved the drug on 16 January 2008 for use as an adjunctive treatment for patients 4 years of age and older with Lennox–Gastaut syndrome. The trade name of rufinamide in Europe is Inovelon®.

In 2005, Eisai Company Ltd filed a new drug application with the USA Food and Drug Administration (FDA) seeking approval for rufinamide as an adjunctive therapy for focal epilepsy with and without secondary generalization in patients 12 years of age and older, and also as adjunctive treatment for seizures associated with Lennox–Gastaut syndrome in patients 4 years of age and older. Trade name rights have been reserved in the USA for the name 'Inavra'.

Development of rufinamide was started by Ciba-Geigy in Switzerland in the 1980s. The drug, then called CGP-33101, initially underwent preliminary assessment for anticonvulsant activity at the USA National Institute of Health (Rockville, MD) and at Ciba-Geigy. After Ciba-Geigy merged with Sandoz and changed its name to Novartis, global development of the compound, which was renamed RUF-331, continued. Phase II and III studies conducted in Japan, Switzerland, the USA and other countries were completed by 2001 [1,2]. In February 2004, Eisai Company Ltd acquired the rights to develop rufinamide for epilepsy from Novartis, and the drug is now being developed by Eisai under the name of E2080.

Efficacy studies of rufinamide in epilepsy have had mixed outcomes. Of two monotherapy trials in adults with partial-onset seizures, one was positive and the other did not meet the primary endpoint. In a trial in Lennox–Gastaut syndrome, a large effect size was demonstrated. In addition, there has been a negative trial in patients with primary generalized tonic–clonic seizures and another negative trial in the add-on setting in paediatric patients with partial-onset seizures. A pilot trial in patients with diabetic neuropathic pain was negative but demonstrated a small effect size. A large-scale study in patients with partial-onset seizures is currently ongoing.

Chemistry

Rufinamide, or 1-(2,6-difluorophenyl)methyl-1H-1,2,3-triazole-4-carboxamide, is a white, odourless and slightly bitter crystalline substance. Rufinamide has a low solubility in water and a limited solubility in 0.1 N hydrochloric acid (63 mg/L) and simulated intestinal fluid (59 mg/L). Rufinamide has a chemical formula of $C_{10}H_8F_2N_4O$, which corresponds to a molecular weight of 238.20. It is available as 100-, 200- and 400-mg film-coated tablets. The drug does not show any hygroscopicity; no water was absorbed by the drug when placed in an environment of up to 100% relative humidity. Its provisional shelf-life is 3 years and it requires storage below 30°C [3].

Pharmacology

Activity in experimental models of seizures and epilepsy

The activity profile of rufinamide in experimental models has been studied mainly through the National Institutes of Health (NIH) anticonvulsant drug development programme and at Novartis.

In the maximal electroshock test, which is known to identify AEDs with the potential to suppress generalized tonic–clonic seizures and, in part, partial seizures, rufinamide demonstrated protective activity in rats and mice with an ED_{50} of 6–24 mg/kg per os (orally, p.o.). Oral and intraperitoneal (i.p.) rufinamide potently suppressed maximal electroshock seizure (MES)-induced tonic–clonic seizures (with ED_{50} values of 23.9 and 15.5 mg/kg, respectively) and pentylenetetrazole (PTZ)-induced clonic seizures (with ED_{50} values of 45.8 and 54.0 mg/kg, respectively) in mice [1,3–6].

Repeated dosing for 5 days at a single dose of 6 mg/kg orally did not induce tolerance to the anticonvulsant effects of rufinamide. The anticonvulsant effect in the maximal electroshock test was maintained for 4 h in mice and 8 h in rats [7–9].

In the PTZ test in mice, which is considered a model of clonic seizures and may correlate with activity against absence seizures, rufinamide had an ED_{50} of 300 mg/kg (with a protection rate of 60%). In the subcutaneous PTZ test in mice, oral administration of rufinamide resulted in an ED_{50} of 458 mg/kg. When PTZ was given intraperitoneally, the ED_{50} of rufinamide was higher at 300 mg/kg p.o. indicating lower potency than in the maximal electroshock test [7,10]. Rufinamide was effective in blocking clonic seizures induced in mice by subcutaneous administration of the GABA antagonists bicuculline and picrotoxin, with ED_{50} values of 50.5 and 76.3 mg/kg p.o., respectively. Rufinamide, however, was hardly effective in the glycine inhibition seizures provoked by strychnine.

Rufinamide (at oral doses of 100–300 mg/kg) was effective in delaying the development of kindling and in suppressing afterdischarges in amygdala-kindled cats with generalized tonic–clonic convulsions [1,2,3,5,8,10]. It has also shown effectiveness in reducing seizure frequency in rhesus monkeys with chronic alumina foci in the motor cortex. Hippocampal and cortical afterdischarges induced by electrical stimulation in non-kindled cats are also inhibited by rufinamide.

In most animal models the therapeutic index of rufinamide was generally higher than that of other commonly used AEDs [8].

Mechanism of action

Although the precise mechanisms of action by rufinamide are incompletely known, based on *in vitro* studies the principal mechanism of rufinamide's antiepileptic activity appears to involve modulation of the activity of sodium channels, mainly via prolongation of the inactive state of the channel [1,6]. An additional potential mechanism is represented by inhibition of responses at the glutamate receptor subtype mguR5, which is observed at high concentrations (60% inhibition of quisqualate-induced phosphoinositol turnover at 100 μmol/L concentrations) [8].

The interaction of rufinamide with various neurotransmitters has been investigated. Rufinamide at 10–100 μmol/L had no effect on radioactive flunitrazepam and GABA receptor binding, nor on adenosine uptake. Rufinamide did not affect the receptor binding of any of the following ligands: prazosin (α_1-adrenergic), clonidine (α_2-adrenergic), dihydroalprenolol (β-adrenergic), 5HT (5HT-1), ketanserin (5HT-2), doxepin, cismethyl-dioxolane (cholinergic muscarinic agonist) and quinuclidinyl benzylate (cholinergic muscarinic antagonist). Rufinamide also did not interact with glutamate receptors including R1, R2, R4 and R5, NMDA,

strychnine-intensive glycine or AMPA/kainate receptors [1–3]. Rufinamide at levels of up to 100 μmol/L has been shown to have no effect on benzodiazepine or GABA receptors.

Pharmacokinetics

Absorption and bioavailability

Rufinamide is relatively slowly absorbed from the gastrointestinal tract with peak plasma concentrations being typically reached within 4–6 h (range 1.5–10 h) after a single dose, irrespective of the formulation used and irrespective of intake with or without food [11]. Many of the early studies used a formulation that had only 50% bioavailability of the currently used commercial formulation.

The absolute bioavailability of the commercial formulation is unknown. In an early study in three healthy adult male volunteers who received single oral doses of 600 mg of radiolabelled rufinamide in gelatin capsules with food, absorption was demonstrated to be at least 85% [12,13].

The absorption of rufinamide appears to be limited by its slow dissolution into gastrointestinal contents [11]. Probably because of this, the bioavailability of the drug is dose dependent and the fraction absorbed decreases with increasing doses, resulting in a non-linear relationship between steady-state plasma concentration and dosage [14,15]. In one study, the ratio between steady-state plasma rufinamide concentration and dose during treatment with a dose of 3600 mg twice daily was approximately one-half of that recorded at a dose of 400 mg twice daily [11].

Food also has a significant impact on rufinamide bioavailability [3,16,17]. In single-dose studies, the area under the rufinamide concentration–time curve (area under the curve, AUC) increased by about 30–40% when the drug was ingested with a high-fat meal compared with ingestion in a fasting state [11]. Although an influence of food on rufinamide bioavailability during multiple dosing has not been clearly established, it is recommended that rufinamide always be taken at meal times.

Distribution

The plasma protein binding of rufinamide is low, at about 26–34% [11]. The volume of distribution normalized to a bioavailability of 100% (V_d/F) is in the order of 0.8 L/kg at a dose of 3200 mg/day, but this value is likely to be an overestimate because bioavailability is probably incomplete at that dosage. As expected, larger V_d/F values have been measured in subjects receiving higher dosages, as a result of the dose-dependent decrease in bioavailability [11]. Rufinamide is evenly distributed between erythrocytes and plasma.

The transfer of rufinamide to the embryo was investigated in rats and rabbits after an administration of radioactive rufinamide. The concentrations in the embryo and the amniotic fluid were about a half of those in the maternal blood after 24 h. This transfer was reversible. In rats and rabbits, radioactivity was also identified in the mammary glands with concentrations similar to those in the blood and plasma, suggesting that rufinamide should be excreted with the milk.

Elimination and metabolism

The mean plasma elimination half-life of rufinamide ranges from 8 to 12 h, with an overall mean of about 10 h. Lower values (about 7 h on average) have been determined in patients with epilepsy [11], possibly as a result of induction of rufinamide metabolism by concomitant AEDs. Despite the relatively short half-life, fluctuations in serum rufinamide concentration during a 12-h dosing interval at steady state are relatively moderate, owing to the prolonged absorption phase of the compound.

In population pharmacokinetic modelling of a pooled database drawing from various studies, it was demonstrated that an important factor affecting rufinamide apparent oral clearance (CL/*F*) is body size. There was also a slightly lower clearance in females. This difference, which persisted after adjusting for body size, was not considered clinically significant [18].

In a study designed to evaluate the metabolism and disposition of rufinamide, three adult healthy male volunteers received single oral doses of 600 mg of ^{14}C-labelled microcrystalline rufinamide in gelatin capsules with food. Concentrations of radioactive rufinamide and its metabolites were measured in blood, plasma, urine and faeces. Absorption at this low dose was demonstrated to be at least 85%. The main radioactive compound in plasma was rufinamide. Excretion of drug-related material was largely renal (85%) and was complete (98%) within 7 days. Rufinamide was extensively metabolized, with only 4% recovered unchanged, in urine (2%) and in faeces (2%) [12]. The most prominent metabolite was the carboxylic acid derivative CGP 47292, which was inactive [13]. A few minor metabolites were detected in the urine that appeared to be acylglucuronides of CGP 47292. No other relevant metabolites were detected in the urine and faeces. These results show that biotransformation by hydrolysis is the main mechanism of elimination of rufinamide.

Studies *in vitro* with human liver microsomes provided no evidence for an involvement of cytochrome P450 (CYP) enzymes in rufinamide metabolism and confirmed that the main metabolic pathway is hydrolysis of the carboxamide group, mediated by carboxylesterases, to form CGP 47292 [11]. Carboxylesterases are known to be inducible by agents which induce CYP enzymes, an observation which explains the increase in rufinamide clearance caused by co-medications such as phenytoin and carbamazepine.

Pharmacokinetics in special populations

Children

Only limited data exist on the effect of young age on rufinamide pharmacokinetics. In studies conducted to date, dosage and co-medications varied among age groups and it has been difficult to differentiate the effects of age from those cause by dose-dependent bioavailability and drug–drug interactions.

Sachdeo *et al*. [14] conducted a study to obtain rufinamide safety and pharmacokinetic data in 16 children with epilepsy with an age range of 2–17 years [14,15]. Rufinamide was administered orally in equally divided twice-daily doses of 10 mg/kg/day (week 1) and 30 mg/kg/day (week 2), and at the end of each week blood samples were taken for pharmacokinetic profiling. The data showed a less than dose-proportional increase in serum rufinamide concentrations when the dose was increased from 10 mg/kg/day to 30 mg/kg/day, similar to the data obtained from studies in the adult population. Although no significant differences in pharmacokinetic parameters as a function of age were noted, the small size of the age subgroups makes the data difficult to interpret.

At present, the most informative assessment of the influence of paediatric age on rufinamide pharmacokinetics is provided by a population pharmacokinetic study conducted in patients included in clinical trials. This study suggested that rufinamide CL/*F* is higher in children than in adults receiving similar doses. For example, it was calculated that, at a rufinamide dosage of 45 mg/kg in the absence of interacting co-medications, rufinamide CL/*F* should be in the order of 0.14 L/h/kg in a 4-year-old child weighing 17 kg compared with 0.09 L/h/kg in a man weighing 80 kg.

The elderly

Chang *et al.* [19] evaluated the pharmacokinetics of rufinamide in seven elderly healthy subjects (age range 66–77 years) compared with seven younger gender-matched healthy subjects (age range 18–40 years). This was a single-dose (400 mg) and multiple-dose (400 mg given twice daily for nine doses) open-label parallel group study. The extent of absorption (AUC) and the absorption rates (peak serum concentrations) were similar between the elderly and the young volunteers under both single- and multiple-dose conditions. Elimination half-life values were also similar in the elderly subjects (for single dose 8.6 ± 1.3 h, for multiple dose 8.3 ± 1.1 h) and younger subjects (single dose 10.8 ± 3.2 h, multiple dose 10.2 ± 2.4 h), and were not altered after multiple-dose treatment [20]. Time-independent kinetics was observed in multiple-dose treatment for both the elderly subjects and the younger subjects, as shown by the fact that AUC values during a dosing interval at steady state were similar to $AUC_{0-\infty}$ values after a single dose. These results show that, within the age range explored, rufinamide pharmacokinetics is not altered in the elderly compared with non-elderly adults.

Impaired renal function

A study in patients with severe renal impairment (creatinine clearance of less than 30 mL/min) did not demonstrate any significant difference in rufinamide exposure compared with healthy volunteers after a single 400-mg dose. Haemodialysis, however, when started 3 h after dosing, did reduce rufinamide AUC values by approximately 30%. This might suggest that dialysis can be used to treat patients with toxic levels of the drug.

Impaired liver function

The effect of hepatic impairment on rufinamide pharmacokinetics has not been evaluated.

Drug interactions

Effect of other drugs on rufinamide pharmacokinetics

Using population pharmacokinetic modelling [21–23,11], enzyme inducers, such as carbamazepine, phenytoin and phenobarbital, have been shown to reduce serum rufinamide concentrations. Depending on age and gender, carbamazepine decreased serum rufinamide levels by 19–26% on average; phenobarbital, phenytoin and primidone (assessed together in the model) by 25–46%; and vigabatrin by 14–30% [11]. Valproic acid increased the serum concentration of rufinamide by 12–70% on average, the highest increases being recorded in children, presumably because in the populations included in this analysis serum valproic acid concentrations were higher in children than in adults [11]. In the same analysis, serum rufinamide levels were not affected by lamotrigine or topiramate.

Effect of rufinamide on the pharmacokinetics of other drugs

In an *in vitro* study [16], rufinamide was incubated at concentrations of up to 300 μmol, with various substrates, in human liver microsomal fractions to evaluate any potential inhibitory effect on the activities of various human CYP isoenzymes that are known to be responsible for the metabolism of several drugs. Rufinamide did not demonstrate any inhibition on the activities of these human P450 isoenzymes: CYP1A2, CYP2A6, CYP2C9, CYP2C19, CYP2D6, CYP2E1, CYP3A4/5 and CYP4A9/11. This suggests that rufinamide is unlikely to inhibit the biotransfomation of drugs that are metabolized by these enzymes.

Formal pharmacokinetic studies to assess the influence of rufinamide on the disposition of other AEDs have not been conducted. However, the effect of rufinamide on the serum levels of carbamazepine, lamotrigine, phenobarbital, phenytoin, topiramate and valproic acid has been evaluated using a population pharmacokinetic analysis of measurements made during clinical trials. Rufinamide, at a concentration of 15 μg/mL, was estimated to cause a small decrease in clearance of phenobarbital and phenytoin. This would result, depending on age groups, in a mean increase of 8–13% in the levels of phenobarbital and an increase of 7–21% in the levels of phenytoin. Rufinamide was also estimated to cause a small increase in the clearance of lamotrigine and carbamazepine, which would result in a decrease of 7–13% in the concentration of these drugs [21]. The serum levels of topiramate and valproic acid were not affected by rufinamide in this analysis.

A single-centre open-label cross-over study in 18 healthy female volunteers was conducted to investigate the effects of rufinamide on the metabolism of an oral contraceptive pill [24]. Subjects were maintained on the pill for at least two cycles prior to initiation of the study, and rufinamide 800 mg b.i.d. was taken on days 22–35. During rufinamide administration, the AUC and the C_{max} (peak plasma concentration) of ethinylestradiol decreased by 22% and 31%, respectively, whereas the AUC and C_{max} of norethindrone decreased by 14% and 18%, respectively. These findings suggest that rufinamide stimulates the metabolism of contraceptive steroids by a moderate degree. Whether a greater magnitude of interaction occurs at higher dosages of rufinamide remains to be determined.

In another study, rufinamide, given at the low dose of 800 mg/day for 11 days to 18 healthy subjects, caused a 36% decrease in the serum levels (AUC) of concomitantly taken triazolam. This suggests that rufinamide induces the CYP3A4 enzyme system [11]. Conversely, rufinamide, also at a dose of 800 mg/day, did not influence the pharmacokinetics of olanzapine, a CYP1A2 substrate [11].

Serum level monitoring

A high-performance liquid chromatography (HPLC) method has been developed for the simultaneous determination of the levels of rufinamide and its main carboxylic metabolite (CGP 47292) in blood [25,26].

Pharmacokinetic/pharmacodynamic relationships have been explored as part of a population pharmacokinetic analysis of data

from patients included in clinical trials [11]. This analysis showed a decrease in seizure counts with increasing serum rufinamide concentrations, at least within the concentration ranges encountered in clinical trials. The plasma rufinamide concentration estimated to be associated with a mean 25% reduction in seizure frequency was 13 μg/mL, which is within the range expected to be achieved with the recommended dose range. Mean serum rufinamide concentrations were also higher in patients with adverse effects than in patients not reporting adverse effects.

These data suggest that clinical response to rufinamide is related to the drug's serum concentration. There are, however, insufficient data to determine the value of serum level monitoring in optimizing therapy with this drug.

Efficacy

To date, a total of nine double-blind efficacy studies have been conducted. An additional large-scale adjunctive therapy study for patients with focal epilepsy is currently ongoing. Table 51.1 summarizes the various studies and their outcomes. Of those studies, one was terminated early due to poor enrolment. Of the remaining eight, five were reported to demonstrate rufinamide efficacy compared with the control group and three were negative studies.

Monotherapy studies in patients with partial-onset seizures

A multicentre, double-blind, low-dose, active-control, randomized, parallel-group monotherapy study (Study 0016) compared 300 mg/day with 3200 mg/day rufinamide in patients with refractory partial seizures who were initially on one or two AEDs [27]. Seventy patients were randomized to 300 mg/day and 72 were randomized to 3200 mg/day for up to 112 days. Concomitant AEDs were simultaneously tapered and discontinued over a 42-day period beginning at randomization. Patients were allowed to exit the study by meeting criteria based on seizure frequency or severity, or completing 112 days of treatment. The primary efficacy outcome was the percentage of patients meeting exit criteria. Overall, 66.7% in the high-dose group and 72.5% in the low-dose group met exit criteria, a non-significant difference. The median time to meeting an exit criterion showed a trend favouring the high dose (56 days) over the low dose (32 days), but again the difference was not statistically significant ($P = 0.0968$).

Another double-blind, randomized, placebo-controlled, parallel group study (Study 0038) was conducted in patients with partial seizures who completed inpatient evaluation for epilepsy surgery, and were not on any AED other than low-dose lorazepam [28]. Each patient had to have 2–10 partial seizures during the 48-h baseline phase. After completing this phase, patients were randomized to receive rufinamide ($n = 52$) or placebo ($n = 52$) for the 10 days of the double-blind phase. Rufinamide dose was 2400 mg/day on day 1 and 3200 mg/day on days 2–10, given on a t.i.d. schedule. The patients continued on treatment until they completed 10 days or met one of the exit criteria. The mean daily dose of rufinamide was 2970.7 mg. Rufinamide-treated patients demonstrated a significantly greater median number of days to meet an exit criterion than placebo-treated patients, 4.8 days versus 2.4 days ($P = 0.0499$). Approximately the same percentage of patients in the rufinamide group (67.3%) and in the placebo group (69.2%) met an exit criterion ($P = 0.8809$). The median times to first, second and third partial seizures were significantly longer with rufinamide than with placebo ($P \leq 0.0348$).

The third study (Study 0039) was a multicentre, double-blind, randomized, placebo-controlled, parallel-group monotherapy trial in currently untreated patients with recent onset of partial seizures. Because only 29 patients were randomized, 14 to rufinamide and 15 to placebo, the study was discontinued owing to a lack of enrolment.

Table 51.1 Double-blind placebo-controlled efficacy studies.

Study	Type of epilepsy	Design	Dosage	No. of patients R/P	Outcome
AE-ET1	Partial	Add-on	200–1600 mg	R-514 P-133	Positive
AE-PT2	Partial or Generalized	Add-on	400–1600 mg	R-25 P-25	Positive
0016	Partial	Monotherapy	300–3200 mg	300 mg-70 3200 mg-72	Negative
0018	Generalized	Add-on	800 mg	R-78 P-75	Negative
0021A	Partial	Add-on	3200 mg	R-156 P-157	Positive
0021P	Partial (pediatric)	Add-on	45 mg/kg	R-136 P-132	Negative
0022	LGS	Add-on	45 mg/kg	R-74 P-64	Positive
0038	Partial (in-patient)	Monotherapy	3200 mg	R-52 P-52	Positive
0039	Partial	Monotherapy (new diagnosis)	1200 mg	R-14 P-15	Early termination[a]
E2080-301	Partial	Add-on >12 years old	3200 mg	408 patients planned	On-going

R, rufinamide; P, placebo.
[a] Insufficient enrolment.

Adjunctive therapy studies in patients with partial-onset seizures

In a multicentre, double-blind, parallel-group study (Study AE-ET1), 647 adults with partial seizures receiving concomitant AEDs were randomized to one of four rufinamide treatment groups (200, 400, 800 or 1600 mg/day, administered b.i.d.) or the placebo group [22,29]. There was a 3-month prospective baseline phase, and patients who had nine or more seizures entered a 3-month double-blind phase. There was a statistically significant linear trend of dose response in seizure frequency per 28 days in the treatment group ($P = 0.003$) and in responder rates (patients with ≥50% decrease in seizure frequency compared with baseline) ($P = 0.00319$). A pairwise comparison of median seizure frequency between placebo and each rufinamide arm revealed a significant reduction in seizures in patients treated with rufinamide 400 mg/day (an 11% decrease, $P = 0.00274$), 800 mg/day (16%, $P = 0.00123$) and 1600 mg/day (17%, $P = 0.00163$) compared with placebo.

Study AE-PT2 was a small multicentre, double-blind, parallel-group weekly rising dose study in 50 adult patients who were on one or two concomitant AEDs [30]. In addition to patients with partial seizures, patients with primary generalized tonic–clonic seizures could be enrolled. Subjects were randomized to 400, 800, 1200 or 1600 mg/day groups or to the matching placebo. On day 1 all patients received a single 800-mg dose of rufinamide. On day 7 patients entered a double-blind phase and were started on 400 mg/day or on the matching placebo. Dose was increased on a weekly basis depending on the randomized group of 800, 1200 and 1600 mg/day. Patients on rufinamide had a median seizure frequency ratio during the treatment phase of 0.59 compared with 1.52 for the placebo group. Responder rates analysis did not reveal any statistically significant differences. This study had significant deficiencies, including a small sample size, a retrospective baseline and inclusion of some patients with no seizures at baseline.

In Study 0021A, which also had a double-blind, parallel-group, adjunctive therapy design, adults with refractory partial seizures were randomized to add-on treatment with either 3200 mg of rufinamide ($n = 156$) or placebo ($n = 157$) [31–33]. Patients ≥16 years of age weighing >18 kg who were on a stable dose of one or two AEDs entered a 56-day baseline phase. Those who had at least six partial seizures were randomized to placebo or rufinamide, starting with a dose of 800 mg/day and increasing this by 800 mg every 2 days to a target dose of 3200 mg/day for 7–14 days. They then entered a 77-day maintenance phase. The median percentage change in partial seizure frequency during the treatment phase relative to the baseline phase was statistically significantly in favour of rufinamide (20.4% reduction in the rufinamide group compared with 1.6% increase in the placebo group, $P = 0.0158$). In the rufinamide group, 28.2% of the patients were responders compared with 18.6% in the placebo group ($P = 0.0038$).

Study E2080-301 is an ongoing double-blind parallel-group study in patients (12–80 years of age) with refractory partial seizures who receive one to three AEDs and have at least six seizures during an 8-week baseline. Patients are randomized to add-on therapy with either rufinamide 1600 mg b.i.d. or placebo. Patients entered a 12-day titration phase beginning with 400 mg b.i.d. or placebo. The dose was increased every 3 days to 1600 mg b.i.d. The patients continued in a 12-week maintenance phase. It is estimated that a total of 408 patients will be included.

A paediatric multicentre, double-blind, adjunctive therapy, parallel-group study (Study 0021P) has also been completed [34]. Children with inadequately controlled partial seizures were randomized to receive either placebo or rufinamide, 45 mg/kg. Patients 4–16 years of age who were on a stable dose of one or two AEDs entered a 56-day baseline phase. Patients who experienced six or more partial seizures were redosed to placebo or rufinamide. They entered a 7- to 14-day titration phase. Depending on weight, they were dosed with 10 mg/kg daily for 2 days or 200 mg/day for patients weighing 18–30 kg (group A); 400 mg/day for patiients weighing 30–50 kg (group B); and 600 mg/day for patients weighing 50–60 kg (group C). The dose was increased by 10 mg/kg every 2 days to reach a target dose of 45 mg/kg on days 7–14, not exceeding 1000 mg in group A, 1800 mg/day in group B or 2400 mg/day in group C. The maintenance phase lasted 77 days, and 268 patients received a study drug; 136 were on rufinamide and 132 on placebo. The mean percentage reduction in partial seizure frequency during the 28-day double-blind phase relative to the baseline phase (primary efficacy variable) was 12.8% in the rufinamide group compared with 7% in the placebo group, a difference which was not considered statistically significant ($P = 0.06214$).

Adjunctive therapy in patients with generalized epilepsies

Primary generalized tonic–clonic seizures

In a multicentre, double-blind, parallel-group study (Study 0018), patients 4 years of age or older with inadequately controlled primary generalized tonic–clonic seizures, receiving one or two AEDs, and with at least three generalized tonic–clonic seizures during an 8-week baseline, were randomized to add-on therapy with either rufinamide 800 mg/day ($n = 78$) or placebo ($n = 75$). Patients entered a 56-day baseline phase followed by a 140-day double-blind phase [35]. The mean age of the patients was 29.3 years (range 4–63 years), and the median number of generalized tonic–clonic seizures per 28 days during the baseline period was 3.5 (range 1.5–84) for the rufinamide group and 4 (range 1.5–74) for the placebo group. The median reductions in seizure frequency were 36.4% and 25.6% for the rufinamide and the placebo group, respectively, differences that were not statistically significant ($P = 0.633$). However, the rufinamide dosage used in this study was low compared with all the other placebo-controlled rufinamide studies, which might have contributed to the negative outcome of this study.

Lennox–Gastaut syndrome

The study in Lennox–Gastaut syndrome (Study 0022) also used a multicentre, double-blind parallel-group design [28,36–38]. Patients were randomized to add-on therapy with either placebo ($n = 64$) or rufinamide at a dose of 45 mg/kg ($n = 74$); patients underwent a 28-day baseline phase followed by a 14-day titration phase and then a 70-day maintenance phase. There was a statistical difference between the two treatment groups in all three of the primary efficacy variables, including percentage change in total seizure frequency, percentage change in tonic–atonic seizure

frequency, and seizure severity ratings. Patients in the rufinamide group experienced a 32.7% median reduction in total seizure frequency per 28 days relative to baseline, compared with 11.7% for the placebo group ($P = 0.015$). Patients on rufinamide also had a 42.5% median reduction in tonic–atonic seizure frequency per 28 days relative to the baseline, compared with a 1.4% median increase for the placebo group ($P = 0.0001$). An improvement in seizure severity was observed in 53.4% of patients assigned to rufinamide compared with 30.6% of those assigned to placebo ($P = 0.0041$). Of the patients who completed the study, 124 entered an extension phase for up to 36 months. The median reduction in total seizures after 12 months compared with the pre-double-blind baseline was over 43%, and the median reduction in tonic–atonic seizures, in particular, was over 58%.

General overview of efficacy data in epilepsy

The mixed outcomes of the double-blind efficacy studies may be due to various causes. In the 0018 study of patients with primary generalized tonic–clonic seizures, the active group was randomized to only 800 mg/day, which is significantly lower than the typical dose of 1600–3200 mg/day. Another possible factor is the inclusion of a high number of patients taking enzyme-inducing AEDs, which reduce considerably the plasma rufinamide levels, resulting in a possible impact on efficacy. Other pharmacokinetic factors might relate to the fact that in many early studies a formulation with suboptimal bioavailability was used, and to the possibility that administration at the time of food intake (a condition known to increase rufinamide bioavailability) might not have been sufficiently controlled.

Nevertheless, the modest percentage reduction in seizure frequency in the various studies suggests at least a moderate level of efficacy with this medication.

Studies in other indications

Rufinamide's mechanism of action suggests a potential value in neuropathic pain [39]. To investigate this possibility, a double-blind, randomized, parallel-group study in diabetic neuropathy was conducted. Sixty patients were randomized to rufinamide (2400 mg/day) and 63 to placebo. The primary efficacy variable (total score of the short-form McGill Pain Questionnaire at the end of the double-blind treatment) did not show any statistical difference between the two treatment groups ($P = 0.3552$). Patients in the rufinamide group experienced a 7.9-point decrease in the total pain score relative to baseline compared with a 5.6-point decrease in the placebo group. The visual analogue scale test also did not show any statistically significant difference between the two groups.

Adverse effects

Overall safety profile

As of November 2005, 1978 patients with epilepsy had been treated with rufinamide in studies. Of these, 1240 were exposed during double-blind studies. In addition, 188 healthy volunteers were exposed to rufinamide during phase I studies and 60 patients with neuropathic pain were also exposed during early clinical studies. Table 51.2 summarizes the safety experience from adjunctive therapy double-blind trials in adults with partial seizures by listing percentages of patients in whom adverse events occurred (more than 5% of of those treated with rufinamide) and in whom these events occurred with a higher incidence than in the placebo group (Table 51.3). The average daily dose was 1700 mg/day. In this analysis, which included a total of 720 patients exposed to rufinamide and 290 exposed to placebo, 80.6% of patients had an adverse event in the rufinamide groups compared with 81.4% in the placebo groups. Headache, dizziness, fatigue, nausea and somnolence were the most commonly reported adverse events [1].

Adverse events were typically mild to moderate in severity. The discontinuation rate, owing to adverse events in patients with partial epilepsy, was 10% for the rufinamide groups and 6% for the placebo groups. The most common causes for discontinuation in the rufinamide groups were dizziness, fatigue, headache, diplopia, nausea and ataxia. The rate of any adverse events and the most frequently reported adverse events increased as dosages were increased.

The adverse events that occurred in more than 10% of all treated patients were compared between the rufinamide ($n = 1240$) and the placebo ($n = 635$) groups. Krauss *et al.* [41] received safety data from 23 studies involving patients with epilepsy. Eleven of these were randomized, double-blind, placebo-controlled studies and 12 were open-label studies. The analysed

Table 51.2 Rufinamide dosing schedule.

Study day (Titration phase)	Approximate dose (mg/kg/day)	18.0–29.0 kg	29.0–50.0 kg	50.0–70.0 kg	+70.1 kg
1–2	10	200	400	800	800
2–4	20	400	800	1200	1600
5–6	30	800	1200	1600	2400
7	40	1000	1800	2400	3200

Rufinamide or matching placebo was administered orally with breakfast and again with supper or an evening snack. A lower titration schedule (over 14 days) was allowable at the discretion of the investigator if tolerability issues became apparent.

Table 51.3 Adverse events for adult double-blind partial epilepsy studies occurring in >5% of population in rufinamide versus placebo.

Adverse events	Rufinamide[a] (%)	Placebo[b] (%)
Any adverse event	*80.6*	*81.4*
Headache	27.6	26.2
Fatigue	17.6	11.7
Nausea	11.7	10.0
Somnolence	10.4	7.2
Diplopia	9.9	3.1
Tremor	6.1	4.5
Blurry vision	6.0	3.1
Nystagmus	5.3	4.5

[a] $n = 720$.
[b] $n = 290$.

population comprised children, adolescents and adults with partial-onset epilepsy, generalized epilepsy or Lennox–Gastaut syndrome. Short-term therapy safety data from double-blind studies included data on 1240 patients who received at least one dose of rufinamide and 635 who were on placebo. Sex distribution was similar: 620 males (50%) in the rufinamide group and 338 (53.2%) in the placebo group. The age distribution in the rufinamide group was <12 years of age (9.6%), 12–16 years (7.5%), 17–64 years (82.2%), >65 years (0.7%) and in the placebo group 17.6%, 13.2%, 68.2% and 0.9%, respectively. In the double-blind trials the most common adverse events (rufinamide versus placebo group,) in all age groups were headache (22.9% versus 8.9%), dizziness (15.5% versus 9.4%), fatigue (13.6% versus 9%), somnolence (11.8% versus 9.1%) and nausea (11.4% versus 7.6%). Typically, the rate of an adverse event increased when doses increased. Adverse events leading to study discontinuation occurred in 8.1% of the rufinamide group compared with 4.3% on placebo. A total of 1978 patients participated in open-label long term trials, of whom 50.5% were male. The mean age was 31.3 (1–81) years: 11.8% were <12 years of age, 9.3% 12–16 years of age, 77.6%, 17–64 years of age and 1.4% > 65 years of age. The most common adverse events were headache (29.5%), dizziness (22.5%) and fatigue (17.7%) and most adverse events were mild to moderate in severity. Adverse events leading to discontinuation occurred in 259 patients (13.1%); the most common ones were fatigue (38), headache (32), dizziness (31) and nausea (31). Of the reported adverse events in the rufinamide groups, 31.8% were mild, 36.1% were moderate and 10.7% were severe. In the placebo groups, these percentages were 37.8%, 31.3%, and 9.1%, respectively. The percentage of rufinamide-treated patients experiencing serious adverse events was 6.3% compared with 3.9% of the placebo-treated patients in the double-blind studies. Two deaths were reported in the rufinamide groups and four in the placebo groups. No patients experienced Stevens–Johnson syndrome or toxic epidermal necrolysis. During long-term therapy, common adverse events were similar to those observed during the short-term blinded studies. The majority of these were mild to moderate in severity and they typically occurred during the first 2 weeks of therapy. Rufinamide doses up to 7200 mg/day did not result in any significant symptoms of toxicity.

The safety data in the paediatric patients who participated in double-blind, placebo-controlled studies were also analysed. Of these, 212 received rufinamide and 197 received placebo. The median age was 11 years, the median body weight was 36 kg and the median daily dose of rufinamide was 42.0 mg/kg. The median duration of exposure was 3 months. The most common adverse events (rufinamide versus placebo) were somnolence (17% versus 8.1%), vomiting (16.4% versus 7.1%), headache (16% versus 8.1%) and pyrexia (11.3% versus 10.7%). Discontinuation rates as a result of adverse events were 7.1% for the rufinamide group and 2% for the placebo group.

Effect on cognitive functions

A positive cognitive profile of rufinamide was suggested by experimental studies in rodents indicating improvement in learning performance in the step-down passive avoidance paradigm, and ability to partially counteract electroshock-induced amnesia. Aldenkamp and Apherts [40] conducted neuropsychiatric testing in 189 patients with partial seizures (age range, 15–64 years) who received rufinamide 200, 400, 800 or 1600 mg/day as add-on treatment in a multicentre, double-blind, placebo-controlled parallel-group study [40]. Cognitive testing was done at baseline and after 3 months of treatment. The results did not reveal any statistically significant decline for patients taking any of the doses of rufinamide compared with baseline.

Current place in therapy

Rufinamide has shown significant efficacy in the trial in Lennox–Gastaut syndrome, and it has been approved for this indication in Europe. Approval for this indication in the USA is currently pending. Suggested maintenance dosages in Europe for the treatment of Lennox–Gastaut syndrome are 200–1000 mg/day (200–600 with valproic acid co-medication) for patients weighing less than 30 kg, and 400–1800 mg/day, 400–2400 mg/day and 400–3200 mg/day for patients weighing 30–50 kg, >50–70 kg and >70 kg, respectively [41]. Higher doses have been used in open-label studies in adults, up to 4800 mg/day. The drug should be given in two divided daily doses, taken at meal times.

Concerning other indications, a study in patients with primary generalized tonic–clonic seizures was negative, which might have been in part due to the low rufinamide dose tested (800 mg/day). Efficacy as add-on therapy has been demonstrated in adults with partial epilepsy. One monotherapy study was negative and one short-term monotherapy study was positive. An ongoing add-on study in partial epilepsy is close to completion.

Pending results of further trials and reports from initial post-marketing experience, there are insufficient data to determine the current role of rufinamide in the treatment of epilepsy. At present, the best-defined indication is the adjunctive treatment of patients with Lennox–Gastaut syndrome who did not respond to first-line therapies.

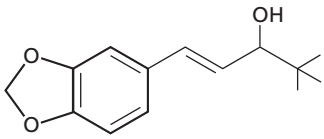
52 Stiripentol

Kai Eriksson and Tapani Keränen
Tampere University Hospital, Tampere, Finland



Primary indications	Adjunctive therapy of refractory generalized tonic–clonic seizures associated with severe myoclonic epilepsy in infancy (Dravet's syndrome) in patients receiving valproic acid and clobazam
Usual preparation	Capsules: 250 and 500 mg Sachets (powder for oral suspension): 250 and 500 mg
Usual dosages	50 mg/kg/day, to be reached over 3 days
Dosing frequency	Two or three times per day
Significant drug interactions	Enzyme-inducing antiepileptic drugs increase stiripentol clearance by stimulating its metabolism. Stiripentol inhibits the metabolism and increases the serum concentration of phenobarbital, carbamazepine, phenytoin, primidone, clobazam, *N*-desmethylclobazam and valproic acid
Serum level monitoring	There is insufficient information on the value of monitoring serum stiripentol levels
Reference range	Not clearly defined
Common/important adverse effects	Drowsiness, ataxia, tremor, hypotonia, dystonia, hyperactivity, aggressiveness and other behaviour disorders, insomnia, nausea, anorexia, weight loss, vomiting and haematological abnormalities (e.g. neutropenia and thrombocytopenia)
Main advantages	Robust efficacy in severe myoclonic epilepsy of infancy
Main disadvantages	Drug–drug interactions, complex pharmacokinetics
Mechanism of action	Not fully understood, but probably includes potentiation of GABAergic transmission. Interactions with concomitant medications contribute to efficacy and averse effects
Oral bioavailability	≥70%
Time to peak levels	0.5–2 h
Elimination	Primarily by metabolism, including glucuronide conjugation, opening of the methylenedioxy ring with formation of a dihydroxyderivative, and O-methylation of catechol metabolites
Volume of distribution	Not known
Elimination of half-life	In the order of 4.5–13 h. Stiripentol follows Michaelis–Menten kinetics, and half-life increases with increasing serum concentrations. As a result, steady-state serum concentrations increase more than proportionately after a dose increment
Plasma clearance	Dose-dependent (clearance decreases with increasing dosage). In adults co-medicated with enzyme inducers, apparent oral clearance decreases from 1.7 L/h/kg at 600 mg/day to 0.35 L/h/kg at 2400 mg/day

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Protein binding	99%
Active metabolites	None known
Comment	A potentially valuable drug for difficult-to-treat cases of severe myoclonic epilepsy in infancy

Introduction

Stiripentol is a novel antiepileptic drug (AED) that belongs chemically to the class of aromatic allyl alcohols, and is therefore structurally unrelated to other currently marketed AEDs [1]. Its main mechanism of action in experimental models has been postulated to involve an increase in gamma-aminobutyric acid (GABA)-ergic neurotransmission [2].

Stiripentol has been developed during the last 30 years and used under a special programme in France and Canada for more than 10 years [3,4]. Stiripentol was given orphan drug designation in 2001 in the European Union, and conditional marketing authorization was granted in January 2007 by the European Medicines Agency (EMEA) [5] as the first orphan AED in children, for the treatment of refractory generalized tonic–clonic seizures associated with severe myoclonic epilepsy in infancy (SMEI, Dravet's syndrome), adjunctively to valproic acid and clobazam.

In clinical trials, assessment of its potential antiepileptic efficacy has been complicated by pharmacokinetic interactions, which result in marked increases in the serum levels of many concomitantly administered AEDs [1].

Chemistry

Stiripentol (4,4-dimethyl-1-[(3,4-methylenedioxy)phenyl]-1-penten-3-ol) belongs to the family of aromatic allyl alcohols. Stiripentol is a chiral molecule with an asymmetric carbon atom at the 3 position [6]. Stiripentol is produced as a racemate, i.e. as a mixture of *R*(+)-stiripentol and *S*(−)-stiripentol in equal proportions.

Stiripentol has a molecular weight of 234. It is virtually insoluble in water and soluble in ethanol and acetone.

Pharmacology

The antiepileptic activity of stiripentol was discovered in the 1970s. The compound shows anticonvulsant effects in the pentylenetetrazole and maximal electroshock models [7,8], as well as in other models [9]. In the pentylenetetrazole model in the rat, *R*(+)-stiripentol is 2.4 times more potent than *S*(−)-stiripentol [10], and it also has a shorter half-life than *S*(−)-stiripentol (2.8 h versus 6.5 h). After repeated administration of the racemate to rats, a five- to sixfold increase in the *S*(−)-stiripentol/*R*(+)-stiripentol ratio was observed compared with the ratio found after a single dose [10]. This phenomenon may explain the observation that after chronic dosing in rats tolerance develops to its protective effects against pentylenetetrazole-induced seizures [8].

The mechanism of action of stiripentol is not fully understood. However, stiripentol has actions on GABA-mediated transmission. In neurochemical studies, stiripentol reduced synaptosomal uptake of GABA and caused a small (+22%) increase in the concentrations of GABA in the brain [7]. Stiripentol has no affinity for either $GABA_A$ or $GABA_B$ receptors [2,7]. Recently, stiripentol has been shown to enhance $GABA_A$ receptor transmission in CA3 pyramidal neurones in the neonatal rat at clinically relevant concentrations (30–200 μmol) [2]. Results from this study suggests that stiripentol may modulate GABAergic function by acting at the barbiturate binding site and thus increasing the duration of opening of the $GABA_A$ receptor-activated chloride channels [2].

Pharmacokinetics

There are only limited published data on the pharmacokinetics of stiripentol in humans. Studies have been carried out in a small number of healthy volunteers and adult patients with epilepsy.

Stiripentol is rapidly absorbed, with peak serum concentrations being observed at 0.5–2 h [6]. The absolute oral bioavailability of stiripentol is not known. Bioequivalence between the capsules and the oral suspension formulations has not been established. Stiripentol should be taken with food because it degrades rapidly in an acidic environment, such as in gastric contents in a fasting state (for further details see ref. 32). It should not be taken with milk, dairy products, carbonated drinks, fruit juices or food and drinks that contain caffeine or theophylline (see ref. 32).

Stiripentol is highly (99%) bound to plasma proteins, and its distribution from the central compartment is slow, making the decline in serum concentration after a single dose multiphasic [11].

Stiripentol has non-linear Michaelis–Menten pharmacokinetics and, as a result, dose increments produce disproportionately larger increments in serum concentration at steady state [11]. Stiripentol clearance also decreases during repeated dosing, presumably inhibiting the enzymes responsible for its metabolism (see ref. 32). In a study conducted in patients with epilepsy who received concomitant enzyme-inducing AEDs, mean apparent oral clearance values were about 1.66 L/kg/h at a dose of 600 mg/day, and 0.83 L/kg/h and 0.35 L/kg/h at daily doses of 1200 mg and 2400 mg, respectively [12]. Because stiripentol clearance is subject to enzyme induction, clearance values in

patients not receiving enzyme inducing co-medication are much lower. The elimination half-life of stiripentol is in the range of 4.5–13 h, increasing with increasing dose (see ref. 32). Non-linearity of stiripentol pharmacokinetics is presumably a result of the saturation of the enzyme systems responsible for the metabolism of the drug [13].

Stiripentol is extensively metabolized in the liver. Altogether five different metabolic pathways have been identified in humans, the most important being glucuronide conjugation, opening of the methylenedioxy ring with formation of a dihydroxy derivative, and O-methylation of catechol metabolites [9]. None of the human metabolites displays pharmacological activity. Over 70% of the dose can be recovered in the urine as 13 different metabolites [14].

There are no published data on the pharmacokinetics of stiripentol in special patient groups, such as pregnant women, elderly subjects or patients with hepatic or renal dysfunction. Also, detailed pharmacokinetic data in children are lacking.

Drug interactions

Stiripentol has a number of clinically significant interactions with other AEDs, mainly as a result of stiripentol's ability to potently inhibit the activity of several cytochrome P450 (CYP) isoenzymes, including CYP1A2, CYP2C9, CYP2C19, CYP2D6 and CYP3A4 [15]. On the other hand, AEDs with enzyme properties accelerate the elimination of stiripentol. The clearance of stiripentol is increased by 300% by carbamazepine, phenobarbital and phenytoin [12].

Stiripentol dose-dependently inhibits the metabolism of phenytoin. The clearance of phenytoin has been found to be reduced by 38% and 78% at stiripentol doses of 1200 mg/day and 2400 mg/day, respectively [12]. The degree of interaction shows wide interindividual variation, but reductions of phenytoin dose of 25–66% may be necessary. The clearance of carbamazepine is reduced by about 50% using stiripentol [16,17]. The effect of stiripentol on carbamazepine metabolism builds up gradually over 7–10 days [16], and, after starting stiripentol, the dosage of carbamazepine should be reduced in steps by a total of 50% to avoid toxicity. Stiripentol also increases the serum concentrations of phenobarbital, primidone, clobazam and, to a much greater extent, *N*-desmethylclobazam (derived metabolically from clobazam) [18–20]. A reduction of about 30% in the dose of phenobarbital may be necessary [18], and reductions may also be needed in clobazam dosage. The increase in serum clobazam and *N*-desmethylclobazam levels may explain the clinical observation that stiripentol appears to enhance the potency of clobazam [20]. Stiripentol may also inhibit the metabolism of valproic acid, but the effect is modest, and a reduction in valproic acid dose may not be necessary [21].

Serum level monitoring

The relationship between serum stiripentol concentrations and clinical effects has not been adequately investigated, and stiripentol levels are not routinely monitored during stiripentol therapy.

Efficacy

Stiripentol has been developed for the last 30 years [4]. Most of the reported clinical studies have been open-label, uncontrolled add-on trials in adults and children with refractory epilepsies. Maintenance dosages of stiripentol in the published studies have been in the range of 1200–3000 mg/day in adults and 20–90 mg/kg/day in children.

One of the first published studies of stiripentol was carried out in the 1980s with seven patients with complex partial seizures [22] in whom adjunctive therapy with stiripentol resulted in reduction of seizure frequency. Another early study [23] reported that 66% of partial epilepsy patients demonstrated at least 50% seizure reduction, and similar results were obtained in a trial assessing stiripentol in refractory partial epilepsy in patients co-medicated with carbamazepine [24]. In other early uncontrolled studies, stiripentol was reported to decrease the frequency of generalized seizures, including typical and atypical absences [25,26]. Overall, however, these results are difficult to interpret because of their uncontrolled nature and because observed improvements in seizure control might have been produced by an increase in the serum concentrations of concomitant AEDs. Attempts to discontinue stiripentol co-medication have resulted in some studies in worsening of seizure control, which may suggest that stiripentol may have only little independent antiepileptic efficacy. Clinical studies of stiripentol in adults were discontinued in 1995 when no significant efficacy was found in a controlled trial in which stiripentol was combined with carbamazepine [9].

In 2006, Perez *et al.* [27] reported the results of a single-blind, add-on placebo-controlled paediatric trial of 108 patients with refractory epilepsies, combined with a further open trial of 104 other selected patients with epilepsy syndrome. Of the patients included in the placebo-controlled part of the study, 49% showed a 50% reduction in seizure frequency and 10% became seizure free. This study also reported for the first time the efficacy of stiripentol in patients with SMEI; 10 of the 20 children with SMEI responded, all of whom were treated with clobazam as co-medication. Subsequently, these promising results in SMEI were confirmed by a randomized, placebo-controlled, double-blind trial in 41 children [20], 71% of whom showed a more than 50% reduction of seizure frequency after stiripentol (50 mg/kg/day) was added to valproic acid and clobazam. Nine of these 41 children became free of clonic or tonic–clonic seizures, at least during the short evaluation period (second month of treatment) of the trial. Whether the observed benefit was the result of a direct action of stiripentol or was mediated by an increase in the serum levels of co-medication (most notably *N*-desmethylclobazam, the serum concentration of which increased prominently) is unclear.

The role of stiripentol in the treatment of SMEI has most recently been evaluated by Kassai *et al.* [28] in a meta-analysis in which they used a fixed-effect model to summarize the odds ratio of seizure rates and a logistic model to evaluate the influence of patient characteristics on treatment effect in uncontrolled and controlled randomized studies that compared stiripentol with placebo. The odds ratio of response to stiripentol relative to placebo was found to be 32 (CI 6.2–161) and seizure reduction rate was 70% (CI 47–93%). However, in this analysis there were no differences between subgroups and type of con-

comitant AEDs. Results of uncontrolled studies were seen as potentially biased, but the two randomized controlled trials were rated as reliable and showed that seizure frequency was greatly reduced by stiripentol in children with SMEI after 2 months of treatment.

The use of stiripentol in children with focal epilepsy was evaluated again in a randomized placebo-controlled setting with enrichment and withdrawal, designed by Chiron *et al.* [29]. Among the 67 children who entered a 4-month open label stiripentol add-on phase after a 1-month single-blind placebo baseline, 32 responders were randomized for 2 months either to continue stiripentol (n = 17) or to withdraw to placebo (n = 15). The primary endpoint was an increase in seizures over 50% compared with pre-randomization phase, and for this endpoint there was a non-significant difference between stiripentol (n = 6) and placebo (n = 8). A decrease in seizure frequency compared with baseline, which was the secondary endpoint, was greater on stiripentol (75%) than on placebo (22%). Twelve (71%) patients experienced at least one adverse event on stiripentol compared with four (27%) patients on placebo, but none of the adverse events was reported as severe.

Adverse effects

Currently available data indicate that stiripentol is relatively well tolerated. The most commonly reported adverse effects are drowsiness, ataxia, tremor, hypotonia, dystonia, hyperactivity, aggressiveness and other behaviour disorders, insomnia, nausea, anorexia, weight loss, vomiting and haematological abnormalities, for example neutropenia and thrombocytopenia [1,30]. Some adverse effects can be attributed to increased serum levels of concomitant AEDs following administration of stiripentol.

In the double-blind trial in SMEI [20], drowsiness, hyperactivity and aggressiveness were reported in 91% of patients on stiripentol and in 25% of those on placebo. Gastrointestinal adverse effects were also prevalent, 67% in the stiripentol group compared with 35% in the placebo group. None of the patients withdrew from the study because of these adverse effects. Even though the overall incidence of adverse effects is relatively high, many of these may result from increased serum levels of concomitant AEDs and can be managed by adjusting the doses of the latter. The impact of stiripentol on psychomotor development, a major concern in SMEI patients, is unknown [1].

Current place in therapy

Results of add-on studies of stiripentol in adults with focal epilepsy have been disappointing, but controlled add-on trials in paediatric populations suggest that stiripentol is efficacious in SMEI, a severe form of early childhood epilepsy and one of the most intractable epilepsy syndromes in childhood. No other AED has presented similar efficacy in SMEI, and a follow-up report from France [31] demonstrated the long-term efficacy also of stiripentol when added on to valproic acid and benzodiazepines in these patients. Even though these results necessitate further research on larger populations, stiripentol was granted orphan drug status and a conditional marketing authorization in the European Union in January 2007 for the treatment of refractory generalized tonic–clonic seizures associated with SMEI adjunctively to clobazam and valproic acid [32].

Overall, available data indicate that stiripentol can be very valuable as adjunctive therapy in the management of SMEI patients who have not responded favourably to the combination of clobazam and valproic acid. The recommended mean dose in children is 50 mg/kg/day, divided into two or three doses taken during a meal. Treatment is usually started with a lower dose, and is gradually increased to the recommended dose over 3 days. The interactions of stiripentol with many AEDs as a result of the inhibition of several CYP isoenzymes, including CYP3A4, create a need to adjust the doses of the concomitant drugs to improve the tolerability of the treatment. Even although stiripentol has definite CNS and gastrointestinal adverse effects, it seems to be, overall, relatively well tolerated.

Future studies with stiripentol should be aimed at characterizing its bioavailability, pharmacokinetic profiles in children, efficacy when combined with the maximum safe doses of clobazam and valproic acid (to determine whether stiripentol has any independent effect, in addition to increasing serum levels of comedications, particularly *N*-desmethylclobazam), effects on psychomotor development (particularly after early use in the course of the disorder), long-term efficacy and possible long-term adverse effects on growth rate.

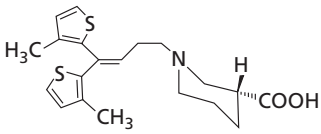
53 Tiagabine

Reetta Kälviäinen
Kuopio Epilepsy Center, Kuopio University Hospital, Kuopio, Finland



Primary indications	Adjunctive therapy of partial seizures, with and without secondary generalization
Usual preparation	Tablets: 2.5, 5, 10 and 15 mg, expressed as free base (in the USA, Canada and Mexico, strengths are 2, 4, 12, 16 and 20 mg, expressed as tiagabine hydrochloride)
Usual dosages	Starting dosage: 4 or 5 mg/day, which may be increased by weekly increments of 4 or 5 mg/day Maintenance: 15–32 mg/day (30–56 mg/day for patients co-medicated with enzyme-inducing drugs)
Dosing frequency	Two to four times per day
Significant drug interactions	Enzyme-inducing antiepileptic drugs increase tiagabine clearance by stimulating its metabolism
Serum level monitoring	Monitoring serum tiagabine levels is not generally regarded as useful in individualizing tiagabine therapy
Reference range	0.02–0.2 mg/L (this reference range corresponds to tiagabine concentrations most frequently recorded in patients receiving therapeutic doses)
Common/important adverse effects	Dizziness, asthenia, nervousness, tremor, attention/concentration difficulties, depressed mood, language problems, seizure exacerbation (myoclonic and absence seizures, non-convulsive status epilepticus)
Main advantages	Mechanism of action distinct from that of other antiepileptic drugs, and clearly demonstrated efficacy in partial seizures
Main disadvantages	Short half-life necessitating multiple daily dosing, need for slow dose titration, CNS adverse effects and efficacy spectrum restricted to partial seizures
Mechanism of action	Inhibition of GABA reuptake
Oral bioavailability	Close to 100%
Time to peak levels	0.5–2.3 h
Elimination	Primarily by oxidative metabolism mediated by cytochrome CYP3A4
Volume of distribution	About 1.2 L/kg
Elimination of half-life	5–9 h (2–4 h in patients receiving enzyme-inducing co-medication)
Plasma clearance	About 2–3 mL/min/kg (about 4–6 mL/min/kg in patients receiving enzyme-inducing drugs). Children show higher clearance values
Protein binding	96%
Active metabolites	None
Comment	A valuable drug for the adjunctive treatment of refractory partial seizures

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Tiagabine is a γ-aminobutyric acid (GABA) uptake inhibitor that was developed in the early 1990s as part of a strategic programme aimed at identifying orally active GABA uptake inhibitors with improved ability to cross the blood–brain barrier compared with nipecotic acid. Tiagabine has proven effective as add-on therapy in patients with refractory partial seizures with or without secondary generalization.

Chemistry

Tiagabine corresponds chemically to (–)-*(R)*–1-[4,4-bis(3-methyl–2-thienyl)-3-butenyl]-3-nipecotic acid hydrochloride. It has an empirical formula of $C_{20}H_{25}NO_2S_2HCl$ and a molecular weight of 412.0. Tiagabine is soluble in water and virtually insoluble in *n*-heptane.

Pharmacology

Activity in animal models of seizures and epilepsy

The anticonvulsant actions of tiagabine have been studied against seizures induced by electrical, chemical and sensory stimuli, and in genetic models of epilepsy. Tiagabine given intraperitoneally (i.p.) was shown to protect against audiogenic seizures in mice, tonic or clonic seizures induced by methyl-6,7-dimethoxy-4-ethyl-β-carboline-3-carboxylate and pentylenetetrazole in mice and by pentylenetetrazole in rats [1]. However, tiagabine did not protect against maximal electroshock-induced tonic seizures in mice or rats [2,1], and did not prevent tonic or clonic seizures induced by the potassium channel antagonists dendrotoxin or 4-aminopyridine in mice [3,4].

When administered intraperitoneally to amygdala-kindled rats, tiagabine attenuates the expression of secondarily generalized seizures, and completely blocks the expression of partial seizures [2]. Tiagabine also suppresses amygdala kindling-induced epileptogenesis in a dose-dependent manner in rats [5].

As with GABA agonists, tiagabine may enhance the occurrence of spike–wave discharges in animal models of non-convulsive generalized epilepsy. In WAG/Rij rats, a genetic model of generalized non-convulsive absence epilepsy, spike–wave discharges were increased by tiagabine 3 and 10 mg/kg i.p., but not by a 1 mg/kg dose [6]. Exacerbation of absence seizures has also been found in rats with genetic absence epilepsy (GAERS; Genetic Absence Epileptic Rat of Strasbourg) and in the lethargic mouse model [7,8].

Walton *et al*. [9] reported that tiagabine was effective in treating status epilepticus in cobalt-lesioned rats. At doses of ≥5 mg/kg i.p., however, tiagabine was also associated with rhythmic high-voltage discharges. At even higher doses, a similar pattern could be produced in normal rats as well.

Tiagabine reduced both seizure-induced damage to pyramidal cells in the hippocampus and impairment of spatial memory associated with hippocampal damage in the perforant pathway stimulation model of status epilepticus in the rat [10]. Neuronal cell death was also reduced by tiagabine in the hippocampus of gerbils subjected to cerebral ischaemia [11] and in the rat cerebral ischaemia model of delayed pyramidal cell death [12].

Mechanism of action

Potentiation of GABAergic inhibition is regarded as one important mechanism of action for some novel antiepileptic drugs (AEDs). GABA uptake inhibitors represent a unique class of AEDs, of which tiagabine was the first to be introduced into clinical practice. This action is thought to offer two potential advantages over direct $GABA_A$ receptor agonists [13]. First, unlike direct agonists, which produce a continuous or non-physiological pattern of receptor stimulation, the inhibition of GABA uptake enhances the effect only of endogenously released GABA, thus retaining physiological specificity. Second, the extent of enhancement of $GABA_A$ receptor-mediated function by a GABA uptake inhibitor will be limited by the amount of GABA released, which is under constant physiological control, thus potentially limiting the side-effect liability of such an inhibitor.

Tiagabine prevents GABA uptake by inhibiting selectively the GAT-1 GABA transporter, with little or no activity on GAT-2, GAT-3 or BGT-1, which also contribute to the uptake of the neurotransmitter into neurones and glial cells after synaptic release [13,14]. Tiagabine's affinity for inhibiting glial GABA uptake is 2.5-fold greater than that for neuronal uptake [15]. Tiagabine is not a substrate for the GABA uptake carrier and is therefore unlikely to act as a false transmitter at GABAergic neurones [3]. Blockade of GABA uptake temporarily prolongs the presence of endogenously released GABA in the synapse [13]. This is the only known mechanism of tiagabine action.

Although both tiagabine and vigabatrin act by enhancing GABA neurotransmission in the CNS, preclinical data show that vigabatrin and tiagabine have different pharmacological profiles and different mechanisms of action at the cellular level [16]. Tiagabine prolongs the duration, but not the magnitude, of the peak inhibitory postsynaptic current, consistent with temporarily sustained levels of endogenously released GABA in the synapse [17]. By contrast, vigabatrin inhibits presynaptic GABA degradation by selective, enzyme-activated irreversible blockade of GABA transaminase, and thus induces a persistent fivefold increase in whole brain GABA concentration, and also high concentrations of GABA in the retina. [18]. Tiagabine does not induce the widespread increase in total brain GABA concentrations that accompanies $GABA_T$ inhibition. Moreover, vigabatrin seems to accumulate in the retina, whereas tiagabine does not [18].

Pharmacokinetics

Key pharmacokinetic features

Tiagabine pharmacokinetics is linear at doses up to 80 mg/day [19]. The drug is rapidly and nearly completely absorbed after oral administration, with peak serum concentrations being attained within 30–90 min of dosing [20,21]. Food delays the time to peak concentration from a mean of 0.9 h to a mean of 2.6 h but does not change the total amount absorbed. Because tiagabine has a short elimination half-life, the smoother absorption produced by concomitant intake of food helps to reduce excessive fluctuations in plasma drug levels during the dosing

interval, and for this reason it is recommended that the drug be taken at meal times, preferably at the end of the meal.

Protein binding is high at 96%, but tiagabine does not displace highly protein-bound drugs, such as phenytoin and valproic acid, from their binding sites. The volume of distribution is approximately 1.2 L/kg [20,21].

The half-life of tiagabine in patients not taking enzyme inducing AEDs is in the order of 5–9 h [19], but much shorter values (2–4 h) are recorded in patients co-medicated with enzyme inducers. Tiagabine is eliminated virtually entirely by oxidative metabolism, mainly by the cytochrome P450 isoform CYP3A4. Less than 1% is excreted unchanged in the urine, and no active metabolites have been identified [22].

Pharmacokinetics in special populations

Pharmacokinetics in relation to age

The apparent oral clearance of tiagabine after multiple dosing in eight elderly subjects was found to be about 30% lower than in younger adults [23]. Elderly patients taking enzyme-inducing co-medication also had tiagabine clearance values that were twice as high as those of age-matched subjects not taking enzyme inducers, indicating that responsiveness to enzyme induction is not impaired in old age [23].

The pharmacokinetics of tiagabine has not been extensively investigated in patients below the age of 12 years. In one study, the apparent oral clearance of tiagabine normalized to body weight was on average markedly higher (by 35–120%, depending on type of co-medication) in 25 children aged 3–10 years than values recorded in historical adult control subjects [24]. This implies that children require higher doses than adults to achieve similar serum drug concentrations. The difference in apparent oral clearance between children and adults was much less when clearance values were normalized for body surface area than for body weight. Children receiving enzyme-inducing co-medication also had higher tiagabine clearance values than children on non-inducing co-medication. In a paediatric study, however, the maximal tolerated doses for children over 2 years old on inducing AEDs were only slightly higher than in children on non-inducing AEDs, and the difference was not significant (0.73 ± 0.44 mg/kg versus 0.61 ± 0.32 mg/kg) [25].

Pharmacokinetics in disease states

The pharmacokinetics of tiagabine is unaffected in patients with renal impairment or in subjects with renal failure requiring haemodialysis [26]. Patients with mild or moderate liver function impairment have been shown to have higher and more prolonged plasma concentrations of both serum total and unbound tiagabine than normal subjects. Patients with hepatic impairment also had more neurological adverse effects. Tiagabine should therefore be given with caution to patients with epilepsy who have a mild to moderate impairment of hepatic function. These patients are likely to require reduced initial and maintenance doses of tiagabine and/or longer dosing intervals compared with patients with normal hepatic function. Patients with mild to moderate impairment of hepatic function should also be monitored closely because of the potential for increased incidence of adverse effects [27]. Tiagabine should not be used in patients with severely impaired liver function.

Drug interactions

There is no evidence that tiagabine causes either induction or inhibition of cytochrome P450 enzymes [20]. Available evidence indicates that tiagabine does not modify the serum concentrations of concomitantly administered drugs [28,21].

Conversely, enzyme-inducing AEDs such as carbamazepine, phenytoin, phenobarbital or primidone increase the hepatic clearance of tiagabine [29], resulting in reduced serum tiagabine levels and a shortening of the half-life to about 2–4 h. *In vitro*, valproic acid may displace tiagabine from plasma protein binding sites, but it is unclear whether serum unbound tiagabine concentrations are increased in patients co-medicated with valproate.

Serum level monitoring

Tiagabine should be titrated according to clinical effect. It is generally not helpful to monitor the serum levels of tiagabine, partly because its short half-life results in considerable fluctuations in serum drug levels during a dosing interval, which makes it difficult to interpret concentration values taken at a single time point. Moreover, due to the high plasma protein binding of tiagabine, total serum concentrations may not provide a reliable estimate of the amount of unbound, pharmacologically active drug. The use of therapeutic drug monitoring for tiagabine is also complicated by the fact that serum tiagabine concentrations are in the nanomolar range, and technically difficult to measure reliably. Based on the above considerations, it is not surprising that clinical effects such as adverse effects have been found to correlate more strongly with dose than with the serum concentration of the drug [30].

Despite these limitations, a tentative reference serum concentration range of 0.02–0.2 mg/L has been suggested, which corresponds to the levels usually encountered in patients taking therapeutic doses [31]. In practice, however, there are no clear indications for monitoring serum tiagabine levels, except for a check for compliance.

Efficacy

Randomized trials in adults with partial epilepsy

Tiagabine has proven effective as add-on therapy in patients with refractory partial seizures with or without secondary generalization. The primary evidence for this is based on five controlled add-on trials in adults with epilepsy unsatisfactorily controlled with other AEDs (Table 53.1).

Cross-over placebo-controlled adjunctive therapy trials

The initial phase II studies of tiagabine in partial epilepsy were two small placebo-controlled, adjunctive therapy, cross-over enrichment trials. In the first of these trials, 94 patients with complex partial seizures, with or without secondary generalization, were started on a tiagabine dose of 8 mg/day, which was gradually increased over a period of up to 8 weeks until seizures

Table 53.1 Data from five double-blind placebo-controlled trials [29–33] and from an integrated analysis [37] of these studies showing the efficacy of tiagabine as add-on therapy in partial epilepsy.

Reference	Number of patients	Daily dose of tiagabine (mg/day)	Responder rate (>50% seizure reduction) for all partial seizures (%)	Placebo (%)
Richens *et al*. [32]	42	33	52	24**
Crawford *et al*. [33]	36	46	40	14*
Uthman *et al*. [36]	297	16	10	4
		32	20	4**
		56	31	4***
Sachdeo *et al*. [34]	318	32 (16 mg b.i.d.)	28	8***
		32 (8 mg q.i.d.)	23	8**

* $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$.

were sufficiently reduced or unacceptable adverse effects occurred [32]. The maximal dose allowed was 52 mg/day. Patients then entered a 4-week fixed-dose, open-label period on the dose attained after titration. Patients were eligible to enter the double-blind cross-over phase if their seizure frequency had been reduced by at least 25% during the fixed-dose period. Eligible patients were randomized under double-blind conditions to switch to placebo or to continue on their previously individualized dose of tiagabine for a 7-week period. After a 3-week washout period, each patient was switched to the alternative treatment, i.e. those who had received tiagabine in the first period were switched to placebo and those who received placebo were switched to tiagabine. The median daily dose of tiagabine in the double-blind phase was 32 mg/day. From the 42 patients who contributed data for both periods of the cross-over phase, responder rates (percentage of patients with at least 50% seizure reduction during the tiagabine period compared with the placebo period) were 26% for complex partial seizures ($n = 42$) and 63% for secondarily generalized tonic–clonic seizures ($n = 27$). The median seizure rate during the tiagabine treatment period was significantly lower than during the placebo period for complex partial seizures ($P = 0.05$) and secondarily generalized tonic–clonic seizures ($P = 0.009$).

The second phase II trial used the same design but allowed a maximal dose of 64 mg/day [33]. The intent-to-treat group comprised 36 patients who received a mean total daily dose of 46 mg in the tiagabine treatment periods. Tiagabine was significantly better than placebo in reducing all partial seizures ($P = 0.002$), complex partial seizures ($P < 0.001$) and partial seizures with secondary generalization ($P = 0.030$). A total of 46% of patients with complex partial seizures had at least a 50% reduction in weekly seizure rates.

Parallel-group placebo-controlled adjunctive therapy trials

In total, 769 patients took part in three randomized multicentre, parallel-group, double-blind add-on studies in which tiagabine was compared with placebo in patients with refractory partial seizures. These studies included a dose–response trial, a dose–frequency trial [twice daily (b.i.d.) versus four times daily (q.i.d.)] and a three times daily dosing (t.i.d.) trial [34–36].

The dose-ranging multicentre study was conducted in the USA in a total of 297 patients with complex partial seizures [36].

Table 53.2 Significantly higher (versus placebo) treatment-emergent CNS-related adverse events reported by ≥1% of tiagabine-treated patients during the experiment period in the three placebo-controlled parallel group add-on epilepsy studies.

Adverse event	Placebo ($n = 275$), *n* (%)	Tiagabine ($n = 494$), *n* (%)
Dizziness	41 (15)	131 (27)**

During a 4-week period, patients assigned to tiagabine were given increasing doses until the dose level to which they had been randomized was reached (16, 32, or 56 mg/day, divided in four equal doses). The patients then remained on a fixed dose for 12 weeks of double-blind treatment. Median decreases in 4-week complex partial seizure frequency for the 32-mg (–2.2) and 56-mg (–2.8) tiagabine groups were significantly greater than for the placebo group (–0.7) ($P = 0.03$ and $P < 0.03$, respectively). Overall, 20% and 29% of patients in the 32-mg and 56-mg groups had a 50% or greater reduction in the frequency of complex partial seizures, compared with 4% in the placebo group ($P = 0.002$ and $P < 0.001$, respectively).

The dose–frequency study was conducted in 318 patients in the USA; it lasted for 24 weeks and consisted of an 8-week baseline, a 12-week double-blind treatment phase and a 4-week termination period [34]. During the first month of treatment, doses were increased weekly to 32 mg/day. The treatment groups were placebo, 16 mg tiagabine twice daily and 8 mg tiagabine q.i.d. The median changes in 4-week complex partial seizure rates were –1.6 ($P = 0.055$) for the 16 mg b.i.d. group and –1.2 ($P < 0.05$) for the 8 mg q.i.d. group, versus –0.2 for placebo. Statistically significant differences between the placebo and two tiagabine groups occurred in the proportion of patients experiencing >50% rate reduction for complex partial, simple partial and all partial seizure rates (Table 53.1).

The t.i.d. dosing study was a northern European trial that compared 30 mg/day tiagabine with placebo in 154 patients [35]. The study included a 12-week baseline, an 18-week double-blind treatment phase and a 4-week termination period. The median change from baseline in 4-week complex partial seizure rates was –1.3 for patients on tiagabine, while placebo patients had a median increase of 0.1 in complex partial seizure rates ($P < 0.05$). Tiagabine was significantly more effective than placebo in patients with simple partial seizures with respect to the proportion of patients achieving a seizure reduction of at least 50% (21% versus 6%; $P < 0.05$), but responder rates for all partial seizures did not differ significantly between groups (Table 53.2).

A meta-analysis of these trials showed that the odds ratio of achieving at least 50% seizure reduction was 3.03 (95% CI 2.01–4.58) in favour of tiagabine [37]. The summary odds ratios for each dose indicated increasing efficacy with increasing doses; there was no suggestion that the effect of the drug had reached a plateau at the doses examined in these studies. A 16 mg/day dose has an odds ratio of 2.40 (95% CI 0.65–8.87), which increased to 3.17 (95% CI 2.03–4.96) at doses of 30 or 32 mg/day and 7.95 (95% CI 3.09–20.49) at a dose of 56 mg/day.

Other randomized adjunctive therapy trials

A multicentre, open-label, randomized, parallel-group study compared the efficacy and tolerability of t.i.d. and b.i.d. dosing of tiagabine as adjunctive therapy in refractory partial seizures [38]. A total of 347 patients were randomized and treated (175 t.i.d and 172 b.i.d.). Tiagabine dose was increased stepwise during a 12-week fixed-schedule titration period to a target dose of 40 mg/day. Patients were then followed for a further 12-week flexible-dose continuation phase. A significantly smaller proportion of patients in the b.i.d. group completed the fixed-schedule titration period (73.1% versus 81.4%; OR 0.571; 95% CI 0.331–0.970; $P = 0.038$). The proportion of responders (patients showing at least a 50% decrease in all seizure frequency from baseline) was similar for both groups (44% for b.i.d. dosing and 48% for t.i.d. dosing) during the last 8 weeks of treatment. Seven (4%) patients in the b.i.d. group were seizure free, compared with 14 (8%) patients in the t.i.d. group.

Another multicentre trial was performed to determine whether a combination of AEDs with different mechanisms of action is superior to a combination of AEDs acting with a similar mechanism. In this study, patients on carbamazepine or phenytoin monotherapy with inadequately controlled complex partial seizures were randomized to add-on therapy with tiagabine or phenytoin (if previously receiving carbamazepine) or tiagabine or carbamazepine (if previously receiving phenytoin), and were titrated to an optimal dose under double-blind conditions [39]. Tiagabine ($n = 170$) showed similar efficacy to carbamazepine or phenytoin ($n = 175$) as adjunctive therapy for complex partial seizures, at low average doses of 24–28 mg/day. The study also suggested that tiagabine may be better tolerated when added to phenytoin or carbamazepine than when carbamazepine and phenytoin are added to each other.

Other studies in (predominantly) adult patients with partial epilepsy

In six long-term open-label trials, more than half of 2248 patients were treated with add-on tiagabine for more than 1 year. For each type of partial seizures, 30–40% of the patients obtained considerable improvement, which was maintained after 12 months of treatment [40]. Daily dosages in long-term studies were between 24 and 60 mg in the majority of patients, and mean and median doses were 45 mg/day for most studies. However, up to 15% of patients received a dose between 80 and 120 mg/day after their first year of treatment [30].

Open-label pragmatic studies allow a longer follow-up than trials required for drug registration and more closely mimic routine clinical practice. Three such studies in patients with refractory partial epilepsy have been conducted in Germany, Poland and Spain [41–43]. All of these studies have a longer follow-up period than the pivotal studies, and together included considerably more patients than the studies submitted in the registration dossier. These trials used the more recently recommended slower titration schedule in a total of 1151 patients, aged 3–93 years, who were followed for up to 6 months. Tiagabine was given three times daily, at an initial dose of 5 mg/day with dose increases of 5 mg per week. The maintenance dose was titrated individually according to the product's labelling. The average dose was 30 mg/day (range 5–90 mg). The proportion of patients with at least 50% improvement in seizure frequency varied from 41% to 61%, and 8–22% of patients became seizure free.

Studies in children

Tiagabine has been studied as adjunctive therapy in over 200 paediatric patients. A 4-month, single-blind study carried out at two centres in Denmark and one centre in France evaluated the response to ascending doses (0.25–1.5 mg/kg/day) of tiagabine as add-on therapy in 52 children over 2 years of age with different refractory epilepsy syndromes [25]. Tiagabine appeared to reduce seizures more in localization-related epilepsies than in generalized epilepsies. Seventeen of the 23 patients with localization-related epilepsies entered the fourth dosing period and had a median reduction in seizure rate in the fourth month of treatment of 33% compared with baseline. In comparison, 13 out of 22 children with seven different generalized epilepsy syndromes entered the fourth dosing period, with a median change in seizure rate of 0%. Among generalized seizures, tonic seizures and atypical absences improved to the greatest extent, with median percentage reductions in weekly seizure rate of 77% and 63%, respectively. The overall maximum daily dose of tiagabine received and tolerated (mean ± SD) was 0.65 ± 0.37 mg/kg.

In the USA, use of tiagabine in children with partial epilepsy has been studied as adjunctive therapy in a placebo-controlled, double-blind multicentre study. Altogether 103 children were randomized to placebo and 108 children to tiagabine. The age range varied between 2 and 11 years. The 7-week titration period was followed by a 12-week fixed-dose period. The initial dose of tiagabine was 0.1 mg/kg/day (given in three divided administrations), which was increased weekly by 0.1 mg/kg/day, and the maximum doses were 0.4 mg/kg/day (subjects taking inducers of CYP3A4) and 0.7 mg/kg/day (subjects not taking inducers of CYP3A4). The median seizure reduction was 16% in the placebo group and 25% in the tiagabine group. Altogether, 31% of children in the tiagabine group had a 50% or greater reduction in

seizure frequency compared with 19% in the placebo group (P = 0.021) [44]. The long-term use of tiagabine was studied in an open-label extension study in 152 children [45]. Of the 140 evaluable patients from the long-term follow-up, 10 were seizure free with tiagabine add-on therapy and 13 achieved seizure freedom with tiagabine monotherapy for periods ranging from 9 to 109 weeks. The shortest seizure-free or monotherapy durations were in patients with recent enrolment dates at the time of the report. The dose range was from 4 to 66 mg/day, and the average dose was 23.5 mg/day.

In a preliminary open-label trial in infantile spasms, 6 out of 12 infants had at least a 50% seizure reduction at dosages of 0.5–3.1 mg/kg/day [46].

Efficacy as monotherapy

The efficacy of tiagabine monotherapy was first assessed in a double-blind parallel-group 29-week study, which compared 6 mg/day with 36 mg/day tiagabine in 198 patients with refractory partial epilepsy who underwent gradual withdrawal of pre-existing AEDs after being started on add-on tiagabine [47]. According to the study design, patients were required to exit the trial when predefined criteria for seizure deterioration were met. Altogether, 33% of the patients on the low dose completed the assessment period, compared with 47% of those taking the higher dose. In both dose groups the median frequency of complex partial seizures decreased significantly during treatment compared with baseline ($P < 0.05$). However, a higher proportion of patients in the 36 mg/day group experienced a reduction in complex partial seizures of at least 50% compared with the 6 mg/day group (31% versus 18%, $P < 0.05$).

The second double-blind study was a randomized comparison of slow versus fast switch to tiagabine monotherapy in 40 patients with partial epilepsy uncontrolled by monotherapy with another AED, followed by an open-label evaluation [48]. If the patients did not tolerate the double-blind tiagabine titration scheme, an even slower open-label titration could be used. Thirty-four (85%) of the 40 patients were successfully switched to tiagabine monotherapy in either the double-blind or open-label drug-switching schemes. The results of this trial suggest that up-titration starting at 5 mg/day with weekly increments of 5 mg/day should be recommended in clinical practice. The retention rate in the study for 12 weeks on tiagabine monotherapy was 63% (25/40) and 48% (19/40) for 48 weeks. The initial target dose for tiagabine monotherapy was 10 mg b.i.d., but in the open-label phase tiagabine dose could be adjusted up or down according to the clinical judgement of the investigator up to a maximum daily dose of 70 mg. The median dose was 20 mg/day, with a range from 7.5 to 42.5 mg/day during the first 48 weeks.

A third monotherapy trial compared the efficacy of tiagabine and carbamazepine according to a double-blind, randomized parallel-group design in 290 patients with newly diagnosed partial epilepsy [49]. In the initial 6-week titration period, patients were titrated from tiagabine 5 mg/day or carbamazepine 200 mg/day to tiagabine 10 or 15 mg/day or carbamazepine 400 or 600 mg/day in a stepwise fashion. During the 44-week assessment period the dose could be adjusted within the ranges of 10–20 mg/day for tiagabine and 400–800 mg/day for carbamazepine. Both treatments were administered b.i.d. The study, which has only been published in abstract form, showed a significant difference between the study groups with regard to 'time to meeting an exit criterion' ($P < 0.05$). An exit criterion was either status epilepticus or the occurrence of a second seizure at the maximum tolerated or maximum allowed dose level. The proportion of patients who completed the assessment period either seizure free or with a single seizure was 41% (77 out of 144) in the tiagabine group and 53% (77 out of 144) in the carbamazepine group ($P < 0.05$). It has been suggested that the inferior efficacy of tiagabine compared with carbamazepine in this trial might have been due to the relatively low maximum dose of tiagabine that was allowed.

Adverse effects

Most common central nervous system adverse effects

In placebo-controlled short-term trials, some adverse CNS effects were found to be particularly common in tiagabine-treated patients (Table 53.2). Of these, the most frequent was dizziness, which consists of a feeling of light-headedness or unsteadiness, develops usually within 1–2 h of taking a tiagabine dose and is usually associated with the peak plasma concentration of the drug. Other adverse effects encountered more commonly with tiagabine than with placebo included asthenia (lack of energy), nervousness, tremor, concentration difficulties, depressed mood and language problems (difficulty in finding words or initiation of speech). The increased risk of CNS-related adverse events compared with placebo was evident in the titration period only, and there was no difference in rate of emergence of adverse effects during the fixed-dose period [30]. Altogether, 5% of the placebo patients and 13% of tiagabine patients discontinued prematurely because of adverse events ($P < 0.001$). Again, the majority of tiagabine-treated patients discontinued during titration and discontinuation rates for placebo and tiagabine were similar during the fixed-dose period. This suggests that tiagabine should be titrated slowly.

Central nervous system-related adverse effects were also shown to be clearly dose related in the US monotherapy study, in which a low dose (6 mg/day) and a high dose (36 mg/day) were compared [47]. When the tolerability of t.i.d. and b.i.d. dosing of tiagabine as adjunctive therapy in refractory partial seizures was evaluated [38], the incidence of adverse effects was similar between treatment groups but adverse effects seemed to be more severe in the b.i.d. dosing group, and more patients in the t.i.d. group could complete the study.

Based on these studies, it is recommended that to minimize adverse effects tiagabine should be given initially twice a day, with a change to three times daily dosing when dosages above 30 mg/day are used. Tiagabine should always be taken with food to avoid rapid increases in plasma concentrations. In individual patients, four times daily dosing may be helpful, at least at higher doses. Somnolence and drowsiness were not seen more frequently in tiagabine patients than in patients receiving placebo.

Other central nervous system adverse effects

Psychiatric adverse effects

There has been concern that tiagabine may be associated with an increased incidence of psychosis, particularly with rapid titration. Evaluation of psychosis-related adverse events showed there was no excess risk of this disorder attributable to tiagabine beyond what would be expected in a population with difficult-to-control partial seizures. In the three parallel-group add-on trials, the incidence of psychosis was 0.8% in the tiagabine-treated patients and 0.4% in the placebo-treated patients [30]. However, in clinical trials the proportion of patients with depression was significantly higher in those receiving adjunctive therapy with tiagabine than in those receiving placebo (5% versus 2%) [30]. Because of this concern, if there is a history of behavioural problems or depression, treatment with tiagabine should be initiated at a low initial dose under close supervision, as there may be an increased risk of recurrence of these symptoms during treatment with tiagabine.

Seizure aggravation and status epilepticus

Several cases of non-convulsive status epilepticus have been reported, with disappearance of status after withdrawal of tiagabine or reduction in dosage. In double-blind placebo-controlled trials in patients with partial epilepsy, however, the incidence of spike–wave status or any kind of status epilepticus was 3% (8 out of 275 patients) on placebo and 4% (22 out of 494 patients) on tiagabine, the difference being not statistically significant [50]. Further study of individual cases suggested that most of the subjects with apparently tiagabine-associated non-convulsive status had pre-existing spike–wave patterns and that, in some cases, the condition was related to drug-induced encephalopathy rather than status epilepticus. However, it would be wise not to use tiagabine in patients with unclassified epilepsy or patients with generalized epilepsy, especially those with a history of absence or myoclonic seizures and/or a history of spike–wave discharges on the electroencephalogram (EEG) or non-convulsive status epilepticus [51]. Tiagabine has not been shown to be effective in these patients, and there is evidence that AEDs increasing GABAergic transmission may exacerbate or induce absences or myoclonus [52]. In patients with a history of spike–wave discharges, cognitive or neuropsychiatric disturbances can be associated with exacerbation of the EEG abnormalities. However, in the documented cases of spike–wave discharges on EEG with cognitive/neuropsychiatric events, some patients with partial epilepsies have been able to continue tiagabine but required dosage adjustment [30].

In 2005 the Food and Drug Administration (FDA) announced that a bolded warning was to be added to the US labelling for tiagabine to warn prescribers about the risk of seizures in patients without epilepsy being treated with this drug. The FDA had become aware of reports of the occurrence of seizures in more than 30 patients prescribed tiagabine for conditions other than epilepsy [53]. Most of these uses were in patients with psychiatric illnesses. In addition to the occurrence of isolated seizures, the FDA received several reports of status epilepticus in patients without epilepsy. The use of tiagabine in psychiatric disorders, sleep disorders and drug dependence has been studied in several trials, but the safety and efficacy of tiagabine have not yet been established for indications other than epilepsy and therefore its off-label use should be discouraged [53].

Effects on cognition

The neuropsychological effects of tiagabine given as add-on therapy and as monotherapy have been evaluated, and no adverse effects on cognitive abilities have been demonstrated. In the largest short-term double-blind add-on study, 162 adults completed a multicentre dose–response study with random assignment to placebo or 16, 32 or 56 mg/day tiagabine [54]. The results of 19 measures of cognitive abilities and 18 measures of adjustment and mood showed only findings attributable to chance. Long-term cognitive results have been assessed in a double-blind, placebo-controlled parallel-group add-on study with an open-label extension involving 18- to 24-month follow-up [55]. The neuropsychological and EEG evaluation did not indicate any adverse effects of tiagabine during the double-blind phase at low doses (30 mg/day) or during the long-term open phase at doses up to 80 mg/day. The daily dosages in the long-term follow-up of this study were higher than in the previous reports.

Potential dose-related effects of tiagabine on cognition and mood were studied in a conversion-to-monotherapy study comparing doses of 6 mg/day and 36 mg/day tiagabine as monotherapy in previously uncontrolled epilepsy patients [56]. The study showed modest improvements in cognitive abilities and adjustment compared with baseline, during which the patients were receiving other AEDs. Tiagabine dose was related to the type of improvement, with the low dose more probably associated with improvement in adjustment and mood and the high dose probably associated with improvement in cognitive abilities. In the second conversion-to-monotherapy study, tiagabine was individually titrated to doses between 7.5 and 35 mg/day; in this study tiagabine did not produce cognitive or behavioural adverse effects compared with previous treatment using standard AEDs [57]. Successful tiagabine monotherapy seemed to be associated with improvement in simple psychomotor speed and to be associated with less fatigue compared with standard AEDs. A pooled analysis of two studies in newly diagnosed patients with partial seizures showed that after 52 weeks of tiagabine monotherapy (20–30 mg/day, $n = 42$) there were no detrimental effects on cognition. Results were similar to those recorded with carbamazepine monotherapy (400–800 mg/day, $n = 42$) [58].

Visual field investigations

Because of its action on GABAergic mechanisms, the question was raised as to whether tiagabine, like vigabatrin, can result in visual field abnormalities. However, there is no evidence that an increased risk of concentric visual field defects is a class effect of GABAergic drugs. The first ophthalmological study of 15 patients using tiagabine as monotherapy (mean daily dosage 21 mg, range 5–60 mg; mean duration of therapy 38 months, range 23–55 months) did not show any evidence of a relationship between visual field constriction and tiagabine treatment [59]. A larger cross-sectional study was set up in newly diagnosed patients with partial epilepsy receiving tiagabine, carbamazepine and lamotrigine as initial monotherapies [60]. Neurological and ophthalmological tests, including Goldmann and Humphrey perimetries, were performed. A neuro-ophthalmologist blindly reviewed all

visual charts. Seventy-three patients were included and completed the study. The population eligible for analysis included 68 patients, of whom 32 were treated with tiagabine (median duration, 25 months), 24 with carbamazepine (21 months), and 12 with lamotrigine (15 months). No patient treated with tiagabine showed a concentric visual field defect on Goldmann perimetry testing. No clinically relevant abnormalities in visual fields resembling those known with vigabatrin were detected, particularly in patients treated initially with tiagabine monotherapy. These findings support the evidence that tiagabine is not associated with retinal toxicity.

Idiosyncratic reactions

No idiosyncratic reactions have as yet been linked to the use of tiagabine [61]. No systematic abnormalities have been noted in haematology or blood chemistry values, and therefore there are no specific guidelines for routine monitoring of laboratory values during tiagabine treatment [30].

Teratogenicity

Teratogenic effects were seen in the offspring of rats exposed to maternally toxic doses of tiagabine, but not in animals receiving non-toxic dosages. Only very limited pregnancy data involving tiagabine, which show no clear evidence of teratogenicity, are available [62]. Therefore tiagabine cannot be recommended for women who are pregnant or at risk of becoming pregnant, and should be used only if the potential benefit justifies the potential risk to the fetus.

Place in current therapy

Tiagabine is indicated as add-on treatment for adults and children over 12 years with partial seizures with or without secondary generalization that cannot be satisfactorily controlled with other AEDs. The use of tiagabine in unclassified epilepsies and generalized epilepsy syndromes should be avoided, and off-label use in other indications is discouraged because of its potential to induce seizures and slow-wave activity in the EEG.

In most preclinical and clinical studies, the tiagabine dose was expressed in terms of milligrams of tiagabine hydrochloride. In the European Union, tiagabine is available as 2.5-, 5-, 10- and 15-mg tablets (content expressed as free base), and in the USA, Canada and Mexico it is available as 2-, 4-, 12-, 16- and 20-mg tablets (content expressed as tiagabine hydrochloride). A conversion factor of 0.91 can be used to convert the dose from tiagabine hydrochloride to tiagabine free base.

The current labelling in most countries states that the initial dosage is 7.5–15 mg/day, followed by weekly increments of 5–15 mg/day. In the USA, Canada and Mexico, the labelling suggests a lower initial dose of 4 mg/day, followed by weekly increments of 4–8 mg/day. Postmarketing studies and clinical experience to date suggest that tiagabine should be preferably started at a dose of 4 or 5 mg/day and gradually increased by weekly increments of 4 or 5 mg/day to minimize CNS-related adverse effects. Initial dosages can be given twice a day, but a switch to three times daily dosing is recommended with dosages above 30–32 mg/day. Tiagabine should always be taken with food, and preferably at the end of meals, to avoid rapid rises in plasma concentrations. Individual dosing four times daily may also be helpful, at least with higher doses.

Because tiagabine clearance is increased by enzyme-inducing AEDs, the usual initial target maintenance dosage in patients taking enzyme inducers is 30–32 mg/day, whereas in patients not taking enzyme-inducing drugs a lower initial maintenance dose of 15–16 mg/day is recommended [51]. The usual upper limit of maintenance dosages is 50–56 mg/day in patients taking enzyme-inducing drugs and 30–32 mg/day in patients not taking enzyme-inducing drugs. However, high daily doses of at least 70–80 mg are well tolerated in some individual patients. Patients taking a combination of inducing and non-inducing drugs (e.g. carbamazepine and valproate) should be considered to be enzyme induced. No AED should be suddenly withdrawn and, although there are no clinical data, it seems sensible to withdraw tiagabine gradually over at least 2–3 weeks [51].

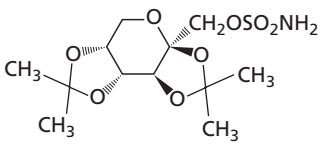
54 Topiramate

J. Helen Cross[1] *and Catherine J. Riney*[2]

[1]Institute of Child Health and Great Ormond Street Hospital for Children NHS Trust, London, UK
[2]University College London Institute of Child Health, London, UK



Primary indications	Adjunctive therapy or monotherapy in partial and secondarily generalized seizures. Also useful for Lennox–Gastaut syndrome and primary generalized tonic–clonic seizures
Usual preparations	Tablets: 25, 50, 100 and 200 mg. Sprinkle capsules: 15 and 25 mg
Usual dosages	Initial: 25 mg/day (adults), 0.5 mg/kg/day (children). Maintenance: 100–500 mg/day (adults), 2–9 mg/kg/day (children)
Dosing frequency	Twice a day
Significant drug interactions	Topiramate levels are lowered by carbamazepine, phenobarbital and phenytoin. Topiramate may increase serum phenytoin levels
Serum level monitoring	May be useful in selected cases
Reference range	5–20 mg/L
Common/important adverse effects	Dizziness, ataxia, headache, paraesthesia, tremor, somnolence, cognitive dysfunction, confusion, agitation, amnesia, depression, emotional lability, nausea, diarrhoea, diplopia, weight loss
Main advantages	High responder rates
Main disadvantages	Central nervous system adverse effects
Mechanisms of action	Blockade of sodium channels; potentiation of GABA-mediated inhibition at the $GABA_A$ receptor; reduction of excitatory actions of glutamate via the AMPA receptor; inhibition of high-voltage calcium channels; inhibition of carbonic anhydrase
Oral bioavailability	Close to 100%
Time to peak levels	2–4 h
Elimination	Partly by renal excretion and partly by oxidative metabolism
Volume of distribution	0.6–1.0 L/kg
Elimination half-life	10–30 h (varies with co-medication)
Plasma clearance	15–50 mL/kg/h (varies with co-medication)
Protein binding	13–17%
Active metabolites	None
Comment	A useful antiepileptic drug with relatively broad-spectrum efficacy

Introduction

Topiramate sulphamate is a second-generation antiepileptic drug (AED) that exerts antiepileptic activities by a combination of mechanisms of action, resulting in a relatively broad-spectrum efficacy in a variety of seizure types and epilepsy syndromes, partial and secondarily generalized seizures, some idiopathic generalized epilepsies and drop attacks associated with the Lennox–Gastaut syndrome. It is used in both adults and children, either as monotherapy or as an adjunctive agent.

Chemistry

Topiramate, 2,3 : 4,5-bis-*O*-(1-methylethylidene)-α-D-fructopyranose sulphamate, is a sulphamate-substituted monosaccharide,

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

derived from D-fructose. Its empirical formula is $Cl_2H_{21}NO_8S$ and its molecular weight 339.37. It is a white crystalline powder with a bitter taste and a pK_a of 8.61 at 25°C. It is highly soluble in alkaline solutions containing sodium hydroxide or sodium phosphate and stabilized at a pH of 9–10. It is also freely soluble in acetone, chloroform, dimethyl sulphoxide and ethanol. The solubility in water is 9.8 mg/mL at pH 6.7.

Pharmacology

Topiramate produces its anticonvulsant effects through inhibition of voltage-sensitive sodium and calcium channels, enhancement of γ-aminobutyric acid (GABA)-mediated activity and inhibition of kainate/α-amino-3-hydroxy-5-methylisoxazole-4-proprionic acid (AMPA)-type glutamate receptors (Table 54.1). It also is known to be an inhibitor of carbonic anhydrase due to similarities in structure to acetazolamide.

In cultured rat pyramidal neurones, topiramate decreases or abolishes sustained repetitive firing and spontaneous epileptiform burst firing in a dose-dependent and partially reversible manner [1]. These actions are consistent with an effect involving modulation of sodium and/or calcium channel conductance. Further studies of rat subicular neurones [2], cerebellar granule cells [3] and recordings from neocortical neurones [4] as well as studies with cultured mouse spinal neurones [5] have all provided evidence of an effect of topiramate on sodium channel conductance. Topiramate induces a hyperpolarization of the resting cell membrane potential and depresses the ability of cells to produce action potential bursts and spontaneous repetitive firing in response to depolarizing pulses. In addition, studies of whole-cell patch-clamp recordings from rat dentate granule cells also provide support for an inhibitory effect of topiramate on L-type high-voltage activated calcium channels [6].

A separate potential mechanism for the anticonvulsant action of topiramate is enhancement of GABA-mediated activity. Topiramate potentiates GABA-mediated chloride flux into neurones in a rapid and reversible manner [7] and the hyperpolarizing effects of topiramate on resting membrane potentials can be reversed using $GABA_A$ receptor antagonists [2]. Topiramate has also been shown to block the kainate-elicited membrane currents in cultured rat hippocampal pyramidal neurones induced by activation of the AMPA-type glutamate receptor [8]. However, it does not block membrane currents elicited through *N*-methyl-D-aspartate (NMDA) activation of NMDA receptors, which is relatively unique for an anticonvulsant drug.

Although topiramate has an inhibitory effect on carbonic anhydrase, this is a relatively weak action (acetazolamide is 10–100 times more potent). The inhibitory effect has been shown to be selective, affecting mostly two out of the six carbonic anhydrase isoenzymes (CAII and CAIV) [9]. This action is likely to be responsible for some of the adverse effects of topiramate, for example the increased incidence of renal stones and paraesthesia.

The multiple pharmacological actions of topiramate, in addition to contributing broad-spectrum efficacy in a variety of seizure types, are likely to be the reason that it also has a wide range of non-epilepsy indications (see section on non-epilepsy indications).

Table 54.1 Proposed mechanisms of action of topiramate.

Site	Action
Voltage-activated sodium channel	Limits sustained repetitive firing via state-dependent blockade of sodium channels
GABA receptor	Potentiates GABA-mediated neuroinhibition at a $GABA_A$ receptor site not modulated by benzodiazepines or barbiturates
Glutamate receptor subtypes (kainate/AMPA)	Blocks glutamate-mediated neuroexcitation with no apparent effect on NMDA receptor activity
Calcium channels	Mild reduction of high-voltage activated calcium current amplitude
Carbonic anhydrase	Antagonizes isoenzymes, types II and IV

AMPA, alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

Pharmacokinetics

Overall pharmacokinetic features

Given within the normal dosing range, topiramate shows linear pharmacokinetics. The drug is rapidly and well absorbed from the gastrointestinal tract, with peak plasma concentrations occurring approximately 2–4 h after administration [10]. Ingestion with food delays topiramate absorption by about 2 h but the maximal plasma concentrations are unchanged for a given oral dose [11]. This is independent of whether the sprinkle or tablet formulation is used. Topiramate does not, therefore, need to be given in any fixed relationship to meal times.

Topiramate is widely distributed in all tissues and primarily to body water. Plasma protein binding is minimal (13–17%) [10]. A steady state is achieved in 4–6 days of regular dose administration in patients with normal renal function and the elimination half-life is in the order of 20–30 h in patients not taking enzyme inducers and 10–15 h in patients co-medicated with enzyme inducers. Apparent oral clearance (CL/*F*) values in non-induced and in enzyme-induced subjects are in the order of 15–30 and 30–50 mL/h/kg, respectively, [11,12].

Topiramate is excreted unchanged through the kidneys [13], although a fraction of the oral dose is metabolized, mostly by the cytochrome P450 (CYP) microsomal enzymes. In the absence of enzyme induction, the fraction of a topiramate dose excreted unchanged in the urine is in the order of 60–70%, but this decreases to about 40% in patients co-medicated with enzyme-inducing AEDs. At least 12 metabolites have been identified, formed by hydroxylation, hydrolysis, glucuronide or sulphate conjugation or cleavage of the sulphamate group [13]. None of these metabolites has antiepileptic activity.

Pharmacokinetics in special populations

Children

Topiramate CL/*F* values in infants older than 6 months and in children are 1.5- to 2-fold higher than in adults [12,14,15]. The increased clearance in children is inversely proportional to the child's age, presumably indicating an age-dependent change in the

rate of drug elimination. As in adults, topiramate CL/*F* values in children are, on average, about twofold higher in the presence of enzyme-inducing co-medication than with children not receiving enzyme inducers. For any given steady-state serum concentration to be achieved, the dosage of topiramate in milligrams per kilogram per day is expected to be higher in children than in adults. In fact, doses of up to 38 mg/kg/day have been used in some studies involving very young children, although such doses would not be usual in current clinical practice [14].

The elderly

Topiramate CL/*F* values are reduced by about 20% on average in elderly patients aged 65–85 years compared with non-elderly adults [12]. However, in patients older than 80, a greater decrease in clearance would be expected. Age-related changes in CL/*F*, together with interindividual variability in pharmacodynamic response, contribute to the need for individualized assessment of dosing in these patients.

Impaired renal function

Topiramate CL/*F* is reduced in patients with impaired renal function. This has been studied by giving a single 100-mg dose to patients with moderate (CL_{Cr} 30–69 mL/min) or severe ($CL_{Cr} \leq$ 30 mL/min) renal impairment and matching volunteers with normal renal function ($CL_{Cr} \geq 70$ mL/min) [16]. Topiramate CL/*F* was reduced by 42% in patients with moderate renal impairment and by 54% in patients with severe renal impairment compared with the volunteers with normal renal function. Therefore, topiramate doses should be reduced in patients with impaired renal function, according to the individual's creatinine clearance. In renal impairment, the time to achieve steady state is increased and dose adjustments should be made at intervals of 2 weeks rather than weekly, as is the practice for patients without renal impairment. With haemodialysis, however, topiramate CL/*F* significantly increases as topiramate is removed during the haemodialysis process. The clearance of topiramate during dialysis may be four to six times that of an individual with normal renal function. Patients undergoing haemodialysis may need additional dosage of topiramate for this reason.

Impaired hepatic function

Compared with healthy matched control subjects, topiramate CL/*F* was 26% lower and topiramate plasma concentrations were increased by 29% in five patients with moderate to severe liver impairment [17]. These changes were not considered clinically significant.

Drug interactions

Enzyme-inducing AEDs, such as phenytoin, phenobarbital and carbamazepine, induce the metabolism of topiramate. For example, concomitant carbamazepine therapy lowers the topiramate concentration by 40% when compared with topiramate monotherapy [18]. Relative to patients (both paediatric and adult) not receiving enzyme-inducing co-medications, those receiving enzyme-inducing AEDs exhibit a 1.5- to 2-fold increase in topiramate oral clearance (CL/*F*) and an approximately 50% reduction in the topiramate half-life. Dose adjustments to topiramate may therefore be required when phenytoin, phenobarbital or carbamazepine are added to or withdrawn from topiramate therapy.

In most patients, topiramate has no significant effect on the plasma concentrations of most concomitant AEDs. No change from baseline has been seen in the steady-state plasma concentrations of carbamazepine or its metabolite carbamazepine-10,11-epoxide with the addition of topiramate treatment [18]. When topiramate has been added to sodium valproate, a slight increase in valproic acid CL/*F* was noted together with a small decrease in plasma concentration, which did not appear to be clinically relevant [19]. Possible synergistic actions have been reported in animals and humans between lamotrigine and topiramate [20]. In children with partial-onset seizures, minor (about 10%) decreases in lamotrigine levels were noted in patients on topiramate compared with those who were given placebo [21].

Topiramate does not inhibit *in vitro* the CYP isoenzymes, except for some inhibition of CYP2C19 at very high concentrations (5–15 times the recommended clinical dosing regimen for adults) [22]. Inhibition of CYP2C19 does suggest that topiramate could inhibit phenytoin metabolism, but this isoenzyme is responsible for only 20% of phenytoin metabolism, so only a slight effect would be anticipated. *In vivo*, in a study of 12 patients on phenytoin treatment, nine patients had no change in plasma phenytoin levels when topiramate therapy was initiated, but an increase in phenytoin levels was noted in three patients [22]. Phenytoin metabolism might have been nearer saturation in these patients, so that a small inhibition of metabolism may have been sufficient to lead to the increase in the plasma phenytoin concentration. A dose reduction of phenytoin may therefore be required in some patients when topiramate is added, and phenytoin levels should be monitored in these patients.

Interactions between topiramate and other drugs, such as low-dose oral contraceptives, hydrochlorothiazide, metformin and risperidone, do occur, and this may require monitoring and/or dose adjustments (Table 54.2). Dose-dependent enzyme induction by topiramate leads to a decrease in the plasma concentration of ethinylestradiol, the oestrogen component of most oral contraceptives, but this interaction occurs only at relatively high topiramate dosages (>200 mg/day) and is not seen when lower doses are used [23–25]. The concomitant use of topiramate and other carbonic anhydrase inhibitors is not recommended.

Serum level monitoring

An overview of studies that assessed the relationship between serum topiramate concentrations and clinical response concluded that patients receiving therapeutic doses usually have levels in the range of 5–20 mg/L [26]. However, there is a considerable overlap between serum levels associated with an optimal response and those associated with toxicity. In recent years, there has been a trend to prescribe a lower dosage of topiramate than the doses used in earlier studies, and it is therefore likely that most patients achieving a good response do so at concentrations in the lower part of the range cited above. Although topiramate dose is usually adjusted on the basis of clinical response alone, monitoring serum concentrations may be of help in selected situations.

Table 54.2 Potential drug interactions with topiramate.

Co-medication	Interaction expected
Carbamazepine	Decreased serum levels of topiramate (see text)
Valproic acid	Possible minor decrease in the levels of valproic acid and topiramate. Possibly increase risk of hepatic encephalopathy
Phenobarbital/primidone	Decreased serum levels of topiramate (see text)
Phenytoin	Decreased serum levels of topiramate (see text) Increased serum phenytoin levels in some patients
Amitriptyline	Modest increase in serum amitriptyline and nortriptyline levels
Carbonic anhydrase inhibitors	Increased risk of renal calculi and hyperthermia
Central nervous system depressants	Increased risk of CNS depression
Digoxin	Minor decrease in serum digoxin levels
Haloperidol	Slight increase in serum haloperidol levels and a moderate increase in serum levels of the reduced haloperidol metabolite
Hydrochlorothiazide	Moderate increase in serum topiramate levels
Lithium	Slight decrease in serum lithium levels
Metformin	Moderate increase in serum metformin levels Decrease (extent unclear) in serum topiramate levels
Oral contraceptives	Decreased serum ethinylestradiol levels with doses of topiramate above 200 mg/day
Pioglitazone	Slight decrease in serum pioglitazone levels, and 60% decrease in serum levels of the active metabolite keto-pioglitazone
Risperidone	Modest decrease in serum risperidone levels, but no change in exposure to active moiety (risperidone + 9-hydroxy-risperidone)

Updated from ref. 25.

Efficacy

The antiepileptic efficacy of topiramate has been evaluated in numerous trials, both as a monotherapy and as an adjunctive therapy. Initial trials were undertaken in adults with refractory partial-onset seizures and high maintenance doses were used. With subsequent experience, it was recognized that greater adverse effects were reported when faster titration schedules and higher dosages were used, and further trials used substantially lower doses. Using slower titration schedules was also recognized to have no impact on the overall efficacy of topiramate [27–29]. The pivotal adjunctive therapy trials have demonstrated a reduction in frequency of seizures by at least 50% in 35–50% of subjects.

Monotherapy

The effectiveness of topiramate as monotherapy is clearly established. In a randomized double-blind dose comparison study in patients with newly diagnosed partial (with or without secondary generalization) or primarily generalized tonic–clonic seizures, topiramate used as monotherapy at a dose of 400 mg/day was associated with a greater proportion of seizure-free patients at 6 and 12 months ($P < 0.01$) than topiramate at a dose of 50 mg/day [30]. The first evaluation point with a significant difference ($P = 0.046$) favouring the higher dose was at day 14, when patients were receiving 100 or 25 mg/day. In an open trial of topiramate monotherapy in 692 patients with partial or generalized epilepsy who were treatment naive or had failed with prior treatment using one AED, 76% of patients were reported to have had a >50% reduction in seizure frequency with 44% of patients rendered seizure free [31]. The proportion of patients with partial seizures treated with topiramate for 6–7 months in these studies achieving seizure freedom was reported to be 40–82%, and the proportion of patients with generalized epilepsy achieving seizure freedom after a similar treatment period was 62–85%. Topiramate has therefore been demonstrated to be effective as monotherapy for both partial and generalized seizure types.

A number of comparative monotherapy trials have also been undertaken, providing data on the comparative efficacy of topiramate relative to other older and newer AEDs. In a randomized double-blind trial in 613 patients with newly diagnosed epilepsy, Privitera *et al.* [32] reported that the time to trial exit (due to inefficacy of treatment, adverse events, subject choice or loss to follow-up) was similar for topiramate, carbamazepine and valproate. In the secondary outcome measures (time to first seizure and proportion of seizure-free patients during the last 6 months of treatment), topiramate, carbamazepine and valproate also performed in a similar fashion. Two further comparative randomized non-blind trials conducted within the context of the SANAD (standard and new antiepileptic drugs) collaboration have been undertaken in patients with generalized or unclassified epilepsy [33] and in patients with partial epilepsy [34]. These flexible-dosage trials compared the efficacy and tolerability of valproate monotherapy (for patients with mostly generalized/unclassified epilepsy) against topiramate or lamotrigine [33], and the efficacy of carbamazepine (for patients mostly with partial seizures) against topiramate, gabapentin, lamotrigine or oxcarbazepine [34]. In the study of patients with generalized or unclassified epilepsy, topiramate was inferior to both valproate or lamotrigine in time to treatment failure (defined as 'time to cessation of treatment because of adverse events, inadequate seizure control or the addition of another AED'). Topiramate was more effective than lamotrigine, but not as effective as valproate in the time taken to achieve a 1-year period of remission from seizures. In the study of patients with partial epilepsy, topiramate was found to fare worse than carbamazepine for time to treatment failure (largely owing to adverse events). For time taken to achieve a 1-year remission from seizures, topiramate was not significantly different from carbamazepine or lamotrigine but for time to a 2-year remission from seizures carbamazepine was significantly better than topiramate.

Adjunctive therapy

A number of randomized placebo-controlled double-blind trials have demonstrated that topiramate is effective as an adjunctive therapy in adults and children with primary generalized tonic–clonic seizures [35], partial seizures with or without secondary generalization [21,36] and major seizures associated with the Lennox–Gastaut syndrome [37].

The efficacy of topiramate as adjunctive therapy for refractory partial-onset seizures was reviewed by the Cochrane collaboration [38]. The analysis included ten randomized placebo-controlled double-blind trials representing 1312 randomized participants. The relative risk for a 50% or greater reduction in

seizure frequency with topiramate compared with the placebo was 2.85 (95% CI 2.27–3.59), and dose regression analysis showed an increasing effect with increasing dose, but no advantage for doses over 300 mg or 400 mg per day. However, an individual study in adults with partial-onset seizures demonstrated a greater effect for topiramate dosages of 400 mg/day than dosages of 200 mg/day [36]. In a double-blind placebo-controlled trial in children with partial-onset seizures on one or two AEDs at the optimal dosage, addition of topiramate was effective in reducing the median seizure frequency from baseline (33% in the topiramate group versus 11% in the placebo group, $P = 0.03$), and there was a statistically significant greater proportion of children in the topiramate arm achieving >75% reduction in seizure frequency [21]. With a baseline seizure rate of 20 seizures per month, 5% of children receiving topiramate were seizure free during the 16-week study; however, no placebo-treated children were seizure free. No children discontinued topiramate treatment because of adverse events in the trial period. An open-label trial of large numbers of patients ($n > 400$) with partial-onset seizures and topiramate dosage adjustments according to clinical response have also demonstrated a reduction in median seizure frequency with topiramate therapy [29]. In this trial, topiramate tolerability was improved, with fewer discontinuations owing to adverse effects when dosages of concomitant AEDs were reduced.

In a randomized double-blind placebo-controlled trial in 80 adults and children with primary generalized tonic–clonic seizures [35], topiramate was titrated to target doses of approximately 6 mg/kg/day over 8 weeks and maintained for another 12 weeks. Median percentage reduction from baseline in primary generalized tonic–clonic seizure rate was 57% in the topiramate group compared with 9% for the placebo group ($P < 0.02$). Responder rates (proportion of patients with at least 50% reduction in primary generalized tonic–clonic seizures compared with baseline) were 56% and 20% for the topiramate and placebo groups, respectively ($P = 0.001$).

In a placebo-controlled trial in adult and paediatric patients with Lennox–Gastaut syndrome, topiramate was associated with a greater reduction in all major seizure types including drop attacks [37]. Patients receiving at least one standard AED had to have a confirmatory electroencephalogram (EEG) showing a slow spike–wave pattern with multiple seizure types including drop attacks (i.e. tonic or atonic seizures) and a history of atypical absences. Following randomization, topiramate was started at 1 mg/kg/day and increased at weekly intervals to 3 mg/kg/day and then 6 mg/kg/day. Stabilized dosages were maintained for an additional 8 weeks. In patients receiving topiramate, the median percentage of reduction in drop attacks was 15% compared with a 5% increase in patients receiving placebo ($P = 0.04$). The median percentage reduction in major motor seizures (drop attacks and tonic–clonic seizures combined) was 26% with topiramate treatment compared with a 5% increase with placebo ($P = 0.02$). The proportion of patients achieving at least 50% reduction in drop attacks was higher in the topiramate group than in placebo-treated patients (28% versus 14%, $P = 0.07$). With 33% of topiramate-treated patients and 8% of placebo-treated patients achieving at least 50% reduction in major motor seizures ($P = 0.002$), the effectiveness of topiramate against major motor seizures was similar to that previously reported with lamotrigine [39].

The benefits of topiramate on seizure reduction have also been documented in longer-term non-comparative open-label trials of topiramate as adjunctive therapy [40,41]. During long-term treatment in patients with generalized epilepsy [40], 16% of patients ($n = 96$) receiving topiramate for at least 6 months had no generalized tonic–clonic seizures for at least 6 months (mean topiramate dose 500 mg/day or 7 mg/kg/day for children). In patients treated for up to 2.5 years in this study ($n = 131$), 5% discontinued owing to inadequate seizure control and 8% discontinued owing to adverse events. Among patients who entered the long-term, open-label extension of the Lennox–Gastaut study [41], during which dosages of topiramate and concomitant AEDs could be adjusted according to response, drop attacks were reduced by at least 50% in 55% of patients receiving topiramate (mean dose 10 mg/kg/day) for at least 6 months ($n = 82$). Despite having had initially an average of 90 drop attacks per day, 15% of patients had no drop attacks for at least 6 months. Substantial reductions were also observed in atypical absence, myoclonic and tonic–clonic seizures. During follow-up for up to 3.4 years ($n = 97$), 12% of patients discontinued treatment owing to inadequate seizure control and 10% discontinued owing to adverse events. In an extension of the controlled trial of topiramate as adjunctive therapy in children with partial-onset seizures [21] with doses adjusted according to clinical response (mean 9 mg/kg/day) and a follow-up period of up to 2.5 years ($n = 83$), 14% of children were seizure free for at least 6 months and seizure frequency over the last 3 months of therapy was reduced in 57% of children. Six per cent of children discontinued treatment because of adverse events and 13% because of inadequate seizure control [42].

Patient retention rates provide another measure of long-term effectiveness. In a retrospective review of patients with refractory partial and/or generalized epilepsy in an adult tertiary referral centre [43,44] 1-year retention rates were 52% for topiramate, 46% for lamotrigine and 23% for gabapentin; 3-year retention rates were 30%, 29% and 10% respectively. Estimated retention rates at 5 years were 28% (topiramate), 12% (lamotrigine) and 2% (gabapentin). Perceived lack of efficacy resulted in treatment withdrawal in 19% of topiramate-treated patients compared with 39% of those receiving lamotrigine and 34% of those treated with gabapentin. Factors associated with long-term retention in topiramate-treated patients included higher maximal daily doses; younger age of epilepsy onset; prior exposure to fewer than two new AEDs; and treatment with no more than one concurrent AED [44]. A similar 1-year retention rate (55%) was reported for 174 patients receiving topiramate in a specialist regional epilepsy clinic [45]. When topiramate was substituted for another drug, the retention rate was 56% compared with 41% when topiramate was added to existing therapy ($P < 0.05$). Adverse events were more frequent in add-on patients than in substitution patients, which may reflect the lower tolerance of the drug when interactions occur with other AEDs. In total, nine (5%) patients became seizure free in the long term.

Studies in other paediatric epilepsy syndromes

In addition to trials that included children with partial-onset seizures, generalized tonic–clonic seizures and seizures associated with Lennox–Gastaut syndrome, there have also been a number

of open-label uncontrolled studies providing some information on the use of topiramate in children with other specific epilepsy syndromes, although the numbers of treated children in some of these studies are small.

West syndrome

The effectiveness of topiramate in West syndrome, characterized by infantile spasms, learning disability and hypsarrhythmia on EEGs, was evaluated in a pilot study in 11 infants refractory to previous AED therapy [46]. Topiramate dose was increased until seizures were controlled, adverse events limited further escalation or a maximum dose of 24 mg/kg/day was reached. The mean frequency of spasms was significantly reduced compared with baseline ($P = 0.003$). Nine patients (82%) had at least 50% reduction in spasms and five patients (45%) became spasm free. During long-term treatment, four out of the five spasm-free children remained spasm free for an average of 18 months (mean topiramate dose of 29 mg/kg/day). A subsequent study has reported success in the treatment of spasms using a combination of vigabatrin and topiramate [47]. In this study of four patients with cryptogenic infantile spasms, topiramate was added to vigabatrin when vigabatrin monotherapy had failed to control spasms or improve the background EEG. In all patients the addition of topiramate achieved rapid control of the spasms, and in three children the EEG also normalized and development progressed.

Childhood absence epilepsy

During a pilot study, children with typical absence seizures (documented as 3-Hz spike–wave on the EEG) who were untreated or taking only one AED were given topiramate. Among five children (6–11.5 years of age) completing the 6-week study, one previously untreated child became seizure free, two showed no improvement in clinical seizures or EEG activity and two showed an initial reduction in seizures, but seizures increased with higher topiramate dosages. With topiramate dose reduction to 6 mg/kg/day in these two children, seizure control improved (one became seizure free and one had at least 50% seizure reduction) [48].

Severe myoclonic epilepsy of infancy

The use of topiramate has also been reported in children with severe myoclonic epilepsy of infancy (Dravet's syndrome) [49]. This is a syndrome first described by Dravet, in which children initially present with prolonged, often lateralized, seizures in the first year of life with the emergence of myoclonus and developmental regression from the second year. Nieto-Barrera *et al*. [49] reported on 18 children with this syndrome who had topiramate added to their current therapy. At the time of entry in the study, these children had been treated with a mean of 6.7 different AEDs. The children were followed up for a mean of 10.5 months after the initiation of therapy with topiramate (range 6–18 months). At the end of the study 72% of patients had at least a 50% reduction in seizures, 50% at least a 75% reduction and 16.6% were seizure free. Other authors have also reported topiramate to be an effective medication for this syndrome [50].

Angelman's syndrome

In a report on the use of topiramate in five children with Angelman's syndrome, two children were seizure free on topiramate monotherapy after a mean of 8.8 months of observation [51].

Special epilepsy populations

Clinical reports suggest that topiramate is effective in controlling seizures in patients with learning difficulties [52,53]. Among 64 patients with refractory epilepsy who were learning disabled, 70% achieved at least 50% seizure reduction with topiramate adjunctive therapy. Sixteen patients (25%) became seizure free, including 10 who were receiving topiramate doses ≤200 mg/day [52]. In a group of 20 patients with intractable epilepsy (mixed seizures), mental retardation and developmental disabilities who were treated with topiramate adjunctive therapy, 69% had at least 50% seizure reduction and two (13%) were seizure free [53].

A recent 24-week pilot trial compared the efficacy and tolerability of topiramate as add-on or monotherapy in 77 elderly patients (mean age, 68 years) with one or more partial-onset seizures in the previous 6 months [54]. Patients were randomized to receive either 50 or 200 mg/day topiramate, titrated by 25 mg/day per week to target or maximum tolerated dose. Seizure control was similar with the two dosages when the drug could be used as a monotherapy, but 200 mg/day was more effective in patients requiring adjunctive therapy. A total of 14 patients (seven in each group) discontinued topiramate use as a result of adverse events. The authors concluded that their findings support the practice of using low-to-moderate dosages of AEDs in older adults.

Non-epilepsy indications

Migraine

Topiramate has now been established as a prophylactic treatment for migraine. Three randomized, double-blind, placebo-controlled trials in over 1500 patients have shown that topiramate decreases the frequency of migraine attacks with a good safety profile [55]. The optimal maintenance dosage for this indication is usually 100 mg/day. Adverse events reported in migraine patients are generally mild, with paraesthesia, fatigue, nausea and impaired concentration being those most commonly reported. Treatment is usually given for 6–12 months, but it is recognized that the antimigraine effect of topiramate can outlast the duration of therapy. In fact, sustained benefit (reduced migraine frequency and better quality of life) have been reported in patients after discontinuation of topiramate treatment [56].

Psychiatric disorders

Although there are a number of open clinical studies reporting that topiramate can be of benefit in a range of psychiatric disorders, including refractory bipolar mania, refractory bipolar depression, mood disorders, post-traumatic stress disorder and substance abuse, controlled studies are few in number. In some double-blind placebo-controlled trials that have been undertaken, there has been no demonstrable effect of topiramate therapy on bipolar I disorder [57], bipolar type schizoaffective disorder [58], acute mania [59] or post-traumatic stress disorder [60].

Neuropathic pain

Like other AEDs, topiramate may have a role in the treatment of neuropathic pain. In one double-blind, randomized, two-period

cross-over trial of topiramate (50–400 mg/day) with diphenhydramine as an active placebo in patients with chronic lumbar radicular pain, global pain scores were better during topiramate therapy ($P < 0.005$), even though many adverse effects and dropouts were reported [61]. A beneficial effect of topiramate was not observed in patients with painful diabetic neuropathy [62].

Obesity

A placebo-controlled trial of topiramate as a treatment of binge eating disorders and body mass index between 30 and 50 kg/m^2 has demonstrated that topiramate has an effect in reducing binge eating and body mass index [63,64]. In addition to reducing weight, topiramate therapy has been associated with improvement in blood pressure and glucose homeostasis in obese patients [65]. Topiramate has also been evaluated in patients with obesity and type 2 diabetes mellitus, in whom it was demonstrated to be effective (when combined with lifestyle alterations) in producing weight loss and improvement in glucose homeostasis [66]. In patients with bipolar-type schizoaffective disorder, topiramate has been shown to reduce weight and body mass index, although without a significant effect on the underlying bipolar disorder [58]. The positive effects of the drug on body weight, however, should be weighed carefully against the risk of adverse effects.

Adverse effects

The efficacy of any AED has to be balanced with the possible adverse effect profile. Early evidence of topiramate's adverse effects came from randomized controlled adjunctive therapy trials, which suggested that the most troublesome adverse effects were CNS related. In these investigations, titration was over a 4- to 6-week period, and adverse effects were influenced by the population studied as well as the specific titration rates and dosages used. Subsequent open-label extensions and observational studies contributed further information on the adverse effect profile of topiramate as well as on its long-term usage.

Central and peripheral nervous system-related adverse effects that occur with topiramate include cognitive effects (confusion, psychomotor slowing, difficulties with concentration and attention, memory problems and speech and language problems, especially word-finding difficulties and reduced verbal fluency), psychiatric or behavioural disturbance (anxiety, depression, mood changes and rarely psychotic symptoms), somnolence, fatigue and other effects such as dizziness, paraesthesia, incoordination, vertigo and involuntary movements. Cognitive adverse effects can occur in isolation. Many of these effects are more common with rapid titration rates and higher initial dosages [27]. Other adverse effects include metabolic acidosis, renal calculi, hypohidrosis, loss of appetite, weight loss, diarrhoea and ophthalmological adverse effects, including blurred vision, diplopia, acute angle-closure glaucoma and ciliochoroidal detachment.

Although initial trials reported a wide range of troublesome CNS effects, in longer-term trials using individualized dosages and titration rates representative of current clinical practice [31,67], the most frequently reported adverse effects were mainly restricted to somnolence and fatigue, paraesthesia, headache, anorexia and weight loss. Flexibility in topiramate dosing rates and in adjustments of the dose of concomitant AEDs has been associated with improved tolerability [30] with a lower proportion of patients exiting the study because of adverse events. There are few head-to-head clinical trials comparing the tolerability of topiramate with other AEDs, but one comparative double-blind trial in patients with newly diagnosed epilepsy found no significant difference in the proportion of patients discontinuing treatment with either topiramate, valproate or carbamazepine [32]. In the arm of the SANAD monotherapy trial that included mostly patients with partial seizures [34], the proportion of patients experiencing at least one adverse event was 53% for topiramate, 48% for carbamazepine and 45% for lamotrigine. In the arm that included mostly patients with generalized or unclassified epilepsy [33], the proportion experiencing at least one adverse event was 45% for topiramate, 36% for valproate and 37% for lamotrigine. In both arms of the trial, discontinuation rates owing to adverse effects were higher for patients receiving topiramate than for those randomized to the other AEDs. Adverse events reported in children are similar to those reported in adults, and, as in adults, adverse events are more prevalent with faster rates of titration and polytherapy.

Central nervous system adverse effects

A clear association has been shown between topiramate and cognitive decline in a study that measured cognitive scores in patients with refractory epilepsy during and after adjunctive topiramate therapy, and in a further group of patients assessed before and during topiramate therapy [68]. There appears to be a specific profile for topiramate-related cognitive adverse effects, with a particular impact on working memory, short-term verbal memory, language skills (including verbal fluency), verbal IQ, attention/concentration, processing speed, complex visuomotor ability and perception [68–75]. In most individuals it appears that these effects can be minimized by a slow, cautious introduction of the medication and by minimizing polytherapy. However, there appears to be a small proportion of patients who are extremely sensitive to these adverse effects and are unable to tolerate topiramate regardless of how cautious the introduction is. It is recognized that the effects of topiramate on cognition may appear even at low doses and persist with long-term treatment [69], but cognitive deficits have been demonstrated to be reversed on withdrawal of topiramate [75].

Topiramate can also have a negative effect on mood, with dose-dependent mood lability and affective disorder reported in around 10% of patients [76]. Symptoms of psychosis have been seen in some patients [76], but it is not clear if the incidence is greater than expected in populations with severe epilepsy.

Paraesthesiae are frequently reported in adult patients on topiramate, and are likely to be related to carbonic anhydrase inhibition.

Metabolic acidosis, bone effects and renal calculi

There are a number of adverse effects of topiramate, in addition to paraesthesiae, that are probably related to inhibition of carbonic anhydrase. These include an association with hyperchloraemic non-anion gap metabolic acidosis (as a result of decreased serum bicarbonate), renal calculi and hypohidrosis. These effects are more commonly reported in children [77,78] but they also occur in adults [79].

A moderate reduction in bicarbonate and hence a mild compensated metabolic acidosis is seen in most children taking topiramate. Metabolic acidosis generally occurs early in treatment and is usually mild and asymptomatic, and reverses with treatment discontinuation. Markedly low serum bicarbonate levels can occur, especially in young infants and also in patients who may already be predisposed to acidosis, for example those on the ketogenic diet. Such patients should be observed for clinical symptoms of acidosis which might necessitate discontinuation of treatment with topiramate. Acute treatment with bicarbonate is usually not required.

Chronic metabolic acidosis can result in osteomalacia and/or osteoporosis, reduced growth in children and renal calculi. Therefore, patients with persisting metabolic acidosis may warrant review of their treatment or initiation of oral bicarbonate treatment, especially if other conditions exist which predispose to any of these complications. The formation of renal calculi has been reported in around 1.5% of adults taking topiramate, with a higher incidence in men (as for renal calculi formation in the general population). Adequate hydration is important in patients at risk of renal calculi formation. If renal calculi occur, medical treatment may be effective and calculi are passed spontaneously in two-thirds of those affected.

Weight loss

Topiramate is associated with a decrease in weight in over 80% of patients, with those who are more overweight experiencing greater weight loss during ongoing therapy [80–82]. The mechanism of weight loss is unknown and is not completely explained by anorexia and reduced caloric intake as weight loss continues even when caloric intake returns to normal [80]. Mean weight decrease seen with topiramate is in the region of 2–7% and occurs early in the treatment with a plateau by 15–18 months [83].

Ophthalmological adverse effects

A range of ocular adverse effects have been reported, including blurring of vision, diplopia, acute angle-closure glaucoma, acute myopia and ciliochoroidal detachment [84,85]. Some of these effects do not appear to be dose related.

Ocular adverse effects are rare and appear to be due to an idiosyncratic reaction that causes ciliochoroidal effusion, anterior displacement of the lens and, subsequently, secondary acute angle-closure glaucoma with increased intraocular pressure. If this occurs, it is usually early in the treatment (within the first month) and resolves with discontinuation of therapy.

Hepatic adverse effects

Hyperammonaemia, with or without encephalopathy, has been reported following concomitant therapy with topiramate and valproate [86,87]. In most cases the manifestations resolved with discontinuation of either topiramate or valproate. Patients who might be predisposed to hyperammonaemia, such as those with inborn errors of metabolism or reduced hepatic mitochondrial activity, may be at higher risk of liver dysfunction with topiramate and/or valproate.

Adverse effects in children

Adverse effects reported in children have been similar to those seen in adults, with CNS effects and anorexia/weight loss being troublesome effects often reported by parents. Paraesthesia appears to be less prevalent, but it may be under-reported in this patient group and has been considered as a possible cause of agitation in some learning-disabled children.

Overall, the most common adverse events recorded in paediatric randomized trials include somnolence, anorexia, fatigue, dizziness, psychomotor slowing, speech difficulties and concentration difficulties. Although children may be particularly at risk of metabolic acidosis, renal calculi are rarely reported in paediatric populations.

Local carbonic anhydrase inhibition at the level of the sweat glands is the proposed mechanism for topiramate-related hypohidrosis and hyperthermia, seen especially in children [88,89]. In one study, 9 out of 14 patients on topiramate were found to have reduced sweating [89], the majority being children. Three of these patients had symptoms of heat intolerance. Patients on topiramate, especially children, should therefore be monitored for increased body temperature during hot weather and/or vigorous exercise.

Adverse effects during pregnancy/puerperium

Topiramate has been found to be teratogenic in animals, but its possible effects on the human fetus is unknown. With the advent of pregnancy registers, data on the comparative human teratogenic risks of AEDs are accumulating, but the relative or exact risk for topiramate is unknown. Although there are case reports of hypospadias occurring in the newborn in conjunction with topiramate exposure in pregnancy, in these cases topiramate was used in combination with carbamazepine and/or lamotrigine.

The concentrations of topiramate have been measured in plasma and breast milk in a small number of women with epilepsy during pregnancy and lactation [90]. Levels of topiramate in umbilical cord plasma and maternal plasma were almost identical, suggesting extensive placental transfer of the drug. The mean milk/maternal plasma concentration ratio was 0.86 (range 0.67–1.1) 2–3 weeks after delivery, and this ratio was similar at 1 and 3 months post partum. Low levels of topiramate were found in the blood of the breastfed infants, and none had any observed adverse effects.

Place in current therapy

Topiramate has proved to be an effective broad-spectrum agent in the treatment of epilepsy. Efficacy has been demonstrated against most seizure types in placebo-controlled and open-label trials, with little evidence of aggravation of seizures. However, it is likely that lower doses are more effective than those initially utilized in randomized trials. Efficacy with relatively good tolerability has also been demonstrated in monotherapy.

Topiramate has a particular place in the treatment of resistant focal seizures and symptomatic generalized epilepsies, where certain AEDs have been shown to be ineffective or contraindicated. It may be of particular benefit in patients who are overweight or obese, and in patients with epilepsy who also suffer

from migraine. Adverse effects may be minimized or avoided by reducing concomitant medication and by cautious titration.

Because of the risk of adverse effects, topiramate should be introduced at a low dose (0.5 mg/kg/day in children, or 25 mg/day in adults), and titration upwards should be slow (initially, no more than 0.5 mg/kg per week in children, or 25 mg/day per week in adults). Efficacy should be reviewed at 50 mg or 2 mg/kg/day, although much higher doses can sometimes be required and tolerated. There remains, however, a small group who are unable to tolerate the medication, regardless of the dose or rate of titration used.

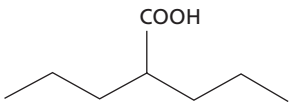
55 Valproate

Blaise F.D. Bourgeois
Children's Hospital, Boston, MA, USA



Primary indications	First-line therapy of idiopathic generalized epilepsies. First-line or adjunctive therapy of cryptogenic or symptomatic generalized epilepsies. Valuable but not generally first-line therapy for partial seizures
Usual preparations	Enteric-coated tablets, 200, 500 mg; crushable tablets, 100 mg; capsules, 150, 300, 500 mg; solution or syrup, 200 mg/5 mL, 250 mg/5 mL; sustained-release tablets, 200, 300, 500 mg; sustained-release microspheres, sachets, 100, 250, 500, 750, 1000 mg; divalproex tablets, 125, 300, 500 mg (as valproic acid equivalents); divalproex tablets delayed release, 125, 250, 500 mg (as valproic acid equivalents); divalproex sprinkles, 125 mg (as valproic acid equivalents); divalproex tablets extended release, 250, 500 mg (as valproic acid equivalents); solution for intravenous injection, 100 mg/mL
Usual dosages	Initial: 400–500 mg/day (adults); 15 mg/kg/day (children). Maintenance: 500–2500 mg/day (adults); 20–40 mg/day (children under 20 kg); 20–30 mg/kg/day (children over 20 kg). Higher doses may be needed, particularly in patients co-medicated with enzyme-inducing drugs
Dosing frequency	Two or three times a day. Some extended/sustained-release formulations may be used once daily, particularly in patients expected to have half-lives in the upper range
Significant drug interactions	Enzyme-inducing drugs and imipenem antibiotics reduce serum valproic acid levels. Felbamate, stiripentol, isoniazid and other drugs may increase valproic acid levels. Valproic acid inhibits the metabolism of a number of drugs, most notably phenobarbital, lamotrigine and rufinamide. Valproic acid displaces phenytoin from plasma protein binding sites and may inhibit phenytoin metabolism at the same time
Serum level monitoring	Dosage usually can be adjusted on the basis of clinical response, but monitoring serum valproic acid levels may be useful in selected cases
Reference range	50–100 mg/L
Common/important adverse effects	Tremor, sedation, asthenia, encephalopathy, extrapyramidal symptoms, nausea, vomiting, hyperammonaemia, weight gain, polycystic ovary syndrome, hair loss, platelet and coagulation disorders, liver toxicity, pancreatitis, teratogenic effects (including spina bifida)
Main advantages	Unsurpassed efficacy in most generalized epilepsy syndromes. Broad-spectrum efficacy in different seizure types
Main disadvantages	Weight gain, severe liver toxicity (particularly in children), teratogenicity
Mechanism of action	Not well defined, but clearly multifactorial. Effects include potentiation of GABAergic inhibition and attenuation of glutamatergic excitation

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Oral bioavailability	>90%
Time to peak levels	1–10 h (dependent on formulation and, with some formulations, concomitant food intake)
Elimination	Oxidation and glucuronide conjugation
Volume of distribution	Approximately 0.2 L/kg
Elimination of half-life	8–16 h in adults and 6–15 h in children (the shortest values in patients co-medicated with enzyme-inducing drugs). Neonates have longer half-lives
Plasma clearance	6–20 mL/h/kg in adults and 10–30 mL/h/kg in children (the highest values in patients co-medicated with enzyme-inducing drugs)
Protein binding	70–95% (decreasing with increasing serum concentration)
Active metabolites	None of major therapeutic relevance. The metabolite 4-ene-valproic acid may contribute to idiosyncratic adverse effects
Comment	A very valuable antiepileptic drug, particularly in the management of generalized epilepsies

Introduction

Valproic acid, or valproate, has been in clinical use for the treatment of epilepsy for more than 40 years. During this period, it has clearly established itself as one of the major antiepileptic drugs (AEDs). Over time, it became evident that valproic acid was the first and, until the 1990s, the only drug with a very broad spectrum of activity against different seizure types, both generalized and focal. It was also soon recognized that it had a relatively low sedative effect. In addition to being the first drug to be highly effective against virtually all primarily generalized seizure types, such as absence seizures, myoclonic seizures and generalized tonic–clonic seizures, valproic acid also was shown to have variable degrees of effectiveness in the treatment of partial seizures, the Lennox–Gastaut syndrome, infantile spasms, neonatal seizures and febrile seizures. Because of this, valproic acid assumed a particularly important role in the treatment of paediatric epilepsies. It is currently a first-line drug in all forms of primary (idiopathic) generalized epilepsy. Lamotrigine has been considered as an alternative for this indication, but its efficacy has not matched that of valproic acid, and it can exacerbate myoclonic seizures, which has not been reported for valproic acid. However, valproic acid does have several adverse effects, some of which can be bothersome or serious, whereas the only potentially bothersome or serious adverse effect of lamotrigine is a rash that may evolve to Stevens–Johnson syndrome.

In addition to its place in the treatment of epilepsy, valproic acid has gained acceptance in the treatment of conditions that will not be included in this chapter, such as affective disorders in psychiatry and the prophylaxis of migraine headaches. It has also been suggested that valproic acid may be effective in the treatment of Sydenham's chorea. The only limitation to the use of valproic acid has been its association with some undesirable and potentially serious side-effects.

Chemistry

Valproic acid, *N*-dipropylacetic acid, is a short-chain branched fatty acid with a molecular weight of 144.21. Chemically, valproic acid differs from all other known AEDs.

Valproic acid itself is a colourless liquid with a low solubility in water. Sodium valproate (molecular weight 166.19) is a highly water-soluble and highly hygroscopic white crystalline material. Other preparations include magnesium valproate, a divalproate salt and sodium hydrogen divalproate (divalproex sodium), a stable coordination compound composed of equal parts of valproic acid and sodium valproate.

Pharmacology

Activity in animal models of seizures and epilepsy

The discovery of the anticonvulsant effect of valproic acid was serendipitous, when it was used as a solvent for compounds being tested in an animal model of seizures [1]. Several animal models have been used to investigate the antiepileptic activity of valproic acid. Demonstrated activities include protection against maximal electroshock–induced seizures, seizures induced chemically by pentylenetetrazole, bicuculline, glutamic acid, kainic acid, strychnine, ouabain, nicotine and intramuscular penicillin, seizures induced by kindling, and spontaneously occurring seizures in genetic models of generalized epilepsy such as the GAERS (genetic absence epileptic rat of Strasbourg) rat. This broad spectrum of efficacy in animal models suggests that valproic acid is effective in both preventing the spread and lowering the threshold of seizures, and this is consistent with its broad spectrum of antiepileptic activity in humans.

Mechanisms of action

The elucidation of the mechanism of action of valproic acid has been the object of extensive studies. At the cellular level, several

effects of valproic acid have been demonstrated, but the mechanism underlying its antiepileptic action has not been precisely identified. It may be that more than one mechanism is involved, and none of the identified actions has been widely accepted as the predominant relevant mechanism [2].

Valproic acid has been shown to raise brain levels of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). This may occur through inhibition of GABA transaminase, the first step in GABA deactivation, through inhibition of succinic semialdehyde dehydrogenase, the second step in GABA deactivation, or through an increase in the activity of glutamic acid decarboxylase, an enzyme involved in the synthesis of GABA. However, these changes occur at much higher than usual therapeutic doses and their time-course lags behind the anticonvulsant effect. Therefore, it does not appear likely that elevation of GABA is the predominant mechanism of the antiepileptic effect of valproic acid. It has also been demonstrated that, in addition to its effect on GABA levels, valproic acid can reduce sustained repetitive high-frequency firing by blocking voltage-sensitive sodium channels [3], although the relevance of this effect at therapeutic concentrations is unclear [2], or by activating calcium-dependent potassium conductance. Valproic acid has also been found to reduce the release of γ-hydroxybutyrate, to decrease brain levels of the excitatory amino acid aspartate in mice and to decrease the expression of the glutamate transporter-1 in the rat hippocampus [4]. To what extent these actions contribute to the clinical effects of valproic acid remains unknown.

Pharmacokinetics

Rate and extent of absorption

Oral preparations of valproic acid have a virtually complete bioavailability when compared with the intravenous route. Rectal administration of valproic acid syrup was shown to have the same bioavailability as the oral preparation. The bioavailability of valproic acid suppositories was found to be 80% in volunteers, when compared with oral syrup. Administration of valproic acid suppositories was well tolerated for several days in a study in patients treated chronically with valproic acid, and the bioavailability was the same as for the oral preparations [5]. Available evidence suggests that there is no need for a dosage change or a change in regimen when oral valproic acid administration is transiently replaced by rectal administration. Compared with other divalproex oral preparations, the oral bioavailability of the divalproex extended-release preparation is 8–20% lower [6].

The rate of absorption of valproic acid is quite variable following oral administration, depending on the formulation. Syrup and uncoated regular tablets or capsules administered orally are rapidly absorbed, and peak serum drug levels are achieved within about 2 h. The purpose of the enteric coating of tablets is to prevent the gastric irritation associated with release of valproic acid in the stomach. Absorption from enteric-coated tablets is delayed until the tablet reaches the alkaline environment of the duodenum, but absorption is rapid once it begins. The onset of absorption from enteric-coated tablets varies as a function of the state of gastric emptying at the time of ingestion, and when the tablets are co-administered with food, peak serum drug levels may be reached only several hours after intake. Because of this delayed absorption, serum levels of valproic acid in patients taking valproic acid enteric-coated tablets continue to decrease for 2 or more hours after drug ingestion, until the absorption begins and exceeds the rate of elimination. Therefore, the assumed 'trough levels' before the morning dose are not the lowest valproic acid levels of a 24-h cycle. The lowest levels may actually occur in the late morning or early afternoon [7]. In 12 children, the absorption of enteric-coated sprinkles was compared with the absorption of valproic acid syrup, and no difference in overall bioavailability was found between the two formulations. The absorption of valproic acid was slower with the sprinkles than with the syrup, with an average time to maximal valproic acid concentrations of 4.2 h after ingestion of sprinkles and 0.9 h after intake of the syrup [8]. Sustained- and extended-release formulations are also available which ensure a smoother absorption profile and minimize fluctuations in serum valproic acid levels during a dosing interval. Most sustained-release formulations are suitable for twice-daily dosing, and some may also be feasible for once-daily administration.

Distribution

Valproic acid has a relatively small volume of distribution (0.13–0.19 L/kg in adults and 0.20–0.30 L/kg in children). This implies that the affinity of valproic acid for binding sites outside the plasma compartment is relatively lower than the affinity for binding sites on plasma proteins. The plasma protein binding of valproic acid is indeed high (about 70–95%), and it is saturable at therapeutic concentrations. Accordingly, the free (unbound) fraction of valproic acid increases as the total concentration increases. For instance, the average unbound fraction of valproic acid in adults was reported to be only 7% at 50 mg/L and 9% at 75 mg/L, increasing to 15% at 100 mg/L, 22% at 125 mg/L and 30% at 150 mg/L [9]. Using these unbound fraction values one can calculate that, with a threefold increase in total serum valproic acid concentration from 50 to 150 mg/L, the unbound concentration would increase more than 10 times, from 3.5 mg/L to 45 mg/L.

Since valproic acid shows restrictive clearance (i.e. total plasma clearance is directly proportional to the drug's unbound fraction), its saturable binding to plasma proteins implies that the relationship between the daily dose and the total concentration of valproic acid in serum is curvilinear, with relatively smaller increases in concentrations at higher doses. However, the relationship between dose and steady-state unbound serum valproic acid concentration (which is the fraction responsible for the pharmacological effect) is substantially linear.

Elimination

In the absence of enzyme-inducing drugs, the elimination half-life of valproic acid in adults is 13–16 h. Shorter values, averaging about 9 h, are recorded in patients co-medicated with enzyme-inducing drugs [10].

The elimination of valproic acid occurs virtually entirely by metabolism. The biotransformation in humans follows several pathways, including glucuronidation, beta-oxidation, hydroxylation, ketone formation and desaturation. The formation of double bonds can result from beta-oxidation as well as from

desaturation. Valproic acid glucuronide and 3-oxo-valproic acid are by far the most abundant metabolites, representing about 40% and 33%, respectively, of the urinary excretion of a valproic acid dose [11]. Anticonvulsant activity that is similar in potency to that of valproic acid itself was demonstrated for two desaturated metabolites of valproic acid, 2-ene-valproic acid and 4-ene-valproic acid, but these metabolites are present in serum at very low concentrations.

Because 2-ene-valproic acid undergoes delayed but significant accumulation in the brain, and is cleared more slowly than valproic acid itself, its formation may provide a possible explanation for the apparent dissociation between the time courses of valproic acid concentrations in plasma and the onset of antiepileptic activity. It appears that 2-ene-valproic acid does not possess the pronounced embryotoxicity and hepatotoxicity of 4-ene-valproic acid, and might thus represent a better AED than valproic acid itself.

The strongly hepatotoxic metabolite 4-ene-valproic acid is produced under the action of cytochrome P450 enzymes. The activity of these enzymes is induced by other AEDs such as phenobarbital, phenytoin and carbamazepine [11], and this may explain the increased risk of hepatotoxicity in patients receiving these drugs together with valproic acid [12]. However, elevation of 4-ene-valproic acid levels has not been clearly documented in patients with valproic acid hepatotoxicity, or in conjunction with short-term adverse effects or hyperammonaemia.

Pharmacokinetics in special groups

Children and newborns

Children have slightly shorter valproic acid half-lives than adults. Cloyd *et al*. [13] found an average half-life of 11.6 h in children on monotherapy and 7.0 h with polytherapy involving enzyme-inducing AEDs. Clearance values are also higher in children (20–30 mL/h/kg) than in adults (6–20 mL/h/kg). As a result, dosage requirements on a milligram per kilogram basis are generally higher in children than in adults.

Newborns eliminate valproic acid slowly, with half-lives that are longer than 20 h and up to 40 h [14]. The free (unbound) fraction of valproic acid is also higher in newborns.

Old age

Reduced plasma protein binding of valproic acid is reported in the elderly, in relation with a physiological reduction in plasma albumin levels. Compared with non-elderly adults, patients in old age also have a moderately reduced clearance of unbound drug, resulting in higher serum unbound valproic acid concentrations for equal dosages. Partly as a result of this, valproic acid dosage requirements tend to be lower in the elderly.

Pregnancy

During pregnancy, there is often a decrease in total serum valproic acid levels and an increase in unbound fraction. Therefore, despite the decrease in total serum concentrations, unbound valproic acid concentrations are generally relatively stable during pregnancy, and may even be slightly increased at the time of delivery. Breast milk contains 1–10% of the mother's plasma concentration, and breastfed infants have been found to have serum valproic acid concentrations of between 4% and 12% of their mothers' serum levels.

Disease states

Liver cirrhosis may lead to decreased plasma protein binding and decreased clearance of unbound valproic acid. Renal disease seems to have little or no impact on the pharmacokinetics of unbound valproic acid, although protein binding may again be reduced.

Drug interactions

Three pharmacological properties of valproic acid determine its involvement in several pharmacokinetic interactions [15]: (1) the metabolism of valproic acid is sensitive to enzymatic induction; (2) valproic acid itself can inhibit the metabolism of other drugs and (3) valproic acid can displace other drugs from serum proteins, because it has itself a high affinity for serum proteins. Pharmacodynamic interactions may also occur.

Effect of other drugs on valproic acid pharmacokinetics

There is ample documentation that enzyme-inducing AEDs, such as carbamazepine, phenytoin, phenobarbital and primidone, decrease serum valproic acid levels when administered concomitantly. In particular, valproic acid levels are lowered significantly, usually by at least one-third to one-half, by the addition of both carbamazepine and phenytoin. In children, these interactions can be particularly pronounced, resulting in valproic acid level reductions of 50% or more. Conversely, when other drugs were discontinued in children receiving enzyme-inducing AEDs, valproic acid levels rose 122% after withdrawal of phenytoin, 67% after withdrawal of phenobarbital, and 50% after withdrawal of carbamazepine [16]. If the same serum level of valproic acid is to be maintained when an enzyme-inducing drug is added or withdrawn, the dose of valproic acid has to be increased or decreased, respectively, by a factor of about two. The addition of lamotrigine may decrease valproic acid levels by about 25%, and a decrease in serum valproic acid levels may also be caused by oestrogen-containing contraceptive steroids. Valproic acid levels can also be decreased to a clinically relevant degree by the carbapenem group of antibiotics, particularly meropenem, although the mechanisms underlying this interaction are unclear [17]. Valproic acid levels may also be lowered by rifampicin and by the anti-HIV agent ritonavir (Table 55.1).

Unlike enzyme inducers, felbamate acts as an enzyme inhibitor and raises the serum levels of valproic acid. At a felbamate dose of 1200 mg/day, the increase in valproic acid levels was found to be 28%, and it was 54% at a felbamate dose of 2400 mg/day [18]. Among AEDs, , stiripentol and clobazam (in addition to felbamate) have also been reported to reduce the clearance and to elevate the serum levels of valproic acid. Among other drugs, fluoxetine, isoniazid and acetylsalicylic acid can also increase serum valproic acid levels. Because acetylsalicylic acid also displaces valproic acid from plasma protein binding sites, changes in total serum valproic acid levels in patients started on acetylsalicylic acid co-medication may underestimate the increase in the

Table 55.1 Pharmacokinetic interactions with valproic acid.

Other drugs decreasing serum valproic acid levels

The clearance of valproic acid is increased and the serum levels of valproic acid are lowered by the addition of the following drugs (discontinuation of these drugs has an opposite effect):

Antiepileptic drugs: phenytoin, carbamazepine, phenobarbital, primidone, lamotrigine

Others: imipenem antibiotics, ritonavir, rifampicin, steroid contraceptives

The clearance of valproic acid is decreased and the serum levels of valproic acid are increased by the addition of the following drugs (discontinuation of these drugs has an opposite effect):

Antiepileptic drugs: felbamate, stiripentol, clobazam

Others: acetylsalicylic acid (increase in unbound serum valproic acid), fluoxetine, isoniazid

Valproic acid increasing the serum levels of other drugs

Valproic acid decreases the clearance and increases the serum levels of the following drugs (discontinuation of valproic acid has an opposite effect):

Antiepileptic drugs: phenobarbital, lamotrigine, ethosuximide, carbamazepine-10,11-epoxide, phenytoin (increase in unbound serum phenytoin), rufinamide, felbamate, lorazepam

Others: amitriptyline and nortriptyline, zidovudine and the calcium channel blocker nimodipine

Plasma protein-binding interactions resulting in higher unbound drug fraction

Unless additional mechanisms are operating, these interactions generally result in decreased total concentration of the displaced drug, without affecting its unbound concentration and pharmacological effect

Valproic acid displaces phenytoin (and may also inhibit phenytoin metabolism)

Aspirin, salicylic acid, naproxen, diflunisal, tolmetin and ibuprofen displace valproic acid. Aspirin and salicylic acid may also inhibit valproic acid metabolism

levels of serum unbound valproic acid. This interaction is at times sufficient to result in clinical valproic acid toxicity.

Effect of valproic acid on the pharmacokinetics of other drugs

Addition of valproic acid has been found to increase the serum levels of phenobarbital by 57–81%. Valproic acid also markedly inhibits the elimination of lamotrigine, leading to a two- to three-fold prolongation of the lamotrigine half-life [19]. This interaction is competitive and rapidly reversible, but it seems to persist at low valproic acid concentrations and to be already maximal, in adults, at valproic acid doses of about 500 mg/day. In patients taking valproic acid, lamotrigine must be introduced at lower doses. Conversely, when discontinuing valproic acid in a patient taking lamotrigine, it is crucial to increase the dose of lamotrigine, at the latest when valproic acid is stopped altogether [20].

The serum levels of ethosuximide can also be raised by the addition of valproic acid, mostly in the presence of additional AEDs. The serum levels of carbamazepine itself are not raised by valproic acid, but the levels of its active metabolite, carbamazepine-10,11-epoxide, may double after adding valproic acid. An even greater increase in the serum levels of carbamazepine-10,11-epoxide is caused by valpromide, an amide derivative of valproic acid which acts at least in part as a valproic acid prodrug. Valproic acid may also raise the levels of rufinamide, felbamate and lorazepam, as well as those of certain tricyclic antidepressants, zidovudine and the calcium channel blocker nimodipine (Table 55.1). In contrast to enzyme-inducing AEDs, valproic acid does not affect the serum levels and the efficacy of oral contraceptives.

Valproic acid displaces phenytoin from plasma protein binding sites, and may simultaneously inhibit phenytoin metabolism. When valproic acid is added on to the therapeutic regimen of patients stabilized on phenytoin, the total phenytoin levels may show little change or even fall, whereas the unbound phenytoin concentration may be unchanged or increased. In any case, in the presence of valproic acid co-medication, the total serum levels of phenytoin underestimate the concentration of unbound, pharmacologically active drug.

Other interactions between valproic acid and other drugs are listed in Table 55.1.

Pharmacodynamic drug interactions

In addition to inhibiting lamotrigine metabolism, valproic acid may interact with lamotrigine pharmacodynamically. In fact, patients with various seizure types that failed to respond to maximally tolerated doses of either drug alone may achieve seizure control when the two agents are combined [21]. This interaction is often beneficial, but it also entails a risk of reciprocal potentiation of adverse effects, particularly tremor, and a reduction in the dosage of both drugs is usually required.

The combination of ethosuximide and valproic acid can also lead to a favourable pharmacodynamic interaction that may allow the control of absence seizures in patients not responsive to monotherapy with either drug.

Serum level monitoring

Monitoring the serum levels of valproic acid is common practice, but it is of relatively limited value [21]. One reason is that there is a considerable fluctuation in valproic acid levels over a 24-h period because of the short half-life of the drug, and the reproducibility of serum levels in a given patient has been shown to be relatively poor. Another reason is that there seems to be a poor correlation between serum valproic acid levels at a given time and clinical effect at the same time, since the pharmacodynamic effects may lag significantly behind the serum drug concentration [22]. The usually quoted reference range for serum valproic acid levels is 50–100 mg/L (350–700 μmol/L). However, levels of up to 150 mg/L may be both necessary and well tolerated in some patients. Serum valproic acid levels can be especially valuable in selected cases, particularly during combination therapy with enzyme-inducing drugs, but the result of a single measurement has limited value and needs to be interpreted cautiously.

Efficacy

Within a relatively short time after its introduction into routine clinical use, it became apparent that valproic acid is highly effective in the treatment of primarily generalized seizures, such as absence seizures, generalized tonic–clonic seizures and myoclonic seizures. Valproic acid was the first true broad-spectrum AED to become available, with good or at least some degree of efficacy

against most seizure types. The treatment of absence seizures was the primary indication of valproic acid when it was released in North America in 1978. A recent randomized study revealed that valproic acid remains the clinically most effective drug for the treatment of idiopathic generalized epilepsies or difficult to classify epilepsies [23].

Absence seizures

The ability of valproic acid to suppress or reduce spike–wave discharges when administered to patients with typical and atypical absence seizures has been reported on several occasions.

In at least two studies, the efficacy of valproic acid and ethosuximide in the treatment of absence seizures was compared and found to be equal [24,25]. A double-blind cross-over study of valproic acid and ethosuximide, in which the measure of efficacy was the frequency and duration of generalized spike–wave bursts on electroencephalogram (EEG) telemetry, was carried out in 16 patients who were not previously treated for absence seizures and 29 refractory patients [25]. In previously untreated patients, ethosuximide and valproic acid were equally effective. Valproic acid achieved seizure control much faster than lamotrigine in an open-label randomized comparison in 37 children, but the difference in overall seizure freedom at 1 year did not reach statistical significance, possibly because of the low statistical power associated with the low sample size [26].

Simple absence seizures could be completely controlled by valproic acid monotherapy in 11 out of 12 patients [27], in 10 out of 12 patients [28], in 14 out of 17 patients [29] and in 20 out of 21 patients [30], respectively. Because of the limited methodological quality or statistical power of the studies, review of the available evidence cannot demonstrate a difference in efficacy between valproic acid, lamotrigine and ethosuximide against absence seizures.

Full control of absence seizures appears more likely if these seizures occur alone than if they are mixed with another seizure type. Patients with recurrent absence status have also been treated effectively with valproic acid. Atypical or 'complex' absences are generally less responsive to valproic acid than simple absences. The combination of valproic acid with ethosuximide or with lamotrigine may be effective in suppressing absence seizures uncontrolled by any of these drugs given alone.

Generalized tonic–clonic seizures

Apart from being a first-line drug for absence seizures, valproic acid can be highly effective in the treatment of certain generalized convulsive seizures [31]. Valproic acid was used in monotherapy in 36 patients with primarily generalized tonic–clonic seizures, of whom 24 had been treated previously with other AEDs [27]. Seizures were fully controlled in 33 of these patients. Generalized tonic–clonic seizures were fully controlled by add-on valproic acid in 14 out of 42 patients with intractable seizures [32]. In 61 previously untreated patients with generalized tonic–clonic, clonic or tonic seizures, valproic acid was compared with phenytoin [33]. In 73% of these patients receiving valproic acid and in 47% of the patients treated with phenytoin, the seizures came under control during the time of observation. This response increased to 82% for valproic acid and 76% for phenytoin when seizures that occurred before therapeutic plasma drug levels had been reached were disregarded. A 2-year remission was achieved in 27 out of 37 patients with valproic acid and in 22 out of 39 patients with phenytoin in another randomized study comparing valproic acid with phenytoin in patients with previously untreated tonic–clonic seizures [34]. In two studies of patients with primary (idiopathic) generalized epilepsies, valproic acid was assessed in monotherapy. In these two studies of patients who had only generalized tonic–clonic seizures, complete seizure control was achieved in 51 out of 70 patients [35] and in 39 out of 44 patients [30]. In children with generalized tonic–clonic seizures, monotherapy with valproic acid was also found to be highly effective.

Myoclonic seizures

Valproic acid is a drug of first choice for most myoclonic seizures, particularly those occurring in patients with primary or idiopathic generalized epilepsies. Sixteen out of 23 patients with myoclonic epilepsy of adolescence experienced full seizure control with valproic acid monotherapy [27]. In addition, out of 22 patients with myoclonic epilepsy of adolescence and with an abnormal EEG response to intermittent photic stimulation, of whom 17 had failed to respond to previous medications, full seizure control was achieved in 17 patients [27]. Regardless of the associated clinical seizure type, EEG sensitivity to intermittent photic stimulation is easily suppressed by valproic acid. In a representative study, treatment with valproic acid monotherapy was assessed in a group of patients with primary generalized epilepsies; 22 patients had myoclonic seizures and 20 of those had at least one other seizure type: either absence or tonic–clonic seizures [30]. In 18 of these 22 patients, myoclonic seizures were controlled by valproic acid monotherapy.

The response to valproic acid in patients with juvenile myoclonic epilepsy is excellent, and valproic acid remains a drug of first choice for this condition in most patients, at least in terms of efficacy. There is also a good response to treatment with valproic acid in benign myoclonic epilepsy of infancy [36], which belongs to the group of the primary or idiopathic generalized epilepsies. Some success has been achieved with valproic acid in postanoxic intention myoclonus, which is usually quite refractory to treatment [37–39]. In the treatment of myoclonic and tonic–clonic seizures in patients with severe progressive myoclonus epilepsy, a combination of valproic acid and clonazepam has been advocated [40].

Infantile spasms and Lennox–Gastaut syndrome

Compared with the more benign idiopathic generalized epilepsies, available information on the use of valproic acid is much less extensive in relation to the treatment of severe generalized encephalopathic epilepsies of infancy and childhood, such as West syndrome and Lennox–Gastaut syndrome. Valproic acid is less effective in the treatment of these severe forms of generalized epilepsy, as is the case for all other antiepileptic medications. In a larger series of patients treated with valproic acid, 38 had myoclonic astatic epilepsy, a term used synonymously with Lennox–Gastaut syndrome by the authors of this study. Seven of these 38 patients became and remained seizure free with valproic acid. A 50–80% improvement was achieved after the introduction of valproic acid in an additional one-third of these patients, and other AEDs could be withdrawn or reduced. Seizures were fully

controlled in three out of six patients with myoclonic absence epilepsy in the same series, all of them on combination therapy. In a group of 100 children treated with valproic acid, seizure control was achieved in 12 out of 27 children with 'absences and other seizures' and in 9 out of 39 children with atonic seizures [16].

In the majority of publications on the use of valproic acid for the treatment of infantile spasms, the number of patients is small, or patients receiving corticotropin and valproic acid simultaneously were included. In one series of 19 infants with infantile spasms, valproic acid was used without corticotropin [41]. Eight of these 19 infants experienced good seizure control with valproic acid as their first drug, and they did not require corticotropin. The patients received valproic acid doses ranging from 20 to 60 mg/kg/day, and those who failed initial treatment with either valproic acid or corticotropin were subsequently switched to the other drug. There was a tendency towards a better response to corticotropin when the two groups were compared, but the incidence and severity of side-effects was lower with valproic acid. In a series of 18 infants with infantile spasms who were not previously treated with corticotropin, a low dose of 20 mg/kg/day of valproic acid was used [42]. The short-term results were described as good to excellent in 12 of these patients. Seven patients had residual seizure activity on follow-up, and moderate to severe mental retardation was diagnosed in 16 patients. The conclusion by the authors was that the efficacy of valproic acid was similar to the efficacy of corticotropin, and that valproic acid was associated with fewer side-effects.

Partial seizures

The efficacy of valproic acid against partial seizures was assessed systematically only after its role in the treatment of generalized seizures had been established. Some benefit of valproic acid against partial seizures was suggested by preliminary information based on subgroups of patients in studies not dealing primarily with partial seizures [16]. The first direct comparison of valproic acid with carbamazepine in the treatment of partial seizures was an open study in 31 previously untreated adults [43]. Seizure control was achieved in 11 patients on valproic acid and in eight patients on carbamazepine, but in 12 out of the 31 patients follow-up was less than 1 year. In a prospective study of 79 patients with previously untreated simple partial or complex partial seizures, comparison between carbamazepine, phenytoin and valproic acid in monotherapy revealed no difference in efficacy among the three drugs [44]. A group of 140 adults with previously untreated seizures were randomized to monotherapy with phenytoin or valproic acid [45]. In 76 patients, the seizures were tonic–clonic and in 64 they were predominantly complex partial. No difference between the two drugs in either subgroup was found in terms of 2-year remission rate or time to first seizure. A remarkable response was found in a retrospective study of valproic acid monotherapy in 30 patients with simple partial and complex partial seizures, in whom previous drugs had failed because of allergies or lack of efficacy [46]. Only eight patients were not improved, whereas seizure control was achieved in 12 patients, and a more than 50% seizure reduction occurred in 10 patients.

The most comprehensive controlled comparison between valproic acid and carbamazepine monotherapy in the treatment of partial and secondarily generalized seizures was carried out by Mattson and co-workers [47]. A total of 480 adult patients were included in this multicentre, double-blind, randomized trial, and several seizure indicators, as well as neurotoxicity and systemic toxicity, were assessed quantitatively. In the final analysis, four out of five efficacy indicators were significantly in favour of carbamazepine against complex partial seizures, and a combined composite score for efficacy and tolerability was higher for carbamazepine than for valproic acid at 12 months, but not at 24 months. For secondarily generalized seizures, outcomes did not differ between the two drugs.

In a subsequent double–blind trial designed primarily to meet regulatory requirements, a group of 143 adults with poorly controlled partial seizures was randomized to monotherapy with valproic acid (administered as divalproex sodium) at low serum levels (25–50 mg/L) or at high serum levels (80–150 mg/L). There was a significantly greater reduction in the frequency of both complex partial and secondarily generalized tonic–clonic seizures among patients in the high-level group [48].

Two studies comparing valproic acid with other AEDs were carried out in children. In the first study, carbamazepine or valproic acid was administered in a randomized fashion to a total of 260 children with newly diagnosed primary generalized or partial epilepsy, and they were then followed up for 3 years [49]. Doses were titrated as needed and as tolerated according to the clinical response. Against generalized as well as partial seizures, equal efficacy was found for the two treatments, and adverse events were mostly mild for both drugs. In the second study, 167 children with untreated tonic–clonic or partial seizures entered into a randomized, unblinded trial in which four AEDs, phenobarbital, phenytoin, carbamazepine and valproic acid, were compared [50]. At 1, 2 or 3 years, there was no difference in efficacy in terms of time to first seizure and time to 1-year remission. Unacceptable side-effects necessitating withdrawal occurred in 6 out of 10 patients on phenobarbital, which was prematurely removed from the study, in 9% of children on phenytoin and in 4% each of children taking carbamazepine or valproic acid.

A meta-analysis of trials comparing valproic acid and carbamazepine concluded that carbamazepine was more effective than valproic acid in reducing time to first seizure and time to 12 months of remission [51].

Status epilepticus

A number of studies have provided evidence that valproic acid, used mostly by the intravenous route, is a valuable agent for the treatment of both convulsive and non-convulsive status epilepticus. The use of valproic acid in the management of status is discussed in some detail in Chapter 18.

Other seizure disorders

The efficacy of valproic acid in the prevention of febrile seizures was assessed in several studies. Valproic acid was found to be as effective as phenobarbital in some studies, whereas in other studies it was more effective than phenobarbital, placebo or no treatment in terms of reducing the risk of seizure recurrence [52]. In children with a high risk of recurrence of febrile seizures, treatment with intermittent diazepam during febrile episodes was as

effective as continuous prophylaxis with valproic acid [53]. However, valproic acid cannot be recommended for the prophylaxis of febrile seizures based on risk versus benefit ratio considerations.

Seizures have also been treated with valproic acid either rectally or orally [14] in a small group of newborns. A loading dose of 20–25 mg/kg was followed by a maintenance dose of 5–10 mg/kg every 12 h [14]. Results were generally favourable. The elimination half-life of valproic acid was shown to be longer in newborns (26.4 h), and these newborns also developed higher levels of ammonia.

Non-epilepsy indications

Valproic acid is an established agent for the management of bipolar disorder, mania and migraine. Its use in these and in other indications has been reviewed [54–57].

Adverse effects

The distinction between adverse effects that are non-idiosyncratic and dose related and those that are idiosyncratic is not always easy in the case of valproic acid. Some reactions are indeed fairly predictable and dose related, such as tremor or thrombocytopenia. However, a number of adverse events that appear to be idiosyncratic because they only occur in a small fraction of patients are also more likely to occur at high doses or high serum drug levels, such as certain cases of confusion or stupor, and neural tube defects. Pancreatitis is also very rare, but its occurrence has not been found to be related to higher serum valproic acid levels. Finally, certain side-effects such as hair changes and weight gain, which are too common to be considered idiosyncratic, could never be clearly shown to be dose related. Table 55.2 summarizes the main adverse effects of valproic acid.

Table 55.2 Adverse effects of valproic acid.

Neurological
Tremor
Drowsiness
Lethargy
Confusion
Reversible dementia
Brain atrophy
Encephalopathy
Extrapyramidal symptoms
Gastrointestinal
Nausea
Vomiting
Anorexia
Gastrointestinal distress
Weight gain
Liver and pancreas
Hepatic failure
Pancreatitis
Haematological
Thrombocytopenia
Decreased platelet aggregation
Fibrinogen depletion
Other coagulation disorders
Neutropenia
Bone marrow suppression
Metabolic/endocrine
Hyperammonaemia
Hypocarnitinaemia
Hyperinsulinism
Menstrual irregularities
Polycystic ovaries
Teratogenic
Major malformations, including neural tube defects and possible developmental delay in offspring
Miscellaneous
Hair loss
Facial and limb oedema
Nocturnal enuresis
Decreased bone mineral density
Hyponatraemia
Skin rashes
Immune-mediated idiosyncratic reactions

Neurological adverse effects

Probably the most common neurological adverse effect of valproic acid is a tremor with the characteristics of an essential tremor. Valproic acid-induced tremor has been shown to be dose related and to occur in about 10% of patients. Propranolol may be effective in controlling the tremor if the symptom does not improve sufficiently following reduction of the dose.

Less common adverse effects of valproic acid are asterixis and reversible parkinsonism. Although drowsiness, lethargy and confusional states are uncommon with valproic acid, they may occur in some patients, usually at levels above 100 mg/L. In patients treated with valproic acid, well-documented cases of reversible dementia and pseudoatrophy of the brain [58] have also been reported.

A unique and rather specific adverse effect of valproic acid, characterized by acute mental changes that can progress to stupor or coma, has been well described [59]. A typical feature is usually a rather abrupt change of the EEG tracing, with generalized delta slowing. The precise mechanism of this idiosyncratic reaction is not known with certainty. Hyperammonaemia or carnitine deficiency can be associated, but do not seem to be the cause [60]. This encephalopathic state appears to be more likely to occur when valproic acid is added to another AED, or vice versa. It is usually reversible within 2–3 days upon discontinuation of valproic acid or of the other AED [61].

Valproic acid does not appear to be associated with a high overall incidence of dose-related effects on cognition or behaviour. A suggested possible psychotropic effect of valproic acid has not been confirmed in a later controlled study [62].

Gastrointestinal adverse effects, including weight gain

Nausea, vomiting, gastrointestinal distress and anorexia are the most frequent gastrointestinal adverse effects of valproic acid. They are likely to be due in part to direct gastric irritation of the gastric mucosa, and their incidence is indeed lower when patients take enteric-coated tablets.

Another quite common problem with valproic acid is excessive weight gain [63]. This is not entirely due to increased appetite, and decreased β-oxidation of fatty acids has been postulated as a possible mechanism. Obese valproic acid-treated men have been reported to have higher serum insulin levels than obese control subjects [64,65]. Rather than increased insulin secretion or insulin resistance, the mechanism for this may be interference with hepatic insulin metabolism [66]. It has also been shown that patients who developed obesity on valproic acid had increased leptin levels and decreased ghrelin and adiponectin levels [65]. Weight gain tends to be a bothersome side-effect, especially in young women, despite recommendations for diet and exercise. In children, excessive weight gain seems to be less of a problem, and one study suggested that valproic acid does not cause more weight gain than carbamazepine in children [67].

Hepatic and pancreatic toxicity

One of the most feared adverse effects of valproic acid remains fatal hepatotoxicity [12]. Patients with inborn errors of metabolism, such as urea cycle defects [68], organic acidurias and a number of other disorders [69], are at special risk for severe liver toxicity, and valproic acid should be preferably avoided in these patients. Apart from this, young age and polytherapy have been identified as the two main risk factors. The risk of fatal hepatotoxicity on polytherapy with valproic acid has been estimated at approximately 1 in 600 below the age of 3 years, 1 in 8000 from 3 to 10 years, 1 in 10 000 from 11 to 20 years, 1 in 31 000 between 21 and 40 years and 1 in 107 000 above the age of 41 years [12]. On monotherapy, the risk is much lower and has been estimated to vary between 1 in 16 000 (3–10 years old) and 1 in 230 000 (21–40 years old). For certain age groups, no fatalities have been reported. Although it is commonly done routinely, laboratory monitoring is of little value, because a benign elevation of liver enzymes is common with valproic acid, and severe hepatotoxicity is usually not preceded by a progressive elevation of liver enzymes. The most important step in the diagnosis of hepatic failure due to valproic acid is probably recognition of the clinical features, which include nausea, vomiting, anorexia, lethargy, jaundice, oedema and at times loss of seizure control. Increased production of toxic valproic acid metabolites has been considered to be a possible cause of valproic acid hepatotoxicity, but this has not been well documented [70]. There is also evidence of a protective effect of carnitine administration (especially intravenously) in cases of severe valproic acid hepatotoxicity [71]. According to a panel of experts, L-carnitine supplementation is strongly suggested in the following groups of patients: those with certain secondary carnitine deficiency syndromes, symptomatic valproic acid-associated hyperammonaemia, multiple risk factors for valproic acid hepatotoxicity or renal-associated syndromes, infants and young children taking valproic acid, patients with epilepsy using the ketogenic diet who have hypocarnitinaemia, patients receiving dialysis, and premature infants who are receiving total parenteral nutrition [72].

The development of acute haemorrhagic pancreatitis is another serious complication of valproic acid treatment [73,74]. The occurrence of vomiting and abdominal pain should raise the suspicion of this complication. The most helpful diagnostic tests are serum amylase and lipase, and abdominal ultrasound may then be considered. However, amylase may be elevated in 20% of asymptomatic patients on valproic acid [75], and pancreatitis has been described in a patient with normal amylase but elevated lipase [76].

Haematological adverse effects

Although valproic acid therapy is commonly associated with haematological alterations, these are seldom severe enough to necessitate discontinuation of the drug [77]. Thrombocytopenia is by far the most frequently diagnosed haematological side-effect [78]. It is usually dose or serum concentration dependent and tends to improve with dosage reduction. In conjunction with other valproic acid-induced disturbances of haemostasis, such as impaired platelet function, fibrinogen depletion and coagulation factor deficiencies [79,80], thrombocytopenia may cause bruising or bleeding. It is therefore generally recommended to discontinue valproic acid about 1 month before elective surgery, especially when the surgical procedure is considered to be associated with high blood losses. However, no objective evidence of excessive operative bleeding during neurosurgical procedures in patients maintained on valproic acid could be found in independent studies [81–83].

In addition to changes related to coagulation, valproic acid can also occasionally cause neutropenia and bone marrow suppression.

Metabolic, endocrine and reproductive disorders, including teratogenicity

Because hyperammonaemia is a very common finding in patients on chronic valproic acid therapy, particularly in those taking valproic acid together with an enzyme-inducing AED, and it is usually asymptomatic, routine monitoring of ammonia is not warranted [84]. It has been proposed that the origin of the excessive ammonium may be renal. It has also been shown that hyperammonaemia can be reduced by L-carnitine supplementation, but there is no documentation that this is necessary or clinically beneficial [85].

Symptomatic cases of hyperammonaemia have also been reported. In fact, ammonia levels were initially measured in symptomatic patients with changes in mental status, and the finding of elevated values was considered to be the cause of the symptoms even though this interpretation might not have been correct in all cases. Valproic acid-induced encephalopathic hyperammonaemia can be severe, and lethal cases of hyperammonaemic coma or Reye-like syndrome have been reported, particularly in patients with urea cycle disorders [85]; this can be regarded as a contraindication to the use of valproic acid.

Independently from hyperammonaemia, carnitine levels can be lowered by chronic treatment with valproic acid, especially in polytherapy [86]. One patient who developed acute encephalopathy and cerebral oedema after acute administration of valproic acid was found to have low carnitine levels, but a prominent role for carnitine deficiency in the development of severe adverse effects of valproic acid has never been established. However, in cases of acute valproic acid overdose, a beneficial role of L-carnitine supplementation has been suggested [87].

Menstrual irregularities, hormonal changes such as hyperandrogenism and hyperinsulinism [88,89], and pubertal arrest in

women have all been reported in association with valproic acid treatment. The association between valproic acid therapy and polycystic ovary syndrome has been another concern. This may include obesity, hirsutism, hyperandrogenism, anovulatory cycles and menstrual disorders. Although polycystic ovary syndrome is more common in women with epilepsy (13–25%) than in the general female population (4–6%), it has been reported to be even higher among those treated with valproic acid (up to 64%). However, it is still openly debated to what extent these observations are significant and reproducible [90–92].

When taken during pregnancy, valproic acid has been found to be associated with an increased risk of major malformations [93]. In particular, treatment with valproic acid during the first trimester of pregnancy has been reported to be associated with an estimated 1–2% risk of neural tube defects in the newborn, mostly spina bifida [94]. The risk of spina bifida and other congenital malformations appears to increase at higher doses of valproic acid. In animal studies, neural tube defects also seem to correlate with higher peak serum levels of valproic acid. A genetic susceptibility may also be involved. Folate supplementation is recommended in all women with childbearing potential treated with valproic acid, although a protective effect of folate against valproic acid-induced teratogenicity has not been established. It has been suggested more recently that exposure to valproic acid *in utero* may also result in developmental delay, including learning disability, in the offspring [95]. Risks for fetal and postnatal development in relation to exposure to valproic acid and other AEDs during pregnancy are discussed in greater detail in Chapter 25.

Miscellaneous adverse effects

Early during treatment with valproic acid, excessive hair loss or thinning of the hair may be seen. This does not represent visible alopecia, but patients or parents may see more hair on the comb or in the shower. Although the hair tends to grow back, its texture or colour may become different. In some cases, more prominent hair loss and full-blown alopecia may occur.

Although valproic acid is not an enzyme-inducing drug, it may also decrease bone mineral density, with a resulting increased risk of fractures. Unlike enzyme-inducing AEDs, valproic acid does not cause bone loss through hypovitaminosis D, and the precise mechanism has not been elucidated.

Rare adverse effects include facial or limb oedema even in the absence of hepatic injury, secondary nocturnal enuresis (especially in children), hyponatraemia [96,97], skin rashes and systemic lupus erythematosus.

Current place in therapy

Valproic acid is a broad-spectrum AED and remains a first-line therapy in idiopathic generalized epilepsies. Its efficacy in these forms of epilepsy has been confirmed by decades of clinical use and has remained unsurpassed. Valproic acid is a first-line or adjunctive therapy in cryptogenic or symptomatic generalized epilepsies. It can also be effective, but does not represent a first-line therapy, against partial seizures. In the treatment of juvenile myoclonic epilepsy, valproic acid is highly effective against all seizure types that may occur and, unlike lamotrigine, it was not found to exacerbate myoclonic seizures.

There are two populations of patients in whom valproic acid should be used with great caution: infants and female patients of childbearing age. The first group is at higher risk of potentially fatal liver toxicity, and in the latter group, teratogenicity in the form of a substantial increase in the risk of spina bifida and other major congenital malformations markedly limits the use of valproic acid.

Although many different formulations of valproic acid have been marketed, their types and availability vary from country to country. Commonly used dosage forms include immediate-release capsules, tablets and syrup, enteric-coated tablets of sodium valproate or divalproex sodium, divalproex sodium enteric-coated sprinkles, various sustained-release oral preparations, valpromide (the amide of valproic acid) tablets and a formulation of sodium valproate for intravenous use. In addition, solid-dose forms especially suitable for younger children are available, such as sprinkles consisting of capsules containing enteric-coated particles of divalproex sodium; the capsules can be opened and the contents can be sprinkled on food, or the capsules can be swallowed unopened. Another convenient formulation for paediatric use consists of sachets containing small particles (microspheres) of sustained-release valproic acid.

The initial recommended dose of valproic acid is approximately 15 mg/kg/day in children or 400–500 mg/day in adults. This can be increased subsequently, as necessary and as tolerated, by 250–500 mg/day (or 5–10 mg/kg/day in children) at appropriate intervals. The optimal dose or serum concentration may be a function of the patient's seizure type and syndromic form. In idiopathic generalized epilepsies, monotherapy with daily doses between 10 and 20 mg/kg is often sufficient for full seizure control [16]. Higher doses in milligrams per kilogram per day are often required in children. In patients who are also taking enzyme-inducing AEDs, doses of 30–60 mg/kg/day (in children even more than 100 mg/kg/day) may be necessary to achieve adequate serum valproic acid levels. When using immediate-release or enteric-coated formulations, it is common practice to divide the daily oral dose of valproic acid into two or three single doses because of the relatively short elimination half-life of the drug. However, equally good results have been achieved with a single daily dose, which may be explained by the pharmacodynamic profile of valproic acid. In fact, it appears that, at least in some cases, the maximal therapeutic effect may lag by days or weeks behind the achievement of stable doses or serum drug levels. Sustained-release formulations are generally administered twice daily or once daily, depending on the properties of the formulation and the characteristics of the patient (twice-daily dosing is generally more appropriate for patients with shorter half-lives, such as children co-medicated with enzyme-inducing AEDs).

Valproic acid can be administered intravenously if therapeutic serum drug levels are to be achieved rapidly, or in patients who are unable to take oral medication [98]. This route may also be used for the treatment of status epilepticus. The usual initial dose is 15–20 mg/kg administered over 5–10 min (at a rate of 1.5–3.0 mg/kg/min), followed by constant infusion at a rate of 0.5 mg/kg/h (1 mg/kg/h for patients on enzyme-inducing AEDs) in adults

and 1.0 mg/kg/h (1.5 mg/kg/h for patients on enzyme-inducing AEDs) in children. However, more rapid administration (up to 6 mg/kg/min) of loading doses (up to 45 mg/kg) has been tolerated well [99]. A subsequent administration should be given within 6 h in those receiving intravenous replacement therapy or bolus dosing, because of the rapid fall in serum drug levels and the possible re-emergence of seizures.

When chronic valproic acid therapy is initiated, it is common practice to routinely monitor liver enzymes and complete blood counts with platelets, starting at baseline, then 1–3 months after initiation, and about every 6 months after this if the results are normal. Haematological abnormalities are likely to be discovered. However, severe hepatotoxicity is unlikely to be detected by routine monitoring of liver enzymes, because of its rapid onset and progression. Serum ammonia should be determined, especially in the presence of mental status changes. If gastrointestinal symptoms occur, especially vomiting and abdominal pain, amylase and lipase should be checked, in addition to liver function tests.
