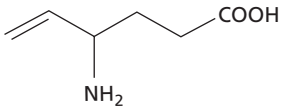
56 Vigabatrin

Günter Krämer[1] *and Gabriele Wohlrab*[2]

[1] Swiss Epilepsy Centre, Zurich, Switzerland
[2] Children's Hospital, University of Zurich, Zurich, Switzerland



Primary indications	Monotherapy of infantile spasms (West syndrome). May also be of value as adjunctive therapy for partial and secondary generalized seizures refractory to other drugs
Usual preparations	Tablets: 500 mg; powder (sachets): 500 mg
Usual dosages	75–150 mg/kg/day (infantile spasms). For partial seizures, maintenance dosages are generally in the range of 1000–3000 mg/day (adults), 500–1000 mg/day (children weighing 10–15 kg), 1000–1500 mg/day (children weighing 15–30 kg) and 1500–3000 mg/day (children weighing over 30 kg). In partial seizures, treatment should be initiated at a low dosage (e.g. 500 or 1000 mg/day in adults) and increased gradually
Dosing frequency	Twice daily
Significant drug interactions	Vigabatrin may reduce serum phenytoin levels
Serum level monitoring	Not useful, except for monitoring compliance
Reference range	Not applicable
Common/important adverse effects	Irreversible visual field constriction, weight gain, sedation, fatigue, dizziness, blurred or double vision, nystagmus, ataxia, paraesthesiae, amnesia, depression, psychosis, aggression, confusion, stupor. Drowsiness, insomnia, hyperactivity, agitation, hypotonia, hypertonia, aggravation of myoclonic seizures and other generalized seizure types, and gastrointestinal symptoms are seen particularly in children
Main advantages	Highly effective and relatively well tolerated in the treatment of infantile spasms
Main disadvantages	Visual field constriction, weight gain and central nervous system side-effects
Mechanisms of action	Irreversible inhibition of GABA transaminase
Oral bioavailability	≥50% for the active *S*-(+)-enantiomer
Time to peak levels	0.5–2 h
Elimination	Primarily by renal excretion in unchanged form
Volume of distribution	0.8 L/kg [1.2 L/kg for the *S*-(+)-enantiomer]
Elimination half-life	4–7 h
Plasma clearance	0.10–0.144 L/kg/h for the active *S*-(+)-enantiomer, assuming complete bioavailability
Protein binding	None
Active metabolites	None
Comment	A first-line drug for the treatment of infantile spasms, particularly those caused by tuberous sclerosis complex. Because of the risk of irreversible visual field constriction, vigabatrin is rarely used in other indications

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Vigabatrin represents one of the few antiepileptic drugs (AEDs) that emerged from a mechanism-driven discovery strategy. Based on the evidence that γ-aminobutyric acid (GABA) is the most important inhibitory neurotransmitter in the mammalian brain, and that epileptic seizures may result from an imbalance between excitatory and inhibitory transmission, vigabatrin was discovered through a systematic search for agents that can increase brain GABA levels by inhibiting GABA transaminase, the main enzyme responsible for the degradation of GABA [1]. Vigabatrin was initially licensed for the treatment of refractory partial-onset seizures. However, after the discovery of serious retinal toxicity, its use is currently restricted primarily to the treatment of infantile spasms.

Chemistry

Vigabatrin is a white to off-white crystalline amino acid which is highly water soluble and only slightly soluble in ethanol and methanol. Its molecular weight is 129.16, and the conversion factor from mg/L to μmoL/L is 7.75 (1 mg/L = 7.75 μmol/L). Vigabatrin exists as a racemic mixture of *S*-(+)- and *R*-(–)-enantiomers in equal proportions. Only the *S*-(+)-enantiomer is pharmacologically active [2].

Vigabatrin is available only in oral formulations (tablets and sachets, containing 500 mg each).

Pharmacology and toxicology data

Activity in experimental models of seizures and epilepsy

The anticonvulsant effects of vigabatrin have been studied in numerous animal models. The onset of anticonvulsant activity in classical models (such as the maximal electroshock test) occurs with a delay of many hours, being correlated with the slowly developing increase in GABA levels in nerve terminals rather than with the concentration of the drug in plasma [3]. Vigabatrin shows protective activity against bicuculline-induced myoclonic seizures, strychnine-induced tonic seizures, isoniazid-induced generalized seizures, audiogenic seizures in mice, light-induced seizures in baboons and amygdala-kindled seizures in rats [4].

Animal toxicology data

Standard preclinical safety studies in rats, mice, dogs and monkeys demonstrated no significant adverse effects of vigabatrin on the liver, kidney, lung, heart or gastrointestinal tract. Vigabatrin is also devoid of mutagenic or carcinogenic effects. However, in the brain, microvacuolation was observed in white matter tracts of rats, mice and dogs at doses of 30–50 mg/kg/day. In the monkey, these lesions were minimal or equivocal. Microvacuolation is caused by a separation of the outer lamellar sheath of myelinated fibres, a change characteristic of intramyelinic oedema. In both rats and dogs, intramyelinic oedema was reversible upon discontinuation of the drug, and even with continued treatment histological regression was observed. In rodents, minor residual changes consisting of swollen axons and mineralized microbodies were observed [5,6].

Vigabatrin-associated retinotoxicity has been observed in albino rats, but not in pigmented rats, dogs or monkeys. Retinal changes in albino rats were characterized as focal or multifocal disorganization of the outer nuclear layer with displacement of nuclei into the rod and cone area. The other layers of the retina were not affected. Although the histological appearance of these lesions was similar to that found in albino rats following excessive exposure to light, the retinal changes may also represent a direct drug-induced effect [5].

Mechanism of action

Vigabatrin is an irreversible suicide inhibitor of GABA transaminase, the enzyme responsible for the transamination of GABA to form succinic acid semialdehyde. Vigabatrin itself is a substrate of GABA transaminase. The mechanism of enzyme inhibition involves the binding of the drug to GABA transaminase, which selectively converts it to a reactive intermediate. The intermediate, in turn, binds covalently to the enzyme, causing its irreversible inactivation [1,7].

Inhibition of GABA transaminase results in reduced catabolism of GABA and prolonged elevation of brain GABA levels, without any major influence on other enzymes involved in GABA synthesis and metabolism. The effect of vigabatrin is maximal 3–4 h after administration, and is maintained for at least 24 h. In fact, the duration of pharmacological effect is determined not by the half-life of the drug, but by the ability of the body to resynthesize GABA transaminase. Restoration of normal enzyme activity after withdrawal of vigabatrin takes several days [8]. Vigabatrin also significantly reduces the activity of plasma alanine aminotransferase by 20–100% [9].

In patients with epilepsy, a dose-related (up to a dose of 3 g/day) elevation in the levels of free GABA, total GABA and homocarnosine (a dipeptide of GABA) in the cerebrospinal fluid (CSF) has been demonstrated [10]. ^{1}H-MR spectroscopy has also shown that the brain GABA content in the occipital region of patients with epilepsy increases two- to threefold [11,12]. Increasing vigabatrin dosage from 3 to 6 g/day did not result in a further increase in brain GABA concentrations, most probably because of feedback inhibition of glutamic acid decarboxylase, the GABA-synthesizing enzyme, at high GABA concentrations.

Pharmacokinetics

Pharmacokinetics in adults

Vigabatrin shows linear pharmacokinetics over the dose range of 0.5–4 g. The drug is rapidly absorbed from the gastrointestinal tract and peak serum concentrations are reached within 0.5–2 h after oral intake [13]. Based on the recovery of unchanged drug in urine, the oral bioavailability has been estimated at ≥50% for the active *S*-(+)-enantiomer and at ≥65% for the inactive *R*-(–)-enantiomer [13]. After a single dose, peak serum concentrations of the *S*-(+)-enantiomer are about one-half those of the *R*-(+)-enantiomer, whereas areas under the serum concentration–time curve (AUC) are about 25% lower for the *S*-(+)- than for the *R*-(–)-enantiomer [13]. Food does not influence vigabatrin absorption [14].

Vigabatrin is widely distributed in the body and is not bound to plasma proteins, The volume of distribution calculated from the serum concentrations of racemic drug is about 0.8 L/kg, but it appears to be higher (about 1.2 L/kg) for the S-(+)-enantiomer [15]. Vigabatrin levels in the CSF are approximately 10% of those in the blood [16]. The passage of both vigabatrin enantiomers across the human placenta is slow, and the breast milk to plasma concentration ratio for the active S-enantiomer is below 0.5 [17].

The elimination of vigabatrin is primarily through the kidney in unchanged form. The elimination half-life is between 5 and 7 h for both enantiomers but slightly shorter half-life values of 4–6 h have been reported in patients taking enzyme-inducing AEDs [18].

Because the clearance of *R*-(–)- and *S*-(+)-vigabatrin is highly correlated with creatinine clearance, a reduction in glomerular filtration rate, as observed physiologically in old age, is associated with a decrease in the clearance of both vigabatrin enantiomers [19].

Pharmacokinetics in infants and children

Mean values of peak serum concentration (C_{max}) and AUC values of the active *S*-enantiomer of vigabatrin were significantly lower for the active *S*-(+)-enantiomer than for the *R*-(–)-enantiomer following single oral doses of 125 mg racemic vigabatrin in six neonates, whereas no difference between the two enantiomers was found in time to reach peak plasma concentrations. Repeated administration of 125 mg twice daily over 4 days did not result in accumulation of either enantiomer [20].

Rey *et al*. [21] used an enantioselective assay to investigate the pharmacokinetics of vigabatrin after a single 50 mg/kg oral dose in six infants (age 5–24 months) and six children (age 4–14 years) with intractable epilepsy. AUC values of both enantiomers were lower in infants than in children, the difference being particularly marked for the *R*-(–)-enantiomer. For each enantiomer, AUC values were also lower than those reported for adult historical controls. Since the renal clearances of both enantiomers were comparable to those reported for adults, the suggestion was made that the lower AUC in infants and children could be related to a reduced oral bioavailability [15,21].

While there are data on the effect of vigabatrin on brain GABA levels measured by magnetic resonance spectroscopy in adults [22], no such data are available for children. One study used [^{11}C]flumazenil-positron emission tomography (PET) imaging in 15 children (aged 1–8 years) with pharmacoresistant epilepsy to determine whether prolonged vigabatrin treatment interferes with age-related changes in $GABA_A$ receptor binding *in vivo* [23]. Seven of these children were treated with vigabatrin (1000–2500 mg/day) for at least 3 months in addition to another AED, while eight age-matched controls were treated with one to three AEDs known not to act directly on the GABAergic system. Vigabatrin-treated children showed a significantly lower hemispheric flumazenil volume of distribution in all cortical regions and the cerebellum. It is assumed that vigabatrin induces a decrease in $GABA_A$ receptor binding in the cortex and cerebellum of the developing epileptic brain.

Pharmacokinetics in disease states

In patients with renal disease, the clearance of both vigabatrin enantiomers is reduced in proportion to the degree of renal impairment, as assessed by measuring the creatinine clearance [19]. As a result, dosage needs to be adjusted accordingly. Bachmann *et al*. [24] reported a patient with severe renal failure (creatinine clearance <5 mL/min) in whom the half-life of vigabatrin was as long as 41 h. His seizures were controlled with only 500 mg vigabatrin every 3 days. Since about 60% of the drug was removed from the blood during haemodialysis, it was recommended that in these patients the vigabatrin dose should be administered after the dialysis.

Drug interactions

Plasma vigabatrin levels [25] are not affected by concomitant intake of established AEDs [25,26], although a slightly shorter vigabatrin half-life has been reported in patients on enzyme-inducing AEDs [18]. Felbamate leads to a slight increase in the levels of the active *S*-(+)-enantiomer of vigabatrin [27].

After a latency of some weeks, vigabatrin reduces serum phenytoin levels by about 25% on average, without altering phenytoin absorption [28] or plasma protein binding [29]. The mechanism of this interaction is unclear. In children with epilepsy, the fall in phenytoin levels can be even more pronounced [30]. The serum levels of phenobarbital and primidone can also be slightly reduced by vigabatrin [18].

Vigabatrin has no effect on the plasma concentrations of valproic acid [25] and felbamate [27]. Serum carbamazepine levels are usually unaffected by vigabatrin, even though there are isolated reports of changes in carbamazepine levels in either direction [31,32].

Vigabatrin has no effect on the pharmacokinetics of oral steroid contraceptives [33].

Serum level monitoring

Since vigabatrin has an irreversible mode of action, the time-course of serum vigabatrin concentrations is dissociated from the time-course of its pharmacological effect. In a study of 16 children with refractory epilepsy, there was no strong correlation between vigabatrin dosages, plasma concentrations and clinical efficacy [34]. A poor relationship between serum vigabatrin concentrations and clinical effects has also been found in other studies, and there seems to be no indication for monitoring serum vigabatrin levels, except for a check for compliance [35].

Efficacy

Infantile spasms (West syndrome)

Infantile spasms, currently the primary indication of vigabatrin, are associated with a variety of neuropathological conditions. About 70% of spasms are symptomatic, with brain malformations and tuberous sclerosis complex accounting for up to 35% of the cases [36]. Adrenocorticotropic hormone (ACTH) or corticosteroids have been, for decades, the gold standard treatment for infantile spasms. In 1990, vigabatrin was also found to be effective against infantile spasms, and in many countries it is now regarded as a first-line drug in this condition due to its rapid onset of efficacy (mostly within 2 weeks) and its negligible adverse

effects during the acute treatment period compared with steroids. The level of evidence provided by the studies that investigated the efficacy of vigabatrin against infantile spasms has been assessed by Mackay *et al.* [37].

Class I evidence

The only study that met criteria for class I evidence was a prospective, randomized, placebo-controlled trial that enrolled 40 children with newly diagnosed infantile spasms, 20 in each cohort [38]. At the end of a 5-day double-blind phase, seven (35%) vigabatrin-treated children were spasm free and five (25%) had a resolution of hypsarrhythmia, compared with two (10%) and one (5%) respectively in the placebo group ($P = 0.063$). Relapse occurred in four (20%) of the vigabatrin-treated patients. At the end of the study, 42% of the 36 patients who entered a 24-week open-label phase were spasm free on vigabatrin monotherapy. No patient withdrew from the study because of adverse effects.

Class III evidence

Three randomized controlled studies have been reported that met the inclusion criteria of documented presence of infantile spasms and hypsarrhythmia.

Vigevano and Cilio [39] compared the efficacy of vigabatrin (100–150 mg/kg/day) and ACTH (10 IU/day) as first-line therapy in 42 infants. Using a cross-over design, the alternative drug was administered to infants who did not respond within 20 days or were intolerant to the initial therapy. Cessation of spasms was observed in 48% (11/23) of infants in the vigabatrin group, with a slightly higher efficacy in cryptogenic than in symptomatic cases (57% versus 44%), and in 74% (14/19) of infants in the ACTH group. The response to vigabatrin occurred within 14 days, and follow-up data for up to 44 months identified only one case of relapse of spasms. In the ACTH group, six patients had a relapse 40–45 days after termination of ACTH and replacement with a benzodiazepine.

A multicentre study randomly assigned 142 infants to low-dose (18–36 mg/kg/day) or high-dose (100–150 mg/kg/day) vigabatrin treatment [40]. Within 2 weeks, 23% of the infants showed complete cessation of spasms and hypsarrhythmia. This response increased to 65% at the end of the 3-month open-label period. A marked difference in clinical and electroencephalographic response in relation to dose was observed. Within the first 2 weeks, 8 of 75 (10.6%) patients in the low-dose group and 24 of 67 (35.8%) in the high-dose group responded. The response rate continued to increase during the follow-up period (42% at 4 weeks, 55% at 2 months and 65% at 3 months) at a median dosage at the time of response of 106 mg/kg (mean 95 mg/kg, range 16.9–199 mg/kg/day). Time to response was shorter in infants allocated to the high-dose regimen and in those with spasms secondary to tuberous sclerosis complex. Of the 87 patients who initially responded to vigabatrin, 14 (16%) relapsed within 3 months during continued therapy.

The third class III evidence trial, the United Kingdom Infantile Spasms Study (UKISS), was a multicentre randomized controlled trial that compared the efficacy of vigabatrin with that of prednisolone or tetracosactide [41]. Of 52 infants randomized to vigabatrin (100–150 mg/kg/day), 28 (54%) were spasm free within 2 weeks. The short-term efficacy of vigabatrin was lower than that of hormonal treatment. In fact, 70% (21 of 30) of infants who received prednisolone (10 mg four times a day for 2 weeks, increasing to 20 mg three times a day after 1 week if spasms continued) and 76% (19 of 25) of those who received tetracosactide showed cessation of spasms within the same time period. Of the 55 infants allocated to hormonal therapy, 27 were treated with vigabatrin after day 14 because of failure to achieve cessation of spasms ($n = 12$), seizure relapse ($n = 14$) or appearance of focal seizures ($n = 1$). In the group initially allocated to vigabatrin, 22 infants were switched to hormonal treatment. Adverse events were reported in 54% (28 of 52) of the infants on vigabatrin (mainly drowsiness and gastrointestinal symptoms) and in 55% (30 of 55) of the infants on hormonal therapy (mainly high blood pressure, irritability and gastrointestinal symptoms). No deaths were recorded. Response to treatment was not influenced by underlying cause, but infants with tuberous sclerosis complex were excluded from this study. At the clinical reassessment at 12–14 months of age [42], freedom from spasms was similar in each treatment group (vigabatrin 76%, hormonal treatment 75%). Five children died during the follow-up period, one due to *Staphylococcus aureus* septicaemia on day 15 of prednisolone treatment, and four children due to their underlying disease.

Relapse rates in vigabatrin-treated infants in these randomized controlled trials ranged between 8% and 20%. Except for the low-dose versus high-dose trial [40], the primary efficacy endpoint was the cessation of spasms as determined by caregiver's observations and the initial dose varied between 50 and 100 mg/kg/day, followed by titration up to 150 mg/kg/day.

Class IV evidence

A retrospective survey of 192 patients from 59 European centres analysed the safety and efficacy of vigabatrin monotherapy in newly diagnosed infantile spasms [43]. Vigabatrin dosage varied between 20 and 400 mg/kg/day (mean dose 99 mg/kg/day) and duration of therapy ranged from 2 weeks to 28.6 months. Complete cessation of spasms was observed in 68% of patients (131 of 192), 19% had a reduction in cluster frequency, 12.5% did not improve and one infant deteriorated. Concerning subgroups of aetiologies leading to infantile spasms, patients with tuberous sclerosis complex showed a very high responder rate of 97% (27 of 28), followed by infants with cryptogenic spasms (69.4%) and symptomatic spasms due to other causes (59.7%). Infants aged less than 3 months at spasm onset responded better (90%, 18 of 20) than those with later onset (65%). Relapses occurred in 21% (28 of 131 initial responders) within a mean period of 4 months. Reported adverse events were generally mild (somnolence, insomnia, hypotonia, hyperkinesias) and drug withdrawal was required in very few patients (~1%).

In addition to the studies summarized above, there have been many other reports dealing with vigabatrin therapy in newly diagnosed or drug-refractory infantile spasms. In six open-label, uncontrolled, prospective studies [44–49], clinical responses (efficacy on hypsarrhythmia was not explicitly mentioned in all studies) varied between 50% and 100% in cryptogenic cases, and between 19% and 57% in those with symptomatic infantile spasms. Relapse rates after initial successful vigabatrin therapy were low, ranging from single cases to a maximum of 14%.

Efficacy in terms of complete cessation of spasms did not differ between newly diagnosed infants (43%, 45%) [44,45] and infants who were initially drug refractory (43%, 48%) [46,50].

Response to vigabatrin occurs relatively rapidly. In all studies and reports, the time between initiation of therapy and cessation of spasms ranged from 2 to a maximum of 35 days. Sometimes response was observed after one or two doses [51]. A 2-week cut-off for qualifying responders was proposed in different controlled and open-label studies [39,40,44,47].

In the prospective studies cited above, vigabatrin was used at doses ranging from 18 to 200 mg/kg/day. Mitchell and Shah [51] suggested that response may be dose independent. They observed complete disappearance of spasms and hypsarrhythmia at doses ranging from 25 to 135 mg/kg/day in 12 of 20 infants. In contrast, an Asian study [52] mentioned a relapse rate of 56% within 6 months in initial responders, which was ascribed to an insufficient dose because those who relapsed were on a lower average dosage of 59 mg/kg/day at the time of relapse and responded to a stepped-up dose of 83 mg/kg/day. The authors suggested that at least 70 mg/kg/day is necessary to achieve adequate seizure control.

Because the occurrence of vigabatrin-induced visual field constriction seems to correlate with the duration of treatment and with the total cumulative dose [53], the question arises of how long patients with infantile spasms should be treated. A maximum treatment duration of 6 months was proposed by Capovilla *et al*. [54]. In their study, successful drug therapy was stopped after 3–6 months (mean 5.1 months) in cryptogenic as well as symptomatic cases without relapse during a follow-up period of 13–50 months. On the other hand, Kröll-Seger *et al*. [55] reported severe relapse of infantile spasms in four children with focal cortical dysplasia (and tuberous sclerosis complex in one of them), who had been treated successfully with vigabatrin for 1–5 years [55]. In these children, vigabatrin withdrawal led to recurrence of spasms refractory to vigabatrin, and to severe mental deterioration in two cases.

Efficacy in relation to aetiology: infantile spasms due to tuberous sclerosis complex

Vigabatrin has been shown to be most effective in the treatment of infantile spasms due to tuberous sclerosis complex. This observation was first made by Chiron *et al*. [50] in the early 1990s and confirmed in a subsequent multicentre retrospective survey [43]. Of 28 children with infantile spasms due to tuberous sclerosis complex, 27 showed complete cessation of spasms, which corresponds to a response rate of 96%.

These results were confirmed in a prospective randomized trial performed by Chiron *et al*. [56] that compared vigabatrin and hydrocortisone with an optional cross-over for non-responders. The study included 22 children with infantile spasms and a confirmed diagnosis of tuberous sclerosis complex. The difference in clinical and electroencephalographic response between the two treatments was highly significant. In patients randomized to vigabatrin (150 mg/kg/day), efficacy in terms of cessation of spasms was 100% (11/11), while less than one-half (5/11) of patients randomized to hydrocortisone responded. All seven patients who crossed over from hydrocortisone to vigabatrin (six for inefficacy, one for adverse events) became seizure free. The mean time to reach seizure cessation was 3.5 days for vigabatrin compared with 13 days for hydrocortisone.

In 1999, Hancock and Osborne [57] reviewed 16 studies published in the English literature on the use of vigabatrin in the treatment of infantile spasms. Out of 390 patients, 77 had been diagnosed as having tuberous sclerosis complex, while 313 has spasms due to other aetiologies or classified as idiopathic or cryptogenic. Responder rates were 95% (73/77) in patients with tuberous sclerosis complex compared with 54% (169/313) in the remaining patients. Response was observed within 1 week in the majority of patients. Cessation of the spasms seems to be associated with a marked improvement in behaviour and mental development [58].

Epileptogenesis in tuberous sclerosis complex may be caused by an imbalance of decreased inhibition secondary to molecular changes in GABA receptors in giant cells and dysplastic neurones, and increased excitation secondary to molecular changes in glutamate receptors in dysplastic neurones [59,60]. A deficiency of GABAergic interneurones may explain the early onset and severity of seizures in tuberous sclerosis complex. The particular efficacy of vigabatrin in this condition suggests that epileptogenesis caused by tuberous sclerosis complex may be related to impairment of GABAergic transmission. However, the exact mechanisms underlying the preferential response of these patients to vigabatrin are still unknown.

Riikonen [61], who considers steroids as the first-choice agents in infantile spasms due to other aetiologies, recommends vigabatrin as first choice for infantile spasms caused by tuberous sclerosis complex. Recent expert opinions in the USA also consider vigabatrin as the treatment of choice for infantile spasms secondary to tuberous sclerosis complex, and regard it as a second-line treatment for infantile spasms secondary to other aetiologies [62].

Efficacy in relation to aetiology: infantile spasms due to other aetiologies

Focal cortical dysplasia is one of the causes of infantile spasms. However, the sensitivity of magnetic resonance imaging (MRI) in diagnosing focal cortical dysplasia in infants is low, and one-third of patients with histopathologically confirmed Taylor-type focal cortical dysplasia have unrevealing MRI images [63]. Therefore, focal cortical dysplasia can be a cause for apparently 'cryptogenic' infantile spasms. Affected patients mostly present with early partial seizures with or without infantile spasms. Lortie *et al*. [64] reported on 11 children with focal cortical dysplasia who presented with early partial seizures and infantile spasms and were easily controlled with vigabatrin or ACTH. Focal seizures remained medically refractory except for one patient. However, no patient treated with vigabatrin for focal epilepsy developed infantile spasms. According to Parisi *et al*. [65], in focal cortical dysplasia vigabatrin treatment 'seems to be able to prevent diffusion of the paroxysmal activity outside of the dysplasia. Cytoarchitectural, molecular, and immunological similarities could explain the positive response of vigabatrin therapy in infants with epileptic spasms due to focal cortical dysplasia or tuberous sclerosis complex.'

A prospective study in five children with infantile spasms associated with trisomy 21 (Down syndrome) reported an immediate

response to vigabatrin in four cases [66]. These patients showed no relapse of spasms or other seizure types when vigabatrin was discontinued after 6 months of treatment.

In a patient with infantile spasms related to succinic semialdehyde dehydrogenase deficiency, a rare autosomal recessive metabolic disorder in GABA catabolism, vigabatrin was effective at the very low dose of 25 mg/kg/day [67]. There is also anecdotal evidence of a favourable response in infantile spasms associated with Aicardi's syndrome [68]. In infantile spasms related to non-ketotic hyperglycinaemia, a rare inborn error of glycine metabolism, high GABA levels produced by vigabatrin can aggravate the epileptic encephalopathy [69].

Partial-onset seizures

Adults

Studies with vigabatrin in adults have included more than 2000 patients, the majority of whom had partial seizures. After initial open and single-blind dose-finding studies, several randomized, double-blind, placebo-controlled adjunctive therapy cross-over studies in adults with refractory partial epilepsies have been completed [1,70]. A review of the first six double-blind studies demonstrated a clear response at dosages of 2 and 3 g/day [71]. Only a limited number of patients appeared to benefit from increasing dosage from 2 to 3 g/day [71], as also shown by a subsequent cross-over study from Australia. The latter study, conducted in 97 patients with uncontrolled partial seizures, compared 2 g/day with 3 g/day and showed a similar efficacy, with 42% of patients experiencing a 50% or greater reduction of seizure frequency in comparison with placebo. In addition, the number of seizure-free days was significantly higher and the duration of seizure-free periods was significantly longer during vigabatrin treatment, and more patients had less severe and shorter seizures [72].

In addition to the cross-over studies, several double-blind, placebo-controlled adjunctive therapy parallel-group studies have been carried out. The therapeutic efficacy of vigabatrin, as assessed by the percentage of patients with at least a 50% reduction in seizure frequency, was quite similar across the studies, with about 40% of patients being responders [1,70]. In the first of two studies from the USA, 92 patients received vigabatrin 3 g/day and 90 patients received placebo [73]. Significantly more patients randomized to vigabatrin were responders in terms of 50–99% reduction in seizure frequency (37% versus 18%) or seizure freedom (6% versus 1%). The second study from the USA examined three different doses (1, 3 or 6 g/day) in a total of 174 patients [74]. Only 7% of patients in the placebo group were responders, whereas responder rates at 1, 3 and 6 g/day were 24%, 51% and 54%, respectively.

A double-blind, double-dummy substitution trial compared add-on vigabatrin (2–4 g/day) and valproic acid (1–2 g/day) in carbamazepine-resistant partial epilepsy, allowing withdrawal of carbamazepine in responders. The two groups showed similar percentages of responders (53% versus 51%) and similar proportions of patients maintained on alternative monotherapy (27% versus 31%) [75].

Vigabatrin monotherapy in partial epilepsy was assessed initially in two open-label, single-centre randomized studies in 100 [76] and 51 patients [77] respectively, using carbamazepine as a comparator. Both studies failed to show statistically significant differences in efficacy, although in at least one of the studies there was a clear trend for seizure freedom rates to be greater on carbamazepine [76]. A subsequent large randomized, double-blind, parallel-group study also compared the efficacy of vigabatrin and carbamazepine monotherapy in newly diagnosed partial epilepsy. In this study, 53% of 229 patients on 2 g vigabatrin daily and 57% of 230 patients on 600 mg carbamazepine daily achieved 6-month remission. However, significantly more patients on vigabatrin withdrew due to lack of efficacy than with carbamazepine, and time to first seizure after the first 6 weeks from randomization also showed carbamazepine to be more effective. It was concluded that vigabatrin cannot be recommended as a first-line treatment for newly diagnosed partial epilepsies [78].

In another randomized trial conducted in a total of 215 patients (age range, 12–76 years), initial open-label monotherapy with carbamazepine was followed in non-responders by adjunctive treatment with either vigabatrin (1–4 g/day) or valproic acid (0.5–2 g/day). Carbamazepine could then be withdrawn and monotherapy with vigabatrin or valproic acid maintained for the final study phase. In this trial, the efficacy of the two study drugs was found to be similar [79].

Several open-label studies have assessed long-term efficacy. One commonly used indicator of long-term response is the proportion of patients remaining on treatment over time. In several long-term studies, between 39% and 72% of patients remained on vigabatrin for more than 3 years. Among the patients electing to continue treatment, the majority maintained their initial positive response, and in this particular subset (for which clearly there is a selection bias) there was no evidence of tolerance developing [80,81]. Some studies, however, did suggest that a fraction of patients may shift from responder to non-responder status over time, as also observed with other AEDs [82].

In most double-blind adjunctive therapy trials in adults with partial seizures, the daily dose of vigabatrin has been in the range of 2–3 g. Some studies, however, suggested that 1 g/day may also have some therapeutic efficacy, while there are patients who benefit from doses of 4 g/day or more. In the US study that compared daily doses of 1, 3 and 6 g, no improvement in efficacy was observed in patients randomized to 6 g compared with those randomized to 3 g, but adverse effects increased substantially at the highest dose [74]. Although vigabatrin is usually administered twice daily, a double-blind pilot study in 50 patients comparing once-daily with twice-daily dosing as adjunctive therapy found no statistically significant differences in seizure control [83].

Children

An open-label prospective study (class III evidence) in 175 children of all age groups (neonates, children and adolescents) suffering from partial-onset seizures assessed the response to vigabatrin given as add-on to carbamazepine, phenytoin or benzodiazepines. Thirty per cent of the children became seizure free, and a >50% reduction in seizure frequency was achieved in 70%. The highest percentage of responders (85%) was reported in children diagnosed with tuberous sclerosis complex, and the

lowest (45%) in those with underlying tumour aetiology [84]. A large series of open-label paediatric trials [85–94] also reported a reduction of at least 50% in seizure frequency in 23–70% of the patients. Efficacy in these studies was comparable to that reported in adults.

A randomized placebo-controlled withdrawal study (class II evidence) investigated 28 children (aged 1.5–18.5 years) with refractory partial seizures and/or other seizure types who had responded to vigabatrin as adjunctive therapy [95]. In one group, vigabatrin was stopped blindly in 3 weeks and substituted with placebo for 2 months, while the other group continued to take vigabatrin. Patients were required to exit the study if a >50% increase in seizure frequency occurred. The proportion of patients remaining in the study (primary efficacy endpoint) was greater in the vigabatrin group (93%) than in the placebo group (46%) ($P < 0.01$) and seizure frequency (secondary endpoint) was lower on vigabatrin than on placebo ($P < 0.05$).

The results obtained in children with drug-refractory partial-onset seizures prompted several investigators to use vigabatrin as a first-line drug. Three open-label studies (class III evidence), with follow-up periods of 6 months [96] or 2 years [97,98], compared vigabatrin ($n = 104$ in total) and carbamazepine ($n = 100$) monotherapy in the treatment of patients with newly diagnosed partial seizures, including idiopathic, cryptogenic and symptomatic cases. In two of the studies, allocation to treatment was randomized [96,97]. In all three trials, the efficacy of vigabatrin and carbamazepine did not reveal significant differences, and there was a suggestion for a better tolerability profile of vigabatrin during the 2-year follow-up [97]. Interictal EEG abnormalities decreased more often in children treated with vigabatrin than in those treated with carbamazepine. These studies have limitations because of their small sample size and lack of blinding, but they do provide suggestive evidence that vigabatrin monotherapy can be effective in controlling partial-onset seizures in children.

Long-term outcome data in children have been investigated in a number of adjunctive therapy studies. A 10-year follow-up study based on a retrospective chart audit [99] compared treatment outcomes in children with different types of refractory epilepsies who had been treated with lamotrigine ($n = 132$), vigabatrin ($n = 80$) and gabapentin ($n = 39$) as add-on therapy. Most of the children (46/80) had partial epilepsies. At the end of follow-up, 33% of the children on lamotrigine showed a sustained improvement in seizure frequency, compared with 19% of children who had received vigabatrin and 15% of children who had received gabapentin. However, no significant differences in efficacy among treatment groups were found in children with partial seizures. Another long-term study compared outcomes in 56 children with difficult-to-treat epilepsies who had received vigabatrin ($n = 56$) or lamotrigine [100]. Most of the patients on vigabatrin had partial epilepsies (39/56, with 11 having unclassified epilepsy), whereas the proportion of lamotrigine-treated patients with partial epilepsy was lower (23/39). Retention rate after 5 years was higher with lamotrigine than with vigabatrin (26% versus 9%). No loss of initially observed efficacy was apparent in the lamotrigine group. Conversely, 10 of the 18 initial responders in the vigabatrin group appeared to lose their response, usually within the first 9 months.

Generalized epilepsies

Some of the studies in patients with refractory partial seizures, particularly those conducted in children, also included patients with drug-resistant generalized epilepsies. One of the first multicentre open-label studies (class IV evidence), reported by Livingston *et al*. [101], investigated the outcome of add-on therapy with vigabatrin in 135 children (age range, 2 months to 12 years), of whom 42% had partial epilepsies, 29% generalized epilepsies, 19% Lennox–Gastaut syndrome and 10% West syndrome. Efficacy was better in children with partial seizures than in those with generalized seizure types. Two other paediatric studies [86,94] found vigabatrin more efficacious against partial seizures, and one [86] reported that non-progressive myoclonic epilepsy tended to be aggravated. Additionally, symptomatic generalized epilepsies tend to be more frequently associated with loss of response to vigabatrin during long-term treatment [99,102].

Similar results have been reported in other studies. In the study by Dulac *et al*. [88], response rates were highest in cryptogenic and symptomatic partial epilepsies, while symptomatic generalized epilepsies responded less favourably, Lennox–Gastaut syndrome even less favourably and three of nine patients with myoclonic epilepsy showed an increase in seizure frequency. In a retrospective study of children who had received vigabatrin or lamotrigine treatment, primary generalized tonic–clonic seizures were reported to be more frequently improved and less frequently worsened with lamotrigine than with vigabatrin, whereas for tonic seizures outcome appeared to be more favourable with vigabatrin [93]. Conversely, no significant differences in clinical response between partial-onset and generalized seizure types were reported in a few open-label paediatric studies [91,92,103,104]. The study by Gherpelli *et al*. [103], which excluded from analysis children with West syndrome and children with idiopathic generalized epilepsy, reported complete seizure cessation in 18.6% of partial-onset seizures and in 17.3% of generalized seizures.

Anecdotal case reports described favourable effects of vigabatrin in neonatal seizures due to Ohtahara's syndrome [105] and in Landau–Kleffner syndrome [106]. A number of uncontrolled studies also explored the potential value of vigabatrin in Lennox–Gastaut syndrome, and results have been controversial. The study by Livingston *et al*. [101] cited above included 26 children with Lennox–Gastaut syndrome, and a good seizure response was observed in less than 30% of these cases [101]. Similar findings were reported in Asian children [107]. Only a few children with Lennox–Gastaut syndrome have been included in other studies, and most have not been regarded as treatment successes. In a retrospective assessment of children who had been started on vigabatrin, gabapentin and lamotrigine 10 years earlier, children with myoclonic–astatic epilepsy or Lennox–Gastaut syndrome were found to have done better on lamotrigine than on the other drugs [99]. More favourable results were found in a retrospective 3-year study, reporting a ≥50% reduction in seizure frequency in 40% of patients with Lennox–Gastaut syndrome, although myoclonic seizures worsened in this patient group [108]. A good response in Lennox–Gastaut syndrome was reported in only one open-label study in 20 children, with 85%

of patients showing a ≥50% decrease in all seizure types, except for myoclonic seizures which tended to increase [109]. The precipitation or exacerbation of myoclonic seizures, absence seizures and non-convulsive status epilepticus has also been reported by other authors [110,111].

Overall, available data suggest that vigabatrin may have a limited role as add-on treatment of some generalized epilepsy syndromes, but not in patients with myoclonic seizures as the main seizure type. Vigabatrin also carries some risk of aggravating seizures in patients with generalized epilepsy, particularly in children [102,112]. In a long-term follow-up study of a cohort of 196 children with various refractory epilepsies, non-progressive myoclonic epilepsy and Lennox–Gastaut syndrome showed the highest increase in seizure frequency (38% and 29%, respectively) [102].

As with carbamazepine, use of vigabatrin in patients with idiopathic generalized epilepsies, including childhood and juvenile absence epilepsy, juvenile myoclonic epilepsy and epilepsy with grand mal on awakening, may result in increased seizure frequency and even lead to absence status or myoclonic status [113,114]. Precipitation and aggravation of myoclonic seizures, myoclonic–astatic and absence seizures have been described particularly in children with Angelman's syndrome [115].

Adverse effects

General overview of adverse effects

If exception is made for visual field constriction, which is discussed in detail below, adverse effects during vigabatrin treatment are usually mild and the drug is relatively well tolerated, even with high doses. In adults and older children, fatigue, drowsiness, dizziness, nystagmus, agitation, amnesia, abnormal vision, ataxia, weight gain, confusion, depression and diarrhoea have been most often reported [74,116]. In children and infants, the most common adverse effects include sedation, drowsiness, insomnia, hyperactivity, agitation, weight gain and hypertonia or hypotonia [41,43,88,103]. Most of these adverse effects are dose related and reversible when the dose is reduced. Discontinuation of therapy because of these effects is necessary only in rare cases [40]. Single observations have also described the occurrence of vigabatrin-induced encephalopathies with stupor, confusion and EEG slowing, one of the cases being in a patient with Alexander's disease [117–119].

An adverse event possibly related to the GABAergic action is an increased incidence of psychosis, sometimes within the context of forced normalization [120]. A retrospective survey of behaviour disorders in 81 patients described 50 cases meeting the criteria for either psychosis ($n = 28$) or depression ($n = 22$) [121]. A comparison with psychotic events in epilepsy patients never treated with vigabatrin suggested that risk factors for vigabatrin-induced psychosis include a more severe epilepsy, a right-sided EEG focus and suppression of seizures. Depression as a treatment-emergent effect of vigabatrin has been associated with a past history of depressive illness [121]. Formal testing of mood disturbances in 73 adults with refractory epilepsy before and under treatment with vigabatrin revealed that mood problems were the main reason for discontinuation [122]. A review of double-blind, placebo-controlled trials of adjunctive vigabatrin therapy in a total of 717 patients with refractory partial epilepsy confirmed that vigabatrin, when compared with placebo, was associated with a significantly higher incidence of depression (12.1% versus 3.5%, $P < 0.001$) and psychosis (2.5% versus 0.3%, $P < 0.028$) [123]. There were, however, no significant differences between vigabatrin and placebo for aggressive reactions, manic symptoms, agitation, emotional liability, anxiety or suicide attempt [123]. Depression and psychosis were usually observed during the first 3 months. Depression was usually mild, and psychosis was reported to respond to reduction or discontinuation of vigabatrin or to treatment with antipsychotic drugs.

Dodrill *et al*. [124] evaluated the effects of vigabatrin on cognitive function in a double-blind, placebo-controlled, adjunctive-therapy, parallel-group dose–response study (1, 3 and 6 g/day) in patients with difficult-to-control partial-onset seizures. At repeated testing with a series of eight cognitive tests, a dose-dependent decrease in performance was detected in only one test (digit cancellation).

Vigabatrin has been reported to cause a significant increase in α-aminoadipic acid levels in plasma and urine, which may mimic α-aminoadipic aciduria, a rare metabolic disease. Therefore, to avoid diagnostic difficulties, when a genetic metabolic disease is suspected, amino acid chromatography should be performed before initiation of vigabatrin treatment [125]. In addition, vigabatrin can interfere with urinary amino acid analysis due to inhibition of catabolism of β-alanine [126].

Visual field constriction

Severe symptomatic and persistent visual field constriction associated with vigabatrin was reported initially in three patients in 1997 [127]. During the subsequent 2 years, additional similar cases of concentric visual field constriction were described in patients with refractory epilepsy receiving adjunctive therapy with vigabatrin [128,129]. A further study in patients on vigabatrin monotherapy confirmed a causal relationship between vigabatrin and a specific bilateral concentric constriction of the visual field [130]. A survey conducted by the manufacturer and involving 335 vigabatrin recipients aged >14 years indicated that 31% of patients [95% confidence interval (CI) 26–36%] had a visual field constriction attributable to vigabatrin, compared with a 0% incidence of visual field constriction (95% CI 0–3%) in an unexposed control group. Other studies in adults have given similar overall prevalences, with a total of 169 of 528 patients diagnosed with vigabatrin-associated field defects (32%; 95% CI 28–36%). Male gender seems to be associated with an approximately twofold increase in the relative risk of developing visual field constriction. The pattern of defect is typically a bilateral, absolute concentric constriction, the severity of which varies from mild to severe [130]. The cumulative incidence increases rapidly during the first 2 years of treatment and within the first 2 kg of vigabatrin intake, usually stabilizing at 3 years and after a total vigabatrin dose of 3 kg. In adults, regular visual field testing should be performed before the start of treatment and at regular intervals during treatment. Patients with pre-existent visual field defects due to other causes should not be treated with vigabatrin.

The prevalence data for vigabatrin-associated visual field constriction in children are contradictory. Disparities are likely to

arise from many causes, including the diversity of the perimetric techniques, the variable cooperation of patients in complying with the testing procedure, the asymptomatic nature of the defect and the relatively small sample sizes. Several studies using Goldmann perimetry or the Humphrey field analyser in patients aged 5–21 years [131–135] reported a prevalence of visual field constriction between 19% [132] and 71% [134]. The number of patients in these studies ranged from 12 to 67. In a larger study, Vanhatalo *et al*. [53] performed Goldmann perimetry tests in 91 visually asymptomatic Finnish children aged 5.6–17.9 years. Visual field constriction was observed in repeated test sessions in 17 children (18.7%), and a significant inverse correlation was found between the temporal extent of the visual fields and the total vigabatrin dose and duration of vigabatrin treatment. The shortest duration of vigabatrin therapy associated with visual field constriction was 15 months, and the lowest total cumulative dose was 914 g. The latter finding is partly in line with data from a previous paediatric study from Korea (n = 67), in which no cases of visual field constriction were found with treatment durations below 2 years and cumulative doses below 10 g/kg [135].

A more recent study by Wild *et al*. [136] analysed perimetric data of 563 paediatric and adult patients with refractory partial epilepsy, stratified by age (8–12 years; >12 years) and exposure to vigabatrin. Group I comprised 201 subjects (including 49 aged 8–12 years) treated with vigabatrin for >6 months, group II had 220 subjects (including 59 aged 8–12 years) previously treated with vigabatrin for ≥6 months who had discontinued the drug for ≥6 months, and group III had 142 subjects (including 35 aged 8–12 years) never treated with vigabatrin. Perimetric testing was performed every 6 months for up to 36 months. In group I, visual field constriction at the last visit with a conclusive examination was diagnosed in 31.2% of patients aged 8–12 years and 41.6% of patients aged ≥12 years, whereas in group II, corresponding rates were 10.3% and 24%, respectively. No case of visual field constriction was detected in group III. Visual field constriction was significantly associated with duration of vigabatrin therapy [odds ratio (OR) 14.2; 95% CI 5.0–40.5], with the mean vigabatrin dose (OR 8.5; 95% CI 2.2–33.2) and with male gender (OR 2.1; 95% CI 1.2–3.7). Visual field constriction was also detected more often with static than with kinetic perimetry (OR 2.3; 95% CI 1.3–4.2). There was a trend for visual field constriction to be less frequent in the younger age groups, but the statistical power of the comparisons was limited by the small size of the subgroups. In conclusion, approximately one-third of patients aged ≥8 years exposed to vigabatrin exhibited visual field defects which were not encountered in unexposed participants. The study did not include infants with infantile spasms.

Preliminary data of a still ongoing prospective long-term follow-up study comprising infants with infantile spasms seem to demonstrate a lower frequency of visual field constriction in children treated with vigabatrin in early infancy (G. Wohlrab, 2008, unpublished). Sixteen children classified as having cryptogenic or symptomatic West syndrome (tuberous sclerosis complex, focal cortical dysplasia) underwent Goldmann perimetric tests at the age of 7.3–15 years. Visual field constriction was detected in two asymptomatic children, in one case repeatedly, while in another lack of co-operation was assumed and repetition of the examination 1 year later showed normal findings. Based on available data, it remains unclear whether younger age is a protective factor against visual field constriction.

Overall, the mechanisms underlying the retinal toxicity of vigabatrin and the associated risk factors have not yet been fully elucidated. The effect may be idiosyncratic in nature [137,138]. A genetic predisposition has been postulated, but studies conducted to date have failed to identify a genetic marker [139]. Total cumulative dose and duration of treatment have emerged as important risk factors in many studies [53,135,136,140], and in at least one study a correlation also emerged with the maximum daily dose [141].

Vigabatrin-induced visual field constriction is generally considered to be irreversible [130]. Reversibility has been reported in few children and adults, verified by repeated examinations [142,143]. However, test results may be unreliable in some patients because of insufficient cooperation, and an improvement in perimetric findings may be an artefact of a learning process.

From a cognitive age of 9 years on, static perimetry seems to be the most sensitive modality for identifying vigabatrin-induced retinal toxicity [132]. Unfortunately, visual field constriction is not ascertainable in infants, young children and patients with severe mental disability. There are no reliable markers for the early detection of visual field defects. Fundoscopy shows no specific abnormalities until the visual field loss is severe. An 'inverse' optic atrophy has been described as a specific marker of vigabatrin toxicity in children [144]. Electroretinography, multifocal electroretinography [145] and field-specific visual-evoked potentials, as described by Spencer and Harding [146], may be useful in monitoring children with mental disability or too young to cooperate. The most consistent electroretinography changes include increased latency of the electroretinography photopic b-wave, reduced or absent oscillatory potential, and abnormalities of the cone function (30 Hz) response. A marked decrease in electroretinography responses from scotopic threshold response has been suggested as early marker of retinal toxicity [147].

Neuropathological findings

Following the discovery of intramyelinic oedema in animal toxicology studies, many investigations have been carried out to determine whether similar changes could occur in humans. A report in 2008 described six vigabatrin-treated infants with infantile spasms, four of whom were severely hypotonic, in whom MRI with diffusion-weighted imaging showed a transient decrease of diffusion in subcortical structures [148]. These abnormalities were considered to be probably related to the epileptic encephalopathy, although a causative role of vigabatrin could be more likely based on findings from subsequent studies. In particular, a large recent retrospective study evaluated 332 MRI examinations from 205 infants with infantile spasms (aged 2 years or less), 93 of whom had received vigabatrin as initial or subsequent therapy [148]. In this population, the prevalence of prespecified MRI abnormalities (defined as any hyperintensity on T_2-weighted or FLAIR sequences with or without diffusion restriction not readily explained by a radiographically well-characterized pathology) was significantly higher in vigabatrin-treated patients than in vigabatrin-naive patients (22% vs. 4%; $P < 0.001$). The MRI

abnormalities were considered asymptomatic. Of nine vigabatrin-treated subjects with at least one subsequent MRI, resolution of MRI abnormalities occurred in six, four of whom had stopped taking vigabatrin while two were still on the drug. The same study also assessed 2074 MRI images from 668 children (aged 2–16 years) and adults (aged > 16 years) with complex partial seizures and found no significant difference in the incidence or prevalence of prespecified MRI abnormalities between vigabatrin-exposed and vigabatrin-naive subjects [149]. The occurrence of vigabatrin-associated MRI abnomalities in infants is documented by two other recent retrospective reports. Pearl *et al*. [150] found that 8 out 23 subjects treated with vigabatrin had MRI abnormalities characterized by new-onset and reversible T_2-weighted hyperintensities and restricted diffusion in thalami, globus pallidus, dentate nuclei, brainstem or corpus callosum. The abnormalities were reversible after discontinuation of vigabatrin. Affected subjects were younger than those unaffected (median age 11 months vs. 5 years) and received a larger dose of vigabatrin (median 170 mg/kg/day vs. 87 mg/kg/day). Milh *et al*. [151] assessed the frequency of vigabatrin-associated MRI abnormalities in 22 infants who had 34 MRI examinations at different time points. Hyperintensity of basal ganglia and brainstem appeared to be transient and maximal at 3 to 6 months after initiation of vigabatrin. All patients were asymptomatic. Overall, available data suggest indicate that vigabatrin does cause reversible MRI abnormalities in an age- and dosage-related manner, with infants being especially vulnerable. The mechanisms and clinical implications, if any, of these changes are at present unclear.

Neuropathological studies have been carried out on patients who died or had epilepsy surgery during vigabatrin treatment [6,116]. These studies assessed 10 post-mortem and 50 surgical samples, with treatment periods up to 108 months. None of the material examined showed evidence of vacuolation.

One study reported MRI evidence of discrete non-haemorrhagic focal lesions in the splenium of the corpus callosum in six patients with epilepsy who had been treated with either vigabatrin or phenytoin [152]. Although in two of the patients the lesions disappeared at a follow-up MRI after withdrawal of vigabatrin or phenytoin, the role of drug treatment in the pathogenesis of the reported lesions is uncertain.

Teratogenic effects

Animal experiments have shown that vigabatrin has no negative influence on fertility or pup development. No teratogenicity was seen in rats at doses up to 150 mg/kg or in rabbits at doses up to 100 mg/kg. However, in rabbits, a slight increase in the incidence of cleft palate at doses of 150–200 mg/kg was observed. Although there are insufficient clinical data to determine the risks associated with fetal exposure to vigabatrin in humans, the use of vigabatrin is not recommended in women of child-bearing potential [153]. In one report of two children examined at the age of 6.1 and 7.9 years, prenatal exposure to vigabatrin in combination with other AEDs did not appear to have resulted in clear-cut neurological or ophthalmological deficits [154]. One of these children had dysmorphic features. The other had several major and minor congenital malformations, but he had been exposed to vigabatrin only after week 16 of gestation.

Current place in therapy

Because vigabatrin is not approved in the USA, the practice parameters published by the American Academy of Neurology and the American Epilepsy Society [155,156] do not contain any information on vigabatrin. On the other hand, vigabatrin has been used in several other countries, initially mostly for the treatment of drug-refractory partial epilepsies, and more recently mainly for the management of infantile spasms.

Infantile spasms, especially those caused by tuberous sclerosis complex, represent the primary current indication of vigabatrin. In our personal experience, doses between 75 and 150 mg/kg/day can be rapidly effective if the treatment is started early after the onset of spasms.

Visual field constriction seems to occur less frequently in the first 2 years of life, but long-term follow-up data in patients treated in this age group are lacking. The risk of visual impairment in patients with infantile spasms may be reduced by limiting the duration of vigabatrin treatment to 6 months [54].

In children, vigabatrin is also a therapeutic option for the adjunctive treatment of partial-onset seizures, with or without secondary generalization, that failed to respond to other AEDs. Although the incidence of vigabatrin-induced visual field constriction is worrisome, in the context of infantile spasms or other intractable seizures, the potential therapeutic benefits must be weighed against the risks. By taking the risk–benefit balance into account, the guidelines from the UK Paediatric Advisory Group on the use of vigabatrin [157] recommend performing visual field examinations with a Goldmann perimeter or a Humphrey field analyser in patients with a cognitive age >9 years before prescribing the drug, and every 6 months during treatment thereafter.

In adults, vigabatrin should be used as add-on therapy for patients with refractory partial epilepsy only when all other appropriate AEDs given alone or in combination have proved ineffective or have not been tolerated. Adults should also undergo visual field testing before and at regular intervals after starting vigabatrin therapy. In the presence of many alternative AEDs for the treatment of the common epilepsy syndromes, the use of vigabatrin has declined drastically in recent years due to the high risk of retinal toxicity. The recently reported MRI abnormalities in children with infantile spasms raise additional concerns which need further careful investigation in adults as well.

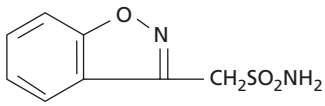
57 Zonisamide

Stephen J. Wroe
National Hospital for Neurology and Neurosurgery, London, UK



Primary indications	Adjunctive therapy of partial and secondarily generalized seizures. May also be useful as adjunctive therapy in a variety of primary generalized seizure types
Usual preparations	Capsules: 25, 50, 100 mg Tablets: 25, 100 mg Powder (20%)
Usual dosage	Adults: 50 mg/day initially, increased to 100 mg/day after 1 week and 200 mg/day after a further 2 weeks. Further dose increments by 100 mg/day may be indicated at intervals of 1–2 weeks, according to clinical response. Usual maintenance dosages are 200–600 mg/day Children (Japan): 2–4 mg/kg/day, which may be increased gradually every 1–2 weeks to 4–8 mg/kg/day. The maximum daily dose is 12 mg/kg
Dosing frequency	Once or twice daily
Significant drug interactions	Serum zonisamide levels are lowered by carbamazepine, phenytoin and barbiturates
Serum level monitoring	May be useful in selected cases
Reference range	10–40 mg/L
Common/important adverse effects	Somnolence, dizziness, ataxia, headache, attention and concentration difficulties, memory impairment, agitation, irritability, diplopia, confusion, depression, nausea, anorexia, weight loss, nephrolithiasis, hyperthermia, oligohidrosis, skin rashes (including Stevens–Johnson syndrome), blood dyscrasias and other hypersensitivity reactions
Main advantages	Long-term clinical experience (Japan) and suggestive evidence of broad-spectrum efficacy
Main disadvantages	Central nervous system adverse effects, and side-effects from carbonic anhydrase inhibition
Mechanisms of action	Multiple, including blockade of sodium channels, blockade of T-type calcium channels, potentiation of GABAergic transmission, and inhibition of carbonic anhydrase
Oral bioavailability	Almost complete
Time to peak levels	2–6 h
Elimination	Partly by renal excretion, partly by metabolism mediated by CYP3A4, *N*-acetyltransferase and glucuronyl transferases
Volume of distribution	1.1–1.8 L/kg
Elimination half-life	50–70 h (25–40 h in patients co-medicated with enzyme inducers)
Plasma clearance	10–20 mL/h/kg (20–30 mL/h/kg in patients co-medicated with enzyme inducers). Higher clearance values are reported in infants and children
Protein binding	About 50%
Active metabolites	None
Comment	A useful antiepileptic drug with a probable broad spectrum of efficacy

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Introduction

Zonisamide is unusual amongst second-generation antiepileptic drugs (AEDs) in that many patient-years of experience in paediatric and adult populations, in a wide variety of seizure types, had been gained following licensing in Japan (1989) and South Korea (1992) before a series of randomized controlled trials led to regulatory approval as add-on therapy for partial-onset seizures in the USA (2000) and Europe (2005).

Chemistry

Zonisamide (1,2-benzisoxazole-3-methanesulphonamide; molecular formula, $C_8H_8N_2O_3S$) is a white crystalline solid or powder with a molecular weight of 212.2. Zonisamide was discovered through the screening of 3-substituted benzisoxazole derivatives for anticonvulsant activity. With a pK_a of 9.7, the compound is highly soluble in alkaline solutions and is stable in acid, neutral and alkaline solutions [1].

Pharmacology

Activity in animal models and mechanisms of action

Zonisamide is effective in several experimental models of seizures and epilepsy. A mechanism of action similar to that of phenytoin is suggested by activity against maximum electroshock (MES) seizures [1,2] and a reduction of sustained repetitive action potential firing in cultured spinal cord neurones at clinically relevant concentrations [3]. This occurs through blockade of voltage-gated sodium channels and prolonged channel inactivation [4], a mechanism shared with other AEDs including phenytoin, carbamazepine and lamotrigine [5].

In the MES test in rats, rabbits, dogs and monkeys zonisamide shows similar potency to phenobarbital, carbamazepine and phenytoin, with a relatively wide therapeutic window [1,2]. Zonisamide is also similar to these AEDs in preventing the propagation of focal seizure discharges as demonstrated in chemically induced focal cortical seizures in rats [6] and electrically induced focal cortical seizures in cats [7,8].

In other studies, however, zonisamide differed from phenobarbital, carbamazepine and phenytoin in preventing interictal cortical spike discharges in a rat model [9]. Alternative mechanisms of action are also suggested by suppression of cortical spiking similar to that seen with sodium valproate in other animal models [7], and suppression of photosensitive [10] and genetically determined reflex seizures [11]. These additional effects may be mediated in part through inactivation of voltage-gated T-type calcium channels [12], demonstrated at clinically relevant concentrations in cultured rat cortical neurones [13]. Zonisamide also binds to the γ-aminobutyric acid (GABA)–benzodiazepine receptor complex [14], elevates brain levels of the inhibitory neurotransmitter GABA [15], and reduces extracellular release of the excitatory neurotransmitter glutamate [16]. The clinical importance of these effects in mediating zonisamide's antiseizure activity is uncertain, as are dose-dependent effects on dopamine [17] and serotonin [18] turnover demonstrated in rat hippocampi. Zonisamide also has an inhibiting effect on carbonic anhydrase, an action that may contribute not only to the drug's anticonvulsant properties, but also to its adverse effect profile.

Pharmacokinetics

Overview of pharmacokinetic properties

Rapid and almost complete absorption of zonisamide occurs after oral dosing, with time to maximal plasma concentrations (T_{max}) of 2.4–3.6 h and peak plasma concentrations (C_{max}) from 2.3 to 12.5 mg/L in healthy volunteers administered 200, 400 or 800 mg doses [19]. Absorption is delayed in the presence of food (T_{max}, 4–6 h), although the extent of absorption is unaltered [20].

Zonisamide has an apparent volume of distribution (V_d/F) of about 1.1–1.8 L/kg. Binding to plasma proteins is about 50%. Animal studies have shown a wide tissue distribution, with the drug crossing the placenta and accumulating in breast milk at concentrations similar to those in plasma [21]. Zonisamide accumulates in erythrocytes, with a low-affinity binding to cellular proteins in red cells and a saturable high-affinity binding to carbonic anhydrase, a property shared with other sulphonamides [22,23].

Although an approximately linear relationship between serum concentration and dose is reported in some studies, and may be evident within the usual therapeutic dose range, other studies suggested that zonisamide may exhibit non-linear pharmacokinetics, with a greater than proportional increase in serum drug concentration with increasing dose [24,25]. In particular, mean serum concentrations obtained at three doses in a randomized trial were 3.6 mg/L at 100 mg/day, 6.9 mg/L at 200 mg/day and 18.3 mg/L at 400 mg/day [26]. Steady-state serum concentrations are achieved within 15 days, with a modest (about 14%) diurnal fluctuation when the drug is administered on a twice-daily schedule [27]. This is in agreement with an elimination half-life of 50–70 h in the absence of enzyme-inducing co-medication. As discussed below, shorter half-lives (25–40 h) are reported in patients receiving enzyme-inducing AEDs such as carbamazepine, phenytoin and barbiturates. The apparent oral clearance (CL/*F*) of zonisamide is in the order of 10–20 mL/h/kg [25,27,28]. Higher values (20–30 mL/h/kg) are found in patients co-medicated with enzyme inducers.

Zonisamide is extensively metabolized, the predominant pathways being reduction to 2-sulphamoylacetyl-phenol (SMAP) by the cytochrome P450 (CYP) enzyme CYP3A4 [29], acetylation to *N*-acetylzonisamide and, to a lesser extent, direct glucuronidation. These metabolites are devoid of anticonvulsant activity. Urinary recovery is accounted for by unchanged drug (approximately 15–30%), SMAP glucuronide (about 50%), and *N*-acetylzonisamide and zonisamide glucuronide (20%) [21,30,31].

Pharmacokinetics in special groups

Information on the pharmacokinetics of zonisamide in special groups is limited. The half-life of zonisamide in three newborns exposed transplacentally to the drug has been found to be in the range of 60–109 h [28]. In a Japanese study of four infants aged

3 months to 1 year, zonisamide CL/*F* values at steady state were about 50% higher than those reported in 6-year-old children, and at least twofold higher than those reported in 12- to 15-year-old adolescents [28]. In largely uncontrolled paediatric studies, weight-adjusted doses reported to be effective and well tolerated were greater than those described in randomized trials in adults, consistent with zonisamide clearance values being higher in children than in adults [32]. Indeed, available evidence suggests that zonisamide CL/*F* values in children are 20–100% higher than in adults [28].

A study in healthy elderly volunteers suggested that no pharmacokinetic changes requiring dose adjustments occur in this population [30]. However, since no patient in that study was above 71 years of age, these findings may not be applicable to subjects in older age groups.

Detailed studies in patients with hepatic or renal disease are not available, although a single dose study in volunteers showed that clearance is significantly reduced in patients with renal impairment [20,31], with a 35% increase in area under the plasma concentration curve (AUC) at creatinine clearance values <20 mL/min [31].

Drug interactions

Like most other second-generation AEDs, zonisamide has an advantage over older agents in that it does not induce or inhibit the hepatic microsomal enzymes responsible for drug metabolism. In patients on monotherapy, the introduction of zonisamide as add-on treatment at a dose of 400 mg/day did not affect the steady-state serum concentrations of carbamazepine [33], valproic acid [34], phenytoin [35] or lamotrigine [36]. Likewise, zonisamide does not appear to affect, to a major extent, the pharmacokinetics of other medications. In particular, following administration of a combined oral contraceptive, the serum levels of ethinylestradiol and norethisterone have been shown to be unaltered by doses of zonisamide up to 400 mg/day [37]. Since zonisamide is a weak inhibitor of P-glycoprotein (P-gp), however, caution is advised when starting or stopping zonisamide treatment in patients receiving drugs which are P-gp substrates (e.g. digoxin, quinidine), since there is a theoretical possibility that the serum concentrations of the latter may change [31].

Since zonisamide is metabolized by CYP3A4, inducers of this enzyme increase zonisamide clearance. Phenytoin, carbamazepine and phenobarbital shorten the elimination half-life of zonisamide to 25–40 h, so that steady-state serum zonisamide concentrations are achieved within a week in patients co-medicated with enzyme inducers [33,35,38]. No clinically significant effects on zonisamide clearance or half-life were demonstrated with the co-administration of valproic acid or lamotrigine [34,36], or the enzyme inhibitors cimetidine (1200 mg/day) [39] or ketoconazole (400 mg/day) [31].

Since both zonisamide and topiramate exhibit carbonic anhydrase inhibitory activity, the possibility of an adverse interaction between these drugs, particularly an increase in the incidence of renal stones, has been raised. No renal calculi were identified in 59 patients exposed to both zonisamide and topiramate for up to 135 weeks in US and European clinical trials, while one case of nephrolithiasis was reported during postmarketing surveillance in the USA [40].

Serum level monitoring

Although serum zonisamide concentrations can be measured by enzyme-linked immunoassay or high-performance liquid chromatography [41], the relationship between serum concentrations and efficacy is not sufficiently characterized to recommend extensive monitoring in routine clinical practice [42]. In one randomized trial, serum concentrations in patients receiving zonisamide 400 mg/day were in the order of 16.5–21.3 mg/L, although a significant difference in serum concentration was not demonstrated between responders and non-responders, as determined by a 50% reduction in seizure frequency [26]. In two flexible-dose studies, most patients received 400–600 mg/day as a single or twice-daily dose, aiming at achieving steady-state concentrations in the 20–30 mg/L range [43,44]. A recent position paper compiled by a commission of the International League Against Epilepsy [45] proposed for zonisamide a reference range of 10–40 mg/L, based on a review of studies published to date. It was emphasized, however, that there is a wide variability in the concentrations associated with an optimal response, and that concentrations associated with a good response in some patients may be associated with adverse effects in others.

Efficacy

Randomized controlled trials

Published data from randomized double-blind placebo-controlled trials provide evidence of zonisamide's efficacy as add-on therapy in patients with partial and secondarily generalized tonic–clonic seizures. Four multicentre studies, two each in the USA [26,43] and Europe [44,46], included 845 patients with refractory partial-onset seizures (Table 57.1).

Two randomized placebo-controlled trials of similar design included patients aged 17 years or older with four or more partial seizures per month and receiving up to two or three AEDs [43,44,47]. The trials included an 8- to 12-week baseline assessment followed by a 12-week treatment phase during which zonisamide dose was adjusted by an unblinded observer to achieve plasma concentrations in the range of 20–30 mg/L. Median daily doses of 430 mg (as a single daily dose) and 530 mg were achieved [47], and zonisamide produced a significantly greater reduction in median seizure frequency than placebo for complex partial and for all seizure types in both studies.

In another trial conducted with a fixed-dose design in 20 centres in the USA, a significant reduction in median frequency of all seizures (the primary outcome measure) and in responder rate (≥50% reduction in seizure frequency compared with baseline) was reported for zonisamide 400 mg/day during the last 5 weeks of treatment when compared with placebo (seizure reduction 40.5% versus 9%, $P < 0.001$; responder rate 42% versus 22%, $P < 0.05$) [26]. A modified intention-to-treat (ITT) analysis included 170 of 203 randomized subjects, and a secondary endpoint analysis allowed comparison during the titration phase

between parallel groups treated with zonisamide 100 mg/day or 200 mg/day, or placebo. Within the limitations of this analysis, significant reductions in median seizure frequency at the lower doses were seen compared with placebo treatment (zonisamide 200 mg/day, 20.4% versus 4.0%, $P < 0.01$; zonisamide 100 mg/day, 24.7% versus 8.3%, $P < 0.05$).

A multicentre trial carried out in 18 European countries and in South Africa investigated zonisamide as adjunctive treatment in 351 patients aged 12 years or older with refractory partial-onset seizures [46]. To assess the dose–response relationship, patients were randomized to placebo or zonisamide 100 mg/day, 300 mg/day or 500 mg/day in the ratio 2:1:1:2, with a 6-week dose titration and an 18-week fixed-dose assessment phase. The primary outcome measures were median percentage changes in seizure frequency from baseline and responder rates (≥50% reduction in seizure frequency compared with baseline) for complex partial seizures. Compared with placebo, zonisamide 500 mg/day was associated with a significant reduction in median complex partial seizure frequency (51.2% versus 16.3%, $P < 0.001$) and a higher responder rate (52.3% versus 21.3%, $P < 0.001$). Significant benefits were also seen for all partial and all seizure types at this dose. Zonisamide 300 mg/day significantly reduced the frequency of all seizures, but not the frequency of complex partial seizures, although this dose group had a low baseline seizure rate and relatively few patients following randomization [46]. A significant association between zonisamide dose and responder rate was demonstrated, and an odds ratio of 4 (for a ≥50% reduction in seizure frequency) was calculated for zonisamide 500 mg/day against placebo [47].

Uncontrolled studies

Uncontrolled observations including small case series and retrospective reports are available in patients with a variety of less common epilepsy syndromes or primary generalized seizures who received treatment with zonisamide.

In two retrospective series, 22 patients with refractory or newly diagnosed juvenile myoclonic epilepsy were treated with zonisamide (13 as monotherapy), and the majority achieved >50% seizure reduction, including two patients who became seizure free on combination therapy. Complete control of generalized tonic–clonic, myoclonic and absence seizures was reported for nine, eight and five patients respectively treated with zonisamide monotherapy [48,49]. In another patient with juvenile myoclonic epilepsy described in a separate case report, seizure control was accompanied by abolition of spike–wave discharges in the EEG [50].

Ten of 30 patients with progressive myoclonic epilepsy who received zonisamide as adjunctive therapy for up to 16 weeks in an open-label study were reported to have achieved a ≥50% reduction in myoclonic seizure frequency [51]. The majority of seven further patients with Unverricht–Lundborg or Lafora body disease were reported to have obtained sustained clinical benefit with follow-up periods of 2 or more years [52].

Extensive clinical experience has been reported from Japan, where zonisamide is licensed for a broad range of seizure types in both adults and children, and as monotherapy [25]. Pooled data from pre-registration studies and postmarketing surveillance include controlled, open-label and unpublished trials in patients with partial seizures, primary generalized tonic–clonic seizures, tonic, atonic and absence seizures and other seizure types [25,53,54]. High responder rates (≥50% reduction in baseline seizure frequency), in some cases exceeding 80%, are reported in the majority of these studies for partial and some generalized seizure types, and for over 400 patients receiving zonisamide monotherapy. This pooled dataset includes over 200 children with Lennox–Gastaut syndrome (up to 35% responders) and 122 cases of West syndrome (29% responders) [53,55]. These observations point to the need for randomized controlled trials of zonisamide against placebo and standard therapy in these treatment-resistant forms of severe childhood epilepsy.

Adverse effects

Common adverse effects

Treatment-related adverse events were reported in 61% of 498 zonisamide-treated patients and in 49% of 350 placebo-treated patients in a pooled analysis of patients enrolled in randomized placebo-controlled trials (Table 57.1) [47]. Central nervous system (CNS)-related side-effects were the most frequently recorded adverse events in these studies. Somnolence or dizziness in up to 18% of patients occurred significantly more frequently than in placebo-treated control subjects, with headache, nausea or anorexia, abnormal thinking (a code term used to indicate attention or concentration difficulties) or confusion, agitation or irritability, depression, memory impairment, diplopia and ataxia also reported in 10% or more of zonisamide-treated subjects in individual trials [26,43–46]. Adverse events were most often reported at zonisamide doses above 400 mg/day and with rapid dose titration. Open-label extension studies including patients from short-duration randomized or uncontrolled trials with up to 9 years' follow-up demonstrated a similar pattern of CNS adverse effects (Table 57.2) [56,57]. Weight loss has also been reported in some patients.

Dizziness or incoordination, impaired concentration and anorexia or nausea most often led to zonisamide withdrawal, with treatment retention rates at 1, 2 and 3 years of 65%, 45% and 29% respectively [57].

Other adverse effects

Although zonisamide differs structurally from arylamine sulphonamide antibacterials, zonisamide treatment is contraindicated in patients with a known hypersensitivity to sulphonamide compounds. Reports of skin rash are uncommon, although 49 cases of Stevens–Johnson syndrome or toxic epidermal necrolysis identified through postmarketing surveillance in Japan gives an estimated risk of 4.6 cases per 100 000 patient-years exposure [20]. Very rare cases of aplastic anaemia, agranulocytosis, other blood dyscrasias and other hypersensitivity reactions have also been reported [31].

Symptomatic renal calculi were identified in 9 of 626 (1.4%) patients taking part in randomized controlled trials or open-label extension studies and in 15 of 1296 (1.2%) patients taking zonisamide for up to 8.7 years in the USA and Europe [40]. Although an overall low incidence of renal stones, similar to the

Table 57.1 Zonisamide: summary of efficacy and adverse events in randomized placebo-controlled double-blind adjunctive therapy trials in patients with refractory partial-onset seizures.

background population risk, is reported through postmarketing surveillance in the USA and Japan, an analysis of individual case reports identifies either a personal or family history of renal stones, or pre-existing renal or urinary tract abnormalities, as possible predisposing risk factors for stone formation. Such potentially at-risk individuals should be advised to maintain an adequate fluid intake if treated with zonisamide [40].

Hyperthermia and oligohidrosis have been reported as rare but potentially serious adverse events, with an estimated risk of 20 cases per 100 000 patient-years exposure in the USA. Children are usually affected, and hot weather or dehydration are potential risk factors [20,58,59].

Teratogenicity

Information published in the Japanese literature and available in the manufacturer's database demonstrates teratogenicity in several animal species. Cardiovascular defects in particular, but also skeletal and other abnormalities, and fetal death are described at serum concentrations comparable to those seen after therapeutic dosing in humans [60,61, cited in 20].

Data from the manufacturer on 26 births or pregnancies in which zonisamide was taken have been reported, and include the earliest experience in Japanese patients [53]. A ventricular septal defect was recorded in one of seven births following fetal exposure to zonisamide monotherapy. Malformations occurred in 2 of 19 cases exposed to polypharmacy during pregnancy, including an atrial septal defect after phenytoin, carbamazepine and zonisamide exposure, and a malformation of the brain and skull after phenytoin and zonisamide exposure. The latter may have been the same case described as an encephaly in an earlier report [62].

Given the experimental evidence of teratogenicity, and since information regarding the safety of zonisamide in pregnancy is extremely limited, zonisamide should preferably be avoided in women of child-bearing potential or used only in the presence of effective contraception.

Place in current therapy

Place in therapy

Since current AED treatment fails to provide complete seizure control without unacceptable adverse effects in up to 35% of patients with epilepsy [63], there is a place for new pharmacological treatments with novel mechanisms of action and improved tolerability. Zonisamide exhibits seizure-suppressing activity similar to that of phenytoin or carbamazepine in animal models, although experimental data and some clinical observations suggest the potential for a broader spectrum of efficacy.

Short-term placebo-controlled trials have established zonisamide as an effective adjunctive therapy in patients with refractory partial-onset seizures. Since the drug is reasonably well tolerated, has few interactions with other medications and the potential for once- or twice-daily administration, it offers a useful additional therapeutic option in this patient population. Extensive clinical experience and open-label observational studies provide evidence for sustained efficacy and suggest that serious adverse effects are uncommon. Further studies directly comparing zonisamide with other established and new AEDs, particularly as monotherapy, are required to fully determine the drug's place in clinical practice.

Uncontrolled observational studies and retrospective case series have suggested that zonisamide may be of benefit in some severe paediatric epilepsy syndromes, or rare seizure disorders for which current therapies are largely ineffective. These observations should be tested in well-designed clinical trials.

Dose, titration rate and laboratory monitoring

Zonisamide has demonstrated efficacy in adults, most clearly at doses above 200 mg/day. Effective doses in routine clinical practice are commonly in the range of 200–600 mg/day. Serum drug levels are not indicated routinely. Common CNS side-effects, particularly drowsiness, dizziness and nausea, are much more likely with rapid dose titration, and it is therefore recommended that zonisamide be started at a dosage of 50 mg/day (preferably in two divided doses), to be increased to 100 mg/day after 1 week [31]. Thereafter, the total daily dose may be increased by no more than 100 mg every 2 weeks.

In Japan, approved dose regimens for children are 2–4 mg/kg/day initially, to be increased gradually every 1–2 weeks to 4–8 mg/kg/day. The maximum daily dose is 12 mg/kg.

Although serious adverse effects are rare and routine laboratory monitoring is not required, treating clinicians should be alert to the development of unexplained skin rashes or haematological abnormalities. Patients with known risk factors for renal calculi should be advised to maintain an adequate fluid intake, and parents of children treated with zonisamide should be made aware of the need to avoid dehydration and overheating.

58 Other Drugs Rarely Used

Hartmut Meierkord and Martin Holtkamp

Charité – Universitätsmedizin Berlin, Berlin, Germany

Introduction

This chapter focuses on a number of medications that are not frequently used in the treatment of epilepsy. However, there is no doubt that some of these drugs may be useful in special clinical situations. A number of the compounds discussed have been used primarily as antiepileptic drugs (AEDs) for many decades, while others include some agents licensed mostly for other indications. The most important features of each drug are briefly discussed, with special emphasis on their potential clinical use.

Allopurinol

Developing AEDs that are specifically tailored to a patient's individual biochemistry has long been a goal of neurology. Allopurinol was introduced initially by Coleman *et al.* [1] for the treatment of epilepsy in patients who also had hyperuricaemia. Subsequently, DeMarco and Zagnoni [2] reported that the drug was also effective in patients with epilepsy without hyperuricaemia.

Chemistry

Allopurinol (4-hydroxypyrazolo-3,4-D-dipyramidine) is a structural analogue of hypoxanthine and has a molecular weight of 136.1.

Mechanisms of action and activity in experimental models of seizures and epilepsy

Allopurinol inhibits the enzyme xanthine oxidase with subsequent reduction of uric acid in the blood, but the mechanism of its antiepileptic action is unclear. It is also unknown if the antiepileptic effect is based on allopurinol only, or on oxypurinol, the main and active metabolite, or on both.

Experimental studies have shown that allopurinol suppresses epileptiform activity induced by penicillin in the rat hippocampus [3]. Hoppe *et al.* [4], on the other hand, did not find anticonvulsant effects in a model of oxygen-induced seizures in mice. The effect of allopurinol on seizures kindled in the feline hippocampus has been investigated by Wada *et al.* [5], employing two different doses (5 and 50 mg/kg). It was found that the high dose had a significant effect on behavioural seizures, but the duration of afterdischarges was not affected by either dose. Thus, allopurinol is an effective anticonvulsant in some models. The underlying mechanisms of action may be due to an effect on excitotoxicity. Allopurinol inhibits tryptophan-2,3-dioxygenase, which causes a reduction in quinolinic acid, an endogenous glutamate analogue with proconvulsant action. It has been postulated that this is the underlying mechanism of at least part of its antiepileptic effect [6]. In addition, allopurinol appears to suppress free radical generation [7] and to act as an adenosine agonist [8].

Pharmacokinetics

Allopurinol is quickly absorbed from the gastrointestinal tract and its bioavailability is about 80%. After oral intake, peak serum drug levels are reached within 30–120 min. The peak levels of oxypurinol, the active metabolite of allopurinol, are found 2–5 h after both oral and intravenous administration [9].

Allopurinol has an elimination half-life of about 1.2 h. The half-life of the active metabolite oxypurinol is in the order of 17–30 h [10]. About 20% of an allopurinol dose is excreted in faeces within 48–72 h after oral intake. The main active metabolite oxypurinol is completely excreted in urine without further metabolism [11].

Drug interactions

Various reports [2,12,13] suggest that plasma concentrations of most AEDs are not affected by the additional administration of allopurinol. There is, however, one report of allopurinol-induced elevation of carbamazepine levels [14].

Allopurinol shows a number of important interactions with drugs used for conditions other than epilepsy. In particular, potentially fatal interactions may occur when allopurinol is coprescribed with azathioprine or 6-mercaptopurine. The metabolism of azathioprine is inhibited by allopurinol, and this combination requires a reduced dosage of azathioprine. A similar interaction occurs with mercaptopurine, which is used in the treatment of leukaemia and is also a metabolite of azathioprine.

Clinical efficacy

The efficacy of allopurinol in epilepsy is controversial. Sander and Patsalos [15] did not find the drug effective in intractable epilepsy, nor did So and Ptacek [16]. Other clinical trials suggest that allopurinol is most effective in patients with focal epilepsy and secondarily generalized seizures. DeMarco and Zagnoni [2,12] found it effective in generalized tonic–clonic seizures. Tada *et al.* [13] reported the antiepileptic efficacy of allopurinol in generalized tonic–clonic seizures and focal epilepsy, but found it ineffective in Lennox–Gastaut syndrome. Conversely, Marrosu *et al.* [17] found it particularly effective in Lennox–Gastaut syndrome, but not in other forms of epilepsy.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Zagnoni *et al.* [18] assessed allopurinol (150 mg/day for children weighing <20 kg and 300 mg/day for other patients) in a double-blind, randomized, placebo-controlled, cross-over trial in 84 patients with seizures refractory to standard AEDs. Allopurinol significantly reduced the number of total seizures ($P < 0.005$) and of secondarily generalized seizures ($P < 0.0015$). Median frequency reduction for total seizures was 10.5% and 27.9% for secondarily generalized seizures. Togha *et al.* [8], in a more recent double-blind randomized adjunctive therapy trial, compared allopurinol (titrated up to 100 mg three times a day) with placebo, each in addition to pre-existing AEDs, in 32 patients with refractory epilepsies. Various seizure types were included: complex partial, tonic–clonic and generalized 'atonic' seizures. A significant reduction in seizure frequency in the allopurinol group compared with controls was reported. Two months after initiation of the study, a reduction in seizure frequency of more than 50% in half of the patients in the allopurinol group was seen. However, this trial was very small and results might have been influenced by selection bias. Another double-blind, placebo-controlled cross-over trial with allopurinol as add-on therapy in childhood refractory epilepsy had less favourable results [19]. Seventeen patients received allopurinol and matched placebo for 12 weeks (10 mg/kg/day during the first week and 15 mg/kg/day thereafter, with a washout period of 2 weeks between treatment phases). The total number of seizures was reduced by 50–98% in four patients (23.5%) and by 25–49% in another four (23.5%). However, the number of seizures remained unchanged in five patients (29.4%) and worsened in four (23.5%). A mean follow-up of 10 months in responders did not show any relevant efficacy of allopurinol as an adjuvant therapy for refractory epilepsy, even at high doses. Thus, further studies are needed to determine the value of allopurinol as an AED.

Allopurinol is used as an add-on therapy with dosages of up to 300 mg/day, given in two or three divided doses.

Adverse effects

Adverse effects, in general, are mild and may occur in up to 25% of patients. Those most common include headache, diarrhoea and malaise [15], decreased appetite, drowsiness and abdominal pain [13]. It is unclear whether adverse effects are dose dependent.

Place in current therapy

Allopurinol may play a minor role as an adjunctive therapy for refractory epilepsy.

Bromide

Bromides were the first effective AEDs [20] but their use in the treatment of epilepsy dropped dramatically after the introduction of phenobarbital and phenytoin [21]. Since then, bromides have gained a reputation of having a very narrow target range and being less effective than other AEDs [22]. However, there are also studies which have shown that bromides are more effective than other drugs in the treatment of special syndromes such as refractory tonic–clonic seizures of childhood [23–25], severe myoclonic epilepsy in infants [26] and malignant migrating partial seizures in infancy [27].

Chemistry

Bromide is formulated in various salts. In clinical practice the salts most commonly used are sodium bromide, calcium bromide and ammonium bromide. Bromine itself is a non-metallic element which does not occur in pure form in nature because of its high reactivity.

Mechanisms of action and activity in experimental models of seizures and epilepsy

The mechanisms by which bromides produce antiepileptic effects are still not entirely clear. According to Balcar *et al.* [28], bromide does not affect the γ-aminobutyric acid (GABA)ergic inhibitory system. This was indicated by a lack of changes in the metabolism or transport of GABA and also by unchanged characteristics of the receptor-associated GABA binding sites under acute or chronic bromide exposure. In contrast, Suzuki *et al.* [29] have shown that bromide potentiates GABA-activated currents in cultured cerebral neurones. To clarify such contradictory results, the effect of the bromide on GABAergic inhibition was tested in a paired-pulse protocol and on inhibitory postsynaptic currents [30]. A significant increase in paired-pulse inhibition was seen in a paired-pulse stimulation protocol used to monitor the efficacy of GABAergic inhibition at concentrations of 5 mmol sodium bromide. This finding was confirmed in whole-cell patch clamp recordings from cultured hippocampal neurones showing an increase in inhibitory postsynaptic current amplitude.

It has also been suggested that bromide may interact with the enzyme carbonic anhydrase, resulting in extracellular acidosis and consequent inhibition of epileptiform activity [31]. This prompted a study to compare the effect of both the carbonic anhydrase inhibitor acetazolamide and sodium bromide on extracellular pH changes at rest and following electrical stimulation [30]. Using pH-sensitive microelectrodes, different effects of sodium bromide as compared with those of acetazolamide on extracellular pH under control conditions and after stimulation were seen. Acetazolamide at 1 mmol caused a reversible acidification of ΔpH (0.2 ± 0.14 at rest), whereas no change on extracellular pH was seen with 5 mmol sodium bromide. Acetazolamide increased the transient alkalosis induced by repetitive stimulation of the stratum radiatum in area CA1 and reduced the subsequent acidosis. Sodium bromide also increased the alkalosis but had no effect on the subsequent acidosis. The results indicate that the antiepileptic properties of bromide are unlikely to be caused by its effect on extracellular pH.

In preclinical studies, Grewal *et al.* [32] demonstrated the anticonvulsant potency of sodium bromide using six different procedures – four electrical and two chemical. The electrical procedures included the maximal electroshock seizure pattern test, the minimal electroshock seizure pattern test, the minimal electroshock seizure pattern in hyponatraemic (low threshold) mice test and a test in which unidirectional currents of four times threshold intensity are delivered. The chemical procedures were based on pentylenetetrazole injections. It could be demonstrated that sodium bromide is effective in all tests employed and modifies seizure pattern as well as elevates seizure threshold.

Using combined rat hippocampus–entorhinal cortex slices, Meierkord *et al.* [30] analysed the effects of sodium bromide on

four types of epileptiform discharges in two different models of epilepsy, the low-Ca^{2+} and the low-Mg^{2+} model. Sodium bromide concentration-dependently reduced the frequency and finally blocked the low-Ca^{2+}-induced discharges. Low-Mg^{2+}-induced short recurrent discharges were also reduced in a concentration-dependent manner. In the entorhinal cortex the frequency of seizure-like events was reduced by 3 and 5 mmol and the discharges were blocked by 7 mmol sodium bromide. Also, the late recurrent discharges in the entorhinal cortex which do not respond to most clinically employed AEDs were reduced by concentrations of 10 and 15 mmol and were completely blocked by 30 mmol sodium bromide (Fig. 58.1).

Clinical pharmacokinetics

Bromide is completely absorbed from the gastrointestinal tract and distributed throughout the body in an almost identical fashion to chloride [33]. It replaces chloride in extracellular fluids and the equivalent amount of chloride is excreted. Intracellularly, bromide is found largely in red blood cells. The rate of distribution to the cerebrospinal fluid, gastrointestinal tract and muscle is slower. The ion easily crosses the placenta. Via breast milk, it can cause hypotonia and irritability in infants when used during nursing [34,35].

Bromide is excreted unchanged by the kidneys. In the distal tubule there is a competitive reabsorption of chloride and bromide, a fact that can be exploited in cases of bromide intoxication as administration of chloride will speed up bromide excretion. The elimination half-life ranges between 10.5 and 14 days [34], so the steady-state concentration is reached 40–50 days after treatment initiation [36].

Drug interactions

Bromide does not bind to plasma proteins and there is no evidence that it induces or inhibits the enzymes responsible for the metabolism of other AEDs. For these reasons, no metabolic drug interactions are expected. However, bromide may enhance the central nervous system (CNS)-depressant effects of other AEDs.

There is a drug–food interaction with the chloride ion. When sodium chloride is ingested in the form of table salt, the chloride ion in sodium chloride displaces the bromide ion so that the bromide does not accumulate as expected. Therefore, it is recommended that the ingestion of sodium chloride is held fairly constant during administration of bromides.

Clinical efficacy

There are no randomized, placebo-controlled trials on the efficacy of bromides in epilepsy. Much of the available literature is in the form of single case reports and anecdotal information. Most therapeutic efforts and recent reports focus on the treatment of infants, children and adolescents.

In 1953, Livingston and Pearson [37] reported on the effects of triple bromide elixir (ammonium bromide, potassium bromide and sodium bromide) in 196 children with epilepsy. Sixty-one patients had complete seizure control, 39 were markedly improved (75% reduction in number of seizures), 15 had less than a 50% improvement and 81 did not improve. Of the various seizure types, bromides appeared to be most effective against generalized tonic–clonic, partial, myoclonic and akinetic seizures. There was no beneficial effect on absence seizures. Dreifuss and Bertram [36] reported six patients treated with bromides. Two patients with complex partial seizures and two patients with generalized tonic–

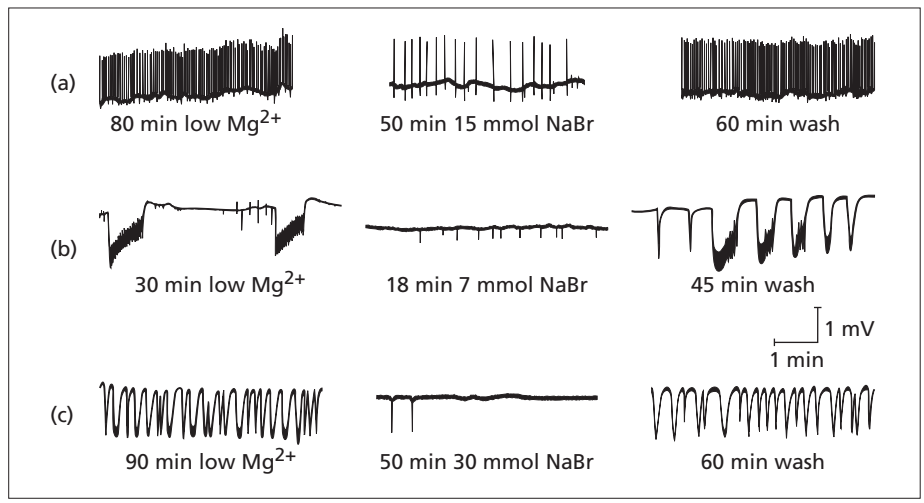

Fig. 58.1 Effects of sodium bromide (NaBr) on different types of spontaneous epileptiform activities. (a) Effects on low-Mg^{2+}-induced short recurrent discharges (SRDs). Low-Mg^{2+}-induced activity in hippocampal area CA1 is characterized by SRDs associated with positive field potentials superimposed by repetitively bursting spikes. Such activity appears following 80 min of Mg^{2+} washout. SRDs in hippocampal region CA1 under 15 mmol sodium bromide are reduced in frequency but not in amplitude, while under 20 mmol SRDs were completely blocked (not shown). The effects on these discharges are reversible. (b) Low-Mg^{2+}-induced seizure-like events. Seizure-like events characterized by tonic- and clonic-like electrographic activity superimposed on slow negative field potentials appear in the entorhinal cortex but not in the hippocampus proper after 30 min of washout of Mg^{2+}. Sodium bromide at concentrations of 7 mmol blocks these discharges reversibly. (c) Effects on low-Mg^{2+}-induced late recurrent discharges. Following prolonged washout of Mg^{2+} (90 min), the seizure-like events in the entorhinal cortex change to late recurrent discharges. Sodium bromide at concentrations of 30 mmol blocks such activity reversibly.

clonic seizures became seizure free. Two patients with absence seizures did not show an improvement. Boenigk *et al.* [23] reported the effects in 68 children and adults. Thirty-three per cent of patients with tonic–clonic seizures of early childhood became seizure free. No improvement in patients with Lennox–Gastaut syndrome was seen.

Woody *et al.* [34] carried out a study in children with different types of epilepsy including photosensitive epilepsy, acquired epileptic aphasia, Lennox–Gastaut syndrome and focal seizures. Six of 11 patients had at least a 75% improvement in seizure control. Three patients had transient improvement, and two had no reduction in seizure frequency. Steinhoff and Kruse [25] reported the results of bromide in 60 patients with generalized tonic–clonic seizures resistant to treatment with standard medication. There was a 50% reduction in seizure frequency in 58% of patients.

Oguni *et al.* [26], in a study on 22 infants with severe epilepsy and various seizure types, saw potassium bromide reduce the frequency of tonic–clonic seizures in 17 of 22 patients. In addition, partial seizures were reduced in all seven patients and myoclonic or absence seizures were also reduced in four patients.

Okuda *et al.* [27] reported complete seizure control in one and 95% reduction in seizure frequency in another infant with malignant migrating partial seizures in infancy. Korinthenberg *et al.* [38] studied potassium bromide in 113 patients (aged 1–20 years) with severe epilepsy manifesting with generalized tonic–clonic seizures. The number of patients who had suffered generalized tonic–clonic seizures during the previous month dropped from 82 to 41, and the median seizure frequency dropped from 4.5 to 0 per month. Of the patients with generalized tonic–clonic seizures during baseline, 49% had none in the last 4 weeks of the study, and another 31% had a reduction by more than 50%.

The usual dosage of sodium bromide in children under 6 years of age ranges from 300 mg twice a day to 600 mg three times a day; over 6 years of age, a dose of 300 mg to 1 g is given three times a day. The therapeutic blood bromide concentration has been reported to range between 10 and 20 mmol/L [34,36].

Adverse effects

Apart from bromide exanthema, adverse effects are generally dose dependent and may be divided into those affecting the gastrointestinal tract, the skin and the nervous system.

Effects on the gastrointestinal tract include anorexia, constipation and weight loss [31]. Pancreatitis as a side-effect of potassium bromide therapy has also been described [39]. In cases of bromism, the tongue may feel coated and sore. When large quantities of bromide salts are ingested, nausea and vomiting may occur [40].

The three main dermatological manifestations are bromide exanthema, acneiform eruptions and bromoderma tuberosum [41]. Acneiform rashes usually occur on the face but may also spread over the neck, chest and arms [36]. If a rash develops, the medication should be discontinued. Bromoderma tuberosum is, in most cases, fully reversible after cessation of the medication. The mechanisms by which the lesions and the associated intraepidermal abscesses are formed are unknown.

Neuropsychiatric adverse effects (bromism) include sedation, action myoclonus, cerebellar signs such as ataxia and dysarthria, decreased libido, dysphagia, decreased tendon jerks, somnolence, tremor and hallucinations [31]. Severe bromism is associated with bromide concentrations above 200 mg/100 mL and manifests as restlessness, headache, delirium and dementia. Other features consist of diminished deep tendon reflexes, loss of pupil reflexes, papilloedema, increased cerebrospinal fluid pressure, slowing on EEG and loss of gag reflex [42].

Place in current therapy

Bromides are no longer a mainstay in the treatment for epilepsy. However, given the fact that bromides are cheap and widely available AEDs with powerful antiepileptic properties, they should have a place as a medication of tertiary choice in severe forms of childhood epilepsy.

Ethotoin

Ethotoin is a phenyl derivative with a structure and mechanism of action similar to phenytoin. Today, it is very rarely used in clinical practice.

Ethotoin has a lower antiepileptic potency than phenytoin and has hypnotic properties; both factors limit its clinical use. It is attractive, on the other hand, because it lacks the adverse effects of gingival hyperplasia and hirsutism. Ethotoin is mostly used as an adjunct in patients with generalized tonic–clonic seizures. Carter *et al.* [43] found it useful in reducing seizure frequency in children with intractable epilepsy. Ethotoin is given in divided doses of 20–40 mg/kg/day.

Adverse effects include ataxia, visual disturbances, rash and gastrointestinal disturbances [44]. Malformations such as cleft lip and cleft palate have been reported in infants born to mothers taking ethotoin [45].

Furosemide

The loop diuretic furosemide has been shown to effectively suppress epileptic activity in experimental studies. Some evidence exists that the drug may also be clinically effective in suppressing epileptic discharges and reducing the frequency of epileptic seizures.

Chemistry

Furosemide is a sulphamoylbenzene derivative of anthranilic acid. Its most important structural characteristic is a carboxide group, while the sulphonamide structure seems to be without pharmacological relevance. The substance appears as a white-yellowish powder and has a molecular weight of 330.74. Furosemide is poorly soluble in water.

Mechanisms of action and activity in experimental models of seizures and epilepsy

In vivo animal data have demonstrated that furosemide terminates self-sustaining status epilepticus induced by chemoconvulsants or electrical stimulation with a delay of 30–90 min [46,47] (Fig 58.2). Such potent anticonvulsant properties are probably based on a number of mechanisms. *In vitro* data suggest that neuronal synchronization is reduced via its inhibitory effect on the $Na^+/K^+/2Cl^-$ co-transport system, resulting in partial preven-

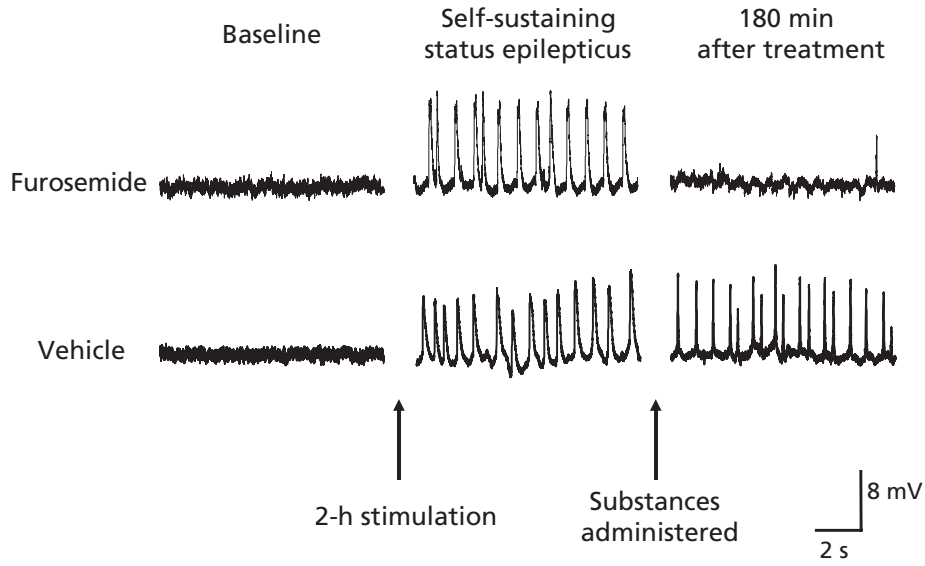

Fig. 58.2 Electrographic recordings from the dentate gyrus *in vivo*. Each trace shows 10 s of the electroencephalogram (EEG) recorded at different points in time. Animals were given furosemide (10 mg/mL) 100 mg/kg intraperitoneally (i.p.) or saline 10 mL/kg i.p. The EEG displays unchanged status epilepticus activity in animals given the vehicle. In contrast, in animals treated with furosemide the ongoing epileptic activity was terminated, apart from occasional spikes. This effect did not occur immediately but in a delayed fashion.

tion of activity-induced extracellular space shrinkage [48]. In addition, reduced neuronal excitability seems to contribute to its anticonvulsant properties [48].

Clinical pharmacokinetics

The oral bioavailability of furosemide is about 50–60%. Peak plasma concentrations are seen about 1 h after oral administration. Furosemide binding to plasma proteins is >95% and the elimination half-life is about 2 h. Furosemide is predominantly excreted unchanged in urine. The only significant metabolite is a glucuronide conjugate.

Drug interactions

Furosemide may cause a modest increase in serum phenobarbital levels [49]. Phenytoin, methotrexate and probenecid may reduce the efficacy of furosemide. If furosemide is co-administered with drugs that prolong the QT interval of the ECG, such as some antiarrhythmics, the risk for ventricular fibrillation is increased. Furosemide may potentiate the antihypertensive effects of many antihypertensive agents and the ototoxicity of aminoglycosides and ethacrynic acid.

Clinical efficacy

In a double-blind placebo-controlled trial, a single intravenous dose of furosemide (40 mg) was found to be as effective as lorazepam (2 mg), clonazepam (0.5 mg) and diazepam (5 and 10 mg) in suppressing interictal spike discharges in the EEG of patients with epilepsy [50]. Interestingly, a subsequent study in patients with neocortical or mesiotemporal epilepsy undergoing resective surgery showed that intravenous administration of 20 mg furosemide resulted in significant suppression of spontaneous epileptic spikes and electrical stimulation-evoked epileptiform discharges [51].

In a double-blind placebo-controlled trial in patients with partial epilepsy, adjunctive therapy with furosemide given orally at a dose of 40 mg/8 h for 4 weeks produced a significant reduction in the frequency of seizures [50]. In the same trial, a small increase in the serum concentration of concomitantly administered phenobarbital might have contributed to the improvement in patients randomized to furosemide.

An epidemiological study has demonstrated that in patients with arterial hypertension or congestive heart failure furosemide was associated with a decreased risk of developing unprovoked seizures [52]. However, odds ratios were not statistically significant when adjusting for matching variables.

Adverse effects

Furosemide may cause a variety of adverse effects, including dehydration, hypovolaemia, hyperglycaemia, hyperuricaemia, dizziness, paraesthesiae and arterial hypotension. Hypokalaemia may be accompanied by hypochloraemic alkalosis. Gastrointestinal symptoms have been described that may be attributed to hypokalaemia. Ototoxicity may occur acutely but is usually a transient phenomenon, although persistent tinnitus may develop.

Place in current therapy

Despite well-established experimental evidence of antiepileptic properties and some supporting clinical observations, furosemide does not, as yet, play a role in the treatment of epilepsy. It seems justified to consider furosemide at high doses in otherwise refractory status epilepticus, but adequate clinical data are currently lacking.

Ketamine

Ketamine is an analgesic and hypnotic drug that was first synthesized in 1962. Its current main use is in emergency and short-lasting procedures as an anaesthetic with strong analgesic and sedative effects. Ketamine has psychotropic effects and may

be abused, which is the reason why it has been illegal in the UK since 2006. Ketamine displays pronounced anticonvulsant properties in animal models of status epilepticus, and some case reports indicate that it may also be clinically effective in the treatment of status.

Chemistry

Ketamine is a chiral cyclohexanon derivative, and a racemate of the enantiomers (*S*)- and (*R*)-ketamine. The pharmacological profile of (*S*)-ketamine is qualitatively similar to the racemate, but the anaesthetic, analgesic and probably anticonvulsant potency of the (*S*)-enantiomer is three times that of the (*R*)-enantiomer and twice that of the racemate.

Mechanisms of action and activity in experimental models of seizures and epilepsy

The anticonvulsant properties of ketamine are assumed to be due to non-competitive antagonism to the *N*-methyl-D-aspartate (NMDA) receptor.

Experimental animal studies have demonstrated that ketamine suppresses epileptiform activity in advanced stages of status epilepticus *in vitro* [53] and *in vivo* [54–56]. Interestingly, such late seizure-suppressing effects are still seen after anticonvulsant drugs acting via enhancement of $GABA_A$ receptors have failed. The 'receptor-trafficking hypothesis' has been suggested to explain such effects [57]. Loss of efficacy of GABAergic agents after repetitive and serial seizures is assumed to be due to progressive decrease of $GABA_A$ receptors at the synaptic membrane. $GABA_A$ receptors are internalized into endocytotic vesicles and subsequently degraded [58]. In contrast, NMDA receptors are progressively transported to the synaptic membrane during ongoing epileptic activity, resulting in increasing numbers of functional excitatory NMDA receptors per synapse [59]. The latter is assumed to play an important role in rendering status epilepticus refractory to GABAergic drugs [60]. In this context, it is not surprising that ketamine co-administered with benzodiazepines in experimental studies has been demonstrated to have strong synergistic anticonvulsant effects [61].

Ketamine has an inhibitory effect on the peripheral reuptake of catecholamines such as noradrenaline and dopamine at the synaptic cleft. Potentiation of the pharmacological properties of endogenous and exogenous catecholamines has a stimulating effect on the cardiovascular system, which discriminates ketamine from all other anaesthetics, and via this property cardiodepressant effects of co-administered benzodiazepines may be neutralized.

Clinical pharmacokinetics

Since the sole indication for ketamine in epilepsy is, as yet, refractory status epilepticus, pharmacokinetic considerations in this chapter are restricted to intravenous administration. After bolus administration, the onset of action is seen within 30 s, and the elimination half-life is 2–3 h. The duration of action depends on the applied dose, and is approximately 5–15 min after 2 mg/kg and 12–25 min after 6 mg/kg.

The drug is extensively metabolized hepatically by the cytochrome P450 system to its active metabolite norketamine, which is excreted by the kidneys.

Drug interactions

Repetitive or continuous administration of ketamine results in enhanced propofol metabolism in rats [62], but the clinical relevance of this finding is unclear. Due to the vasopressor effects of ketamine, co-administration with thyroid hormones or sympathomimetic drugs may result in arterial hypertension or tachyarrhythmias.

Clinical efficacy

Ketamine may be an alternative anaesthetic drug in patients with status epilepticus refractory to other drugs. However, despite promising data from animal experiments and the availability of ketamine for decades, there are only very few publications on the clinical use of ketamine in status epilepticus. In a series of seven patients treated with ketamine for refractory status epilepticus, electrographic seizure control was reported in four patients on 0.3–5.8 mg/kg/h infusion for up to several days [63]. In other patients, a 7.5 mg/kg/h infusion was administered to terminate status epilepticus [64,65]. In five children aged between 4 and 7 years suffering from non-convulsive status epilepticus, oral administration of ketamine (1.5 mg/kg/day in two divided doses) for 5 days resulted in cessation of continuous epileptic activity in all cases [66].

Adverse effects

The main undesirable effects of ketamine are hallucinations, excitation and delirium due to the drug's psychotropic properties. Such effects can usually be avoided by co-administration of sedatives such as barbiturates, benzodiazepines or propofol. In a patient treated with ketamine for refractory status epilepticus, long-term follow-up revealed diffuse cerebellar and worsened cerebral atrophy [65]. This finding may not be specific and may well be the consequence of prolonged generalized status epilepticus itself. Other adverse effects of ketamine include hypertension and increased heart rate (though hypotension and bradycardia have also been reported), respiratory depression (at high doses), gastrointestinal disturbances, enhanced muscle tone manifested with tonic and clonic movements resembling epileptic seizures, and anaphylactic reactions.

Place in current therapy

In patients suffering from difficult-to-treat forms of status epilepticus, intravenous ketamine may be tried after failure of GABAergic anaesthetics. Improvement of haemodynamic conditions with ketamine infusion is an advantageous property compared with other catecholamine-requiring anaesthetics.

Lidocaine

The local anaesthetic and antiarrhythmic agent lidocaine was first synthesized in 1943 and marketed in 1948. Lidocaine has been reported to be effective in serial seizures and status epilepticus in children and adults.

Chemistry

Lidocaine [2-(diethylamino)-*N*-(2,6-dimethylphenyl)ethanamide] is an amino amide-type anaesthetic.

Mechanism of action

Lidocaine acts via inhibition of voltage-gated sodium channels during abnormal membrane depolarizations [67]. Therefore, the drug has membrane-stabilizing effects and probably inhibits fibre systems involved in direct cortical stimulation [68].

Clinical pharmacokinetics

Lidocaine is rapidly distributed into the brain and thus has an onset of action within minutes. The distribution half-life is 8–17 min and the elimination half-life is about 1.5–2 h. The drug is extensively metabolized in the liver by the enzyme CYP1A2 (and to a minor extent by CYP3A4) to metabolites which retain a pharmacological activity weaker than that of the parent drug.

Drug interactions

Enzyme-inducing agents such as phenobarbital or phenytoin may reduce the serum levels of lidocaine. The effects of lidocaine may be increased by beta-blockers. Lidocaine should be used with caution in patients receiving other local anaesthetics or agents structurally related to amide-type local anaesthetics (e.g. certain antiarrhythmics, such as mexiletine) since toxic effects are additive. Specific interaction studies with lidocaine and class III antiarrhythmic drugs (e.g. amiodarone) have not been performed, but caution is advised.

Clinical efficacy

Intravenous lidocaine has been reported to be effective in terminating 44% of cases of neonatal or infant convulsive status epilepticus after failure of conventional anticonvulsant treatment with diazepam, phenobarbital or phenytoin [69]. Lidocaine was bolus administered at 2 mg/kg, followed if necessary by infusion of 4 mg/kg/h for a mean of 14 h. Lidocaine seems to be useful in cases of status epilepticus attributable to acute medical conditions, such as convulsions with mild gastroenteritis [70]. In a randomized trial on 11 neonates with continuous and rapidly repeating seizures not terminated by phenobarbital, second-line treatment with lidocaine (4 mg/kg bolus, 2 mg/kg/h infusion) was successful in three out of five patients, while midazolam did not stop seizure activity in any of six patients [71].

Rare reports in adult status epilepticus described anticonvulsant effects of lidocaine either after failure of conventional AEDs including pentobarbital [72] or as a first-line agent in patients not treated with diazepam due to limited pulmonary reserve [73]. Lidocaine was bolus administered at 1–2 mg/kg followed by infusion rates of 1–4 mg/kg/h, a regimen that results in therapeutic plasma levels of 3–5 μg/mL [74]. In patients with intractable epilepsy, direct cortical administration of lidocaine during resective surgery resulted in marked reduction of spontaneous spike activity [75].

Adverse effects

The advantage of lidocaine in the treatment of status epilepticus lies in its lack of sedative effects and lack of depression of respiration at clinically relevant doses. Manifestations of CNS toxicity include confusion, drowsiness, tremulousness, tinnitus and psychosis. At serum concentrations >5 μg/mL the drug may have proconvulsant effects. Possible cardiovascular adverse effects include bradycardia, hypotension, arrhythmias and cardiovascular collapse, which may lead to cardiac arrest. Allergic reactions are characterized by skin rashes, oedema or, in the most severe instances, anaphylactic shock. Allergic reactions of the amide type are rare and may occur as a result of sensitivity either to the local anaesthetic agent or to other components in the formulation.

Place in current therapy

Lidocaine infusion may be administered in neonates and children with prolonged or repeated convulsions after failure of conventional anticonvulsants. The role of lidocaine in the management of adult refractory status epilepticus is less well defined, but the drug is also likely to be effective in this age group.

Mephenytoin

Mephenytoin has a hydantoin structure that resembles phenytoin and ethotoin. Its mechanisms of action are presumed to be similar to those of phenytoin. In animal models, its efficacy against pentylenetetrazole-induced seizures is greater. Mephenytoin inhibits post-tetanic potentiation and prevents the tonic phase in tonic–clonic seizures. It is also effective against seizures induced by bicuculline and picrotoxin [44].

Mephenytoin is stereoselectively converted to an active metabolite (nirvanol) and its metabolism is strongly influenced by the CYP2C19 genetic polymorphism.

Clinically, mephenytoin has the same spectrum of indications as phenytoin, but because of its common adverse effects its use should be limited to those patients unable to tolerate other drugs. Mephenytoin is effective against complex partial seizures and tonic–clonic attacks, but it may exacerbate absence seizures [44]. The usual daily dose is 300–600 mg in adults, given in divided doses.

Adverse effects include skin rashes, uncoordinated movements, sedation, hepatotoxicity, periarteritis nodosa and lupus erythematosus. Other adverse effects include psychotic reactions and behavioural disturbances.

Paraldehyde

Paraldehyde is a hypnotic that has been used primarily for the treatment of substance withdrawal seizures and status epilepticus. The mechanisms underlying its anticonvulsant action are unclear.

Paraldehyde is rapidly and almost completely absorbed and reaches a peak concentration in the plasma within 30–60 min after intramuscular administration and 1.5–2 h after rectal administration. About 30% is eliminated via the lungs and the remainder is metabolized in the liver [76]. The elimination half-life ranges from 5 to 8 h and can be greatly increased in hepatic disease.

Today, the sole indication for paraldehyde is in the treatment of acute seizures or status epilepticus. The literature concerning efficacy comprises case reports and small case series, and there are no modern assessments or controlled studies. It is apparent that paraldehyde is highly effective in stopping seizures, and although there are no controlled comparisons, paraldehyde prob-

ably has similar efficacy in acute seizures as benzodiazepines, barbiturates or phenytoin.

Paraldehyde has a small but useful place in contemporary therapy. It is mainly used as an alternative or sequel to the administration of diazepam in acute seizures or the stage of early status epilepticus [77,78]. It has the great advantage of little sedation or cardiorespiratory risk, and therefore it can be given rectally in situations where there are no facilities for resuscitation (e.g. at home or in residential institutions).

The usual rectal or intramuscular dosage is 5–10 mg (1 mg/mL) (adults) or 0.07–0.34 mg/kg (children). The drug should be diluted before rectal administration by mixing it with an equal volume of olive oil (or mineral oil). The dose can be repeated after 15–30 min. For intravenous use, according to Lockman [79], the drug is diluted with saline to a concentration of 10%, which is slowly infused at a dose of 0.3 mL/kg. In contemporary clinical practice, the intramuscular and the intravenous routes are rarely used because safer alternative routes of drug administration are available.

The main toxicity risks result from the use of inappropriately diluted or decomposed paraldehyde. Paraldehyde has a short shelf life, and to prevent decomposition, the drug should be freshly made and should not be unduly exposed to light. Paraldehyde solutions that have a yellowish colour may have deteriorated and should be discarded. The decomposed compound can result in precipitation, microembolism, thrombosis or cardiovascular collapse. The drug also reacts with rubber and plastic, therefore intravenous infusions must be given via glass sets and syringes. Paraldehyde has the advantage that arterial hypotension and respiratory arrest are less common than with benzodiazepines, phenytoin or barbiturates. Direct injury from arterial injection leading to both arterial and venous thrombosis has been reported [80]. Paraldehyde can also cause lactic acidosis. The intramuscular injection is extremely painful and can result in a sterile abscess and inflammatory response. Sciatic nerve damage is a risk if the injection is too close to the nerve.

Phenacemide

Phenacemide was introduced by Gibb *et al.* [81] for the treatment of refractory complex partial seizures. In animal models, the drug has been found to be effective in maximal electroshock-induced seizures and in increasing seizure threshold to pentylenetetrazole [82,83]. Clinically, a major problem of phenacemide is its tendency to induce personality disorders, aggression and acute psychosis [84]. Other adverse effects include sedation, insomnia, vertigo, headache and drowsiness. Because of its serious adverse effects, the drug is very rarely used today, although its efficacy may be greater and its toxicity less than previously thought [85]. Phenacemide is indicated only in intractable complex partial seizures when other drugs have failed. The total daily dose ranges from 20 to 40 mg/kg.

Propofol

Propofol is an intravenous anaesthetic which represents one of the therapeutic options in the management of status epilepticus refractory to benzodiazepines and phenytoin [86,87].

Chemistry

Propofol (2,6-diisopropylphenol) is a water-immiscible oil and is used as an emulsion of a soya oil–propofol mixture in water, which is why it appears as a highly opaque white fluid.

Mechanisms of action and activity in experimental models of seizures and epilepsy

Propofol has been shown to suppress epileptiform activity in experimental models *in vitro* and *in vivo* [88,89]. Propofol induces in neurones an inward hyperpolarizing current carried by chloride ions [90,91], through a mechanism of action that is different from that of barbiturates and benzodiazepines. Besides this direct effect on chloride channel conductance [91], propofol enhances $GABA_A$ receptor-mediated responses [92] and thus potentiates the effect of GABA on neurones [93–95]. Propofol also interacts with calcium channels and has a number of additional pharmacological effects, including decreased secretion of pro-inflammatory cytokines, modulation of the expression of nitric oxide, impairment of monocyte and neutrophil functions and potent radical scavenging activity [96].

Clinical pharmacokinetics

Propofol is highly protein bound (98%) and has a rapid onset of action within 2–4 min. The pharmacokinetic advantage of propofol is a short initial half-life of 30–60 min. As a result of this, however, clinical effects after bolus administration last only 4–8 min. Following a single bolus, propofol has no propensity to accumulate, while prolonged infusion may result in accumulation in fat tissue due to the high lipophilicity of the drug. Even after prolonged infusions (1–10 days), the decline in serum propofol concentration is initially relatively rapid, which may lead to awakening in a relatively short period when administration is discontinued. The terminal half-life, however, is quite long, in the order of 1–3 days after a 10-day infusion.

Propofol is metabolized mainly in the liver through the cytochrome P450 system and glucuronidation [96], and its plasma clearance is in the order of 1.6–3.4 L/min.

Drug interactions

Propofol is pharmacologically compatible with all other anticonvulsants used in status epilepticus, though additive effects on cardiopulmonary function have to be considered. Some opioids used in anaesthesiological practice may increase serum propofol concentrations, and propofol itself may increase the serum concentration of some opioids. Co-administration of ciclosporin with lipid emulsions such as in propofol may result in leucoencephalopathy.

Clinical efficacy

Propofol is administered in patients with generalized convulsive status epilepticus refractory to benzodiazepines and phenytoin [97]. Retrospective data have shown success rates of 67% with a median infusion rate of 4.8 mg/kg/h for a median of 3 days [98]. An uncontrolled prospective study has demonstrated termination of status epilepticus in 70% of patients, but propofol infusion rates had to be increased to a median maximum of 9.5 mg/kg/h to maintain an EEG burst–suppression pattern [99].

Adverse effects

Like other GABAergic anaesthetics, propofol has depressant effects on cardiopulmonary function. At doses administered for the treatment of refractory status epilepticus, mechanical ventilation is required. Arterial hypotension has to be treated with fluid resuscitation in all patients and up to 70% additionally require catecholamines [99].

Severe anaphylactic and anaphylactoid reactions may occur. The propofol infusion syndrome, which is characterized by cardiac failure, severe metabolic acidosis, rhabdomyolysis, hyperkalaemia and renal failure, is a severe and often fatal but rare complication, the risk of which increases with prolonged infusions >48 h at doses >4 mg/kg/h [100].

Place in current therapy

Propofol is one treatment option in those clinical forms of status epilepticus that require administration of anaesthetics after failure of first- and second-line anticonvulsants. In this condition, propofol is equally effective as barbiturates or midazolam, though the latter does not have the potency to induce an EEG burst–suppression pattern.

Trimethadione

Trimethadione was the first drug of choice for absence seizures until the introduction of ethosuximide and valproic acid. It was one of the first drugs that was shown to act selectively on a specific seizure type [101].

In animal models, trimethadione is more effective against pentylenetetrazole-induced seizures than against electrically induced seizures. Several mechanisms of action have been suggested, including augmentation of GABA [102], blocking of extracellular potassium accumulation [103] and induction of extracellular acidosis [104].

The drug is rapidly absorbed after oral administration and reaches a peak plasma concentration within 0.5–2 h. The half-life of trimethadione is about 16 h, but its active metabolite, dimethadione, has a half-life of about 10 days.

Trimethadione is highly teratogenic and must not be given to women of child-bearing age [105]. Adverse effects are dose related and include sedation and blurred vision [106], and skin reactions such as rash and erythema multiforme. Pancytopenia has been reported and a myasthenic syndrome may also occur [107].

The main indication for trimethadione is absence seizures that are not adequately controlled by other AEDs or in patients who do not tolerate these. Trimethadione is not effective in partial seizures or generalized tonic–clonic seizures. The usual daily dose is 20–40 mg/kg/day. The therapeutic plasma concentration of dimethadione ranges between 500 and 1200 μg/mL. Trimethadione is very rarely used today, and its production was discontinued in most countries by the end of 1994.

59 Antiepileptic Drugs in Early Clinical Development

Philip N. Patsalos and Josemir W. Sander
UCL Institute of Neurology, London, UK

Introduction

Seizure freedom with no adverse effects so as to enable the person with epilepsy to lead as normal a lifestyle as possible is the paramount treatment aim in epilepsy. This utopian ideal has not been realized by the generation of antiepileptic drugs (AEDs) licensed worldwide since 1989. Because the ideal treatment of many patients with intractable epilepsy still relies on the development of new AEDs, there is a substantial need for drugs with novel therapeutic targets that are more efficacious and which have improved adverse effect profiles and better pharmacokinetic characteristics. AEDs that improve the outcome of epilepsy and which prevent epileptogenesis and any secondary cerebral damage which may occur in epilepsy are needed. Drugs that could prevent the development of epilepsy following traumatic head injury, neurosurgical procedures and cerebrovascular accidents are very much needed, as well as AEDs that may prevent premature mortality, particularly due to sudden unexpected death, which often affects people with epilepsy.

In this chapter, various potential AEDs in early clinical development are reviewed in alphabetical order. These agents are summarized in terms of their mechanism of action, pharmacokinetic and interaction profiles, efficacy and adverse effect characteristics.

2-Deoxy-D-glucose

2-Deoxy-D-glucose, a chemical analogue of glucose that differs from normal glucose only by lacking a single oxygen atom at the 2 position, has been used for many years as a tracer in autoradiography and positron emission tomography imaging. 2-Deoxy-D-glucose is taken up into cells by normal glucose transport mechanisms, but unlike glucose cannot undergo metabolism and thereby acts as an inhibitor of glycolysis.

Mechanism of action

Inhibition of glycolysis results in an anticonvulsant action and it is through this mechanism that 2-deoxy-D-glucose is considered to act.

Activity in experimental models

2-Deoxy-D-glucose is effective in a variety of models, including seizures induced by pentylenetetrazole, maximal electroshock and pilocarpine, audiogenic seizures, kindled seizures and seizures induced in a corneal stimulation model [1].

Pharmacokinetics

2-Deoxy-D-glucose is rapidly absorbed and distributed after oral administration, with peak plasma concentrations occurring at 0.5–1 h and a half-life of 5–10 h [2]. As an analogue of glucose, 2-deoxy-D-glucose freely passes the blood–brain barrier and is delivered preferentially to brain regions in response to energy demand, specifically regions with circuitries generating seizures [3].

Drug interactions

The drug interaction profile of 2-deoxy-D-glucose is, at present, unknown.

Efficacy and adverse effects

The efficacy and tolerability profiles of 2-deoxy-D-glucose in patients with epilepsy are, at present, unknown.

Fluorofelbamate

Fluorofelbamate (2-phenyl-2-fluor-1,3-propanediol dicarbamate) is an analogue of felbamate, devoid of toxic metabolites, that has been designed to emulate the clinical efficacy of felbamate without its safety problems (potential to cause aplastic anaemia and liver toxicity) [4].

Mechanism of action

The exact mechanism of action of fluorofelbamate is unknown, but it appears to decrease responses to γ-aminobutyric acid (GABA), kainate and *N*-methyl-D-aspartate (NMDA) and to reduce voltage-dependent sodium currents [5].

Activity in experimental models

Fluorofelbamate has a greater potency than felbamate in a variety of models including seizures induced by picrotoxin and pentylenetetrazole, audiogenic seizures, kindled seizures and a self-sustaining status epilepticus model [5,6].

Pharmacokinetics

In male volunteers, fluorofelbamate is rapidly absorbed, with peak plasma concentrations (T_{max}) at 1.1 h, and exhibits linear pharmacokinetics. Its elimination half-life is ~16.7 h [5]. Although the exact metabolic pathways of fluorofelbamate are unknown, fluorofelbamate, unlike felbamate, is not metabolized to atropal-

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

dehyde, the reactive aldehyde metabolite which is considered to be responsible for the rare but serious cases of felbamate-induced aplastic anaemia and liver toxicity [7].

Drug interactions
The drug interaction profile of fluorofelbamate is, at present, unknown.

Efficacy and adverse effects
The efficacy profile of fluorofelbamate is, at present, unknown. In male volunteers, single doses of fluorofelbamate up to 3 mg/kg were not associated with adverse events.

Ganaxolone

Ganaxolone (3α-hydroxy-3β-methyl-5α-pregnan-20-one), a neurosteroid that lacks classical hormonal activity, is a synthetic analogue of allopregnalone, a metabolite of progesterone [8]. It is a member of a novel class of neuroactive steroids called epalons, which allosterically modulate the $GABA_A$ receptor complex via a unique recognition site [9].

Mechanism of action
Ganaxolone is a potent positive modulator of $GABA_A$ receptors containing α1, α2 or α3 subunits, and does not show marked α-subunit selectivity [9].

Activity in experimental models
Ganaxolone is active in numerous seizure models, its profile being similar to other $GABA_A$ receptor modulators. It exhibits potent activity against seizures induced by pentylenetetrazole, bicuculline, aminophylline and corneal kindling, whilst it is less potent against maximal electroshock-induced seizures [9]. It is also effective against amygdala-kindled seizures [10] and various models of status epilepticus [11].

Pharmacokinetics
In healthy volunteers, ganaxolone, given in formulations containing a complex with cyclodextrin, was rapidly absorbed after oral ingestion, with peak plasma concentrations achieved within 1–3 h [12]. Peak plasma concentrations associated with a high-fat meal were three times higher than those achieved after intake with a high-carbohydrate meal, and nearly 12 times higher than those observed in fasted subjects. Plasma concentrations increased essentially dose-dependently (dose range 50–1500 mg) and subsequently declined biexponentially with a terminal half-life of 37–70 h. Plasma concentration versus time profiles after multiple doses of ganaxolone did not suggest any significant accumulation. There is no gender difference in respect to its pharmacokinetic characteristics [12]. Ganaxolone is highly bound (>99%) to plasma proteins and is metabolized, primarily by cytochrome P450 (CYP) enzymes CYP3A4/3A5, to yet unknown metabolites which are eliminated from plasma at a rate three to six times faster than the terminal half-life of ganaxolone [12].

Recently, several unique formulations of ganaxolone have been developed so as to address the variable absorption under different dietary conditions [13]. These include two solid capsule forms, one providing immediate release and the other providing pH-sensitive delayed release, and a new suspension form (50 mg/mL) for possible paediatric use. None of these formulations contains cyclodextrins. In healthy subjects the new suspension was associated with greater bioavailability in the fasted state and exposures after intake with food were comparable to those seen with the historical cyclodextrin complex. In the same studies, areas under the concentration–time curve (AUC) after intake with food were no more than two- to threefold greater than those observed after intake in the fasted state. Furthermore, the immediate-release capsule dosage form, in healthy volunteers, demonstrated comparable performance in the fed and fasted state to that of the new suspension, with a slightly prolonged T_{max} value. The delayed-release capsule is associated with a T_{max} of about 6 h and approximately one-half the exposure compared with the suspension or immediate-release capsules [13].

Drug interactions
Preliminary trials have not identified significant drug interactions with concomitant AEDs [12,14].

Efficacy
A non-randomized, non-blinded, open-label, dose-escalation trial of ganaxolone in paediatric patients (5–15 years) with refractory partial or generalized epilepsy reported that of the eight patients who completed the study, six responded to treatment and two were non-responders [15]. Three subjects entered the extension phase and one remained essentially seizure free for over 3.5 years. A double-blind, randomized, placebo-controlled study of ganaxolone (titrated up to a dose of 1875 mg/day) in 52 patients with refractory partial seizures preparing for surgical intervention, and whose concomitant AEDs were withdrawn, showed a strong trend in the ganaxolone patients towards a seizure reduction [16]. Overall, 50% of ganaxolone-treated patients compared with 25% of the placebo-treated patients completed the 8-day study period, and the unusually large survival rate in the placebo group probably reduced the response separation between the two groups. Ganaxolone has been reported to be effective in children with infantile spasms [17]. Of a total of 20 children with refractory infantile spasms, 16 completed an open-label study. Spasm frequency was reduced by at least 50% in 33% of subjects, with an additional 33% experiencing a 25–50% reduction.

Adverse effects
Adverse events reported in healthy volunteers given ganaxolone include sedation, dizziness, headache, gastrointestinal disturbances and fatigue. Interestingly, these were twice as common in females as in males, even though plasma ganaxolone concentrations were indistinguishable in the two genders [18]. In patients, treatment-emergent adverse events comprised a variety of central nervous system (CNS)-related effects, the most prominent being dizziness, somnolence, diarrhoea, nervousness and vomiting [14,15,18]. In adults with partial-onset seizures, the new suspension formulation at doses up to 500 mg three times a day, the highest dose regimen currently being tested, was well tolerated. Similarly, doses of up to 54 mg/kg/day (18 mg/kg three times a day) in 4- to 24-month-old infants with infantile spasms were well tolerated. A favourable tolerability profile was also obtained

in healthy volunteers with a 400-mg immediate-release solid dose form.

JZP-4

JZP-4 [3-(2,3,5-trichloro-phenyl)-pyrazine-2,6-diamine] is a structural analogue of lamotrigine, which resulted from a search for compounds with potentially improved pharmacokinetic and safety profiles compared with lamotrigine.

Mechanism of action

JZP-4 is a potent sodium ($Na_{v1.2a}$ and $Na_{v1.3}$) and high-voltage-activated calcium (types N, L and P/Q) channel blocker.

Activity in experimental models

JZP-4 appears to possess a broad spectrum of activity, in that it is effective in a variety of seizure models including the mouse and rat maximal electroshock models of generalized tonic–clonic seizures; the epilepsy-like (El) mouse model, which is predictive of efficacy in partial seizures; the rat hippocampal- and amygdala-kindling models; and the mouse 6-Hz model [19].

Pharmacokinetics

In healthy volunteers, orally administered JZP-4 was rapidly absorbed and eliminated primarily by metabolism. Excretion of JZP-4 in urine is low, with less than 0.1% of the administered dose recovered in urine as unchanged JZP-4.

Drug interactions

In vitro studies show that JZP-4 has no inhibitory effect on CYP2E1 and a weak inhibitory effect on CYP1A2, CYP2A6, CYP2B6, CYP2C8, CYP2C9, CYP2C19, CYP2D6 and CYP3A4. Additionally, JZP-4 had no significant inhibitory effect on UDP-glucuronosyltransferase (UGT) enzymes UGT1A1, UGT1A4 or UGT1A9 and minimal effect on UGT1A6, UGT2B7 and UGT2B15. JZP-4 did not induce CYP1A2 or CYP3A in isolated human hepatocytes [19].

In healthy volunteers, the apparent oral clearance of a single dose of JZP-4 was reduced by approximately 50% during co-administration with an oral contraceptive (Necon® 1/35 for one cycle), and increased approximately twofold during co-administration with carbamazepine (up to 600 mg/day for 17 days). Co-administration with valproic acid (500 mg twice daily for 10 days) did not result in a clinically significant change in JZP-4 pharmacokinetics [13].

Efficacy and adverse effects

The efficacy and tolerability profiles of JZP-4 are, at present, unknown.

Safinamide

Safinamide (FCE 26743; PNU-151774E; NW-1015) was developed based on the observation that milacemide, a compound no longer in development, possesses weak anticonvulsant activity combined with monoamine oxidase (MAO)-A and -B inhibitory activity. Safinamide is expected to have greater anticonvulsant activity than milacemide [20–23]. Its clinical development programme, however, is currently focused on the treatment of Parkinson's disease [24].

Mechanism of action

Safinamide, which chemically corresponds to (*S*)-(+)-2-[4-(3-fluorobenzyloxy)benzylamino]propanamide, methansulfonate, acts via an action on site 2 of the sodium channel. It is also said to modulate calcium currents and to inhibit MAO-B activity [20,21].

Activity in experimental models

Safinamide is effective in a variety of seizure models (bicuculline, picrotoxin, 3-methyl-aspartate, strychnine, NMDA and electrically induced seizures), in which it acts by preventing seizure spread [22,23]. In these models, safinamide is associated with a very high therapeutic index, suggesting minimal toxicity. In the kainic acid model, safinamide protects against both the seizures and the ensuing neuronal damage [23].

Pharmacokinetics

In healthy volunteers, safinamide is rapidly absorbed, with peak concentrations occurring within 2 h of oral ingestion. A high-fat meal delays absorption without affecting the extent of absorption. Safinamide is 92% bound to plasma proteins. Plasma safinamide concentrations increase linearly with dose and the elimination half-life is 21–23 h.

Drug interactions

In vitro studies suggest that safinamide has no inducing or inhibiting activity on the different CYP isoenzymes that are known to be involved in the metabolism of other AEDs. Nevertheless, plasma safinamide concentrations have been reported to be decreased in patients co-prescribed with enzyme-inducing AEDs such as carbamazepine and phenobarbital [24].

Efficacy

In a phase II open-label trial of safinamide as add-on treatment for uncontrolled epilepsy (different seizure types), 41% of 38 subjects obtained >50% seizure reduction during a 12-week escalating dose period (up to 300 mg/day) compared with baseline [24].

Adverse effects

Overall, safinamide was well tolerated in the trial described above. The most common treatment-emergent adverse events included dizziness, vertigo, nausea and transient visual disturbance, all of which were judged as mild to moderate in nature.

Seletracetam

Seletracetam (ucb 44212) is an analogue of levetiracetam.

Mechanism of action

Seletracetam's chemical structure corresponds to that of levetiracetam with a substitution at the 4-position on the

2-pyrrolidinone ring [25]. Seletracetam binds selectively, stereospecifically and with high affinity (10-fold greater that that of levetiracetam) to synaptic vesicle protein 2A (SV2A), which is thought to be involved in synaptic vesicle exocytosis and neurotransmitter release [26].

Activity in experimental models

Seletracetam, like levetiracetam, is inactive in maximal electroshock and pentylenetetrazole seizure models. However, it is 10-fold and 25-fold more potent than levetiracetam in the corneal kindling and in the Genetic Absence Epilepsy Rat of Strasbourg (GAERS) models [27]. It is also effective in the genetically sound-susceptible mouse model.

Pharmacokinetics

Seletracetam is rapidly absorbed, with a T_{max} of <1 h, and has linear pharmacokinetics. Its volume of distribution is 0.6 L/kg. Seletracetam is minimally bound (<10%) to plasma proteins [28]. Ingestion with a high-fat meal delays the rate of absorption (median T_{max} delayed from 0.5 to 4 h) and results in a 39% reduction in the maximum seletracetam concentration achieved, but had no effect on overall extent of absorption [29]. Seletracetam is eliminated by hydrolysis and excretion in urine, with a total apparent clearance of approximately 0.8 mL/min/kg. Its primary metabolite is an acidic inactive metabolite (ucb-101596-1), the concentration of which in plasma is approximately 10-fold lower than that of the parent compound. Two additional minor metabolites have been identified in urine. Overall, 25% of a seletracetam dose is excreted in the unchanged form [28]. In young healthy subjects, the half-life of seletracetam is about 8 h.

Drug interactions

Based on *in vitro* data, there is a low potential for interactions involving seletracetam. The drug interaction profile of seletracetam in the clinical setting is, at present, unknown.

Efficacy

In a placebo-controlled study of patients with photosensitive epilepsy, seletracetam was markedly effective in reducing the photo-paroxysmal EEG response [30].

Adverse effects

In healthy volunteer studies, seletracetam was well tolerated following both single (200–600 mg) and multiple oral doses (200 mg two times a day) [28,29,31]. The most frequently observed adverse events, which were considered to be mild to moderate and resolved without medical intervention, included somnolence, dizziness, euphoria and nausea.

T2000

T2000 (1,3-dimetoxymethyl-5,5-diphenylbarbituric acid) is a prodrug which is rapidly metabolized to monomethoxymethyl-5,5-diphenylbarbituric acid (MMMDPB) and 5,5-diphenylbarbituric acid [32]. Its current clinical development focuses on its potential usefulness in the treatment of essential tremor rather than epilepsy [13].

Mechanism of action

The mechanisms of action of 5,5-diphenylbarbituric acid, the metabolite best characterized pharmacologically, resemble those of both phenytoin and barbiturates. It suppresses high-frequency repetitive neuronal discharges in cat motor nerve terminals in a manner similar to that of phenytoin, whereas it depresses synaptic discharges in the cat spinal cord in a manner similar to that of phenobarbital [33]. Furthermore, it enhances slow outward current and suppresses repetitive firing in *Aplysia* giant neurones with similar efficacy to and higher potency than phenobarbital [34].

Activity in experimental models

5,5-Diphenylbarbituric acid is effective in the pentylenetetrazole and maximal electroshock tests in mice and rats, decreases the development of pentylenetetrazole-induced kindled seizures in mice and exhibits antiepileptogenic properties in kindled seizures induced by repeated administrations of low doses of cocaine in mice [13].

Pharmacokinetics

Because food enhances the absorption of T2000, the compound is usually ingested with food [35]. In healthy subjects, the pharmacokinetics of T2000 and its primary metabolites 5,5-diphenylbarbituric acid and MMMDPB show near-linearity up to 1200 mg/day dosing [32], with steady-state concentrations achieved within 2 weeks. Plasma protein binding values for T2000, 5,5-diphenylbarbituric acid and MMMDPB are 67%, 35% and 51%, respectively [36], and mean terminal half-lives are in the range of 9–29 h, 27–65 h and 8–27 h, respectively. T2000, 5,5-diphenylbarbituric acid and MMMDPB are further metabolized via hydroxylation and form glucuronide conjugates that are eliminated in urine [32,37]. Diphenylbarbituric acid, MMMDPB, and hydroxy-MMMDPB are formed by CYP2C19, while hydroxy-diphenylbarbituric acid is formed primarily by CYP2C9.

Drug interactions

In vitro studies using human liver microsomes indicate that MMMDPB is a competitive inhibitor of CYP2C19 and CYP2C9 and that 5,5-diphenylbarbituric acid is a competitive inhibitor of CYP2C9 and CYP3A4 [38]. Additionally, 5,5-diphenylbarbituric acid and MMMDPB are potent inducers of CYP3A4 [38].

Efficacy and adverse effects

The efficacy and tolerability profiles of T2000 are, at present, unknown.

Talampanel

Talampanel (LY300164; GIKY 53773) is structurally similar to conventional 1,4-benzodiazepines, but it does not share the same pharmacology and does not interact at the benzodiazepine–GABA receptor complex.

Mechanism of action

Talampanel, which corresponds chemically to (*R*)-7-acetyl-5-(4-aminophenyl)-8,9-dihydro-8-methyl-7*H*-1,3-dioxolo(4,5-

H)(2,3)benzodiazepine, is probably a non-competitive antagonist at the α-amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA) receptor subtype of glutamate [28]. It seems to act not directly on the AMPA receptor, but at an allosteric site referred to as the GYKI receptor [39].

Activity in experimental models

Talampanel shows a broad spectrum of anticonvulsant activity in animal models, including maximal electroshock- and pentylenetetrazole-induced seizures in mice, chemically and electrically kindled seizures in mice, and a mouse model of phenytoin-resistant status epilepticus. In addition, talampanel enhances the anticonvulsant effects, in various seizure models, of numerous AEDs including phenytoin, phenobarbital, valproic acid and clonazepam [40–42].

Pharmacokinetics

After oral ingestion, talampanel is rapidly absorbed, with peak plasma concentrations occurring within 1–3 h [43]. A high-fat or high-caloric meal delays the absorption of talampanel, with T_{max} values ranging from 1.9 to 2.4 h. Binding to plasma proteins is of the order of 75% (range 67–88%). The elimination of talampanel is probably via a combination of first-order and capacity-limited processes. Its elimination half-life in healthy volunteers is about 4 h. Although its metabolic pathways have not been completely characterized in man, acetylation appears to occur whereby talampanel is converted to *N*-acetyl-talampanel by hepatic *N*-acetyltransferase 2 [44]. This metabolic route is not major but there appears to be significant inter-patient differences in plasma concentrations of *N*-acetyl-talampanel, which is pharmacologically active, and may also contribute to adverse effects in some patients.

Drug interactions

Talampanel has been shown in an *in vitro* setting to be an irreversible inhibitor of CYP3A and consequently it would be anticipated that it may inhibit the metabolism of CYP3A substrates such as carbamazepine. Indeed, carbamazepine plasma concentrations are elevated during carbamazepine and talampanel co-administration. Also, there is evidence to suggest that talampanel inhibits valproic acid metabolism, resulting in increased plasma valproic acid concentrations [43]. In patients with epilepsy, the clearance of talampanel is enhanced by enzyme-inducing AEDs such as carbamazepine and phenytoin, so that its half-life is reduced to about 3 h, whilst valproic acid does not appear to affect talampanel clearance [43,45,46].

Efficacy

A double-blind, placebo-controlled, cross-over study evaluated talampanel in 49 patients with refractory partial seizures. Three target talampanel doses were chosen (up to 75 mg three times a day in patients co-medicated with enzyme-inducing AEDs, up to 60 mg three times a day in patients co-medicated with enzyme-inducing AEDs plus valproate and in patients not receiving enzyme-inducing AEDs or valproate, and up to 25 mg three times a day in patients receiving valproate without enzyme inducers). Compared with placebo, talampanel was associated with a 21% reduction in median seizure frequency [47]. An interim analysis of the open-label arm of 100 patients who participated in an earlier randomized double-blind, placebo-controlled, multicentre study showed responder rates (≥50% seizure reduction from baseline) of 39.6% for simple partial seizures, 33.8% for complex partial seizures and 32.3% for partial seizures with secondary generalization [48].

Adverse effects

In healthy male volunteers, who received either a single 100 mg dose or multiple doses (20–50 mg three times a day) of talampanel, the drug was well tolerated [49]. Adverse events included mild drowsiness, dizziness, ataxia and paraesthesiae and occurred at doses above 50 mg [45]. In patients with epilepsy, the most significant adverse events have been dizziness, ataxia, headache and somnolence [37,43,48].

Tonabersat

Tonabersat (SB-220453) is a chiral novel benzoylaminobenzopyran compound that has a similar structure to carabersat (SB-20469), a potential AED no longer in clinical development. Its current clinical development focuses on its potential usefulness in migraine, rather than epilepsy [13].

Mechanism of action

Tonabersat [(3S-cis)-*N*-(6-acetyl-3,4-dihydro-3-hydroxy-2,2-dimethyl-2*H*-1-benzopyran-4-yl)-3-chloro-4-fluorobenzamide] represents a 'first-in-class' neurotherapeutic agent that does not act via any established anticonvulsant mechanism. Instead, tonabersat selectively and specifically binds to a unique stereoselective site in the CNS, thought to be at the neuronal gap junction, and its potency as a gap junction blocker is two- to threefold greater than that of carabersat [50].

Activity in experimental models

Tonabersat increases the threshold for electrically induced seizures in mice and rats and is also active against pentylenetetrazole-induced seizures, inhibiting tonic but not myoclonic seizures [13].

Pharmacokinetics

After oral ingestion of a single dose (2–80 mg), tonabersat is rapidly absorbed with a median T_{max} of 0.5–3 h. Absorption is delayed by a high-fat meal (T_{max} is extended by approximately 3 h) but food has no effect on the extent of absorption. Peak plasma concentrations were generally dose proportional between 2 mg and 40 mg. Tonabersat is highly bound to plasma proteins (98.2%) and undergoes metabolism by cytosolic carbonyl reductase enzymes to a reduced ketone, with negligible amounts excreted in urine unchanged. The primary metabolite is detectable in plasma. Acetyl hydroxylation via the CYP3A family of enzymes accounts for a minor hydroxyl metabolite. Tonabersat plasma concentrations decline in a biexponential manner with mean terminal half-life values of 24–40 h [13].

Drug interactions

Co-administration of the oral contraceptive Microgynon® (active ingredients ethinylestradiol and levonorgestrel) with 80 mg tona-

bersat for 7 days (days 4 to 10 of the menstrual cycle), resulted in an increase in peak plasma ethinylestradiol concentration by a mean of 14% [90% confidence interval (CI) 1.0–28.0%] and of ethinylestradiol AUC by a mean of 21% (90% CI 1.3–30.0%). However, tonabersat had no effect on the metabolism of levonorgestrel.

Sumatriptan and tonabersat co-administration in healthy subjects resulted in no significant effects of either drug on the pharmacokinetic profile of the other [13].

Efficacy and adverse effects

The efficacy profile of tonabersat in patients with epilepsy is, at present, unknown.

Tonabersat has been administered to more than 1000 subjects (both healthy subjects and migraine patients), either as single oral doses (up to 80 mg) or as repeated doses (up to 80 mg/day for up to 7 days). Overall, the drug was well tolerated, with headache, nausea, dizziness and somnolence being the most commonly reported adverse events, the majority of which were mild or moderate and rapidly resolved [13].

Valrocemide

Valrocemide (*N*-valproyl-glycinamide; TV 1901) is a valproyl derivative of glycine.

Mechanism of action

The mechanism of action of valrocemide is unknown. An effect on GABA or glutamate-sensitive ion channels has been ruled out.

Activity in experimental models

Valrocemide exhibits broad-spectrum anticonvulsant activity in numerous seizure models including maximal electroshock, pentylenetetrazole, picrotoxin and bicuculline-induced seizures as well as sound-induced seizures in Frings mice, and hippocampal-kindled seizures and focal seizures from corneal-kindled rats [51].

Pharmacokinetics

In healthy volunteers, valrocemide is rapidly absorbed and exhibits linear pharmacokinetics after single oral doses ranging between 250 and 4000 mg and multiple doses ranging between 250 and 1000 mg three times a day [52]. The plasma protein binding of valrocemide is <25%. Its elimination half-life is 6.4–9.4 h after single-dose administration and 7.2–8.5 h after multiple-dose administration. Oral clearance is 5–7 L/h. Approximately 10–20% of an administered dose is excreted unchanged in urine, and 40% is excreted in the form of valproyl glycine. Urinary valproic acid accounts for 4–6% of an administered valrocemide dose.

Drug interactions

In vitro studies using CYP isoenzymes indicate that significant drug interactions with other AEDs would not be anticipated. Nevertheless, in a series of 22 patients with epilepsy receiving concomitant AEDs, higher valrocemide clearance and shorter valrocemide half-life values were observed in patients receiving enzyme-inducing AEDs. In contrast, valrocemide clearance and half-life in patients not on enzyme-inducing AEDs were similar to those recorded in healthy volunteers [53].

Efficacy

Using an open-label study design during a 13-week period, the efficacy of valrocemide has been investigated in 22 patients with epilepsy. Valrocemide was associated with reduced seizure frequency in 15 patients, two of whom became seizure free [53].

Adverse effects

In preliminary open-label adjunctive therapy studies in patients with epilepsy, whereby valrocemide was administered at doses up to 2000 mg two times a day, no serious treatment-emergent adverse events were recorded. Most adverse events reported were mild to moderate and were CNS or gastrointestinal tract related [53].

YKP3089

YKP3089 is a novel compound with broad-spectrum anticonvulsant activity.

Mechanism of action

The mechanism of action of YKP3089 is, at present, unknown.

Activity in experimental models

YKP3089 is effective in a broad range of models including maximal electroshock-induced seizures in mice and rats, pentylenetetrazole- and picrotoxin-induced seizures, the hippocampal-kindled rat, the mouse 6-Hz model and the rat lithium–pilocarpine-induced intractable seizures model [53].

Pharmacokinetics

In healthy volunteers, YKP3089 shows linear pharmacokinetics over a large dose range (5–750 mg), with a median T_{max} of 1.5–3.5 h. Co-ingestion with a high-fat meal had no significant effect on the pharmacokinetics of YKP3089. Its mean volume of distribution (V_d/F) was 37–55 L, with a mean apparent oral clearance of 0.63 L/h and a half-life of 30–75 h. Dose linearity was also observed in a multiple-dose 14-day study with once-daily dosing, whereby both peak plasma concentrations and AUC increased linearly [13].

Drug interactions

The interaction profile of YKP3089 is, at present, unknown.

Efficacy and adverse effects

The efficacy profile of YKP3089 is, at present, unknown. YKP3089 was well tolerated in healthy volunteers, the most common adverse events being CNS related. Adverse events were of mild to moderate intensity and resolved rapidly.

60 Overview of Surgical Treatment for Epilepsy

Jerome Engel Jr
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

Epilepsy is one of the most serious primary disorders of the brain, accounting for 1% of the global burden of disease [1]. Pharmacotherapy is unsuccessful in controlling seizures in 30–40% of patients [2], and 80% of the cost of epilepsy in the industrialized world is accounted for by patients with medically intractable seizures [3]. It is estimated that four million people worldwide with pharmacoresistant epilepsy might be candidates for a surgical procedure that could stop disabling seizures in 60–80%. However, only slightly more than 8000 therapeutic surgical procedures were performed for epilepsy between 1986 and 1990, the last time a worldwide survey was performed [4]. There is little evidence that this number has increased substantially in recent years. Surgical treatment for epilepsy is arguably the most underutilized of all accepted therapeutic interventions in the entire field of medicine. Furthermore, when patients *are* referred for surgery, there is an average duration of 22 years between the onset of epilepsy and referral [5]. Therefore, not only do most surgical candidates never get referred for surgery, but those who do usually receive it too late to prevent or reverse disabling psychological and social consequences of recurrent seizures [6]. In theory, for many of these patients, early surgical intervention could prevent a lifetime of disability.

It is understandable that surgical treatment has not been considered feasible in the developing world, where most people with epilepsy live; however, on the positive side, tremendous advances have been made in recent years to establish epilepsy surgery programmes in several developing countries (see Chapter 85). Given this, it is unclear why epilepsy surgery remains so underutilized in virtually all industrialized countries in view of continuing advances in the safety and efficacy of surgical treatment, the numerous books that have been published on this subject [7–27] and the uncontested cost-effectiveness of surgical treatment, which must be contrasted not only with the monetary cost of a lifetime of disability, but also with the human cost of premature death [28,29], morbidity [30] and social and psychological compromise [31–33]. One often stated reason in the past, confirmed by a US National Institutes of Health (NIH) Consensus Panel in 1990 [34], was the absence of a randomized controlled trial (RCT), the 'gold standard' needed to demonstrate the superiority of surgical intervention over continued pharmacotherapy. In 2001, however, an RCT carried out at the University of Western Ontario on patients with long-standing temporal lobe epilepsy (TLE) found that 64% of patients were free of disabling seizures 1 year after surgery, compared with only 8% after continued drug trials [35,36]. As a result of this study and a meta-analysis of 24 surgical series published between 1990 and 2000, a practice parameter was issued by the American Academy of Neurology (AAN), in collaboration with the American Epilepsy Society and the American Association of Neurological Surgeons, concluding that surgery is the treatment of choice for medically intractable TLE [37]. It is important here to note that the conclusion of the practice parameter would not have been permitted by the AAN, according to their current standards of evidence-based medicine, on the basis of published uncontrolled surgical series alone, due to the belief that the results of such series can be biased. The AAN accepted this conclusion only because of the RCT. Interestingly, the figure of two-thirds of operated patients free of disabling seizures in the RCT was exactly the same as the average for the practice parameter meta-analysis and the data presented at the 1992 Palm Desert Conference on Treatment of the Epilepsies [38], indicating that bias was not a significant factor in uncontrolled reports.

There are many other types of surgery performed for epileptic seizures due to conditions other than TLE, as discussed later in this chapter, and in the rest of this section, and there is, therefore, no reason to believe that the successful outcomes reported by published series of these surgical procedures are any less valid than those reported for TLE, even though RCTs have not been performed.

The AAN practice parameter recommended early surgical intervention for TLE in order to avoid irreversible adverse psychological and social consequences, as well as significant morbidity and mortality in some populations; however, there are insufficient data to provide definitive guidelines on when to refer patients for surgical treatment. Although it is essential to more effectively disseminate information to primary care physicians, general neurologists and patients about the proper role of surgery in the armamentarium of therapy for epilepsy, there remains a need to collect many more data about the natural history of surgically remediable epilepsies, such as TLE, after failure of a few appropriate drug trials. Identification of reliable risk factors for continued pharmacoresistance would permit establishment of rational guidelines to dissuade physicians and patients alike from trying yet another drug when disabling epileptic seizures are seriously disrupting school, work or interpersonal relations. It is clear that extensive documentation of the safety and efficacy of epilepsy surgery has been insufficient to alter the standard of practice in the community, and that convincing data are now needed to permit reliable identification of patients who will continue to

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

experience psychological and social deterioration, and increased risk of morbidity and mortality, as a result of persistent seizures, if surgical intervention is to be performed in a timely fashion in the future.

Historical perspective

The development of the modern era of epilepsy surgery paralleled the development of concepts of localization of function within the brain, and the field of neuroscience [39]. Beginning in the mid-nineteenth century, studies on patients with focal epilepsy provided seminal insights into the location of functions within the human cortex and, conversely, this information led directly to the localization of surgically resectable epileptogenic lesions that were not readily visible on routine examination.

At the turn of the 19th century, popular interest in phrenology, a misguided belief that personality types could be diagnosed by palpation of bumps on the head believed to reflect various localized brain functions [40], was so vehemently rejected by the scientific community of the time that half a century passed before neuroscientists were willing to take localization of brain function seriously. The British philosopher Herbert Spencer [41] returned respectability to this area of investigation by stating, in 1855, that 'localization of function is the law of all organizations whatever: separation of duty is universally accompanied by separateness of structure; and it would be marvelous were an exception to exist in the cerebral hemispheres'. Spencer had a profound influence on John Hughlings Jackson, who mapped human cortical functions by observing patients with focal seizures and correlating initial ictal semiology with pathological abnormalities identified at autopsy [42]. Jackson, who was appointed consultant at London's National Hospital for the Paralysed and Epileptic at Queen Square in 1862, is credited with recognizing focal seizures of cortical origin as epilepsy, at a time when most physicians were concerned only with generalized tonic–clonic convulsions, which they believed originated in the medulla oblongata. Although Pritchard [43], Bright [44] and Todd [45] in Britain, Bravais [46] in France and Griesinger [47] in Germany had previously described ictal and postictal focal phenomena, Jackson's clinical–pathological correlations established the cortex as the origin of focal seizures, which ultimately developed into an approach for localizing epileptogenic regions for surgical resection. His theories were tested by his colleague David Ferrier [48], an electrophysiologist who reproduced the ictal behaviours described by Jackson with faradic stimulation of appropriate areas of monkey cortex. In 1886, Victor Horsley performed three successful surgical resections for epilepsy by removing lesions that were 'invisible' preoperatively, but predicted by seizure semiology, and published this the same year [49]. Of note is that Jackson and Ferrier were also present in the operating theatre for the first surgery, constituting the team of neurologist, electrophysiologist and neurosurgeon that is still essential for the surgical treatment of epilepsy today.

Although the modern era of epilepsy surgery is traditionally considered to begin with the 1886 paper by Horsley, he was not the first to successfully remove epileptogenic brain tissue. The first publication was probably that of Benjamin Winslow Dudley [50], who reported on five patients operated on between 1808 and 1818 at Transylvania University in Lexington, Kentucky, USA. Three became seizure free and the other two had marked improvement. Survival alone was remarkable prior to the common use of antiseptic and anaesthetic techniques, and Dudley commented that his results would not have been possible in an unhealthy urban environment. The Scottish neurosurgeon William Macewen predated Horsley with a series of publications [51–53] describing a number of successful surgical interventions for epilepsy, many of which involved removal of 'invisible' lesions identified solely on the basis of Jackson's clinical–pathological correlations. Bennett and Godlee [54] in England and Durante [55] in Italy also performed surgery prior to Horsley; however, it was Horsley's publication that stimulated interest in surgical treatment for epilepsy in carefully selected patients. Germany was particularly active, with Feodor Krause [56] and Otfrid Foerster [57] being the most prominent epilepsy neurosurgeons in the early 20th century, but it was Foerster's pupil, Wilder Penfield, who subsequently founded the Montreal Neurologic Institute and set the standards for surgical treatment of epilepsy for decades to come.

Early surgical therapy for epilepsy was lesion directed, and only patients with visually apparent structural abnormalities of neocortex were considered surgical candidates. Lesions were localized directly by skull deformities, or indirectly by neurological exam and ictal semiology, then defined intraoperatively, until the development of pneumoencephalography in 1919 [58] and cerebral angiography in 1934 [59]. Confirmation of epileptogenic tissue was usually obtained by faradic stimulation of cortex at surgery. Penfield and Jasper also used this technique to map the human motor and sensory homunculus [60]. Although most surgical procedures involved localized cortical resection, a variety of other surgical approaches were attempted during the first half of the 20th century, including corpus callosotomy, first performed by van Wagenen and Herren in the USA in 1940 [61], and hemispherectomy, first performed by McKenzie in 1938 in Canada [62] and expanded upon by Krynauw in South Africa in 1950 [63].

The field of epilepsy surgery was radically changed with the advent of electroencephalography (EEG) and its application to epilepsy diagnosis, most importantly by Gibbs, Gibbs and Lennox [64] in the USA and Jasper and Kershman [65] in Canada. The latter were the first to recognize that temporal lobe EEG spikes were characteristic of what had been referred to as psychomotor seizures, and Bailey and Gibbs [66] were the first to report a series of temporal lobe corticectomies, based on EEG evidence alone. In the same year, however, Jasper and colleagues [67] provided detailed descriptions of the scalp and intraoperative EEG findings, including a seizure originating in mesial temporal structure, on a larger series of patients who had undergone temporal corticectomies, reported by Penfield and Flanigin [68] a year earlier. Following these reports, centres all over the world began performing temporal lobe resections for psychomotor seizures, and a new era of epilepsy surgery had begun. Subsequent important developments included recognition that mesial temporal structures needed to be resected [69], the development of chronic intracranial recording [70,71], EEG telemetry [72] and *en bloc* resection of mesial temporal structures [73], which ultimately led to the recognition of hippocampal sclerosis [74] as the most common lesion in what has now come to be known as mesial temporal lobe epilepsy (MTLE).

For several decades, interictal and ictal EEG abnormalities derived from scalp recordings, depth and subdural electrodes, and intraoperative electrocorticography, provided the most important localizing information for epilepsy surgery, but additional important confirmatory evidence was provided by a number of other approaches, including neuropsychological evaluation [75], including the intracarotid amytal test [76], until the advent of modern neuroimaging in the late 1970s. The first, X-ray computed tomography (CT), identified relatively large structural lesions, but not hippocampal sclerosis [77]. Next, positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose (FDG) identified mesial temporal hypometabolism in a large percentage of patients with TLE [78,79] and children with cortical dysplasia [80]. Then, ictal single-photon emission computed tomography (SPECT) revealed areas of hyperperfusion that often delineated the epileptogenic region [81]. Later, the development of high-resolution magnetic resonance imaging (MRI) not only revealed various structural lesions that could be seen on CT, but also delineated hippocampal sclerosis [82] and areas of cortical dysplasia [83] in patients who previously would have been diagnosed with non-lesional, cryptogenic epilepsy. With this development, the field of epilepsy surgery has, for the most part, returned back to its lesion-directed roots, with electrophysiology providing essential confirmatory evidence that the lesion is epileptogenic. Localization of so-called non-lesional, or cryptogenic, focal epilepsies, as well as epilepsies associated with diffuse or multifocal lesions in which only a small area generates the habitual seizures, must still be based primarily on electrophysiological, usually invasive, investigations, and these conditions remain a major frontier for future research. There continue to be rapid developments, however, in both structural and functional neuroimaging that undoubtedly will contribute importantly to facilitation of presurgical evaluation, and the cost-effective identification of greater numbers of surgical candidates in the future, as well as improved safety and efficacy of surgical intervention.

Epileptic disorders

The International League Against Epilepsy (ILAE) has defined epilepsy as 'a chronic disorder of the brain characterized by an enduring propensity to generate epileptic seizures, and by the neurobiological, cognitive, psychological and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one seizure' [84]. Although the ILAE is in the process of reviewing the definition and classification of epilepsy syndromes [85], according to the 1989 International Classification [86], which remains in effect, the underlying predisposition may be idiopathic (primary) or symptomatic (secondary). At the present time, only symptomatic epilepsies are treated surgically.

The progressive nature of epilepsy

Whereas idiopathic epilepsies are largely benign and seizures often remit in adolescence or early adulthood, some symptomatic epilepsies exhibit progression; epileptic seizures can become more frequent and/or more severe, and disabling interictal behavioural disturbances can appear. Early surgical intervention is particularly important when progressive features of an epileptic condition are present. Symptomatic epilepsies due to diffuse bilateral brain damage are usually associated with generalized seizures, as well as developmental delay and mental retardation, which, to a large extent, can be attributed to the underlying pathophysiological substrate. The complex partial seizures of mesial temporal lobe epilepsy (MTLE) [87–89] often become pharmacoresistant [90]. In this situation, the appearance of certain disabling interictal behavioural disturbances can be directly attributed to psychological and social causes; however, there is also evidence that other disturbances, and also worsening of seizures, and even structural changes, can reflect direct progression of the epileptogenic process [91,92]. Phenomena described in experimental animal models, such as kindling [93] and the mirror focus phenomenon [94], provide indisputable evidence of secondary epileptogenesis, whereby repeated epileptic discharges give rise to additional distant areas of epileptogenicity and enduring disruption of normal function. Furthermore, chronic epileptic activity induces natural homeostatic seizure-suppressing mechanisms that act to terminate ictal events, prevent their generation, and limit their spread. These protective influences account for some postictal deficits and undoubtedly have a more persistent effect on normal neuronal function, perhaps contributing to the occurrence of interictal behavioural disturbances [91]. There is also evidence to support concern that frequent seizures or epileptiform discharges can interfere with normal growth and development of the immature brain [95], and contribute directly to progressive memory disturbances that, in some cases, can be irreversible [96].

Clinical evidence supports the detrimental effect of continuing seizures on subsequent ictal manifestations and interictal behaviour. For instance, outcome after surgical resection for TLE and neocortical epilepsy appears to be better when the interval between the onset of seizures and surgical intervention is short [97]; surgical resection of a localized area of cortical dysplasia in infants and small children with infantile spasms can not only eliminate spontaneous seizures, but also reverse developmental delay [98]; and anterior temporal lobectomy, which is successful in abolishing spontaneous seizures, improves memory function of the contralateral temporal lobe, and commonly increases intelligence [99].

The concept of surgically remediable epilepsies

So many new antiepileptic drugs have been introduced in the past two decades that it would now literally take a lifetime to prove the inability of each drug, alone and in combination, to stop seizures in any individual patient. Consequently, true medical intractability, or pharmacoresistance, is an impractical concept for selecting surgical candidates. A major advance in the field of epilepsy surgery, therefore, has been the identification of specific epilepsy syndromes that are *surgically remediable* [100] (Table 60.1). Best patient care requires identification of such patients early in the course of their disorders, as soon as first-line antiepileptic medications fail, and referral to epilepsy surgery centres at

Table 60.1 Surgically remediable epilepsy syndromes.

Characteristic features
Known pathophysiology
Predictable natural history
Unresponsive to pharmacotherapy
Progressive features (e.g. developmental delay or interictal behavioural disorders)
Most cost-effective surgical candidates because
Presurgical evaluation can be performed non-invasively
70–90% chance of complete elimination of disabling seizures
Disabling behavioural consequences can be avoided or reversed, but only if surgical intervention is early
Examples
Mesial temporal lobe epilepsy
Epilepsies due to well-circumscribed resectable lesions
Epilepsies in infants and young children due to large or diffuse lesions limited to one hemisphere (e.g. porencephalic cysts, Rasmussen's encephalitis, Sturge–Weber, hemimegencephaly, and other large malformations of cortical development)

Table 60.2 The syndrome of mesial temporal lobe epilepsy.

History
Increased incidence of complicated febrile convulsions or other cerebral insults early in life
Increased incidence of a family history of epilepsy
Onset in second half of first decade of life
Auras common and occur in isolation
Secondary generalized seizures occur infrequently
Seizures often remit for several years until adolescence or early adulthood
Seizures often become medically intractable
Interictal behavioural disturbances can occur (most commonly depression)
Clinical seizure
Aura is usually present. Most common is epigastric rising, often other autonomic or psychic symptoms, with emotion (e.g. fear), can be olfactory, gustatory or non-specific somatosensory sensations (several seconds)
Complex partial seizure. Often begins with arrest and stare, oro-alimentary automatisms and complex automatisms common. Posturing of one upper extremity may occur contralateral to the ictal discharge (1–2 min)
Postictal phase. Usually includes disorientation, recent memory deficit, amnesia for the event and dysphasia if seizures begin in the language-dominant hemisphere (several minutes)
Neurological and laboratory evaluation
Neurological examination usually normal except for memory deficit
Unilateral or bilateral independent anterior temporal EEG spikes, maximum amplitude in basal electrodes
Extracranial ictal EEG activity appears only with complex partial symptoms, usually initial or delayed focal onset pattern of 5–7/s rhythmic activity, maximum amplitude in one basal temporal derivation
Usually temporal lobe hypometabolism on interictal FDG-PET, often involves ipsilateral thalamus and basal ganglia
Usually temporal lobe hypoperfusion on interictal SPECT and characteristic pattern of hyper- and hypoperfusion on ictal SPECT
Usually material-specific memory disturbances on neuropsychological testing and amnesia with contralateral intracarotid sodium amytal injection
Hippocampal atrophy usually visible on MRI

EEG, electroencephalogram; FDG-PET, fluorodeoxyglucose-positron emission tomography; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single photon emission computed tomography.

Table 60.3 Common surgical procedures for epilepsy and numbers performed worldwide between 1986 and 1990.

Procedure	Number of patients (%)
Anterior temporal resections	4862 (59)
Amygdalohippocampectomy	568 (7)
Extratemporal resection	1073 (13)
Lesionectomy	440 (5)
Hemispherectomy and large multilobar resections	448 (5)
Corpus callosotomy	843 (10)
Total	8234 (100)

From ref. 4 with permission.

a time when surgical intervention provides the greatest opportunity for curing the epilepsy condition and preventing the appearance of irreversible adverse psychological and social consequences. The prototype of a surgically remediable epilepsy syndrome is MTLE, particularly when it is associated with hippocampal sclerosis (Table 60.2). Other examples include limbic and neocortical epilepsies due to well-circumscribed structural lesions that can be easily resected, and certain childhood syndromes amenable to large multilobar resections or hemispherectomy, such as Sturge–Weber syndrome, Rasmussen's encephalitis, hemimegencephaly, large porencephalic cysts and catastrophic secondary generalized epileptic disorders of infancy and early childhood due to localized areas of cortical dysplasia. In such patients, surgery can usually be recommended with minimal, non-invasive, presurgical evaluation, and outcome is excellent by definition; therefore, continuing exhaustive trials of antiepileptic medications unnecessarily delays a definitive therapeutic intervention. Patients with medically refractory symptomatic epilepsies who do not have surgically remediable epilepsy syndromes, as defined here, may still be candidates for surgical intervention. For these patients, the underlying substrate is more complicated, chronic intracranial recordings most likely will be necessary, and there is less of a chance that they would be become seizure free than if they had a surgically remediable syndrome. It may, therefore, be reasonable to continue pharmacotherapy longer in this group of patients, and surgical treatment may not be sufficiently cost-effective to warrant pursuing such therapy in developing countries with limited resources.

Types of surgical treatment for epilepsy

The surgical treatments commonly used for epilepsy are shown in Table 60.3, with the numbers of each procedure performed worldwide between 1986 and 1990, when the last global survey was taken. Most surgical procedures involve resection of a presumed epileptogenic region. The area of resection may be standardized, determined by what is assumed to be a pathophysiological mechanism common to all patients with a particular form of epilepsy, or it may be tailored to the particular needs of each patient. Other surgical interventions

include disconnection, ablation and chronic stimulation. Surgical therapy for epilepsy can require awake procedures, and specialized anaesthetic approaches are often required (see Chapter 80).

Standardized resections

Examples of standardized resections include amygdalohippocampectomy and hemispherectomy (see Chapters 69 and 73). The former approach was designed to remove the least amount of tissue responsible for spontaneous complex partial seizures originating in mesial temporal structures. Evidence suggests that inclusion of the parahippocampal gyrus is important for successful results of amygdalohippocampectomy [101]. Performance of a hemispherectomy, on the other hand, is based on the assumption that the entire hemisphere is involved in the epileptogenic process, and that so little normal function remains that there is no reason to attempt to spare any particular cortical area. Complete removal of one hemisphere, termed an 'anatomical hemispherectomy', causes a relatively high incidence of late complications, including hydrocephalus and intracranial haemorrhage due to decreased absorption of cerebral spinal fluid by remaining arachnoid villi, and movement of the remaining hemisphere within the cranial vault. Several modifications of the hemispherectomy procedure are currently performed in an attempt to reduce the risk of late complications, and many centres today perform various types of hemispherotomy: removal of a minimal amount of brain tissue, followed by disconnection of the remainder of the hemisphere, leaving it *in situ* (see Chapter 73).

Anterior temporal lobectomies can be either standardized or tailored (see Chapter 69). Early standardized resections removed 4–7 cm of the anterior temporal lobe, including mesial temporal structures, sparing the superior temporal gyrus on the dominant hemisphere. A more recent modification, the anteromesial temporal resection, removes the temporal pole, spares most of the lateral cortex and extends the mesial temporal resection posteriorly. Standardized temporal resections are performed in patients with MTLE because the pathological substrates, usually hippocampal sclerosis, are presumed to create an epileptogenic region that is sufficiently similar from patient to patient that the same resection is generally effective. The presurgical evaluation for a standardized resection need only demonstrate that the patient has the type of epilepsy that responds to the surgical procedure, and that the primary epileptogenic region is within the boundaries of the brain tissue to be removed.

Tailored resections

Tailored temporal lobe resections require presurgical evaluation that identifies not only the location of the epileptic brain tissue, but also its extent. This commonly requires intracranial recordings, either intraoperative interictal spike mapping or extraoperative ictal recordings with subdural grid or depth electrodes (see Chapter 62). There remains controversy, however, concerning the relative values of ictal versus interictal epileptiform abnormalities as guides for determining the extent of a tailored temporal lobe resection, and justification for these added diagnostic procedures in patients with MTLE has been questioned. Nevertheless, there are situations when intracranial recording can suggest active epileptic activity in the posterior temporal region, indicating the need for a more extensive resection, on the one hand, or epileptic activity limited to cortical areas (e.g. the temporal pole, adjacent to a structural lesion that would permit a resection that spares mesial temporal structures), on the other.

Neocortical resections are always tailored, but again there is controversy concerning the relative value of interictal versus ictal epileptiform activity recorded directly from the surface of the brain for determining the extent of tissue to be removed. In some patients, merely removal of a discrete structural lesion (lesionectomy), such as a glioma, is sufficient to eliminate spontaneous ictal events, while in other patients removal of cortical margins is also necessary (see Chapters 70 and 71). Although lesionectomy is clearly the procedure of choice when the epileptogenic lesion is within essential primary cortex, more data are needed to determine what types of epileptogenic lesions are most likely to respond to this conservative approach. A unique application of lesionectomy is removal of hypothalamic hamartomas, which can successfully abolish gelastic seizures (see Chapter 75). In patients with malfunctions of cortical development, such as focal cortical dysplasia and other subtle lesions, MRI may not be helpful and direct cortical recording is necessary to define the epileptogenic zone (see Chapters 72 and 77). Neocortical resections are also tailored to avoid damage to adjacent essential primary cortex that could cause additional neurological deficits. In these situations, functional mapping is necessary, which can be performed intraoperatively (see Chapter 76), or extraoperatively with subdural grid electrodes (see Chapter 62). More recently, functional magnetic resonance imaging (fMRI) or magnetoencephalography (MEG) can be sufficient for this purpose in some patients (see Chapters 63 and 64).

Disconnection surgery

Disconnection surgery is performed as a treatment for epilepsy to disrupt propagation along pathways that determine the clinical manifestation of ictal events. The most commonly performed disconnection surgery is corpus callosotomy (see Chapter 74); prevention of interhemispheric propagation appears to abolish or reduce the occurrence of drop attacks due to atonic seizures, brief tonic seizures and myoclonic seizures. Most patients experience beneficial results from an anterior two-thirds callosotomy, which is not likely to be associated with adverse disconnection syndromes. When anterior two-thirds section is unsuccessful, and in patients with severe mental retardation in whom disconnection symptoms would not add to the disability, complete section of the corpus callosum can be performed. Because vagus nerve stimulation (VNS) can be effective against drop attacks, this less invasive approach is now usually tried *before* callosotomy, and there has been a decrease in the number of patients undergoing corpus callosotomy in recent years (see Chapter 81).

Multiple subpial transection (MST) disconnects corticocortical fibres in order to prevent lateral spread of epileptic activity while retaining the structure of cortical columns responsible for func-

tion (see Chapter 75). This procedure can be carried out in primary motor and language cortices, with little or no neurological deficit, and can be effective in eliminating or reducing seizure generation. It is most often used in combination with a tailored cortical resection, when the epileptogenic region encroaches on primary essential cortex and cannot be completely removed, but occasionally has been successfully used alone. Recent studies suggest that the effectiveness of MST is not as great as had originally been reported.

Stereotactic ablative surgery and stimulation

Stereotactic ablative surgery is also performed in some patients with epilepsy (see Chapter 78). Although amygdalotomy is no longer considered to be effective, there is increasing interest in the use of the gamma knife not only as a treatment for focal neocortical lesions, but also for MTLE (see Chapter 83). Continuous deep brain stimulation, targeting various subcortical structures, as well as response stimulation, which employs electrodes implanted into the epileptogenic region and connected to a device embedded in the skull that detects ictal onset and delivers an abortive stimulus, are promising experimental approaches currently under investigation (see Chapter 82). Gamma knife ablation and stimulation remain experimental therapies. Other investigative approaches to surgical treatment are discussed in Chapter 84.

Presurgical evaluation

Definition of terms

Clarification of terminology used for identifying abnormalities associated with an epileptogenic area of the brain has aided development of multidisciplinary presurgical evaluation protocols [102] (Table 60.4). When resective surgery is planned, presurgical evaluation is aimed at identifying the *epileptogenic zone*, which is defined as the area of brain necessary and sufficient for generating spontaneous seizures. This, therefore, is the minimal amount of brain tissue that must be removed to eliminate habitual seizures. The epileptogenic zone is a theoretical concept, and its boundaries cannot be accurately identified; however, they can be approximated by a variety of diagnostic procedures that define other areas of abnormality associated with the epileptogenic zone.

The *irritative zone* is that area of cortex that generates interictal spikes. Although the scalp electroencephalogram (EEG) in some patients can reveal a single EEG spike focus, defined as the area where interictal spike amplitude is maximal, direct recording from brain with depth, subdural strip or grid electrodes reveals that these scalp transients reflect widespread cortical generators (see Chapters 61 and 62). The irritative zone, therefore, can be extensive, and multiple irritative zones may exist. For instance, in MTLE it is common for interictal spikes to be recorded independently from both mesial temporal areas. Functional MRI (fMRI) with EEG is now being used to identify anatomical substrates of the irritative zone (see Chapter 66). The irritative zone is usually much larger than the epileptogenic zone.

The *ictal onset zone* refers to that area of cortex where initial EEG ictal discharges are recorded. Whereas a characteristic sphenoidal ictal onset pattern has a high correlation with mesial temporal ictal onsets [103], and scalp electrodes can occasionally identify the site of onset of neocortical seizures, precise definition of the ictal onset zone often requires intracranial electrodes (see Chapters 61 and 62). In some circumstances, propagation at seizure onset is rapid, and areas of early propagation might also be considered part of the epileptogenic zone. Identification of the ictal onset zone helps to localize the epileptogenic zone, but it is uncertain how this information can contribute to determining its actual extent. Ictal SPECT and fMRI can now also be used to help delineate the ictal onset zone (see Chapters 64 and 65).

The *epileptogenic lesion* is the structural abnormality believed to cause the epilepsy condition. This can include hippocampal sclerosis, malformations of cortical development, neoplasms, congenital defects, scars, vascular malformations, cysts and all

Table 60.4 Definition of abnormal brain areas.

	Definition	Measures
Epileptogenic zone	The area of brain that is necessary and sufficient for initiating seizures and whose removal or disconnection is necessary for abolition of seizures	Theoretical concept
Irritative zone	Area of cortex that generates interictal spikes	Electrophysiological (invasive and non-invasive)
Ictal onset zone	Area of cortex where seizures are generated (including areas of early propagation under certain circumstances)	Electrophysiological (invasive and non-invasive)
Epileptogenic lesion	Structural abnormality of the brain that is the direct cause of the epileptic seizures	Structural imaging and tissue pathology
Symptomatogenic zone	Portion of the brain that produces the initial clinical symptomatology	Behavioural observation and patient report
Functional deficit zone	Cortical area of non-epileptic dysfunction	Neurological examination, neuropsychological testings, EEG, PET, SPECT

From ref. 102 with permission.

EEG, electroencephalogram; PET, positron emission tomography; SPECT, single photon emission computed tomography.

other pathological substrates for epilepsy. For some lesions, such as hippocampal sclerosis, the ictal onset zone can be within the lesion; for others, seizures begin adjacent to the lesion; while in still others, EEG epileptiform abnormalities can be most prominent at a distance from the lesion. Although the epileptogenic zone includes the epileptogenic lesion, the former is usually more extensive than the latter. Surgical results are poor if the epileptogenic lesion is not entirely removed; however, there are exceptions, as with schizencephaly, where only part of this extensive lesion is usually epileptogenic and localized subtotal removal can eliminate seizures [104]. Most epileptogenic lesions can now be identified by high-resolution MRI, but some are diagnosed only on pathological evaluation of resected tissue (see Chapter 64). It is important to note that patients with focal seizures can occasionally have incidental structural lesions that are not epileptogenic and therefore do not help in defining the epileptogenic zone.

The *symptomatogenic zone* refers to the area of brain responsible for generating the initial clinical symptoms. Frequently, the epileptogenic zone is in a so-called 'silent area' of the brain, and ictal symptoms reflect propagated discharges. In these situations, the symptomatogenic zone is not within the epileptogenic zone; however, identification of the symptomatogenic zone can help determine propagation pathways that confirm the location of the epileptogenic zone defined by other data.

Areas of epileptogenicity in the brain are also associated with non-epileptic dysfunction that can appear as neurological or cognitive deficits on neurological or neuropsychometric examinations (see Chapter 67), non-epileptic EEG abnormalities (see Chapters 61 and 62), areas of hypometabolism on FDG-PET and areas of hypoperfusion on SPECT (see Chapter 65). These non-epileptic disturbances define a zone that reflects disturbances directly due to the epileptogenic lesion, as well as areas that undergo enduring changes due to ictal generation and propagation. Consequently, the *functional deficit zone* can be much larger than the epileptogenic zone, although in some patients there is no identifiable functional deficit zone.

The battery of diagnostic tests that constitute the presurgical evaluation is determined in part by the type of epilepsy or epileptic seizures exhibited by the surgical candidate, and in part by the type of surgical procedure to be performed. For instance, estimates of the location and extent of the epileptogenic zone are necessary when surgical resection is planned; however, this need not be exact for large standardized resections, such as hemispherectomies, should be limited to mesial and anterior temporal lobe for standardized anteromesial temporal resections, and must be localized specifically to mesial temporal structures for amygdalocampectomies. On the one hand, precise delineation of the extent of the epileptogenic zone is necessary when tailored resections are to be undertaken, but, on the other, this is not necessary at all for lesionectomy, or when corpus callosotomy is intended, except as required to rule out the possible benefit of a more definitive resective procedure. In infants and small children, larger tailored resections can be performed without producing irreversible neurological deficit, because of the plasticity of the developing brain. Furthermore, localization of the epileptogenic zone is difficult; therefore, the risk and expense of chronic intracranial electrophysiological recordings to more precisely identify the boundaries of an epileptogenic zone may not be as justified as in older patients undergoing tailored resections (see Chapter 77).

Candidate selection

Identification of potential surgical candidates requires a detailed history, including a description of all habitual epileptic seizures, a neurological examination, and psychiatric and social evaluations. This leads to (1) a presumptive diagnosis of epileptic seizures and, if possible, an epilepsy syndrome; (2) an impression of the likelihood that surgical intervention will be of benefit; and (3) insight into the most appropriate surgical procedure to be considered. Psychosocial issues are important for determining how the patient will respond to presurgical evaluation and surgical treatment, and whether improvement or cure of the epileptic condition will have sufficient impact on quality of life to justify the risks and expense. Psychopathology, such as depression, may even predict seizure outcome (see Chapter 68). Patients are not considered candidates for surgical treatment if they have an underlying neurodegenerative disease or there is a medical contraindication to surgery. An intelligence quotient (IQ) below 70 suggests widespread brain involvement and is likely to be associated with a diffuse or bilateral epileptogenic zone, so this is a relative contraindication for localized resective surgery. Mental retardation is not a contraindication for corpus callosotomy, and developmental delay is actually an indication for hemispherectomy or multilobar resection in infants and small children, in whom psychomotor deterioration can be reversed by a beneficial surgical procedure (see Chapter 77). Chronic psychosis is also a relative contraindication for surgical treatment, because the psychotic symptoms do not usually resolve, even when surgery is effective in abolishing epileptic seizures. However, there is no evidence that the surgical treatment makes psychosis worse (see Chapter 68). Therefore, successful surgical intervention simplifies management and improves quality of life to the extent that it can be justified in some psychotic patients, even though they will remain disabled. It is important in this situation to distinguish between patients with chronic psychosis and those with seizure-related psychotic symptoms, such as postictal psychosis, because in this situation surgical intervention that eliminates seizures will also eliminate the psychotic behaviour.

Non-invasive tests of epileptic abnormalities

The electrophysiological presurgical evaluation begins with the interictal EEG (see Chapter 61). Localized interictal spike discharges help to define the irritative zone, and localized non-epileptiform abnormalities, such as slowing and attenuation of normal rhythmic activity, help to identify the functional deficit zone. Neuroimaging is now an essential part of the initial presurgical evaluation. High-resolution MRI identification of hippocampal atrophy and/or hyperintensity on T2 imaging, as well as hypometabolism on FDG-PET, correlate highly with the presence of hippocampal sclerosis (see Chapters 64 and 65). In patients with neocortical focal epilepsy, high-resolution MRI will now usually identify a structural lesion, but when MRI is negative, FDG-PET can still reveal focal hypometabolism of the

epileptogenic zone, particularly in cases of focal cortical dysplasia (see Chapter 65).

Patients with neuroimaging evidence of a focal abnormality spatially consistent with the seizure semiology are likely to have a surgically remediable epilepsy syndrome, particularly when interictal EEG spikes are predominantly localized to the same area. The next step in the presurgical evaluation is inpatient video-EEG monitoring to capture spontaneous seizures (see Chapter 61). If MTLE is suspected, basilar electrodes are used. Although sphenoidal electrode placements were recommended in the past, T1T2 surface placements appear to be equally useful for most patients, and sphenoidals are now used mainly when results with these electrodes are equivocal. A typical 5–7 Hz build-up of activity in one basal electrode, within 30 s of a more diffuse (but not contralateral) EEG change, is highly diagnostic of ictal onset in the ipsilateral hippocampus; however, such patterns can be falsely lateralizing, particularly when the involved hippocampus is severely atrophic (the burned-out hippocampus). Ictal EEG onset patterns are less useful for neocortical epileptogenic regions, but usually provide lateralizing information at least. Although it has been argued that inpatient video-EEG monitoring is not always necessary, particularly when there is excellent correlation among seizure semiology, a focal structural lesion on MRI and focal interictal EEG spikes, in most patients ictal recordings are also important to ensure that the events in question are not psychogenic non-epileptic seizures.

Neurocognitive testing provides additional information concerning the location and extent of the functional deficit zone (see Chapter 67). A routine battery of psychometric tests is used, particularly to distinguish between temporal lobe and frontal lobe disturbances and to lateralize these disturbances to the language-dominant or non-dominant hemisphere.

Information regarding the location of the irritative zone can now be reliably obtained with magnetoencephalography (MEG) (see Chapter 63), as well as EEG fMRI (see Chapter 64). Information concerning the location of the ictal onset zone can be obtained with ictal SPECT (see Chapter 65), and occasionally with MEG or fMRI when patients have seizures in the magnet. Localized functional and structural abnormalities can also be identified with MR spectroscopy (MRS), and functional deficit zones may be obtained by mapping cortical functions with fMRI (see Chapter 64). At present, all of these tests are considered to be confirmatory, and are usually used in patients who are not considered surgical candidates on the basis of non-invasive evaluation alone, in order to help determine the placement of intracranial electrodes for invasive evaluation.

Intra-arterial amobarbital procedures (IAP) are used to (1) determine hemispheric dominance for language; (2) confirm that the temporal lobe contralateral to an anterior temporal lobe resection can support memory; and (3) evaluate memory function in the temporal lobe ipsilateral to a presumed mesial temporal epileptogenic region (see Chapter 67). When IAP reveals that language dominance is in the right hemisphere, particularly in a right-handed patient, this suggests a left hemisphere functional deficit, confirming other evidence for an epileptogenic zone in the left hemisphere. When one temporal lobe is unable to support memory, this suggests a functional deficit zone that confirms a suspected epileptogenic region in that temporal lobe. Most centres still consider the IAP necessary to demonstrate that the hemisphere contralateral to a planned mesial temporal resection can support memory. It is becoming increasingly difficult to perform the IAP in many countries, however, because of a chronic shortage or unavailability of amobarbital. fMRI is now considered adequate for demonstrating hemispheric dominance for language, but has not yet provided a reliable way to confirm unilateral hippocampal dysfunction. Etomidate has been successfully used in some centres as a substitute for amobarbital (see Chapter 67).

Invasive testing

If the tests discussed above are not concordant, or fail to yield sufficient information to identify the location of the epileptogenic zone, but a reasonable hypothesis can be made concerning the likely location of a resectable epileptogenic zone, intracranial recordings can usually provide the additional necessary localizing information (see Chapters 62 and 78). Stereotactically implanted depth electrodes are the usual chronic recording technique preferred when the hypothesis for the epileptogenic zone includes the mesial temporal area, or deep neocortical areas that are not easily approached from the surface of the brain. Otherwise, subdural grid or strip electrodes can be used. The former provide a much more extensive cortical coverage and are necessary when there is a need for functional mapping, but these electrodes require a craniotomy and are usually only placed when the epileptogenic zone has been reliably lateralized. Subdural strip electrodes can be inserted through burr holes, so they can be placed bilaterally, and can also be placed under the temporal lobe to approximate mesial temporal areas as an alternative to depth electrodes. In some institutions, a semi-invasive approach utilizes foramen ovale electrodes, which can be inserted percutaneously into the ambient cistern to record from mesial temporal structures; however, they provide no invasive information regarding seizures that might originate outside this area [105]. Because interpretation of ictal EEG onsets with subdural grid electrodes is difficult, when additional information is required to determine the extent of the epileptogenic zone for a tailored neocortical resection, most centres now prefer intraoperative mapping of interictal EEG spikes to chronic invasive recording. Functional mapping can also be adequately performed intraoperatively, except in small children and the rare patient with limited capacity to cooperate under these conditions (see Chapter 76).

Diagnostic tests under investigation

There are a number of experimental techniques that may be useful in the future for defining the epileptogenic zone (see Chapter 66). A variety of neurophysiological procedures and novel PET tracers have demonstrated utility in identifying either the epileptogenic zone or an associated functional deficit zone. Optical imaging makes use of light reflectants to measure the state of neuronal activation, and can be used intraoperatively to visualize epileptic cortical activity [106]. Animal studies suggest the possibility that this technique might eventually be applicable through the intact skull. One experimental invasive technique involves implantation of microdialysis probes, which permit sampling of extracellular fluid before, during and after seizures [107].

There has been considerable recent interest in biomarkers of epileptogenesis and epileptogenicity. Biomarkers that indicate epileptogenesis would be useful for identifying not only patients at risk for epilepsy, but also patients with epilepsy who may have progression of their condition and, therefore, may be candidates for early surgical treatment. Interictal biomarkers that reliably delineate epileptogenic tissue could make it possible to determine the location and extent of the epileptogenic region without the need for expensive inpatient telemetry to capture seizures. Two such biomarkers are currently under investigation. One is the PET ligand α-methyl-tryptophan (AMT), which can, in some patients with seizures due to tuberous sclerosis who have multiple tubers, identify the one responsible for generating seizures [108]. AMT-PET has also been used to identify the epileptogenic region in other forms of focal epilepsy [109]. The other is high-frequency oscillations (HFOs) associated with interictal spikes and ictal onsets, particularly those in the frequency range of 200–600 Hz, termed fast ripples (FR) (see Chapter 62). FR recorded with microelectrodes from hippocampus and parahippocampal structures of patients with MTLE, and animal models of this condition, appear to be unique to areas that generate spontaneous seizures [110]. Recent investigations indicate that FR can also be recorded with standard depth and subdural electrodes, and that they have the same significance for neocortex as they do for hippocampus [111,112]. For HFOs to be most useful for presurgical evaluation, it would be necessary to devise ways to identify them non-invasively. It may be possible to do this with MEG, or there may be correlates of interictal spikes associated with FR on EEG-fMRI that are different from EEG-fMRI correlates of interictal spikes that are not associated with FR (see Chapter 66). Another promising technique involves statistical parametric mapping (SPM) of hippocampus and neocortex thickness mapping, which permits identification of discrete patterns of atrophy not apparent on visual analysis of MRI or volumetry [113,114]. FR appear to be uniquely associated with discrete areas of hippocampal atrophy [115], suggesting that these structural abnormalities could reliably identify epileptogenic areas.

Strategy for presurgical evaluation

Localized resections

When patients with suspected MTLE are considered for standardized anteromesial temporal resection, the presurgical evaluation begins with interictal EEG to identify the irritative zone, and MRI to localize an epileptogenic lesion (see Chapter 69). In many centres today, an FDG-PET scan is also performed to localize a functional deficit zone in the appropriate temporal lobe, while some centres prefer ictal SPECT. Inpatient video-EEG monitoring is then carried out to characterize the ictal EEG onset. If a localized mesial temporal ictal onset correlates with a mesial temporal lesion on MRI, or temporal hypometabolism on FDG-PET, and there are no confounding features from interictal EEG, seizure semiology, neuroimaging or neurocognitive studies, patients usually undergo IAP, and if the contralateral hemisphere supports memory, a standardized anteromesial resection can be performed. In some centres, if there is clear evidence of hippocampal sclerosis on MRI, and temporal hypometabolism on FDG-PET as well, only a lateralized EEG onset is required for anteromesial temporal resections without invasive testing. Most centres require more invasive information if amygdalohippocampectomy is intended, to ensure that the epileptogenic zone is not in temporal neocortex.

Tailored resections, either temporal lobe or extratemporal, require an initial non-invasive approach similar to that discussed above (see Chapters 69–72). However, additional evaluation is required to determine the extent of the epileptogenic zone. Furthermore, if the suspected epileptogenic zone is adjacent to essential cortex, functional mapping is also necessary. Specific delineation of the epileptic abnormality and functional mapping are achieved either by chronic subdural grid or by intraoperative recording and stimulation. If the results of invasive studies reveal that the epileptogenic zone includes primary essential cortex that cannot be resected, lesionectomy is one option, and MST of the epileptically involved essential cortex is another (see Chapter 75).

Multilobar resections and hemispherectomy

Patients with severe hemispheric dysfunction and unilateral seizures who are candidates for hemispherectomy or hemispherotomy require interictal and ictal EEG studies to confirm that the dysfunctional hemisphere is a source of epileptic activity, and that no seizures originate contralaterally (see Chapters 73 and 77). Structural imaging usually, but not always, demonstrates atrophy or other extensive pathology in the dysfunctional hemisphere. FDG-PET not only confirms the dysfunction by demonstrating hypometabolism of the involved hemisphere, but is also of value in determining that the metabolic activity of the contralateral hemisphere is normal. Evoked potentials can be used to identify residual function in the epileptogenic hemisphere. In some instances, when the occipital lobe appears structurally and functionally normal, and does not generate interictal spikes, a subtotal hemispherectomy may be performed, sparing the posterior visual cortex and pathways.

Multilobar resections are not only performed as subtotal hemispherectomies, but also as a form of tailored resections when the presurgical evaluation indicates that the epileptogenic zone is likely to involve parts of more than one lobe. In some centres, anterior temporal lobe resections are combined with partial frontal lobe resections when the ictal onset reveals rapid projection of the initial ictal discharge from one to the other.

Multilobar resections are also performed in infants and young children with secondary generalized catastrophic epilepsy when MRI and FDG-PET reveal large unilateral lesions, usually malformations of cortical development in the posterior brain area. In these patients, the interictal and ictal EEG and seizure semiology are often of little value in localizing the epileptogenic region; however, non-epileptic EEG abnormalities, such as asymmetrical sleep spindles, increased slowing or even attenuation of generalized epileptiform transients, are more likely to identify the epileptogenic zone. Intraoperative electrocorticography is usually necessary for delineation of the area to be resected.

Corpus callosotomy

Localization of the epileptogenic region is obviously not necessary for performing corpus callosotomy (see Chapter 74). Neverthe-

less, patients with drop attacks as the most disabling feature of a secondary generalized epileptic disorder are evaluated with interictal and ictal EEG, as well as structural and often functional imaging and neuropsychological testing, in order to be certain that there is no localized epileptogenic zone that would be amenable to a more definitive resection.

Ablative surgery and stimulation

Localization of the epileptogenic region, as discussed previously, is necessary prior to gamma knife ablation, and also for response stimulation, because electrodes need to be placed in the epileptogenic zone (see Chapters 82 and 83). It is possible to carry out response stimulation with electrodes in more than one epileptogenic zone, even when these areas are bilateral. Because deep brain stimulation is not dependent on the location of the epileptogenic zone, presurgical evaluation, as for corpus callosotomies, is merely necessary to confirm that the patient is not a candidate for a more definitive localized surgical resection.

Outcome

Outcome assessment is essential for evaluating the sensitivity and specificity of presurgical diagnostic tests and the efficacy of surgical interventions. Improvements in surgical treatment for epilepsy ultimately need to be validated by quantitative data on outcome, which also aid in improving the selection of appropriate candidates for the various surgical procedures. Outcome is measured with respect to not only the epileptic seizures, but also health-related quality of life (HRQOL), cognitive and social function and surgical complications.

Outcome with respect to seizures

Most centres currently utilize the seizure outcome classification shown in Table 60.5 from the Palm Desert conferences [38]. Although the alternative International League Against Epilepsy classification, shown in Table 60.6, is also used, it requires accurate documentation of preoperative seizure frequency [116].

Table 60.7 indicates outcome with respect to seizures for mesial temporal resections, neocortical resections, hemispherctomies and corpus callosotomies, obtained from a worldwide survey carried out in 1986, and another in 1991, when the last such survey was performed [38]. These data show a definite increase in the percentage of patients becoming seizure free, and a decrease in those not improved following anterior temporal lobectomy, in the more recent survey, suggesting that improvements in diagnostic

Table 60.5 Classification of postoperative outcome.

Class I: free of disabling seizures[a]
Completely seizure free since surgery
Non-disabling simple partial seizures only since surgery
Some disabling seizures after surgery, but free of disabling seizures for at least 2 years
Generalized convulsions with antiepileptic drug discontinuation only
Class II: rare disabling seizures ('almost seizure free')
Initially free of disabling seizures but has rare seizures now
Rare disabling seizures since surgery
More than rare disabling seizures since surgery, but rare seizures for the last 2 years
Nocturnal seizures only
Class III: worthwhile improvement[b]
Worthwhile seizure reduction
Prolonged seizure-free intervals amounting to greater than half the follow-up period, but not <2 years
Class IV: no worthwhile improvement
Significant seizure reduction
No appreciable change
Seizures worse

From ref. 38 with permission.

[a] Excludes early postoperative seizures (first few weeks).

[b] Determination of 'worthwhile improvement' will require quantitative analysis of additional data such as percentage seizure reduction, cognitive function and quality of life.

Table 60.6 ILAE proposal for a new classification of outcome with respect to epileptic seizures.

Classification	Definition
1	Completely seizure free; no auras
2	Only auras; no other seizures
3	One to three seizure days per year; ± auras
4	Four seizure days per year to 50% reduction of baseline seizure days; ± auras
5	Less than 50% reduction of baseline seizure days to 100% increase of baseline seizure days; ± auras
6	More than 100% increase of baseline seizure days; ± auras

From ref. 116 with permission.

Table 60.7 Outcomes before 1985 and from 1986 to 1990.

		Number of patients (%)			
		Seizure free	Improved	Not improved	Total
Limbic resections					
Before 1985		1296 (55.5)	648 (27.7)	392 (16.8)	2336 (100)
1986–1990	ATL	2429 (67.9)	860 (24.0)	290 (8.1)	3579 (100)
	AH	284 (68.8)	92 (22.3)	37 (9.0)	413 (100)
Neocortical resections					
Before 1985		356 (43.2)	229 (27.8)	240 (29.1)	825 (100)
1986–1990	ETR	363 (45.1)	283 (35.2)	159 (19.8)	805 (100)
	L	195 (66.6)	63 (21.5)	35 (11.9)	293 (100)
Hemispherectomies					
Before 1985		68 (77.3)	16 (18.2)	4 (4.5)	88 (100)
1986–1990	H	128 (67.4)	40 (21.1)	22 (11.6)	190 (100)
	MR	75 (45.2)	59 (35.5)	32 (19.3)	166 (100)
Corpus callosotomies					
Before 1985		10 (5.0)	140 (71.0)	47 (23.9)	197 (100)
1986–1990		43 (7.6)	343 (60.9)	177 (31.4)	563 (100)

AH, amygdalohippocampectomy; ATL, anterior temporal lobectomy; ETR, extratemporal resection; H, hemispherectomy; L, lesionectomy; MR, large multilobar resection.

approaches, including long-term EEG monitoring with basal electrodes and structural and functional imaging, have had a positive impact on the results of this procedure. These data also reveal that amygdalohippocampectomy and neocortical resections that include an epileptogenic lesion, only tabulated in the later series, are associated with an outcome with respect to epileptic seizures that is similar to that for anterior temporal lobectomy.

The results of extratemporal resection reveal no change in the percentage of patients becoming seizure free between the two surveys; however, there is a reduction in the percentage of patients not improved in the later series. With the widespread use of subdural strip and grid recordings for extratemporal resections after 1985, however, there have been many patients who received this surgical procedure based on electrophysiological evidence alone who would not have been considered surgical candidates prior to 1985. These patients, who do not have obvious structural lesions, do not do as well as patients with structural lesions, and account for the fact that there was no significant improvement in the percentage of patients who became seizure free. On the other hand, these new techniques appear to have reduced the number of patients who have inappropriate surgical resection and end up with no benefit.

In contrast to the outcome data for patients undergoing localized resections, patients with hemispherectomies and corpus callosotomies had poorer results in the more recent series compared with results obtained prior to 1985. It is important to note, however, that there has been a considerable increase in the number of patients who undergo these procedures, largely due to the fact that modified hemispherectomies greatly reduced the incidence of late complications, and that microsurgical approaches to corpus callosotomy, as well as the increased use of only anterior two-thirds section, greatly reduced occurrence of the disconnection syndrome. Consequently, both hemispherectomy and corpus callosotomy were being applied to a much larger group of patients for whom the risk prior to 1985 would have been too great to be justified by the chance of benefit. Because many more patients underwent these surgical interventions between 1985 and 1990 than previously, and most experienced some benefit while very few suffered severe complications, the advances in diagnostic and surgical technology also resulted in overall improved results. Continued improvements in outcome for these procedures are documented in Chapters 73 and 74.

More recently, the Western Ontario RCT [35] and the AAN practice parameter [37], which was a meta-analysis of 24 non-overlapping surgical series published between 1990 and 2000, also showed two-thirds of patients seizure free after temporal resections for TLE. The meta-analysis also evaluated neocortical resections and found 50% of patients seizure free, similar to results in Table 60.7. Although the AAN permitted the recommendation that temporal resection is the treatment of choice for pharmacoresistant TLE, they did not permit a similar recommendation for neocortical resections, because there was no RCT; however, given the similarities of outcome results among the RCT, the meta-analysis, and the figures in Table 60.7 for TLE, there is no reason to believe that the meta-analysis and Table 60.7 outcome figures for neocortical surgeries are any less biased. More recent published series of surgery for TLE have provided even better results.

Outcome with respect to seizures is more complicated than most studies would suggest, because a certain percentage of patients tend to relapse or remit over time. Relatively few long-term studies have been carried out, and these will be necessary in the future in order to fully understand the beneficial effects of surgical intervention [99,117].

Quality of life, cognitive and social outcomes

There are numerous ways of assessing quality of life in epileptic patients, but most studies today utilize one of the three versions of the Quality of Life in Epilepsy (QOLIE) scale, which was specifically designed to measure HRQoL in surgical series [118]. The Western Ontario RCT found quality of life to be significantly better in surgical patients than in those treated medically by the end of 1 year of follow-up, and there was a trend towards improved social function at that time measured by percentage of patients in school and employed [36]. The meta-analysis carried out for the AAN practice parameter included studies that utilized a variety of different instruments to assess HRQoL, and found this measure to be most improved if temporal or extratemporal resection eliminated all seizures [37]. However, in one study, HRQoL was not as good in patients who continued to have auras as in patients who were completely seizure free, but better than in patients who continued to have disabling seizures [119]. Transient psychiatric disturbances, most commonly depression, occurred in 25–40% of patients during the postoperative year, whether or not they were seizure free, but *de novo* psychiatric symptoms, which were rare, were much more common in patients whose seizures continued (see Chapter 68). Verbal memory deficits were the most common postoperative cognitive disturbances following mesial temporal resections in the language-dominant hemisphere, particularly in patients whose verbal memory was normal preoperatively. Conversely, verbal memory improved after successful non-dominant temporal lobe surgery, and many patients who became seizure free postoperatively experienced an increase in IQ (see Chapter 67). Patients with pharmacoresistant epilepsy are often unemployed or underemployed; however, published studies were inconsistent with respect to whether successful surgical treatment improves their employment situation. In older studies, this is probably due to the fact that patients had seizures for many years prior to surgery, and were sufficiently disabled during critical periods of social and vocational development that they did not possess the skills to become employed and live independently, even if surgery relieved them of their seizures. It is anticipated that, with earlier interventions before psychological and social disabilities become irreversible, successful surgery will permit many patients to live relatively normal, independent lives. The practice parameter found that after temporal lobe resections, 79% of patients operated a motor vehicle, compared with 20% preoperatively, and 88% were living independently, compared with 68% preoperatively [37]. There is also evidence that mortality rate is reduced in patients who are seizure free post operatively [120], and the one patient who died during the Western Ontario RCT was in the medical arm of the study [35].

Surgical complications

The AAN practice parameter meta-analysis identified seven publications that permitted adequate analysis of surgical complica-

tions in 556 patients [37]. Two deaths occurred within 1 month of surgery, one due to trauma and the other not described. Six per cent of patients experienced new neurological deficits consisting of mild aphasias, cranial nerve III and IV palsies, visual field deficits greater than a quadrant and hemiparesis. Half of these resolved within 3 months and the other half were considered permanent. Most of the aphasias were receptive following temporal resections, and the hemipareses developed following cortical resections adjacent to motor cortex. Postoperative infections occurred in 5% of patients, most commonly in the wound, but also including meningitis and at least one brain abscess. Only one deep vein thrombosis was reported, and hydrocephalus occurred in three patients with large resections. Surgical complications are discussed in more detail in Chapter 79.

61 Scalp EEG in the Epilepsy Surgery Evaluation

Christine Bower Baca and John M. Stern

David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

Electroencephalography has been a central diagnostic test in epilepsy since the 1930s, and its role in the presurgical evaluation of patients with medically intractable epilepsy continues to be paramount. The goal of the presurgical evaluation is to identify the putative epileptogenic zone, which is the area of cortex that is necessary and sufficient for the generation of clinical seizures. This zone is operationally defined as the minimum amount of tissue that, if removed, would result in seizure cessation. Therefore, confirmation of the location, but not necessarily the extent, of the epileptogenic zone is best accomplished when the patient has achieved seizure freedom after a surgical resection. Nonetheless, preoperative identification of the putative epileptogenic zone is necessary, and this includes evaluation of the ictal behaviour and the interictal and ictal scalp electroencephalogram (EEG). Such analysis is conducted in concert with a variety of other diagnostic modalities assessing structure and function including high-resolution MRI, interictal fluorodeoxyglucose (FDG)-positron emission tomography (PET), ictal single photon emission computerized tomography (SPECT), neurocognitive testing, and sometimes magnetoencephalography (MEG) and functional MRI (fMRI) (see Chapters 62–66). The role of the EEG has changed over time with the additional structural and functional information that is provided by more recently developed investigative studies, and this has allowed for more patients to be eligible for epilepsy surgery and to proceed to resective surgery without the need for intracranial electroencephalographic monitoring (see Chapter 62). In patients for whom intracranial monitoring is necessary, scalp electroencephalography plays an integral role in planning the electrode placement locations.

Technical considerations

Scalp electrodes

Because focal epilepsy commonly arises from the mesial temporal region, additional electrodes are often added to the standard electrode locations specified by the international 10–20 electrode placement system. These electrodes consist of cheek (T1/T2), mastoid or sphenoidal electrodes, or, less commonly, foramen ovale electrodes. Although the use of these supplementary electrodes may facilitate the identification of mesial temporal epileptiform discharges, there is debate as to whether indwelling sphenoidal electrodes are more sensitive than surface basilar electrodes. In a study by Binnie *et al.* [1], 111 patients with epilepsy were evaluated with both sphenoidal and cheek electrodes. In 17 patients a superficial cheek electrode recorded all discharges seen at the sphenoidal electrode. For all but 2 out of 165 epileptic foci, cheek electrodes detected more than 90% of the discharges detected by the sphenoidal electrodes, which suggests that sphenoidal recordings conferred no meaningful advantage in the detection of interictal epileptiform discharges over anterior temporal cheek electrodes. In contrast, others have reported sphenoidal recordings to be superior to temporal scalp electrodes in ictal recordings. Pacia *et al.* [2] found that in 3 out of 31 patients all seizures appeared in the sphenoidal electrode at least several seconds (range 4–31 s) before the appearance in the temporal scalp electrodes. The opposite result was observed by Mintzer *et al.* [3], who found that sphenoidal electrodes were not superior to cheek electrodes for detection of seizures with mesial temporal lobe onset in an analysis of 101 ictal tracings in 31 patients with possible temporal lobe epilepsy (TLE). The yield of sphenoidal electrodes may depend, however, on their mode of insertion and the position in relation to the foramen ovale. Kanner *et al.* [4] found that sphenoidal electrodes inserted via fluoroscopic guidance (positioned immediately below the foramen ovale) displayed temporal lobe seizures earlier (≥5 s) and more reliably than did cheek electrodes. Seizure detection increased from 12% of foci among patients with unitemporal foci to 25% among patients with bilateral independent temporal foci, suggesting that carefully inserted sphenoidal leads may clarify ambiguities in some presurgical patients. Although the sensitivity of sphenoidal electrodes may depend on the mode of placement, their utility may decrease over time, depending on the degree of displacement. Wilkus and Thompson [5] found that there was an 8.1- to 8.5-mm displacement over an average of 5 days in place, with the degree of displacement correlating with duration since insertion, not seizure number. The use of indwelling sphenoidal electrodes has decreased over recent years, given the absence of definitive benefit from them, the discomfort of their insertion and their degradation of signal with movement. Similarly, the use of nasopharyngeal electrodes has fallen out of favour.

Additional scalp electrodes interspaced between the 10–20 electrode system also have been used to potentially improve the localization accuracy of scalp EEG [6]. However, approximately 10 cm^2 of cortical surface must be synchronously activated in order for there to be a potential recorded at the surface, and cortical potentials are volume conducted through the skull and

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

scalp [7]. This results in significant attenuation and blurring of activity. As such, the use of electrodes in a denser array is not standard or commonly performed.

Types of scalp EEG recording

Most epilepsy surgery centres use dedicated video-EEG monitoring equipment with simultaneous recording of EEG and video to identify the correlation between electrophysiological change and clinical behaviour during seizures. This establishes the diagnosis of epilepsy and helps localize the ictal onset and symptomatogenic zone (cerebral region of the seizure's first behavioural manifestation). The use of digital recording of both EEG and video has become common in recent years, as the cost of data storage has decreased and the quality of digital video recordings has improved. Such systems also allow for data reduction, online processing of the EEG for automatic detection of seizures and interictal epileptiform discharges (IEDs), and offline seizure analysis allowing for more detailed analysis of the spatial and temporal extent of ictal rhythms. Digital EEG also allows for montage reformatting, quantitative analysis of the EEG and digital filtering.

Recording other physiological parameters along with the EEG [including electrocardiogram (EKG), electromyogram (EMG), electro-oculogram (EOG) and respiratory rate] is also useful. Although these other parameters undoubtedly benefit the evaluation of physiological non-epileptic disorders associated with paroxysmal behavioural events, they are also important parameters to evaluate during epileptic seizures because of the physiological changes that accompany seizures. Reported EKG changes include tachycardia, bradycardia, conduction block, repolarization abnormalities and asystole [8]. Such EKG changes can occur around the time or even before the earliest EEG or clinical change and thus can potentially clarify the timing of the seizure onset. Moreover, although the exact relationship between these changes and sudden unexpected death in epilepsy (SUDEP) is not known, screening for serious EKG changes during seizures may benefit the patient's overall clinical care. EKG irregularities may appear in the EEG and can resemble the electrographic pattern of seizures, so including electrocardiography also benefits this possibility within the differential diagnosis.

Occasionally, ambulatory EEG has been used in the presurgical evaluation. Outpatient monitoring may be less informative than inpatient monitoring in some cases due to the inability to safely reduce medications, the inability to repair faulty electrode contacts, the limited video surveillance and the shorter duration of testing. However, ambulatory presurgical electroencephalography monitoring may be useful in a subset of patients. Chang *et al*. [9] reported a group of seven patients who had successful temporal lobe resections after presurgical EEG monitoring that was performed solely on an outpatient basis. Finally, it may be possible in a select number of patients with very frequent seizures, to utilize repeated periods of outpatient recordings (preferably with concomitant video) in order to avoid more costly inpatient testing [10].

Interictal EEG

The localization of IEDs is one means by which to identify the irritative zone, which may be related to the brain area that generates seizures, but also may reflect propagated abnormality or a region that is epileptically abnormal but not capable of generating seizures. As such, the irritative zone may extend beyond the epileptogenic zone. Localization of the irritative zone depends on the neurodiagnostic method used, which includes scalp and intracranial electroencephalography and magnetoencephalography/magnetic source imaging (MSI) [11,12] (see Chapters 62 and 63). IEDs may be infrequent and sometimes do not appear in routine electroencephalography studies of patients with known epilepsy. The yield of observing IEDs is increased with repeated routine EEGs; 50% of patients with interictal epileptiform abnormalities manifest this abnormality in the first EEG, whereas 92% of patients demonstrate it by the fourth EEG [13]. Nonetheless, a small proportion of patients with epilepsy will lack IEDs despite repeated EEGs [14], which may be due to an irritative zone that is not detectable with scalp EEG or the specific epilepsy condition. Long-term monitoring with scalp EEG may help identify rare IEDs in patients with repeatedly normal routine EEGs.

Evaluation of the interictal EEG and identification of the irritative zone is an integral part of the presurgical evaluation. Anterior temporal lobe resection (ATLR) remains the most commonly performed epilepsy surgery (see Chapter 68). Strictly unilateral anterior temporal IEDs have been reported to be associated with higher seizure control rates after ATLR. Walczak *et al*. [14] reported the results of 100 anterior temporal resections for complex partial seizures performed over 21 years and found that the presence of >5% of IEDs outside the surgical area correlated with a poorer outcome in the second postoperative year.

Unilateral focal temporal interictal epileptiform discharges

Several studies have questioned the need for long-term monitoring, particularly in cases of concordant hippocampal sclerosis and unilateral anterior temporal IEDs. For example, Cendes *et al*. [15] studied 184 consecutive patients with TLE and reported that unilateral hippocampal atrophy predicted ipsilateral interictal epileptiform abnormalities and ipsilateral seizure onsets with no false lateralization. The conclusion was that ictal EEG did not provide any additional useful information beyond that of MRI for these patients. As such, bypassing the ictal EEG and its associated hospitalization may be possible if all other data are concordant, and there is a reliable description of ictal behaviour that does not suggest the possibility of non-epileptic seizures (NESs). Others have shown that the concordance of MRI and interictal EEG is closely associated with surgical outcome in mesial TLE [16]. Cambier *et al*. [17] reported a series of 84 patients who underwent ATLR, in which those with unilateral hippocampal atrophy and concordant IEDs were found to be excellent surgical candidates even when long-term monitoring showed discordant or non-localizing ictal recordings. Specifically, 63 out of 69 patients (91%) with confirmatory and 14 out of 15 (93%) patients with non-confirmatory ictal EEG recordings were either seizure free or had only auras at mean follow-up of 24.1 months.

These studies raise the question of whether or not ictal recordings are a prerequisite for surgery in cases of isolated hippocampal sclerosis and unilateral concordant temporal IEDs. However, anterior temporal IEDs can sometimes represent false localization or lateralization from other epileptogenic regions, including

lateral temporal and frontal, parietal and occipital regions, and so localization outside of the mesial temporal lobe also needs consideration [18–21]. As such, ictal recordings remain a standard component of the epilepsy surgery evaluation regardless of the presence of unilateral anterior temporal IEDs and imaging abnormality.

Bilateral independent interictal epileptiform discharges

More than 25% of possible resective epilepsy surgery candidates have bilateral independent temporal IEDs on routine scalp EEG [22]. The degree of lateralization of IEDs in this population may be associated with postsurgical outcome. That is, a preponderance of IEDs on one side may result in a better outcome postoperatively [23,24]. Chung *et al*. [23] evaluated whether or not the degree of lateralization of bilateral independent temporal IEDs is correlated with a good outcome (number of seizures in second postoperative year) in a group of 59 patients who underwent ATLR, 31 of whom also underwent intracranial monitoring with depth electrode recordings. Ninety-two per cent of patients with greater than 90% lateralization had a good surgical outcome compared with 50% of those patients who had less than 90% lateralization, even when all depth electrodes identified an ictal onset zone that was always ipsilateral to the side of resection.

Extratemporal interictal epileptiform discharges

Interictal epileptiform discharges are usually less useful for localization in extratemporal epilepsies than in mesial TLE. For example, unilateral frontal lobe epilepsy may produce unilateral, bilateral independent, bilateral synchronous (bifrontal) and generalized IEDs [21]. In a study by Laskowitz *et al*. [21], which included 16 patients with refractory frontal lobe epilepsy, the interictal and ictal scalp EEGs had a relatively poor sensitivity and specificity for the localization of the epileptogenic zone. Similarly, occipital lobe epilepsy can be associated with non-localizing and non-specific IEDs, including bilateral independent occipital IEDs, bilaterally synchronous frontal and occipital IEDs, and bilateral independent temporal (including anterior, mid and posterior) IEDs [18,25,26]. However, exceptional situations exist in which posterior epilepsies may manifest focal IEDs. Such patients may be better candidates for resective surgery. In a series published by Blume *et al*. [18], a principal interictal spike focus was present in 15 out of 19 (79%) patients who underwent a posterior corticectomy [18]. This IED focus correlated with the scalp or subdural ictal recordings in 14 patients and with clinical analysis and CT scan in one patient. Within this series, patients who had IEDs distant from the focus were less likely to achieve seizure freedom following surgery. Likewise, IEDs are rarely localized and more commonly diffuse or bilateral independent in parietal lobe epilepsy. Interictal scalp electroencephalography did not localize the epileptogenic lobe in 14 seizure-free patients in a study of patients with parietal lobe epilepsy by Kim *et al*. [20]. In four patients, IEDs were lateralized to the epileptogenic hemisphere, whereas they were non-lateralized in seven patients and were falsely localized to the frontal–temporal region in three patients. In many cases of extratemporal epilepsy, IEDs are non-localizing and, therefore, not typically useful in determining the epileptogenic region or predicting surgical outcome. However, Holmes *et al*. [27] reported that a strictly unifocal, interictal epileptiform pattern on scalp EEG in a minority of patients with refractory extratemporal partial seizures is predictive of ictal onset and successful postsurgical outcome.

Interictal non-epileptiform changes

Non-epileptiform focal changes also can be useful in determining the ictal onset zone, but such changes are not as well studied. Koutroumanidis *et al*. [28] reported that lateralized, polymorphic temporal delta activity had a lateralizing value similar to that of temporal IEDs in a group of 141 patients who had undergone temporal lobe resection and whose MRI was normal or showed mesial temporal lobe sclerosis. Interestingly, resections that were ipsilateral to the slowing were significantly more likely to have a favourable outcome, regardless of the laterality or topography of IEDs. This suggests that candidates with lateralizing temporal delta and normal MRI should not be barred from further preoperative assessment. Slowing that is temporal intermittent rhythmic delta activity (TIRDA) is also highly associated with TLE and has been reported to represent an epileptiform abnormality [29]. Gambardella *et al*. [29] found that TIRDA was highly lateralized in patients with unilateral mesial temporal sclerosis and also concordant with IEDs, but was not as well lateralized in patients with bilateral atrophy.

Interictal epileptiform discharges and excluding patients from presurgical evaluation

Interictal data have been suggested to be helpful in identifying patients who may not benefit from epilepsy surgery, thereby, excluding patients who are unlikely to proceed to surgery from inpatient evaluation. DellaBadia *et al*. [30] evaluated the predictive value of 2 h of interictal sleep-deprived EEG, MRI and PET in advance of inpatient EEG monitoring in a group of 69 patients, 35 of whom were offered resective epilepsy surgery; very few patients with normal EEG, MRI and PET [1 out of 13 patients (7.7%)] proceeded to surgery.

Ictal scalp EEG

Ictal patterns

The ictal onset zone identified with EEG provides a critical component of the testing battery necessary to plan epilepsy surgery and typically is analysed in the context of other structural and functional testing to define the resection's boundaries. Identifying the earliest portion of the EEG's ictal onset is necessary to maximize the accuracy of the ictal onset zone's localization, but this is difficult because EEG patterns during seizures vary considerably. The EEG pattern for partial seizures typically includes an evolution of the ictal rhythm in its frequency, amplitude, spatial distribution and morphology. Although the ictal signature of partial seizures varies, there are certain patterns that are more common in certain brain regions. For example, seizures originating from the mesial temporal region are often associated with the development of sinusoidal activity in the delta frequency range, which increases in frequency into the theta range with simultaneous development of phase reversals across the anterior temporal electrodes (F7/F8, T1/T2, S1/S2) followed by postictal delta slowing in the same region [31,32]. Risinger *et al*. [32] analysed

706 ictal EEGs from 110 patients who subsequently underwent intracranial depth electrode placement and found that the presence of a 5-Hz, or greater, unilateral temporal/sphenoidal rhythm within the first 30 s in 57 patients correctly predicted an ipsilateral temporal depth onset in 82% of cases. This predictive accuracy increased to 94% in the 33 patients whose ictal EEGs met this standard for all of their seizures. Seizures of lateral temporal onset may have an electrographic signature similar to those of mesial temporal onset, but typically show a lower mean frequency (2–5 Hz) of lateralized polymorphic rhythmic activity with a more hemispheric distribution [33]. Foldvary *et al*. [33] analysed 486 ictal EEGs in 72 patients with focal epilepsy from the mesial temporal, neocortical temporal, mesial frontal, dorsolateral frontal, parietal and occipital regions and found that surface ictal EEG was localized in 72% of cases, more often in temporal versus extratemporal cases, with 57% of localized onsets originating from the mesial temporal, lateral frontal and parietal lobe regions. Lateralized onsets were seen more frequently in neocortical TLE and generalized onsets were seen more frequently in mesial frontal lobe epilepsy and occipital lobe epilepsy, with more false localization/lateralization occurring in occipital and parietal seizures. In patients with mesial frontal lobe epilepsy, the ictal EEG is frequently obscured by muscle artefact or shows no abnormality [21]. Alternatively, if ictal changes are present, they often appear generalized and can be misleading [31].

Postictal EEG changes

In addition to ictal changes, postictal changes can also be instrumental in identifying the epileptogenic region. Postictal slowing or attenuation of normal rhythms is usually lateralized to side of ictal onset, although it can be falsely lateralized due to variable propagation. Lateralized postictal changes were present in 64% of recordings and concordant with the side of surgical resection in 96% in a study by Jan *et al*. [34], which evaluated postictal scalp EEG changes in 80 seizures from 29 patients with TLE.

Inter-rater reliability of ictal EEG

Given the range of patterns that can be seen on ictal EEG, interpretation of ictal EEG can be difficult, but the need for high inter-rater reliability is paramount. In a study of 144 ictal recordings of 54 patients who underwent scalp and depth electrode monitoring, Spencer *et al*. [35] found 58–60% agreement for lobe of seizure onset and 64–74% agreement for side of seizure onset on ictal scalp EEG. This agreement was greater for patients with TLE and less for patients with frontal lobe epilepsy. Inter-rater reliability was high, with 76–83% of seizures correctly lateralized in a study by Walczak *et al*. [36], which analysed 137 complex partial seizures (119 temporal and 18 extratemporal) from 35 patients who subsequently underwent resective epilepsy surgery and were seizure free for 2 or more years. This number improved to 93–99% when seizures with generalized features or those with obscuration of the record by artefact were excluded.

Limitations of scalp ictal EEG

Although the ictal EEG is an integral part of the presurgical evaluation, there are certain situations in which interpretation of the ictal scalp EEG is compromised to a clinically significant extent. First, scalp EEG typically does not show ictal discharges during simple partial seizures, even if the seizure produces bilateral movements (i.e. seizures from the supplementary motor area) [21]. Similar limitations may occur during a subset of complex partial seizures, particularly those arising from the mesial frontal lobe [21]. In cases of frontal lobe onset, or sometimes occipital lobe onset, the ictal EEG may show generalized spike–wave activity [31]. In some young children with focal brain lesions, generalized or multiregional interictal and ictal EEG abnormalities may be present [37]. However, these abnormalities do not necessarily preclude resective epilepsy surgery. Wyllie *et al*. [37] reported 50 paediatric patients, aged 0.2–24 years (median 7.7 years), with severe refractory epilepsy and a potentially epileptogenic lesion on brain MRI (congenital or early acquired), who underwent hemispherectomy (or lobar or multilobar resection) (see Chapter 73). Despite the observation that 30–100% of preoperative epileptiform discharges (interictal and/or ictal) were generalized or contralateral to the side of surgery, 72% patients were seizure free at the 24-month median follow-up, suggesting that the diffuse EEG abnormalities may reflect an interaction between the developing brain and an early lesion.

False lateralization: mesial temporal lobe epilepsy

Scalp ictal electroencephalography recordings sometimes provide false lateralizing information. In the case of mesial TLE, this false lateralization is typically secondary to rapid contralateral propagation, which is undetectable with scalp electroencephalography. Rates of false lateralization of ictal scalp electroencephalography have varied. Spencer *et al*. [35] reported the accuracy of scalp ictal EEG reading to be 21–38% for the lobe and 46–49% for the lateralization of seizure onset [35]. More recent reports have disagreed with this high incidence of false lateralization in the case of TLE. Alarcon *et al*. [38] found that 10.9% of seizures were falsely lateralized in a study of 314 seizures in 110 patients with TLE who underwent simultaneous scalp and foramen ovale ictal recordings. Additionally, in a retrospective study by Mintzer *et al*. [39], five patients with unilateral hippocampal atrophy and contralateral surface ictal recordings had depth electrode implantation that showed clear ictal onset in the mesial temporal lobe ipsilateral to the imaging abnormality in four of five patients and an unusual bitemporal onset pattern in one patient. It was interpreted that this ictal scalp pattern was secondary to severe hippocampal sclerosis or 'burned-out hippocampus', causing atypical depiction of ictal discharges.

False lateralization: lesional epilepsy

Falsely localizing or lateralizing information also can be seen on scalp ictal EEG in the case of lesional epilepsy. Sammaritano *et al*. [40] reported that scalp/sphenoidal EEG recordings showed ictal onset on the side contralateral to a known gross focal cerebral lesion that was acquired early in life in a group of three patients. These patients subsequently had implanted depth electrodes documenting onset ipsilateral to the lesion and then remained seizure free for 3–13 years postoperatively [40].

Williamson *et al*. [41] found that only 1 out of 11 patients with parietal lesions showed a focal EEG onset concordant with the parietal lesion, whereas 2 of the 11 patients showed an ictal onset ipsilateral to the lesion, and 8 of the 11 patients showed no focal changes at ictal onset. Despite the high rate of discordance between the side of lesion and the ictal onset, 10 of the patients underwent lesionectomy and all had a good outcome.

Late-appearing scalp ictal EEG

Sometimes scalp ictal electroencephalography changes appear late. Risinger *et al*. [32] analysed 706 ictal EEGs from 110 patients and found that 28 patients had one or more seizures with a focal 5-Hz (or greater) temporal rhythm that developed after the appearance of some other type of diffuse or ipsilateral electrographic change. In 22 out of the 28 cases, this delayed rhythm correctly predicted an ipsilateral temporal onset that was confirmed with depth electrode recordings. In one out of the six remaining patients the delayed focal pattern was falsely lateralizing, whereas in the other five cases the subsequent depth electrode monitoring did not show a unifocal temporal ictal onset. Nonetheless, the predictive accuracy of the initial focal pattern (≥5 Hz within 30 s) compared with the delayed focal pattern was not statistically significant. However, it is not known from this study whether or not delayed patterns predict a different seizure-free rate after resective surgery. Blume *et al*. [42] evaluated delayed ictal onset on scalp in a study of 52 consecutive patients at University Hospital, London, who became seizure free during 2 years of follow-up after temporal lobectomy. In total, 13 out of the 52 patients (25%) had a clear focal onset ipsilateral to the side of lobectomy, whereas 39 (75%) patients did not; late (≥5 s after hemispheric, diffuse or artefact obscured change) lateralizing or localizing features ipsilateral to the side of lobectomy were apparent in 37 out of 39 (95%) patients, and two (5%) patients had late contralateral and shifting features. The authors concluded that late lateralizing or localizing seizures are still valuable in establishing the laterality of temporal epileptogenic zones but should not be used in isolation. Supplementary clinical testing data should support the lateralization and provide a suspected localization.

Bilateral independent temporal ictal EEG

Scalp ictal EEG sometimes shows evidence of bilateral independent temporal ictal EEG changes, and this often requires subsequent intracranial electroencephalography for localization of a singular ictal onset zone. Holmes *et al*. [24] reported a study of 42 adults with bilateral independent temporal ictal onset on scalp EEG. In total, 26 (62%) out of 42 patients had unilateral ictal onsets on subsequent intracranial studies – 25 of these patients were offered resective surgery and subsequently underwent a tailored temporal resection; overall, 64% of these patients were seizure free postoperatively, whereas 12% had a >75% reduction in seizures when one of the following factors was concordant with the side of surgery: preponderance of interictal scalp EEG discharges, unilateral temporal lesion on MRI or lateralized mesial temporal memory dysfunction on neuropsychological testing. The seven patients who had bilateral independent intracranial ictal onsets subsequently underwent resection based on a preponderance of seizures on one side (>80%) or other lateralized non-invasive abnormalities, and five of these patients (those with >80% seizures from one side) had a >75% reduction in seizures postoperatively. It was therefore concluded that intracranial monitoring may benefit patients with bilateral independent temporal seizures when other non-intracranial assessments show evidence of lateralization. In a study by Jenssen *et al*. [43] 24 patients had evidence of bilateral independent temporal seizures on scalp EEG [43]. Twenty of these patients subsequently underwent intracranial monitoring, of whom 12 patients had localized ictal onsets, whereas eight did not. Sixteen patients subsequently underwent anterior temporal lobectomy and 13 out of 16 (81%) were seizure free. Lateralized findings on MRI and PET, a history of febrile convulsions and shorter duration of epilepsy were all associated with a focal onset on intracranial EEG, perhaps suggesting that intracranial monitoring is not always necessary in the setting of bilateral independent temporal seizures. Further studies are needed to clarify whether or not intracranial monitoring can be avoided in patients with bilateral independent temporal seizures on scalp EEG and evidence of lateralization on other non-intracranial assessments (see Chapter 62).

Scalp ictal EEG in non-lesional MRI

Despite its many limitations, scalp electroencephalography is an integral part of the presurgical evaluation and its role in patients with brain MRI-negative scans is paramount. Although the number of MRI-negative patients undergoing resective epilepsy surgery has decreased with the improved resolution of MRI, normal MRI is not rare. High-resolution MRI may fail to detect pathologies, including focal cortical dysgenesis, focal atrophy and gliosis (see Chapters 64 and 72). Although the lack of MRI abnormality does not preclude eventual resective epilepsy surgery, it does require additional diagnostic tests, which typically includes intracranial monitoring [44]. Scott *et al*. [45] reported that only 3 out of 40 non-lesional patients eventually proceeded to epilepsy surgery compared with 100 out of 182 who had MRI abnormalities, which demonstrates the value of MRI abnormality when considering epilepsy surgery [45]. However, a recent study by McGonigal *et al*. [46] reported no difference in the number of proposed surgeries between MRI-negative and lesional cases in a group of 100 consecutive patients who underwent intracranial monitoring. Regardless of the number of MRI-negative cases proceeding to surgery, scalp EEG studies are essential for planning intracranial monitoring studies, and implantation locations typically depend upon localizing data from other investigative studies. Hong *et al*. [47] reported ictal scalp EEG, interictal FDG-PET and ictal SPECT in a group of 41 patients with non-lesional neocortical epilepsy and found that all three tests provided equal lateralizing value; however, ictal EEG was most likely to depict a focal region concordant with the resection when surgery was successful. Moreover, 33 (81%) patients were seizure free or had a seizure reduction greater than 90% at a mean follow-up of 2.77 years. Sylaja *et al*. [48] reported a group of 17 patients with normal MRIs who underwent successful epilepsy surgery and found the following common features: the ictal EEG was a 5- to 9-Hz unilateral and/or subtemporal rhythm, the IEDs were concordant with the ictal lateralization and the patient had a

history of febrile seizures. Five patients (29%) were totally seizure free and an additional five patients had a greater than 75% reduction in seizure frequency.

Ictal behaviour: the role of video

The evaluation of presurgical candidates also includes a close study of the patient's seizure behaviour in conjunction with the ictal EEG. Ictal behaviour reflects the propagation of epileptic activity into eloquent cerebral areas and thereby represents the symptomatogenic zone [49]. In this regard, ictal behaviour improves lateralization and localization of the epileptogenic zone when used in conjunction with the ictal EEG, but it does not necessarily indicate the ictal onset zone or the epileptogenic zone. In a group of 55 patients with TLE, Marks and Laxer [50] found that unilateral clonic, dystonic and tonic activity were strong lateralizing signs of a contralateral epileptic focus, with a predictive value ranging between 86% and 100% [50]. Versive head rotation occurring less than 10 s before secondary generalization was predictive of a contralateral epileptic focus in all patients. Unilateral automatisms were predictive of an ipsilateral seizure focus in 80% of patients, whereas ictal speech preservation was indicative of seizure focus in the non-dominant hemisphere in 80%. Others have reported additional lateralizing ictal manifestations, including asymmetric visual, auditory or somatosensory auras, ictal spitting, vomiting, unilateral eye blinking, dysphasia, postictal hemiparesis, aphasia and nose-wiping (Table 61.1) [49]. Serles *et al*. [51] analysed the ictal scalp EEG recordings and clinical behaviour associated with 262 seizures recorded in 59 patients with TLE and found that ictal behaviour lateralized 46% of seizures and 78% of patients with a high degree of concordance with ictal scalp EEG lateralization. Moreover, the combination of ictal scalp EEG with ictal behaviour allowed for lateralization in a greater proportion of seizures (80%) and patients (95%) compared with each method alone. This combined lateralization was concordant with the side of operation in 33 out of 34 patients with a successful postoperative outcome (Engel class I/II).

Table 61.1 Lateralizing value of different ictal and postictal behaviours.

Sign	Side	Percentage
Aura		
Unilateral sensory aura	Contralateral	89
Hemifield visual aura	Contralateral	100
Motor		
Version (<10 s before generalization)	Contralateral	100
Clonic activity	Contralateral	83
Tonic activity	Contralateral	89
Unilateral dystonic posturing	Contralateral	100
Unilateral automatisms	Ipsilateral	80
Ictal spitting	Non-dominant	75
Ictal vomiting	Non-dominant	81
Unilateral eye-blinking	Ipsilateral	83
Language		
Ictal speech	Non-dominant	83
Ictal dysphasia and aphasia	Dominant	100
Postictal behaviour		
Postictal palsy	Contralateral	93
Postictal nose-wiping	Ipsilateral	92

Adapted from refs 49 and 50.

Psychogenic non-epileptic seizures

Close evaluation of ictal behaviour is also important for the diagnosis of patients with NESs, which is particularly important when considering patients for epilepsy surgery. NESs are seen in roughly 10–30% of patients who are referred to epilepsy centres for the evaluation of medically intractable seizures [52,53]. For example, Henry and Drury [53] unexpectedly recorded NESs in 12 patients (8%) referred for long-term monitoring for presurgical evaluation of medically intractable seizures who had interictal temporal spikes and reported ictal behaviour characteristic of temporal lobe seizures. Benbadis *et al*. [52] reported that NESs were diagnosed in 75 out of 251 (30%) inpatient video-EEG monitoring sessions of all patients (adults and children) who underwent inpatient video-EEG monitoring (≥24 h) at a university centre hospital over a 1-year time period. Conversely, some patients referred with suspected psychogenic non-epileptic seizures (PNESs) are found to have epileptic seizures. Referring physicians correctly suspected a diagnosis of epileptic seizures in 9 (43%) out of 21 patients, whereas 12 (57%) patients were incorrectly thought to have PNESs in a study by Parra *et al*. [54]. Ictal behaviour, in addition to history and electrophysiological data, helps to establish the diagnosis of NES. While there are no clinical manifestations that are entirely specific to PNESs, particular behaviours and patterns tend to be associated with PNESs more than with epileptic seizures. PNESs typically have longer durations, waxing and waning behaviours, and are less stereotyped in terms of behaviour and duration. Eye closure, especially when forced, and crying are much more common than in epileptic seizures.

Some behaviours may occur with similar features in both PNESs and epileptic seizures, which complicates the diagnosis and may lead to a misdiagnosis of epilepsy as PNESs as easily as PNESs as epilepsy. Both PNESs and frontal lobe epileptic seizures may include screaming, violent thrashing of the extremities or whole body, opisthotonic arching of the back, side-to-side head movement and bilaterally out-of-phase clonic jerking [55]. The out-of-phase movements may resemble kicking or pedalling. Seizures originating in the supplementary sensory motor cortex may present with preserved consciousness despite bilateral tonic posturing, both of which may be misinterpreted as behaviours suggestive of PNESs. This similarity is demonstrated by the observation by Kanner *et al*. [56] that clinical behaviours suggestive of PNESs were present in 82% of all seizures recorded from 91% of the studied patients with frontal lobe epilepsy.

Although a diagnosis of additional psychogenic seizures in patients with medically intractable surgically remediable epileptic seizures should not be considered an absolute contraindication to surgery, identification of the PNESs is important for careful preoperative psychiatric evaluation [57]. Ultimately, the evaluation of ictal behaviour is an important component of the presurgical evaluation, and when used in conjunction with the EEG, neuro-

imaging, functional mapping and neuropsychological testing it can help to estimate the epileptogenic zone and adapt surgical intervention.

Seizure activation during long-term monitoring

Because of the nature of epilepsy, seizures are usually unpredictable, may not have an obvious trigger, and occur sufficiently infrequently that several days or more of video-EEG monitoring are required. Most epilepsy surgery programmes require the recording of three to five independent seizures in order to formulate a surgical decision [58]. The number of seizures ultimately depends upon whether or not the recorded seizures have a stereotyped pattern. Todorov *et al*. [59] found that the mean length of stay was 2.9–3.7 days to record one seizure. To record three seizures was 4.5–5.5 days and to record five seizures was 6.1–7.6 days. Given the expense of long-term monitoring, activation procedures are routinely used to shorten the length of stay and thereby improve cost-effectiveness and efficient use of this medical resource.

Antiepileptic drug withdrawal

A facilitative procedure that is commonly used during long-term monitoring is antiepileptic drug (AED) withdrawal. Although some patients (particularly those with extratemporal partial seizures) may need minimal reduction of AEDs to capture a sufficient sample of seizures, many patients (particularly those with temporal lobe seizures) commonly require a large reduction in AEDs to record an adequate number of seizures in a reasonable period of time [60]. The rate and order of AED withdrawal is determined by the clinical judgement of the treating physician and is largely contingent on a patient's baseline seizure frequency at home and his/her tendency to have generalized seizures or status epilepticus. The taper for some patients may be started before admission, particularly if the patient provides history that the medication has not been helpful or if medication levels are low. Typically, physicians taper AEDs by one-quarter to one-half of the maintenance dose every day. Some taper all AEDs simultaneously, based on the observation that increased seizure frequency may be delayed for weeks if other AEDs are continued [61]. Our practice has been to taper the AEDs individually by about one-third of the dose in order to maximize both safety and the quality of the ictal onset recordings. Slower tapers decrease the likelihood of seizures that are more severe than the patient's usual, and produce an ictal spread on the EEG that is too quick to clearly depict a focal onset region. There is controversy as to whether seizure activation occurs when the anticonvulsant levels are falling [62] or when the levels reach a threshold low value [61,63]. Abrupt discontinuation of barbiturates [64] and benzodiazepines [65] can result in withdrawal seizures, even in those without epilepsy. In a study of patients with complex partial seizures who were withdrawing from phenobarbital, Theodore *et al*. [66] found that seizure rates were highest when high serum concentrations fell below 15 μg/mL.

Regardless of the mechanisms of increased seizure frequency with AED tapering, there has been concern that seizures observed during this activation may originate from ictal foci different from those producing a patient's habitual seizures [62,67]. However, the significance of these case reports is uncertain. Subsequent studies have shown that the origin of seizures during AED tapering does not change as long as seizures have behavioural features identical to the habitual seizures [63]. AED tapering has been shown to result in increased frequency of complex partial seizures, seizure clusters and an increased frequency of secondarily generalized seizures [60,63,68]. Yen *et al*. [63] reported a series of 102 consecutive patients with refractory TLE who were admitted for presurgical evaluation in whom AEDs were rapidly decreased and discontinued within 4–6 days. Eighty-nine patients had 429 complex partial seizures (mean of 4.8 per patient), including 156 (36%) that secondarily generalized, whereas 43 (48%) patients had seizure clusters and eight patients (9%) had generalized seizures that had not occurred or been absent for years. Swick *et al*. [60] reported that the only significant predictor of secondarily generalized seizures during monitoring was a history of such activity at home in patients with temporal lobe seizures (versus extratemporal seizures). Although rare during monitoring, status epilepticus may occur and this risk is a factor when planning the tapering [68]. AED tapering also may result in an increased risk of seizure clustering [63]. Haut *et al*. [69] found that risk factors for seizure clustering (defined as ≥3 seizures in 24 h) during long-term monitoring included a history of clustering at home, MRI evidence of mesial temporal sclerosis and multiple seizures types. In this study, however, seizure clustering was not associated with ictal localization or AED withdrawal, suggesting that clustered seizures are useful in identifying the epileptogenic zone [69].

Sleep deprivation

Sleep deprivation is another method employed to facilitate seizures during long-term monitoring. This method is based on the premise that many epilepsy patients report seizure exacerbation, or precipitation, with sleep deprivation [70]. In a study by Rajna and Veres [71] the likelihood of occurrence of a seizure was significantly higher after a period of partial sleep deprivation than in normal sleep or oversleep in a group of 14 patients with TLE. Sleep deprivation also activates IEDs [72]. As such, many epilepsy centres utilize sleep deprivation protocols. However, Malow *et al*. [73] found that sleep deprivation every other night did not affect seizure frequency during inpatient monitoring in a group of patients with medically intractable seizures who were undergoing inpatient monitoring. Overall, sleep deprivation often does not facilitate seizures but its occasional utility makes it a worthwhile procedure in some clinical circumstances.

Hyperventilation

Hyperventilation is an activation method that is less commonly employed in the presurgical evaluation. This is partly due to this method's greater specificity to EEG abnormalities of idiopathic generalized epilepsies than to those of focal epilepsies. Holmes *et al*. [74] reported that hyperventilation activated seizures in only 0.5% of 384 patents with partial epilepsy who were

undergoing routine outpatient EEG testing. Although some have reported an increase in interictal discharges and seizures during hyperventilation in patients with complex partial seizures, especially prolonged hyperventilation, others have not found this to be the case. More specifically, Miley and Forster [75] found that hyperventilation increased the frequency of interictal discharges and activated seizures (6% and 4% respectively) in 255 patients with complex partial seizures. In contrast, Guaranha *et al*. [76] found that hyperventilation activated focal seizures in 25% of 97 patients with medically intractable partial epilepsy when performed every 3 h, with temporal lobe epilepsies significantly more activated than frontal lobe epilepsies.

Photic stimulation

Photic stimulation can also be used to activate seizures. Photosensitivity typically does not occur in patients with partial seizure disorders, although it may activate focal occipital spikes. Such sensitivity is uncommon and typically occurs in patients with a history of a lesion in the occipital cortex [77] and a more anterior lesion in rare circumstances [78]. Most people with photosensitivity have idiopathic generalized epilepsy, and if a seizure is elicited it is typically a primary generalized tonic–clonic seizure, an absence seizure or a myoclonic seizure.

Potential complications

Although several activating techniques can be used to provoke seizures and reduce the duration of video-EEG monitoring, safety is of paramount importance as complications can occur during inpatient monitoring. Up to 50% of patients have secondarily generalized seizures during monitoring, many of whom rarely generalize at home, and many patients experience seizure clustering [63,68]. Prolonged or recurrent seizures can lead to a variety of complications including aggressive postictal behaviour and psychosis [79] and an increased risk of status epilepticus [80]. Whether occurring in clusters or isolation, seizures, particularly secondarily generalized, can result in falls leading to potential fractures, joint dislocations or soft tissue injuries [68]. Although status epilepticus is a rare complication, occurring in 3% of patients admitted for video-EEG monitoring [68], it is associated with numerable potential serious complications, including metabolic derangement, infections (such as aspiration pneumonia and sepsis), autonomic instability, renal failure and death. Given the nature and range of possible complications, safety precautions, including a well-trained staff, intravenous access, and continuous observation of patients, should be taken [81].

Conclusion

Scalp EEG is a fundamental test in the presurgical evaluation of patients with medically refractory epilepsy who are being considered for resective epilepsy surgery. Evaluation of interictal and ictal scalp EEG patterns and corresponding ictal behaviour are critical steps in the identification of the epileptogenic zone. As structural MRI resolution continues to improve, the results of video-scalp EEG monitoring contribute to the determination of whether or not the identified structural abnormalities are likely to be epileptic. In this regard, the results shown by the scalp EEG are commonly used in direct conjunction with structural MRI in order to formulate a plan for resective epilepsy surgery or alternatively intracranial electroencephalography monitoring.

63 MEG in Presurgical Evaluation of Epilepsy

Hermann Stefan, Stefan Rampp and Rüdiger Hopfengärtner

University Hospital Erlangen, Erlangen, Germany

Introduction

Epilepsy surgery primarily aims to control seizures in pharmacoresistant epilepsies; in addition, neurological or neuropsychological deficits should be avoided and social integration improved. Before imaging techniques became increasingly important, for a long time electroencephalography had been the only functional investigation technique for presurgical evaluation. The individual determination of the localization and extent of interictal (irritative) and ictal epileptic (seizure onset) brain regions is the main task during presurgical evaluation of partial epilepsies. Another important issue concerns the delineation of functionally important areas (e.g. motor, somatosensory, language). Therefore, functionally important areas have to be correlated with the localization of epileptogenic areas.

As neurosurgical approaches have become routine procedures in the treatment of pharmacoresistant focal epilepsies, the diagnostic challenge culminates in determining the site and extent of epileptogenic tissue to be removed without risk of functional deficits. To this purpose, the combined findings of diagnostic methods may contribute anatomical (CT, MRI), blood flow [single photon emission computerized tomography (SPECT)], metabolism-related [positron emission tomography (PET)] and electrophysiological information. This information comprises long-established non-invasive surface electroencephalography and invasive electroencephalography recordings and, as a comparatively new method, magnetoencephalography (MEG). MEG is a non-invasive method with high temporal and potentially high spatial resolution, offering data on electrophysiological phenomena from a point of view that is somewhat different to that of the electroencephalogram (EEG), and has been found to be a potentially useful addition to the pool of techniques that are applied in preoperative focus localization of pharmacologically intractable epilepsies. As the standard procedure for MEG processing includes coregistration with MRI, centres of activity localized from MEG data are usually displayed in the corresponding anatomical images. This particularly advantageous combined technique [1,2] has been labelled 'magnetic source imaging' (MSI).

Epileptic activity can be generated both in superficial cortex and in deeper brain regions, thus influencing detectability [3]. The feasibility of localization has to be considered for any given type of focal epilepsy (neocortical or limbic). Basically, a certain amount of cortex has to be involved by epileptic discharges to be accessible non-invasively [4–7]. Therefore, presurgical evaluation requires extensive experience in deciding whether or not non-invasive interictal or ictal recordings are sufficient for the localization of focal epileptic activity in any individual case, or if invasive recordings have to be carried out in order to improve the accuracy of preliminary non-invasive results. For instance, if the generator is located in the hippocampus then non-invasive detection of epileptic activity may be difficult or impossible. The distribution of interictal spikes in deep hippocampal electrodes and surface electrodes was analysed by Alarcon *et al.* [4]. The results of this study indicate that single hippocampal discharges could not always be detected by scalp EEG, but excision of 'leading regions of spike activity' in the temporal lobe yielded good surgical outcome [8].

According to our experience with simultaneous invasive recordings from hippocampus, temporal basal, mesial temporal and temporal neocortical areas in many patients with cryptogenic temporal lobe epilepsies, hippocampal and parahippocampal or basal areas or inferior temporal gyrus are involved in the epileptic aggregate. Rather frequently we observed spike onset in the entorhinal, parahippocampal cortex and sometimes in the lateral neocortex [8]. Invasive ictal recordings revealed that the entorhinal cortex of the basal temporal cortex itself can be the region of ictal onset [9]. Thus, it may happen that the hippocampus is only secondarily involved in the epileptic excitation process. The epileptic network in such an instant involves temporomesiobasal areas as well as the hippocampus.

As discharges involving only several thousands of neurones are assessable non-invasively, only approximated localizations within the neuronal network of the brain are possible. The question arises if magnetoelectroencephalography is able to define 'critical hot spots' in the neuronal network, which are necessary and sufficient for seizure generation and control. In this chapter, procedures and applications of MSI in epileptic patients for the detection of focal epileptic interictal and ictal activity and functionally important areas are discussed.

Method

It is well known that activated groups of neurones in the human brain produce electrical potentials that can be recorded with scalp electroencephalography. At the same time, the neuronal activity also produces very small magnetic fields outside the head in the range of 50–1000 femtotesla (fT), which can be detected by MEG. Special sensors [superconducting quantum interferometer devices

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

(SQUIDs)] are essential for the assessment of these small magnetic fields. In addition, MEG recording is usually performed in a specific shielding chamber to attenuate the influence of external magnetic noise. For technical details about registration and instrumentation of MEG, see refs 10–13.

Magnetoencephalography is a non-invasive method requiring neither referencing nor direct contact between the recording equipment and the patient's head. Its high temporal resolution in the milliseconds range is similar to that of the EEG. Owing to the use of multichannel systems, and particularly the so-called whole-head systems with up to more than 200 sensors, good spatial resolution has also been achieved.

The so-called neuromagnetic 'inverse problem' – the tracing of an unknown source in the brain from magnetic field data recorded outside the head – is approached using special model assumptions concerning the type of underlying source that produces the magnetic field and the shape and structure of the volume conductor. For the determination of the location, orientation and strength of focal activity in the brain, the model of a single equivalent current dipole is often used (with a specific physical feature of magnetic field recording being its 'blindness' to radial portions of the dipoles). However, when sources overlap both spatially and temporally (i.e. in the case of multifocal sources and extended networks) the approach of a multidipole model might be more appropriate [14–16]. Furthermore, different current density reconstruction approaches, e.g. minimum norm, weighted minimum norm and low-resolution brain electromagnetic tomography (LORETA) [17,18] and beamformer methods [19], are also used for the localization of more extended generators.

As to the volume conductor, besides the most frequently used spherical model, more realistically shaped models are also available [e.g. boundary element method (BEM)]. In this case, the volume conductor model consists of the three different compartments – brain, skull and skin – assuming that each compartment has homogeneous and isotropic conductivity [20]. The BEM is based upon segmentation of MRI datasets, thus accounting for the individual patient's anatomy. This is taken further by finite element models (FEMs), which also take conductivity anisotropies into account [21].

Clinical aspects of MEG methodology have been presented in the work of Stefan and Hummel [22].

Applications of magnetic source imaging in epileptic patients

Evoked activity

When neurosurgery remains the only therapeutic hope for epileptic patients, it is essential to know not only the site of the epileptogenic region (see below), but also whether or not removal of the tissue in question may cause functional deficits.

Recently, functional validation of MSI has been obtained with various sensory modalities, source localization being based upon evoked magnetic responses to repeated stimulation, in accordance with the well-established technique for evoked potentials, averaged over a number of stimulus-related electroencephalography epochs [23].

Evoked magnetic responses to acoustic [auditory evoked field (AEF)] [24,25], visual [visual evoked field (VEF)] [26–28], somatosensory [somatosensory evoked field (SEF)] [29] and olfactory [olfactory evoked field (OEF)] [30] stimulation can be obtained. Magnetic fields representing motor activity [motor evoked fields (MEFs)] generated by voluntary finger and limb movements have long been assessed [31–33]. Thus, localization of cortical generators calculated from magnetic evoked activity has become an established tool to provide information about functionally significant areas, and particularly so if MSI and neurosurgery have access to compatible systems of space coordinates ('neuronavigation' systems are already established in operation theatres – see Plate 63.1). Using a variety of stimulating sites, SEF localizations illustrate the 'homuncular' organization and its variations of the somatosensory cortex [22,34,35]. It is also possible to localize functional regions for language [36–38].

Spontaneous activity

An increasing number of publications are dealing with the application of MEG in presurgical evaluation, giving evidence of its capability to localize spontaneous epileptic activity (Plate 63.1).

Validation of source localizations with respect to the 'true' source is necessary. MEG findings on epileptogenic foci need to be compared with the results of other diagnostic techniques that are considered to be the most reliable in detecting the epileptogenic brain tissue. Whether ictal invasive electroencephalography (widely considered to be the 'gold standard' [39]), long-term video electroencephalography monitoring or intraoperative electrocorticography (EcoG) is wanted to check the accuracy of MEG focus, localization, depending on other clinical findings, has to be decided upon in each individual case. It has been shown that MEG indeed yields fairly good accuracy, even although the activity investigated is mostly interictal [40–47].

Eliashiv *et al.* [48] reported congruency of MEG localizations with other findings of presurgical evaluation in 70–80% of cases. We found a similar percentage (72%) of patients after successful temporal lobe epilepsy surgery with good spatial correlation between predominant focal epileptic activity in MEG and other localization results from presurgical evaluation and intraoperative EcoG [49]. In another study, a comparison of MEG localizations with MRI and various video electroencephalography findings in 58 patients with pharmacologically intractable epilepsy showed that in patients who, after surgery, were seizure free (class I, according to Engel's classification) or had only rare seizures, MEG was inferior to only subdural video electroencephalography recordings in predicting the epileptogenic zone. MEG was superior to MRI, interictal and ictal non-invasive video electroencephalography and interictal invasive subdural electroencephalography [50]. The data suggest that MEG is at least as effective as the established methods for localizing the epileptogenic network in temporal and extratemporal lobe epilepsies. In a study comparing MEG with PET and stereoelectroencephalography (SEEG), MEG localizations agreed with PET and SEEG results in seven out of nine patients. If PET and MEG findings agreed, the outcome after surgery was favourable [51].

King *et al.* [52] reported outcome data (according to Engel's classification) in 19 patients after resection of the primary MEG spike region: 14 patients were grouped in class I, four in class II, one was in class III and none in class IV. On the other hand,

out of 17 patients after resection of tissue with marginal or no relationship to MEG spike localization, only three were in each of the best and second-best outcome category, whereas in four cases the outcome ranked in class III and a major portion of seven cases were graded in the worst outcome class.

These results indicate that resection of the primary MEG spike focus correlates strongly with excellent outcome. In this context, it seems important to note that MSI dipole localizations are considered neither to represent point-shaped sources with millimetre accuracy nor to yield an outline of the epileptogenic tissue, but rather to indicate centres of epileptic activity, revealing compartmental information on a sublobar level. In many patients with pharmacoresistant focal epilepsies, circumscribed clusters of localizations, indicating centres of predominant epileptic activity, can be found [53]. If MEG localizations in temporal lobe epilepsy showed more than one distinct cluster in different regions, this was interpreted as a hint towards multifocal temporal lobe epilepsy. Similar results were found for neocortical extratemporal epilepsies [54].

Although, in many cases, cerebral MRI of epileptic patients shows abnormal morphology, varying from subtle alterations to extensive mass lesions, abnormal MRI findings are not necessarily epileptogenic and, even if so, it may be important to clarify the relation between anatomical and functional pathology in detail. Furthermore, if there is more than one lesion, those crucial to epileptogenicity must be determined. In a considerable number of patients with neocortical temporal or extratemporal epilepsies, MSI yielded localizations of epileptiform activity in proximity to an epileptogenic structural lesion [42,55–57].

On the other hand, before surgery there is sometimes no evidence of morphological pathology associated with epilepsy [58,59]. However, with the availability of new powerful imaging systems, and more sophisticated software to identify discrete alterations, the number of patients with 'cryptogenic' aetiology is decreasing, and it is not yet possible to identify a structural abnormality to account for any epileptic focus. The lack of morphological clues renders the functional diagnostic methods more significant and even enables detection of subtle morphological changes in MRI re-evaluation [60]. MSI has been found to offer useful source locations of cryptogenic epileptic activity in accordance with other non-invasive results, thus facilitating the detailed planning of invasive procedures and neurosurgical regimen. In a study by Knowlton *et al.* [55], in 11 out of 12 patients without focal abnormality on MRI, MEG discharges were localized to the epileptogenic zone as determined by standard preoperative evaluation.

A review carried out by King *et al.* [52] found numerous studies showing that MEG can detect interictal epileptiform discharges in patients with intractable epilepsies. However, there are cases in which MEG spike localization does not result in focal source findings.

A major problem in using MEG for focus localization arises from the fact that sources of spontaneous epileptic activity are often located less superficially than, for example, the comparatively easily accessible cortical generators of evoked responses. As the signals recorded at the surface decline drastically with increasing depth of the source, deep sources are more difficult to locate than superficial ones. A crucial question in the management of drug-resistant epilepsy is the capacity of magnetic field recordings of spontaneous brain activity to assess deep sources in the mesial structures of the temporal lobe. Initial attempts have been made to resolve this issue. In an unpublished study in which experimental dipoles were established at the tips of foramen ovale electrodes, we found that the dipoles were localized in deeper parts of temporal brain regions, with the distance between estimated source and experimental dipole ranging from 8 to 22 mm. This result gives some encouragement to the use of MSI localizations for presumed deep epileptic foci. However, the circular arrangement of cell layers, for example in the amygdala, may cause cancellation of magnetic fields, thus jeopardizing detection of the signals. In addition, an unfavourable sensor configuration may also impair sensitivity. Smith *et al.* [61], comparing MEG localization with 'standard localizations' (based upon MRI, non-invasive and invasive electroencephalography) found agreement in about two-thirds, with spontaneous spikes available in approximately one-half of the the mesial temporal lobe epilepsy (MTLE) cases. Knowlton *et al.* [55] confirmed that the yield of MEG is higher in patients with neocortical epilepsies than in those with MTLE.

A frequently used measure to increase the signal–noise ratio when dealing with small amplitudes of epileptic discharges in patients with foci in deeper brain regions is the averaging of similar specific patterns. When subjected to spatiotemporal analysis, the resulting signals are more likely to produce a reliable estimate of focal epileptic activity than the unaveraged data [62,63].

Based primarily on dipole analyses of EEG spikes, Ebersole *et al.* [40] stressed the usefulness of interpreting dipole orientation in order to obtain additional information about sublobar attribution of localizations in the temporal lobe and this technique was also described by Pataraia *et al.* [64].

A further difficulty for source localization lies in the epileptogenic network itself. Although the concept of a circumscribed epileptic focus is a valid and useful hypothesis for most patients with focal epilepsies, some patients present with complex signals that challenge the simplicity of this model. In these, the histological cause of epilepsy is better described in terms of interconnected networks with distinct and extended components. Source localization then faces the challenge of modelling this complex structure to explain observed signals.

Owing to the distribution of focal origins of seizure disorders, early clinical MSI studies in epileptic patients were mostly restricted to temporal lobe cases [40,42,62,64–66]. Nevertheless, presurgical evaluation of patients with extratemporal epilepsies has also been reported to benefit from MSI [22,67–71]. In frontal and other extratemporal epilepsies, intralobar localizations (predominantly lateral and frontobasal) could be confirmed by invasive recordings, but until now the number of investigated patients is rather small. Plate 63.1 gives an example of localization results in a patient with frontal lobe epilepsy. A special challenge in frontal lobe cases is propagation analysis [72].

The newer generations of biomagnetic systems, allowing for simultaneous examination of large fields of interest (both hemispheres or the entire head), are particularly suited for the investigation of epileptic spikes [73,73] as they offer the opportunity to investigate temporal relationships of events with extended spatial distribution, for example mirror foci [68].

Owing to relatively short MEG recording times (compared with long-term electroencephalography monitoring), spikes are not detected in all patients with focal epilepsy. The rate of MEG spike detection in focal epilepsies varies between 70% and 90% of spontaneous spikes. In order to induce more frequent spiking, activation using methohexital and/or clonidine can be used [74,75].

Furthermore, with limited recording duration, most MEG recordings miss ictal activity, even in inpatients whose antiepileptic medication is reduced for presurgical evaluation purposes. The restricted access to ictal recording presently remains one of the basic problems of MSI. Even if ictal activity is obtained, it is known from electroencephalography that motor artefacts are likely to disturb the brain signals. Yet, MEG data recorded during auras or seizure onset [40,44,49, 76–78] may yield dipole localizations reflecting focal activity (Plate 63.2). According to investigations by Ebersole *et al*. [40] and Tilz *et al*. [79], ictal recordings permitted the detection of epileptiform signals in the MEG in 40–50% of cases. Prolonged MEG recordings, split into repeated sessions and interspersed with breaks for the patient to have a stretch, might be a strategy to provide ictal data during spontaneous seizures. Another way to obtain seizure-related MEG measurements is to take advantage of procedures that provoke the attacks. For seizure precipitation, sleep deprivation and antiepileptic drug (AED) withdrawal can be used.

The correlation of ictal and interictal localizations is among the important issues that have to be assessed systematically in future research in different types of epilepsies.

In small children, limited cooperation and small head size may impose limitations on recording and analysis. Still, even under these conditions, MEG proved advantageous. In childhood epilepsy with Landau–Kleffner syndrome, Paetau *et al*. [80], using a whole-head system, showed that in all investigated patients the earliest spike activity originated in the intrasylvian cortex. In one subject, activity spread to the contralateral sylvian cortex within 20 ms. Secondary spikes occurred within 10–60 ms in the ipsilateral perisylvian temporo-occipital and parieto-occipital areas. In these cases, MEG provided useful presurgical information regarding cortical spike dynamics.

Studies comprising MEG and electroencephalography data recorded and analysed simultaneously [65,81,82] are of particular interest, enabling clinicians to take full advantage of the merits of both methods and to overcome their drawbacks.

Despite the specific limitations of the MSI technique – MEG being apt to detect only tangential components of dipoles and the comparatively short recording periods rendering spontaneous ictal recordings unlikely – the advantages of MSI are undeniable. Its non-invasiveness, high spatial and temporal resolution, superior accuracy due to magnetic fields' independence of conductivities and its merging functional and anatomical information suggest that MSI plays a significant role among the diagnostic methods that contribute to finding epileptic networks. Being non-invasive, MSI is restricted neither to inpatients nor to presurgical evaluation, and is also applicable to projects screening outpatients. It may be particularly useful in patients in whom, post operation, seizures have decreased but have not altogether ceased and when, due to asymmetrical conductivities, the defect of the cranial vault and the cavity resulting after resection impede electroencephalography but not MEG analysis.

The applications of MSI in presurgical epilepsy evaluation can be summarized as follows:

- delineation of functionally significant areas (which must be spared in neurosurgery) by means of evoked activity (Plate 63.3);
- localization of epileptic activity to guide invasive procedures and thus reduce invasive regimens;
- localization of epileptic activity to guide detailed planning of neurosurgical procedures, for example with neuronavigation, aiming at the removal of as little tissue as possible;
- contribution to elucidating spatial relationships of epileptic spike generation and (even subtle) anatomical pathologies;
- postoperative follow-up and facilitation of the decision concerning the possibility of a second operation in cases when the first neurosurgical treatment has failed to render the patient seizure free.

64 MRI in the Presurgical Evaluation

Jörg Wellmer and Christian E. Elger
University Hospital Bonn, Bonn, Germany

Introduction

The development of high-resolution MRI has noticeably modified the presurgical evaluation of pharmacoresistant epilepsies over the last decade. While previously electrophysiological focus localization was the primary diagnostic tool, today MRI can be regarded as the entrance criterion to a successful presurgical evaluation. On the one hand, it may help to identify good surgical candidates. On the other hand, detecting inoperable lesions can avert complex and risky work-ups and futile resections without a realistic chance of seizure freedom and can reduce superfluous health-care costs. Today's role of MRI is established on the experience that surgery is most effective when an epileptogenic lesion can be identified preoperatively and completely removed [1]. Owing to the constant improvements in MRI technology, now even subtle epileptogenic lesions can be detected.

The importance of MRI in epilepsy surgery is underlined by the fact that during the course of the disease, it helps define the time at which the patient should be considered a surgical candidate. The classical route to epilepsy surgery assessment required 'proven pharmacoresistance'. However, the concept of pharmacoresistance was and still is controversial [2]. Many patients are exposed to a multitude of anticonvulsive drugs and after approximately 20 years they are finally identified as good surgical candidates [3]. For a good surgical candidate, 20 years of seizures are lost years.

Because the chance of achieving seizure freedom through medication after the first drugs have failed is fairly low [4–6], patients with easily accessible epileptogenic lesions should be considered for a surgical treatment early on. Patients with lesions that are not well suited for surgery, or who do not show lesions on MRI, should undergo surgical treatment only after more extensive pharmacotherapy. In other words, pharmacoresistance should be defined individually, based on MRI (Table 64.1).

However, the lesion-oriented definition of individual pharmacoresistance requires high-quality MRI assessment during the early stages of the disease. Surgery is delayed for many patients considered difficult surgical candidates simply because of insufficient MRI performance, evaluation and/or judgement [7].

In this chapter, we outline the MRI requirements for the effective identification of surgical candidates and describe the role of MRI in the presurgical evaluation. We illustrate a system of patient classification by providing exemplary cases of 'easy', 'moderately difficult', 'very difficult', palliative and 'non-surgical' candidates. We also discuss the role of MRI postprocessing for patients with non-lesional MRI. We address MR-based auxiliary techniques such as MR-volumetry, MR-relaxometry, functional MRI (fMRI) and diffusion-based imaging. Finally, we address the usefulness of combining multiple imaging techniques, including multimodality neuronavigation.

Structural imaging

Timing of MRI examination and technical requirements

Focal epilepsy can manifest itself at any age and seizure aetiologies are highly heterogeneous. Accordingly, MRI of patients with focal epilepsy can reveal many different lesions [8]. Except for emergency situations and in rare patients with calcified lesions in whom CT scans are advantageous (better accessibility, shorter examination time, fewer contraindications, etc.), MRI offers much better chances of identifying the causes of newly manifested seizures. Because different seizure aetiologies require principally different therapies (e.g. neoplasm versus encephalitis versus malformations), it is generally agreed that each epilepsy patient should undergo diagnostic MRI as early as possible.

However, it is the quality of MRI which determines if lesions can be detected. Large lesions can be identified even on a low-quality MRI and by a radiologist who is not experienced in the evaluation of epilepsy patients. The poorer the MRI performance, evaluation or judgement is, the higher the danger of overlooking epileptogenic lesions [7]. This may be problematic particularly for patients with subtle yet highly epileptogenic lesions such as focal cortical dysplasia (FCD). Once the diagnosis 'non-lesional' is fixed in the charts, it can persist for years and the patient may be categorized as a bad surgical candidate for a long time despite having an excellent chance of achieving seizure freedom through resective surgery.

In most countries, 1.5-tesla MRI (1.5-T MRI) is the standard and most publications on epilepsy surgery strategies and outcomes rely on magnetic resonance images that are acquired at this magnetic field strength. Therefore, for the purposes of diagnosing and treating epilepsy, MRI with field strength of less than 1.5 tesla should no longer be performed. Today, 3-tesla MRI (3-T MRI) is widely available. By using higher magnetic field strength, examinations can be performed at higher resolution and with higher signal-to-noise ratio in less time [9,10]. In particular, the contrast of grey and white matter and the resolution of the internal struc-

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Table 64.1 Individual definition of pharmacoresistance depending on (1) the expected chance of seizure freedom; (2) the degree of difficulty of presurgical evaluation; and (3) the risk of neurological deficits through epilepsy surgery.

Candidate classification	Timing of surgery
A: *Easy candidates* Very high chance of seizure freedom through surgery (≈80%) Low risk of neurological/neuropsychological deficits	Early
B: *Moderately difficult candidates* High chance of seizure freedom (≈60%) Complicated (invasive) presurgical evaluation and/or some risk of neurological/neuropsychological deficits	Later
C: *Very difficult candidates* Reduced chance of seizure freedom (<50%) Significant risk or certainty of neurological/ neuropsychological deficits	Late
D: *Palliative surgery candidates* Chance of seizure freedom only for seizure subtypes	Late
E: *Non-surgical candidates* No realistic chance of seizure freedom Surgery impossible without intolerable neurological deficits	–

ture of the hippocampus is much better at 3 T (Fig. 64.1). Although the superiority of 3 T over 1.5 T has not yet been formally proven with respect to surgical outcome, centres working with 3 T report a much higher level of confidence when using this technique.

Yet because of the high incidence of epilepsy, not all patients can receive an initial 3-T MRI scan. For logistical reasons, and to avoid unnecessary costs, it is reasonable to perform initial 1.5-T MRI after seizure onset. If no typically epileptogenic lesion that is consistent with the epilepsy syndrome is found but the seizures prove difficult to control by pharmacotherapy then 3-T-MRI should be performed.

Regardless of the field strength, MRI undergoes constant improvement. New sequences that promise higher sensitivity for lesions are developed and introduced into clinical application. This means that in pharmacoresistant, non-lesional patients in whom epilepsy surgery might be considered, repeated 1.5-T MRI examinations can make sense, too. We usually recommend repeating an MRI every 4–5 years if from the improved technology a clinical yield can be expected. Table 64.2 summarizes the recommendations for a staged performance of cranial computerized tomography (CCT), 1.5-T MRI and 3-T MRI.

Because of the superior quality and the trend towards wider distribution of 3-T MRI, all of the MRI examples shown in this chapter are 3-T MRI (unless otherwise stated).

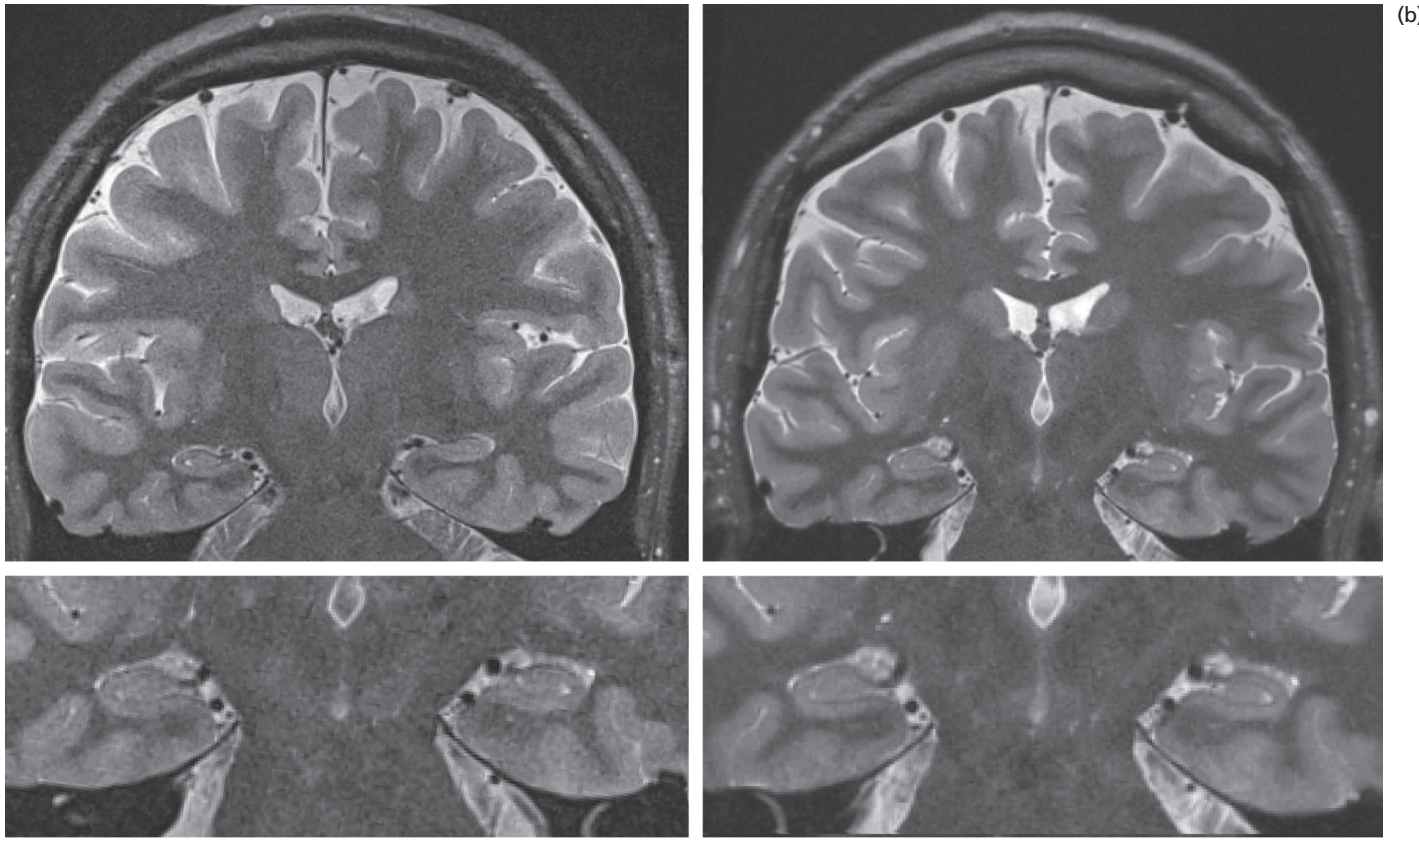

Fig. 64.1 Comparison of resolution and contrast between 1.5-tesla MRI (a) and 3-tesla MRI (b) in a healthy adult. Both images are acquired with a T2-weighted sequence with an additional inversion pulse prior to image acquisition [short time inversion recovery (STIR)] with 40 2-mm slices, no gap. (a) Siemens 1.5-T Avanto: TR 5600 ms, TE 17.0 ms, TI 100 ms, acquisition time 7.29 min. (b) Siemens 3.0-T Trio: TR 5600 ms, TE 18.0 ms, TI 100 ms, acquisition time 9.30 min. Note the better signal–noise ratio on the 3-T MRI. The hippocampal structure can be better identified on the 3-T MRI.

Table 64.2 Recommendation for a staged application of CCT, 1.5-T MRI and 3-T MRI. In rare cases CCT may be helpful in addition to MRI for the diagnosis of lesions that can present with intralesional calcification (dysembryoplastic neuroepithelial tumours (DNETs), gangliogliomas, tubers of tuberous sclerosis).

Clinical setting	Recommendation
First seizure (acute setting)	CCT
First seizure (subacute setting), or beginning epilepsy, or long-lasting epilepsy but lack of sufficient imaging, or presurgical evaluation and MRI finding consistent with epilepsy syndrome	1.5-T MRI, if available 3-T MRI
If 1.5-T MRI is inconclusive/non-lesional and first two AEDs do not lead to seizure control, or if 1.5-T MRI is inconclusive/non-lesional and the patient undergoes a presurgical evaluation	3-T MRI

Epilepsy-specific MRI protocols

It is not just the field strength of MRI scanners that determines the yield of diagnostic MRI. Two other important aspects are the optimal choice of MRI sequences and the optimal orientation/angulation of images. The latter is essentially based on the assumption of whether a temporal or extratemporal focus is expected. With this *a priori* information the referring epileptologist can increase the sensitivity of the MRI examination.

Recommendations regarding sequences depend on the prevalence of lesions in epilepsy patients and their MRI properties. The most common sequences are: *T1 (longitudinal relaxation)-weighted imaging* [very short echo time (TE) and intermediate repetition time (TR), good contrast and anatomical resolution, poor lesion detection power]; *T2 (transversal relaxation)-weighted imaging* (intermediate TE and very long TR, relatively good resolution, sensitive to water content and

Table 64.3 Overview of preferred MRI sequences and expected signal alterations for the most common lesions found in epilepsy patients who are referred for persurgical evaluation (1.5-T; modified from ref. 7).

Aetiology	Preferred sequences	Signal changes	Other features	Example (Fig.)
Mesial temporal sclerosis (MTS/AHS)	T2/STIR, FLAIR	Hippocampal T2/STIR ↑, FLAIR ↑	Hippocampal atrophy, loss of internal structure	3, 5
FCD IIB	FLAIR	Subcortical>cortical FLAIR↑	Blurred grey–white matter junction, funnel towards ventricle, thickened cortex	2b, 4, 9, 13
FCD IIA	FLAIR	FLAIR↑ (↑)	Blurred grey–white matter junction, (thickened cortex)	–
Periventricular nodular heterotopia (PNH)	T2/STIR, T1-IR, 3D-T1	Cortex isointense	Often located at the lateral ventricles, often in clusters Overlying cortex mostly MRI normal	2a, 11c, 12d
Polymicrogyria (PMG), schizencephaly (SE)	T2/STIR, T1-IR, 3D-T1	Cortex isointense	PMG: multiple small gyri, often perisylvic; SE: complete or incomplete hemispheric cleft, often lined with PMG	11a, 12a and b
Subcortical band heterotopia (SBH; double cortex)	Sagittal or 3D-T1	Nearly cortex isointense subcortical band	SBH can be discontinuous and asymmetric, even very subtle	12c
Ganglioglioma	T2/STIR + FLAIR	Cysts in T2/STIR ↑, solid component in FLAIR ↑	Often cystic component, CM enhancement <50%	2c, 8b
DNT/DNET	T2/STIR + FLAIR	Cysts in T2/STIR ↑	Often multicystic or large, septated cyst, predominantly intracortical	8a
Cavernoma	T2*, T2, T1 + CM	Signal extinction (haemosiderin ring), CM+	Occasionally multifocal	8c
Arteriovenous malformations	T2* T2, T1 + CM	CM+ convolute of vessels, signal extension in T2*	Notch-like configuration	–
Traumatic brain injury	FLAIR, T2/STIR, T2*	Gliosis: FLAIR↑ STIR↑, hemosiderin T2* ↓	Often multiple, contrecoup	2a, 10a
Tuberous sclerosis	FLAIR, T2/STIR	Tubers, SEGA: FLAIR ↑ T2/STIR ↑, calcifications: FLAIR and T2/STIR ↓	Cortical tubers, calcifications, CM enhancement possible, SEGA	11b
Rasmussen's encephalitis	FLAIR, T2	FLAIR↑ STIR↑	Initial focal swelling, progressive unilateral atrophy	10c
Sturge–Weber	T1-CM, T2/STIR, T2*	T2/STIR↑ ↔, T2*↓	Calcifications, atrophy, angioma, epicortical CM enhancement	–
Hypothalamic hamartoma	Cor T1, T2/STIR	T1↑, T2/STIR↓	Gelastic seizures	11d
Pachygyria, lissencephaly	All, 3D surface-rendering	–	Thickened cerebral cortex with few and large gyri	–

Note: This list is intended to provide an overview for epileptologists. It does not replace the expertise of a trained neuroradiologist who is experienced in the interpretation of MR scans of epilepsy patients.

AHS, ammons horn sclerosis; CM, contrast medium; DNT/DNET, dysembryoplastic neuroepithelial tumour; FCD, focal cortical dysplasia; MTS, mesial temporal sclerosis; SEGA, subependymal giant cell astrocytoma; T1,T2, T2*, FLAIR, STIR, T1-IR: MRI sequences, *see text*.

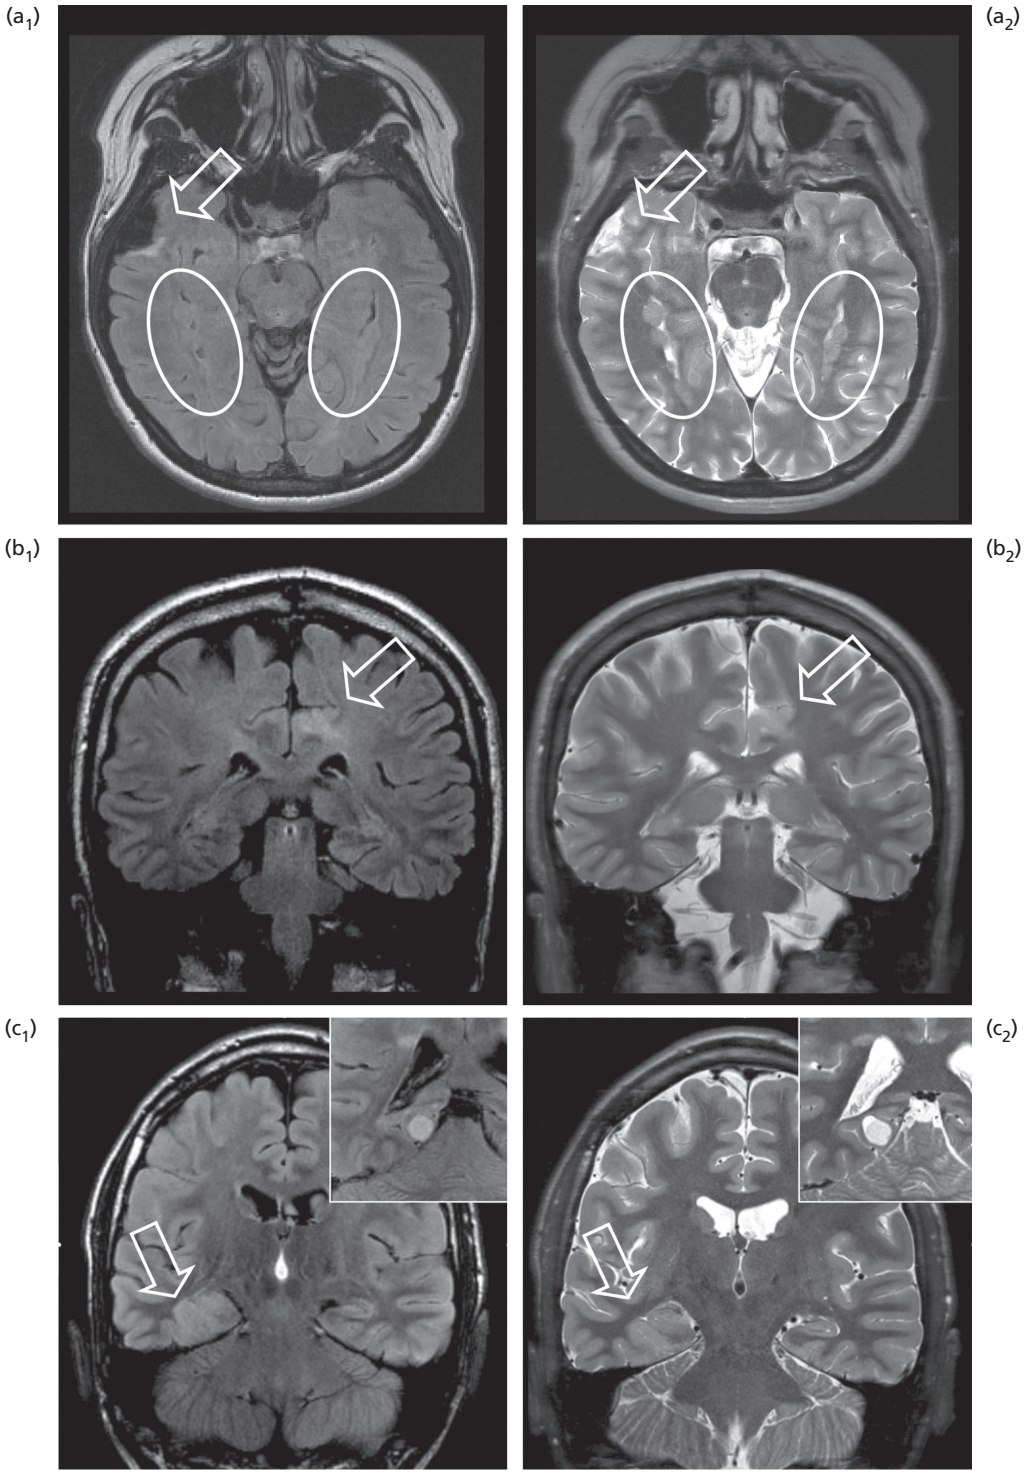

Fig. 64.2 Not all lesion types are equally easy to see in all sequences. (a) The bilateral periventricular nodular heterotopia is more likely to be overseen on the FLAIR (a_1) than on the STIR (a_2) image. In contrast, the concomitant right temporolateral post-traumatic defect (arrow) is possibly easier to recognize in FLAIR. (b) A focal cortical dysplasia (type IIB, arrow) in the left dorsal cingulate gyrus is easier to recognize in FLAIR (b_1) than in STIR (b_2). (c) A ganglioglioma (WHO grade I) presenting with a cystic (inset) and a solid component. The solid component of the lesion extends to the anteromesial temporal lobe and can be seen more easily in FLAIR (c_1) than in STIR (c_2). These differences may determine whether or not a lesion or its extent is correctly detected, particularly for a radiologist with limited experience with epileptogenic lesions.

therefore good lesion detection power); *FLAIR* (modification of T2 with suppression of free water by an inversion pulse for better lesion detection); and *T1-inversion recovery* (same applied to T1, excellent grey–white matter contrast). T2 signal quality can be enhanced by an additional inversion pulse before actual image acquisition (TI ~100 ms), which suppresses fat signal [short time inversion recovery (STIR)]. For the technical details of different sequences as well as detailed lesion properties, refer to MRI textbooks. A practicable overview of characteristic signal alterations associated with common epileptogenic lesions is provided in Table 64.3. Examples underlining the necessity to apply several MRI sequences to patients are provided in Fig. 64.2.

Each MRI examination should comprise at least three different sequences and three different orientations (coronal, transversal and sagittal). To avoid missing small lesions and to avoid partial volume effects, slice thickness should not exceed 5 mm/no gap.

In regions of interest (at the request of the epileptologist) even thinner slices can be helpful. The T1-weighted images are often acquired as sagittal *m*agnetization *p*repared *ra*pid *g*radient *e*cho (MPRAGE) with isotropic voxels (i.e. $1 \times 1 \times 1$ mm/no gap). These three-dimensional datasets can be reoriented and resliced for the precise anatomical localization of lesions seen in other sequences, but can also be used for postprocessing or fusing multiple imaging modalities. Recommendations for epilepsy-specific, basic MRI imaging are given in Table 64.4. The duration of data acquisition for the basic protocols is about 35–40 min. Going below this basic standard in order to shorten the examination time increases the danger of missing therapy-relevant lesions.

Using the temporal instead of the anterior commissure–posterior commissure (AC–PC) angulation in patients with temporal lobe epilepsy (TLE) might make mesiotemporal sclerosis easier to identify. On the other hand, temporal angulation renders the localization of lesions in the central region and in the frontobasal/orbital cortex more difficult. This fact emphasizes the importance of obtaining a detailed patient history (particularly seizure semiology) before performing an MRI. Figure 64.3 illustrates the principle of temporal and AC–PC angulation.

If patients are considered for presurgical evaluation then they may require MRI examinations that exceed the minimum standard. Additional examinations may comprise more sequences or orientations (e.g. sagittal FLAIR), other presentation formats such as curved surface projection ('pancake' – Fig. 64.4) [11], or additional MRI techniques such as fMRI or diffusion tensor imaging (DTI) (discussed later in this chapter).

Before surgery, patients should have had the best possible imaging. The rationale behind this is that detecting and correctly estimating the extent of epileptogenic lesions are not the only factors that determine whether or not a patient is a good surgical candidate. High-resolution imaging can also reveal secondary lesions that might not have been identified with less sophisticated examinations. In a recently described illustrative case a patient suspected of having cryptogenic left temporal lobe epilepsy was found to be suffering from bilateral subcortical band heterotopia. This was only recognized after MRI postprocessing but still prior to invasive recordings or surgery [12]. With less imaging effort this patient might have been exposed to unnecessary risk.

Technical progress is being made in different fields at present. It remains to be seen whether or not new MRI sequences such as double inversion recovery [13] or PROPELLER (periodically rotated overlapping parallel lines with enhanced reconstruction) [14] or the improvement of head coil technology [15] or field strengths that are higher than 3 T will further improve presurgical MRI.

Table 64.4 Recommendations for basic and special MRI protocols in patients with epilepsy.

Temporal lobe epilepsy: basic protocol	
Hippocampal oriented T2-weighted (coronal + axial)	
Hippocampal-oriented fluid attenuation inversion recovery (FLAIR) (coronal + axial)	
Isotropic T1-weighted three-dimensional sequence (MPRAGE)	
(Gadolinium contrast enhanced T1-weighted image if non-contrast enhanced image is inconclusive)	
T2*-weighted sequence	
Extratemporal lobe epilepsy: basic protocol	
AC–PC oriented T2-weighted (coronal + axial)	
AC–PC oriented FLAIR (coronal + axial)	
Isotropic T1-weighted three-dimensional sequence (MPRAGE)	
(Gadolinium contrast-enhanced T1-weighted image if non-contrast enhanced image is inconclusive)	
T2*-weighted sequence	
Special protocols	*Rationale*
T2-relaxometry	Hippocampal signal abnormalities
MR-spectroscopy	Detection of metabolic abnormalities
Diffusion tensor imaging (DTI)	Investigation of fibre tracts
Funtional MRI	Investigation of eloquent cortical areas
Three-dimensional sequences	Automated voxel-based analyses
MR-angiography	Investigation of brain vascularization

Time for performing the basic protocols is about 35–40 min. Instead of T2 we perform T2-STIR sequences (see text).

Examples of common epileptogenic lesions

In the following section we present typical features of pathologies that are commonly associated with epilepsy. To allow for a systematic approach of the heterogeneous aetiologies, we followed the principle of easy (A), moderately difficult (B), very difficult (C), palliative (D) and non-surgical candidates (E).

Class A: easy candidates

For successful epilepsy surgery, the classical 'easy' patient is the one who presents with a clear history of mesial temporal lobe epilepsy (MTLE) and shows unilateral mesial temporal sclerosis [MTS, also referred to as Ammon's horn sclerosis (AHS)]. In the past, seizure freedom rates used to be around 65% (meta-analysis of Téllez-Zenteno and colleagues [16] evaluating studies published between 1990 and 2003), but with modern imaging and elaborate presurgical work-up in selected patients seizure freedom rates can exceed 80% [17]. The MRI features of MTS are signal increases in FLAIR and T2/STIR and atrophy of the hippocampus. Depending on the MRI quality, another frequent feature of MTS is a loss of internal hippocampal structure [18]. A typical example of left-sided AHS is shown in Fig. 64.5.

However, diagnosing of MTS is not always easy. On the one hand, the visual identification of MTS is mostly based on the comparison of the left and right hippocampi. If both are relatively small and show some signal intensity, it can be difficult to discriminate bilateral MTS from bilaterally small, but still normal, hippocampi. Here, hippocampal volumetry and relaxometry can be helpful (discussed later in this chapter).

On the other hand, if only single MRI features of MTS are present, other diagnoses must also be taken into account. T2/FLAIR signal increases in combination with normally large or swollen hippocampi or amygdalae, for example can occur in acute limbic encephalitis [19], and transiently after a series of seizures [20]. Figure 64.6 shows an example of the course of hippocampal volume and signal changes through the different stages of an acute limbic disorder [suggestive of voltage-gated potassium channel

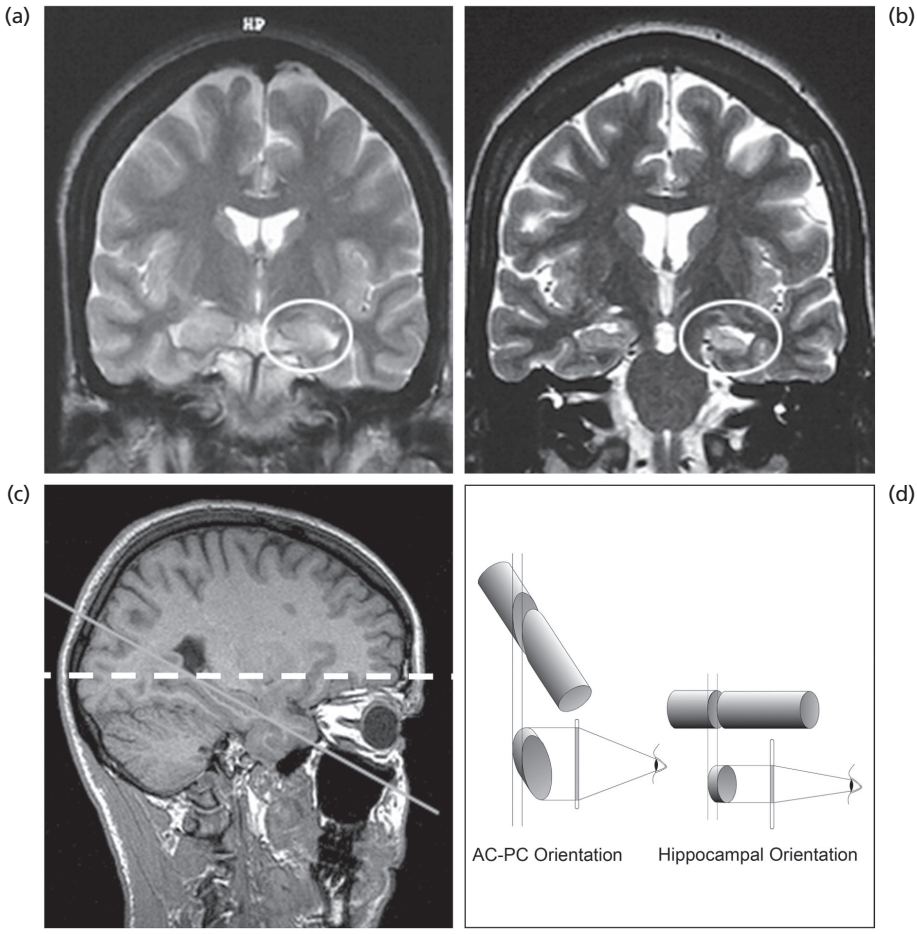

Fig. 64.3 Importance of the correct angulation of the MR scan in a patient with MTLE and a left mesiotemporal sclerosis. In (a), AC–PC oriented, the diagnosis of MTS is far more difficult to discern than in (b) (same patient, MRI orientated along the hippocampal axis). (c) and (d) illustrate the principles of AC–PC and hippocampal orientation. (a) and (b) modified from ref. 7.

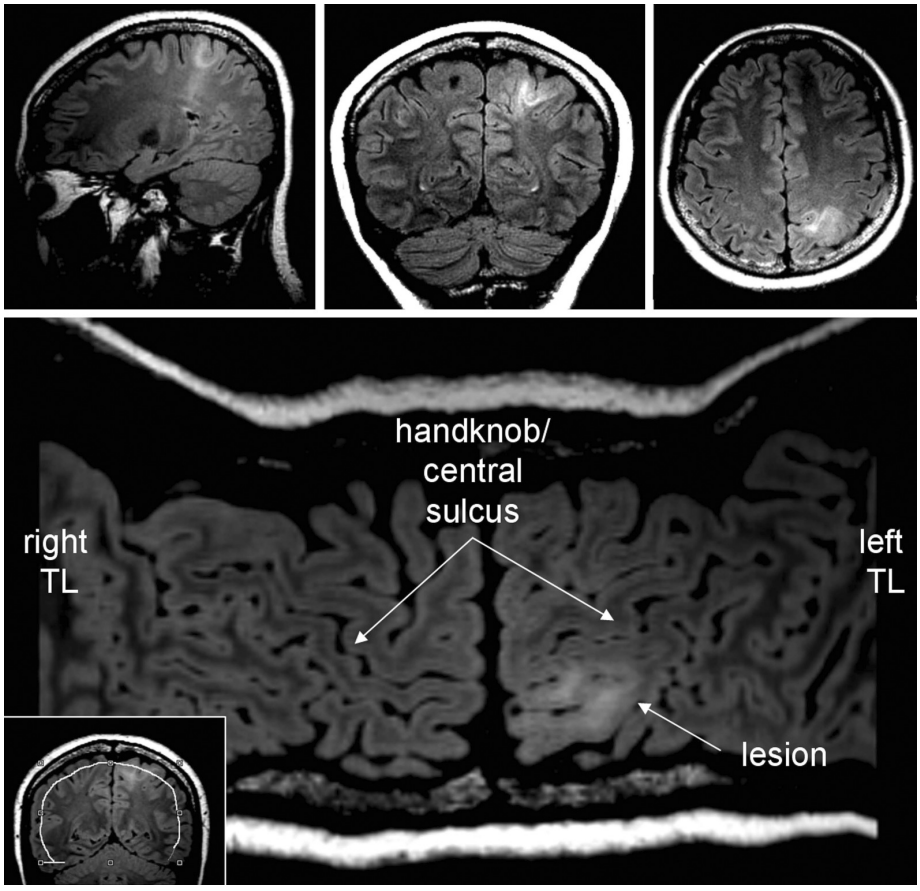

Fig. 64.4 A patient with focal cortical dysplasia in the left post-central area. The lesion is easy to recognize in the axial, sagittal and coronal planes, but its exact localization in relation to the precentral gyrus is better illustrated in the curved surface projection ('pancake').

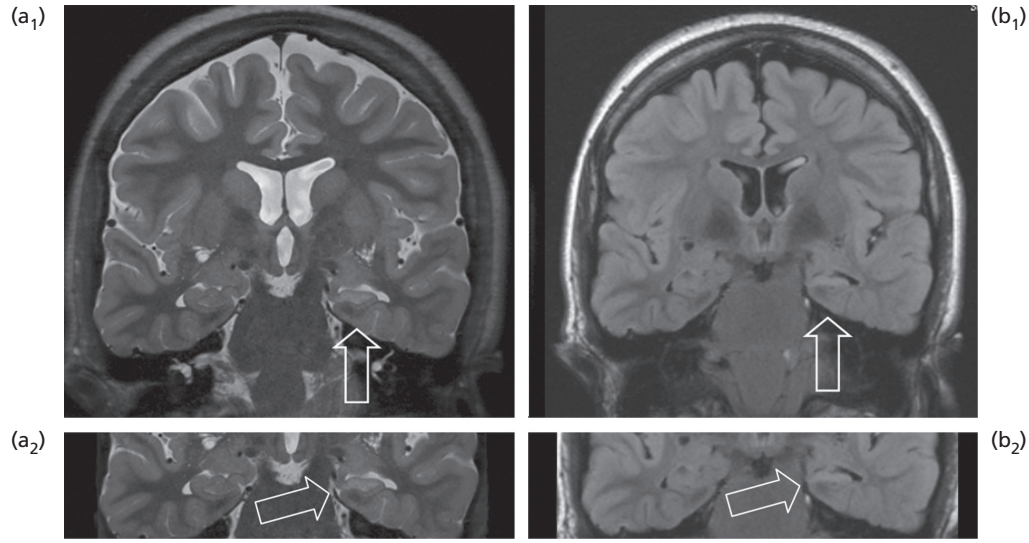

Fig. 64.5 A typical example of unilateral left MTS, showing a loss of hippocampal volume, a signal increase and a loss of internal anatomical structure on the pathological side. (a_1) and (a_2), STIR; (b_1) and (b_2), FLAIR.

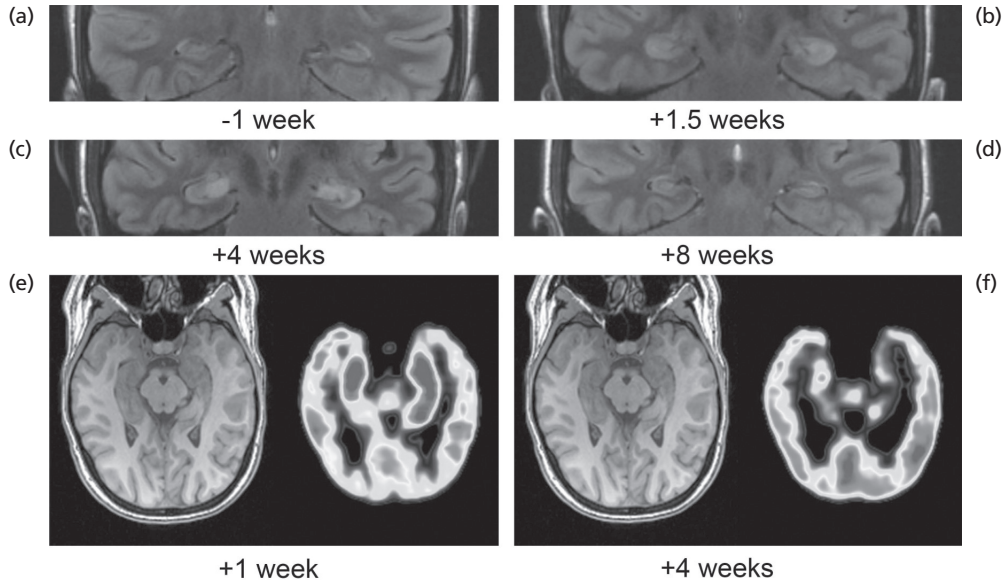

Fig. 64.6 Images of a 23-year-old woman with suspected acute limbic encephalitis. After experiencing two generalized tonic–clonic first-time seizures, she was referred to our department. Her first MRI was non-lesional. She did not experience any further seizures and had no neuropsychological deficit until 2 weeks later when she developed a complex partial status epilepticus and an amnestic syndrome. Under anticonvulsive and anti-inflammatory (intravenous immunoglobulins, cortisone pulses) therapy, seizures stopped within days and an improvement in amnestic function was documented over the following months. (a) to (d) Time-course of signal intensity and hippocampal volume in both hippocampi (all images 3T Siemens, FLAIR). (e) and (f) Concomitant to MRI changes, we observed a marked bitemporomesial hypermetabolism in FDG-PET at the early stage, and a left pronounced hypometabolism 4 weeks after initiation of therapy (both PET are coregistered to the 3D-T1 MRI at –1 week). The time points refer to the beginning of the complex partial status.

(VGKC)-negative limbic encephalitis]. This course illustrates that for those patients with recent seizure manifestation, singular MRIs might be misleading. In case of doubt, we recommend performing a second MRI some weeks to months after the initial MRI. Patients with acute limbic encephalitis are usually not considered surgical candidates.

Features of still uncertain relevance are a blurring of the grey–white matter junction and a signal increase in the white matter in the anterior part of the affected temporal lobe. They are predominantly found in patients with MTS and seizure onset before the second year of life, and are most likely the result of impaired myelinization [21]. However, whether the presence of this feature indicates a wider epileptogenic zone which makes temporal pole resection in addition to amygdala-hippocampectomy necessary for seizure freedom is not yet clear. An example of disturbed grey–white matter demarcation is shown in Fig. 64.7.

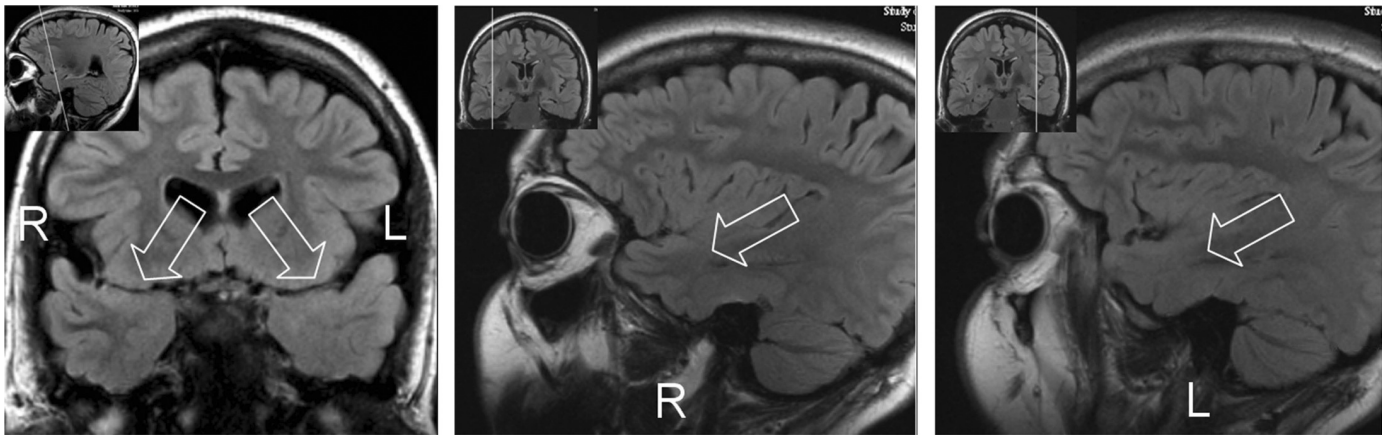

Fig. 64.7 Typical example of a grey–white matter junction blurring and increased temporopolar white matter signal in the left temporal lobe of a patient with left MTS and seizure onset in the first year of life (same patient as in Fig. 64.5).

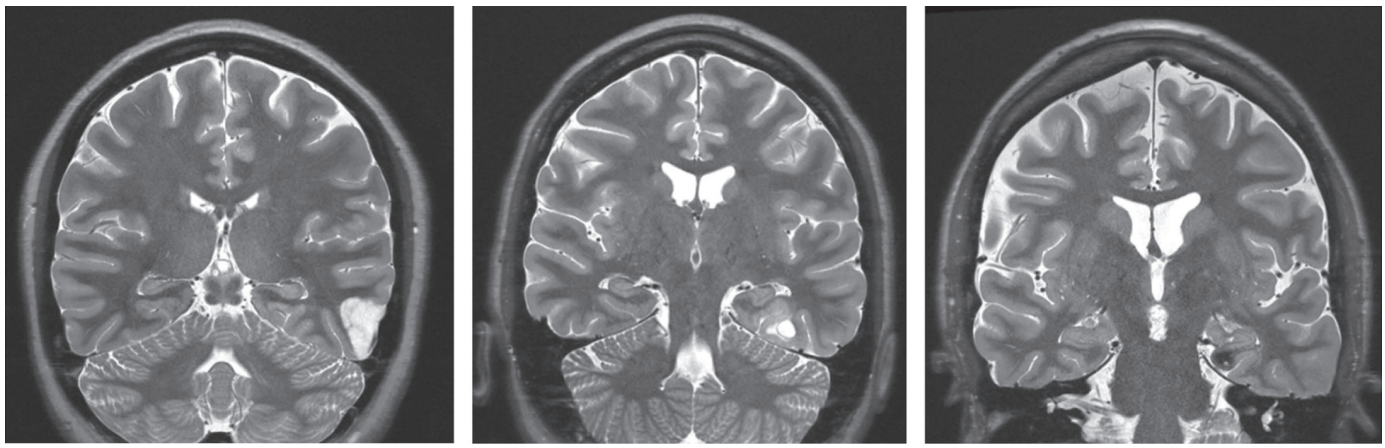

Fig. 64.8 Three patients with highly epileptogenic but easily accessible lesions. (a) Dysembryoplastic neuroepithelial tumour (DNET) WHO grade I. (b) Ganglioglioma WHO grade I. (c) Venous cavernoma. All lesions are known to be highly epileptogenic. If the seizure semiology and interictal/ictal EEG fit with the location of the lesion then these patients are excellent surgical candidates (through extended lesionectomy).

Patients who show easily accessible singular lesions that are known to be epileptogenic and whose localization is concordant with the clinical and EEG presentation of the seizures are even better surgical candidates than those with MTLE. Typical examples include patients with dysembryoplastic neuroepithelial tumours (DNT/DNETs) and glioneuronal tumours (gangliogliomas, gangliocytoma) [22]. Patients with single venous cavernomas also have a very high chance of achieving seizure freedom if a complete resection is possible [23]. However, as multiple cavernomatosis exists and the resection of only one of several cavernomas is not as likely to result in seizure freedom, sequences with high sensitivity for haemosiderin-induced susceptibility artefacts should be applied [T2* of fast field echo (FFE)] [24]. Figure 64.8 shows examples of lesions in easy-to-operate candidates (class A). Recognizing the named entities is not only important from the epilepsy surgery point of view. Some of these lesions can have large extensions and look bizarre; they may also take up contrast medium and therefore be misdiagnosed as high-grade tumours and wrongly treated as such. However, most of these tumours have no growth potential [22]. Extended lesionectomy usually leads to favourable seizure outcome.

Another type of lesion which can be attributed to class A epilepsy surgery candidates is circumscribed focal cortical dysplasia type IIB (FCD IIB), according to Palmini and Lüders [25]. Although not completely overlapping, in other nomenclatures these lesions are referred to as Taylor-type dysplasia [26] or cortical dysplasia with balloon cells [27]. This entity is highly epileptogenic. When FCD IIB is located remotely from eloquent cortex and is easy to delineate on MRI (showing a markedly hyperintense, funnel-shaped area in the white matter, which may extent towards the ventricle [28]), very high surgical success rates can be achieved through MRI-based extended lesionectomy [29]. If, however, dysplasia with balloon cells is rather diffuse [such in the case of transmantle dysplasia or (partial) hemimegalencephaly] or

lesions are located close to eloquent cortex then patients have to be placed in a category other than the easy-to-operate candidates. (For examples of focal cortical dysplasia, see Figs 64.2, 64.4, 64.9 and 64.13.)

Class B: moderately difficult candidates

Patients attributed to class B may have lesions that are identical to those of class A patients. However, their localization requires a more complicated, potentially risky, presurgical evaluation (i.e. invasive recording or mapping with implanted subdural or depth electrodes) or they run a higher risk of postoperative functional deficits.

This category also comprises patients with a slightly to moderately reduced chance of postoperative seizure freedom. As previously mentioned, patients with malformation of cortical development (MCD) other than the circumscribed FCD IIB belong to this group (Fig. 64.9c and d). It will be an issue for clinical research to determine if 3-T MRI combined with improved sequences and postprocessing allows one to better identify the extent of cortical malformations and thus result in the improved categorization of good and bad surgical candidates.

Class B surgery candidates may also be those with post-traumatic defects. Although some small studies report favourable outcome after complete resection of trauma-induced encephalomalacia [30], post-traumatic seizures are reported to occur in particular in patients with multiple post-traumatic defects [31]. Resection of multiple, bihemispheric defects, however, is mostly impossible. Another problem are patients with primary epileptogenic lesions with secondarily acquired traumatic brain injury. It is likely, but not yet proven, that patients with secondary brain injury have a lower chance of achieving seizure freedom after resection of the primary epileptogenic lesion (but sparing the

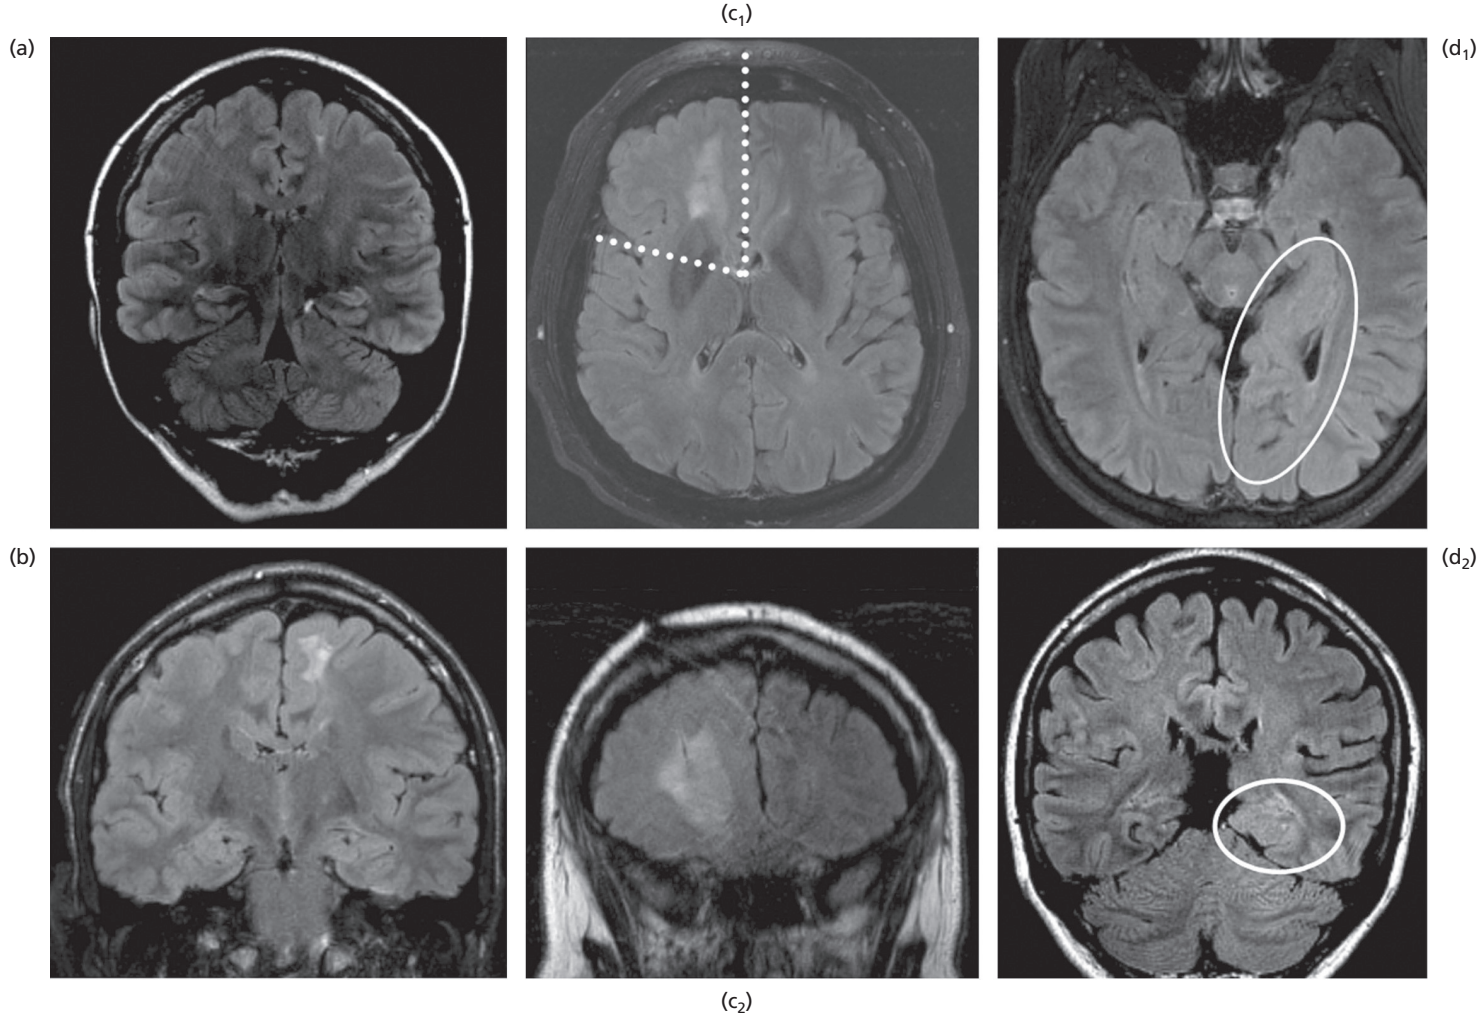

Fig. 64.9 Four patients with different malformations of cortical development. (a) A circumscribed FCD IIB (according to Palmini and Lüders [25]) left frontodorsal. (b) Larger FCD IIB in the left supplementary motor area (SMA). (c_1) and (c_2). Large balloon cell containing malformation of the entire right frontal lobe (see dotted line). Better than FCD IIB, this lesion may be categorized as transmantle dysplasia or partial hemimegalencephaly (in the classification of Barkovic *et al.* [27]). (d) Diffuse malformation of the left temporomesial to occipital structures. Histology showed ectopic neurones in the white matter, no balloon cells and no dysmorphic neurones. Therefore, despite clear pathology in MRI, this pathology cannot be classified according to present classifications. Patients in (a) and (b) are easy surgery candidates (class A patients}, whereas the patients in (c) and (d) belong to class B or C, depending on whether or not the limits of dysplasia/the necessary extent of resection can be detected by MRI or invasive recordings.

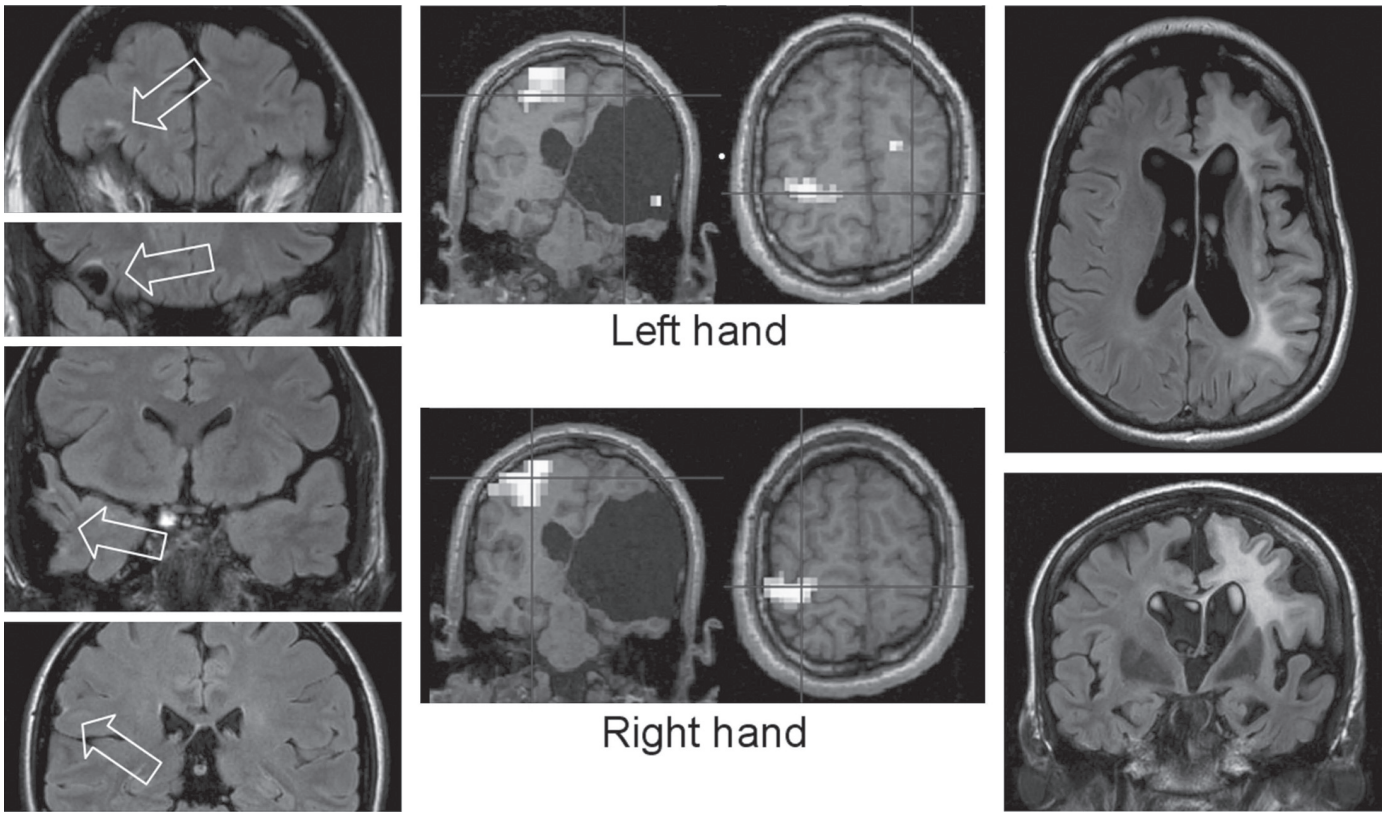

Fig. 64.10 (a) A patient with multiple right hemispheric post-traumatic substance defects (see arrows). Note that in FLAIR even subtle defects can be detected. (b) A patient with porencephaly of the left hemisphere due to perinatal media infarction. There was some preserved motor function of the right hand, but the fMRI indicates ipsilateral representation of the right hand motor function. After a functional hemispherotomy, the patient was seizure free (4.5 years off medication) and there was no deterioration of motor function. (c) Rasmussen's encephalitis of the left hemisphere.

post-traumatic lesion) than those without secondary brain damage. However, with regard to presurgical MRI it is essential to search for even subtle post-traumatic defects if the patient reports a positive trauma history. Examples of post-traumatic lesions in MRI are shown in Figs 64.2 and 64.10.

Patients with porencephaly due to perinatal media infarction can also be classified as class B surgical candidates. Their seizure freedom rate is high [32,33], but the presurgical evaluation is usually more complicated than that of class A patients. Although presurgical hemiparesis is common, usually some motor function in the paretic side is preserved. Patients often undergo fMRI (see Fig. 64.10) or Wada test before surgery. Because of its ipsilateral representation, motor function is usually preserved after hemispherectomy/functional hemispherotomy.

A matter of controversy is when to operate on a patient with Rasmussen's encephalitis. The decision will be influenced by the dominance of the hemisphere and made only after individual risk–benefit estimation [34]. However, because hemispherectomy is a real therapeutic option for many patients, a first presurgical evaluation should not take place too late in the course of the disease. Therefore, we propose to classify these patients as class B surgical candidates.

Class C: very difficult surgical candidates

Patients who do not show lesions on MRI (cryptogenic patients) are bad surgical candidates because they require comprehensive, often invasive, presurgical work-up and their chance of postoperative seizure freedom is relatively small [35]. Much effort should be undertaken to detect existing lesions (by 3-T MRI, post processing) because this can still make patients class A or B candidates with a better chance of seizure freedom. If the best available MRI is non-lesional, it can be reasonable to postpone surgery and speculate on improving future imaging rather than performing an unsuccessful surgery. At this point, we must allude to the fact that the implantation of a vagal nerve stimulator (VNS) should be considered critically in non-lesional patients. With a VNS, access to an MRI higher than 1.5 T is restricted and thus VNS can hinder the imaging process and adversely affect the patient's realistic chance of curative surgery.

Other class C surgical candidates show lesions that usually entrain poor seizure outcome. Depending on the individual risk–benefit ratio, surgery should be performed only in desperate seizure situations and after proof of pharmacoresistance to multiple drugs. One explanation for this is that the epileptogenic area may exceed the MRI-detectable lesion or that these lesions are multifocal or bilaterally distributed. For example, this is true for

polymicrogyria (PMG) and the polymicrogyria–schizencephaly complex. However, optimized imaging may help in detecting the extent of the malformation, and complete resection may result in favourable outcomes in patients with unilateral PMG [36]. Although 3-T MRI shows polymicrogyria to a much better extent than 1.5 T, it is still unknown if this has any impact on the surgical outcome.

Patients with monofocal nodular heterotopia must also be considered very difficult surgical candidates, as the extent of the epileptogenic zone will exceed the nodule (including parts of the overlying cortex [37,38]) and the identification of the epileptogenic zone requires invasive recordings. After careful selection, however, patients with unilateral periventricular nodular heterotopia (PNH) can profit from surgery [38]. If multiple heterotopic nodules are detected then postoperative seizure freedom is unrealistic. Therefore, high-quality MRI (in particular with T1- or IR-sequences) is essential to identify non-operable patients (class E).

Despite promising results in selected patients [39], most patients with multiple tubers in tuberous sclerosis must also be classified as very difficult surgical candidates. For these patients, the staged epilepsy surgery approach has been proposed [40,41]. Before this risky, multistep surgery is considered, the patient should be proven pharmacoresistant for multiple medications.

Patients with hypothalamic hamartomas are also class C patients (see ref. 42 for radiological features of hypothalamic hamartomas). The chance of seizure freedom after surgery is not very high and surgery of hypothalamic hamartomas is not free from complications. It remains to be seen whether or not radiosurgery will finally offer a better risk–benefit ratio than resective surgery [43,44]. Figure 64.11 shows some examples of patients considered class C or D.

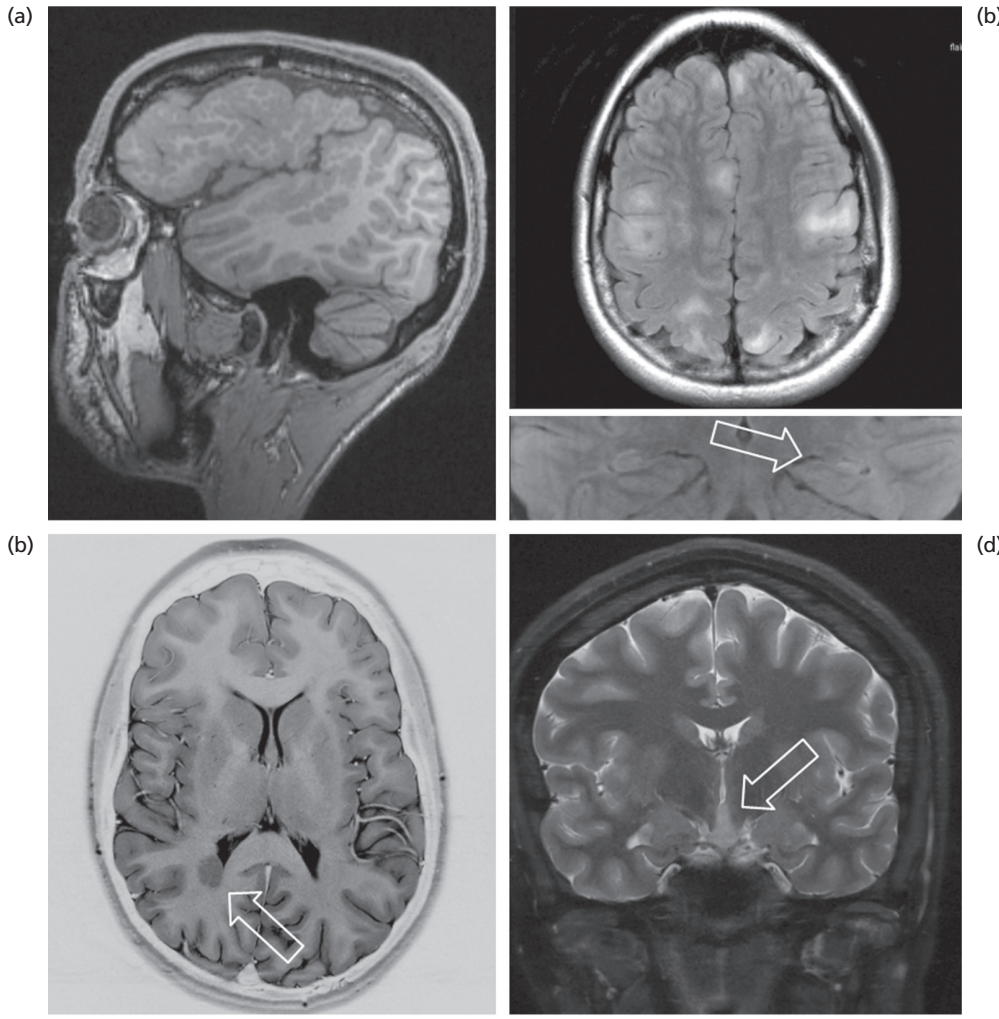

Fig. 64.11 Very difficult or palliative surgical candidates. (a) A patient with extended unilateral right polymicrogyria (3D-T1). Because of multiple seizures per week, often with severe injuries, and pharmacoresistance to virtually all AEDs the patient qualifies for surgery. However, because of bad prospects for seizure freedom and inevitable postoperative neurological deficits he is considered a class C to D candidate. If polymicrogyria is detected contralaterally as well then this patient will be classified as a non-surgical candidate (class E). (b) A patient with multiple tubers in tuberous sclerosis and left MTS. Her seizures have clear left temporomesial semiology and the EEG shows left temporal seizure onset. With a clearly reduced chance of seizure freedom, this patient can be offered left temporal lobe surgery (as a candidate for palliative surgery – class D). (c) A patient with monofocal periventricular heterotopia. Epileptogenicity of the overlying cortex is possible and determining the necessary extent of surgery is complicated; as such this patient would be assigned to class C or D. (d) A typical example of a hypothalamic hamartoma (class C).

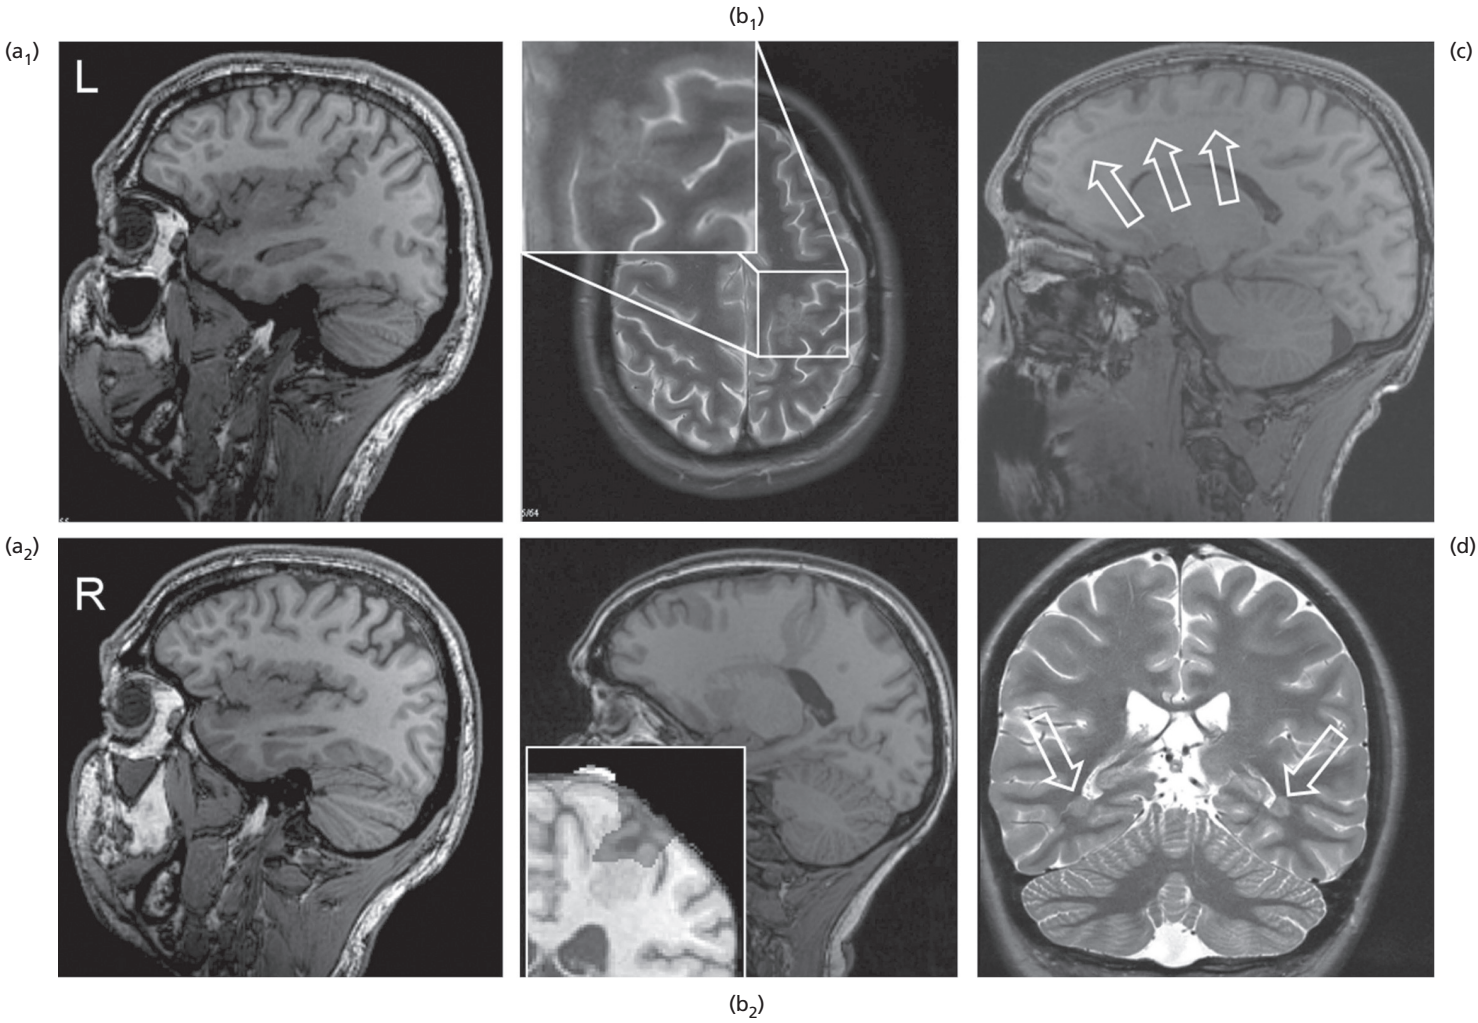

Fig. 64.12 Non-surgical candidates. (a_1) and (a_2) A patient with left and right hemispheric perisylvian PMG. (b_1) and (b_2) PMG schizencephaly-type lesion in the central region. fMRI (inset) indicates the overlap of motoric hand representation and malformation. (c) A patient with prominent subcortical band heterotopia. (d) A patient with bilateral periventricular nodular heterotopia.

Class D: palliative surgery candidates

Palliative surgery is undertaken when epilepsy surgery cannot realistically bring about seizure freedom but may result in relief from particularly disabling seizure types. Typical examples are patients who undergo a corpus callosotomy for relief from tonic or atonic drop attacks. Also patients who undergo resection of only one out of several proven seizure foci can be considered class D. These candidates can have all types of lesions or be cryptogenic. One exemplary case is shown in Fig. 64.11b.

Class E: non-surgical candidates

Reasons for not performing epilepsy surgery on a patient include no chance of achieving seizure freedom or the likelihood of unacceptable neurological deficits. Among the first of the conditions that fall into this category are bilateral migration disorders such as bilateral periventricular nodular heterotopia [37,45], bilateral polymicrogyria or double cortex syndrome (subcortical band heterotopia [46]). Double cortex syndrome can be very prominent and is detectable on all sequences. However, there are very subtle forms that can be recognized only on high-resolution sagittal or three-dimensional T1 images or only through postprocessing [12]. Also, complex malformations such as pachygyria and lissencephaly are not curable by epilepsy surgery, although their detection is usually not difficult using MRI.

Lesions overlapping the eloquent cortex also preclude surgical therapy. They are not restricted to certain aetiologies. Figure 64.12 shows examples of class E patients.

MRI postprocessing

Identifying malformations of cortical development on conventional MRI by plain sight is often difficult owing to their subtlety and the complexity of the brain's convolutions [47]. MRI postprocessing can facilitate lesion detection. By following the

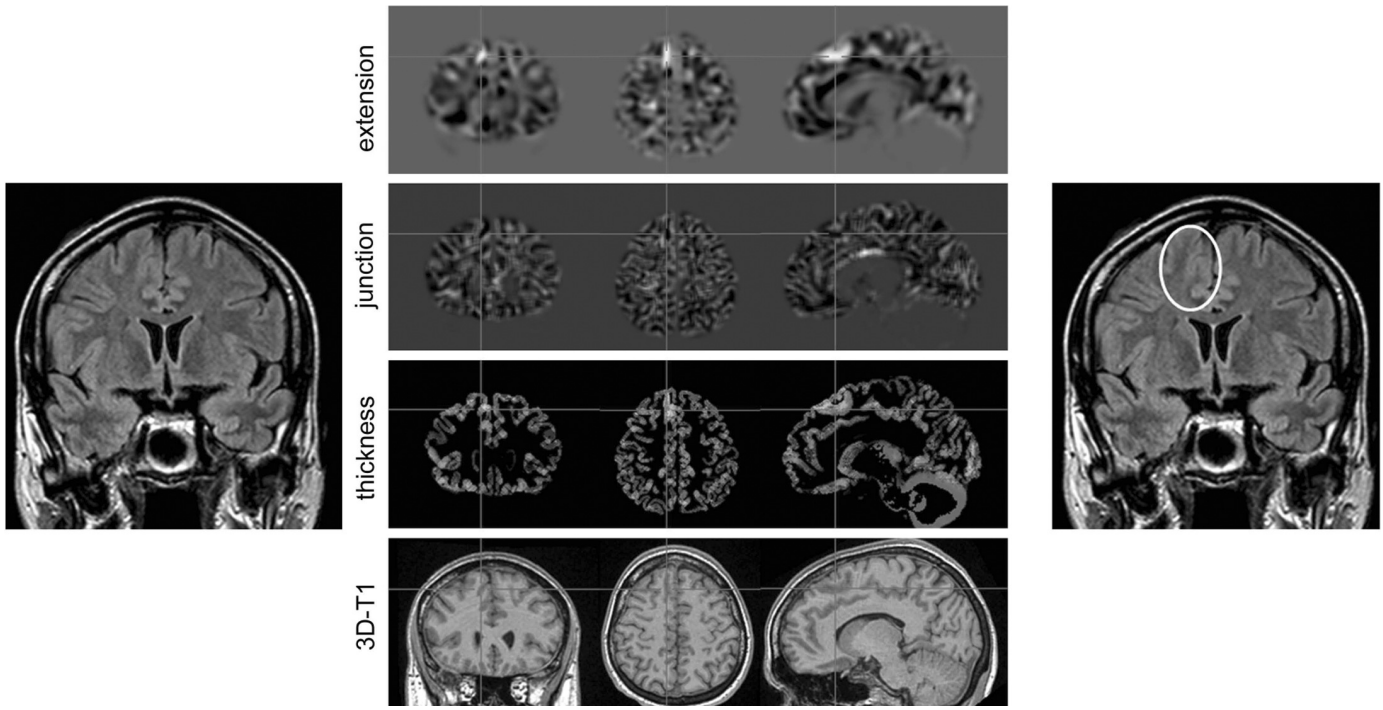

Fig. 64.13 Automated morphometric analysis of a patient with formally cryptogenic epilepsy. Repeated 1.5-T MRI was read as non-lesional (no 3-T MRI possible because of VNS). MRI postprocessing (Morphometric Analysis Program [48]) highlighted a right frontoparasagittal region, which, by invasive recordings, proved to be the seizure onset zone. After extended lesionectomy the patient is seizure free for 1.5 years. Histology: FCD IIB.

principle of voxel-based morphometry, morphometric MRI analysis allows for the objectivisation of abnormalities of cortical texture [47] or grey–white matter junction, cortical thickness or extension of cortex into the white matter [48], all of which are features of focal cortical dysplasia. By highlighting suspicious cortical regions, MRI postprocessing can guide the neuroradiologist or epileptologist for a second look and thereby increase the sensitivity of MRI evaluation. In our personal experience, patients who have been rated non-lesional for years have become seizure free after resection of an FCD identified by morphometric analysis (see Fig. 64.13). Data from the SwissEpi Center in Zurich, Switzerland, indicate that morphometric analysis may provide relevant new information regarding the presence or extent of FCD in the range of 7–8% of patients who are referred to a tertiary epilepsy centre [as compared with expert visual analysis of the same MRI; data refer to 215 patients who received MRI postprocessing at the SwissEpi Center in 2006 (personal communication, H.J. Huppertz, 2007)].

Not only FCD can be recognized through postprocessing. We recently described the value of MRI postprocessing for the detection of subcortical band heterotopia [12]. However, MRI postprocessing is still in the process of being optimized and at present is applied at a minority of epilepsy centres. Questions that remain to be evaluated over the next years are: (1) What is the yield of MRI postprocessing in 'non-lesional' patients? (2) What epilepsy relevant aetiologies can be identified by postprocessing? (3) Which postprocessing method proves effective, easily applicable and finally broadly available? From today's perspective, MRI postprocessing is a promising technique that has the potential to improve presurgical evaluation of cryptogenic epilepsy patients. Figure 64.13 shows an example of an FCD detected only after MRI post processing (method of H.J. Huppertz [48]).

MR-volumetry

Quantitative MRI evaluation of the hippocampus and amygdala can be applied as an auxiliary method in the presurgical evaluation of patients with MTLE. Especially in case of uncertainty regarding bilateral damage, it can be helpful identifying the side(s) of pathology [49]. Hippocampal volumetry aims to identify atrophy in individuals compared with a normative database. If performed by manual tracing, hippocampal volumetry is time-consuming, and intensive training is required to achieve good inter-rater reliability. However, newer studies show that automated techniques are much faster than and equally precise as manual hippocampal volumetry [50]. For hippocampal volumetry, positive prediction of histology (MTS) and surgical outcome has been shown [49].

MR-relaxometry

Like MR-volumetry, MR-relaxometry is a quantitative MRI measure that is mostly applied to the hippocampus. Estimating the transversal relaxation time on T2- or FLAIR-weighted images, it provides an objective and similar value of 'signal intensity' on those sequences. Compared with a normal database, pathological

signal increase corresponding to MTS can be identified. The method has good sensitivity and specificity for MTS, and shows a high positive predictive value not only for postoperative histology, but also for surgical outcome [49]. However, the technique is not usually applied to all patients with MTLE; it is restricted to those with suspected bilateral hippocampal pathology.

Functional MRI

Functional MRI is a non-invasive method of localizing functional brain areas. It detects subtle magnetization changes in response to local blood perfusion changes that are elicited by neuronal activation. fMRI is primarily used for the presurgical determination of language dominance and the localization of motor cortex. The fMRI-based prediction of memory outcome after temporomesial surgery is still experimental.

In the context of epilepsy surgery, the most widely used (but nevertheless not standardized) presurgical application of fMRI is the *determination of language dominance* [51]. After initial studies showed good correlation between fMRI and the gold standard Wada test, there was growing evidence to suggest that language dominance prediction may be not reliable at the individual patient level. A recent study from our group showed that even those patients with Wada test-proven atypical language dominance can show strongly lateralized fMRI [52]. Thus, discriminating between typically and atypically dominant patients and predicting the credibility at fMRI at the individual patient level often becomes impossible. Even more questionable than fMRI-based language *lateralization* is the *localization* of language function. The main pitfalls of fMRI in this context are the lack of discrimination between language-essential cortex and language use-associated cortex as well as the subjectivity of threshold determination for activated versus non-activated cortex [53].

Despite the fact that fMRI underlies continued attempts to improve its validity, it is unlikely that it can be more than a screening method for patients with clearly unilateral language dominance. If fMRI fails to show unilateral dominance, a Wada test should be applied for language lateralization. For language localization, electrical stimulation mapping remains the gold standard.

Functional MRI is also used for the identification of the motor cortex. Activation tasks are rather simple (i.e. alternating blocks of finger movement and rest to identify cortical hand representation) and cerebral activation is robust. Modern technology allows the integration of activation maps into neuronavigation systems and thereby helps neurosurgeons to identify cortical areas that should be spared from resection. However, as for language localization, there are again some critical aspects that must be kept in mind. No surgeon should choose the resection margins on the basis of the spatial extent of fMRI activation. The extent of activation is simply a function of the selected statistical threshold demarcating activated from inactive brain tissue. The choice of the threshold is arbitrary and cannot be transferred between patients or even between sessions for the same patient. Additionally, in the vicinity of cerebral lesions the fMRI results may appear as false negative or positive [54,55]. This can be due to lesion-induced susceptibility artefacts that prevent the identification of magnetization changes or impaired vascular response within lesional or perilesional tissue. Therefore, fMRI should only be used to estimate the brain area where the motor functions should be detected but direct electrophysiological verification is recommended before resection is undertaken. Figures 64.10 and 64.12 show examples of fMRI for the localization of cortical hand representation.

Less well established is the application of fMRI for the presurgical lateralization of memory functions and prediction of postsurgical memory deficits. Although some studies report favourable results [56], the method must be further evaluated to understand its reliability at the individual patient level.

Diffusion-based MRI and tractography

Diffusion-based MRI [diffusion-weighted imaging (DWI)] measures the diffusion of water molecules in different directions. A diffusion-weighted sequence calculates the diffusivity of water in at least three planes, although the number of directions is being progressively increased and leads to a more accurate estimation of the diffusion direction. Two basic parameters are used to describe the diffusivity: the *apparent diffusion coefficient* (ADC), which describes the amount of diffusion, and the *fractional anisotropy*, which describes directed diffusion. There are three emerging applications of DWI which can provide valuable information in the evaluation of an individual with epilepsy (for a review see ref. 57). One application is the identification of the seizure focus. Local ADC changes following partial seizures open up the possibility of localizing seizure onset in patients with partial epilepsy. However, the restricted data are not yet conclusive regarding the percentage of patients in whom focus localization is reliable this way. A practical problem is that diffusion changes after single seizures are only transient. Therefore, an enormous logistical effort seems necessary to enable early postictal access to MRI possible.

A more practicable application of DWI is the identification of interictal DWI abnormalities as hints of the localization and extent of epileptogenic lesions. DWI studies found abnormal anisotropy values in the epileptic hippocampus compared with the contralateral side, as well as in hippocampi of epilepsy patients compared with healthy subjects. In addition, neocortical seizure foci can be identified via DWI. Malformations of cortical development have been examined and showed reduced anisotropy and increased diffusivity. Other studies identified DWI abnormalities in MRI-negative but stereo EEG-positive neocortex (meaning the seizure onset area). Therefore, DWI might help in identifying epileptogenic lesions not detected by MRI. However, this application has not yet been sufficiently evaluated for routine application [57].

Diffusion-weighted imaging-based tractography [diffusion tensor imaging (DTI)] is used at present in clinical application. DTI is a relatively reliable method for identifing white matter pathways *in vivo*. On the one hand, visualization of fibre tracks in the vicinity of epileptogenic lesions allows one to assess the risk of resection-related neurological deficits in patients. On the other hand, including tractography information in the neuronavigation system allows neurosurgeons to adapt their resection in a way which may circumvent postoperative neurological deficits

(with regard to the pyramidal tract or the fibres of the Meyers loop). For the application of this technique in epilepsy surgery, further validation studies are required [57].

Fusion of multiple imaging techniques (including neuronavigation)

The imaging-based presurgical evaluation of complicated epilepsy patients can comprise multiple modalities such as structural imaging (MRI, DTI and MRI postprocessing), functional imaging (fMRI, PET, SPECT, MEG) and information obtained from implanted electrodes. Mentally synthesizing the results of the different modalities is essential for the epileptologist in order to draft resective surgery. Bringing this information together within a common stereotactic room for neuronavigation, however, can facilitate execution of the resection by neurosurgeons. The challenge with these procedures is that all of the information must be coregistered upon the individual patient's brain. The reference dataset for the fusion is usually an isotropic, gap-less three-dimensional T1 sequence, but isotropic three-dimensional-T2 or three-dimensional FLAIR can also be used for this purpose. If data are determined for a normalized brain (i.e. MRI postprocessing) then data must be inversely normalized. All of this is technically possible with a variety of individually programmed software tools (see ref. 58 for a neuronavigation-guided implantation of an FCD which was detected only after morphometric MRI analysis relying on the comparison of the spatially normalized individual brain with a normal data base).

However, regarding the utility of multiple image fusion one has to be aware of the fact that not everything that is technically possible is clinically reasonable. Disregarding the issue of activation thresholds for fMRI, PET, SPECT and even morphometric MRI analysis may lead to dangerous overinterpretation of imaging results [53]. The final value of multimodality fusioning for epilepsy surgery will have to be examined by future studies [58,59].

65 PET and SPECT in Presurgical Evaluation of Epilepsy

Wim Van Paesschen, Karolien Goffin and Koen Van Laere

University Hospital Leuven, Leuven, Belgium

Introduction

A presurgical evaluation starts with a complete seizure history, physical and neurological examination, routine scalp electroencephalography and high-resolution magnetic resonance imaging (MRI) of the brain to assess structural abnormalities [1]. These investigations are complemented by video-EEG monitoring, which allows evaluation of the clinical features of seizures, interictal and ictal EEG, ictal SPECT, interictal 2-[^{18}F]fluoro-2-deoxyglucose (FDG) PET and neuropsychological examination. The aim of presurgical evaluation of patients with refractory partial epilepsy is to localize and to determine whether or not a patient has a single epileptogenic zone. The *epileptogenic zone* is the cortical region that is indispensable for the generation of seizures, and which has to be removed to render a patient seizure free. It is a theoretical construct, defined in terms of different *cortical zones* [2]. The *irritative zone* is the region of cerebral cortex producing the interictal spikes. The *seizure onset zone* is the region in which the seizures actually originate. Ictal SPECT is the only imaging modality that can define in a reliable and consistent manner the ictal onset zone. The *symptomatogenic zone* is the (sub)cortical region producing ictal symptoms. The *epileptic lesion* can be visualized on morphological imaging such as MRI. The *functional deficit zone* is the part of the cortex with an abnormal function in between seizures, due to morphological or functional factors, or both [3]. Interictal FDG-PET provides information on regions of cortex displaying decreased glucose metabolism, which usually contain, but tend to be larger than, the ictal onset zone. Epilepsy surgery has the best results if the different cortical zones are concordant, i.e. point towards the same cortical region, provided that there is no overlap with *eloquent cortex*.

PET

Methodology

PET is based upon the detection of radioligands and computerized tomographic reconstruction of the emitted annihilation rays. It permits the non-invasive measurement of the regional biodistribution of trace amounts of a radioligand and, therefore, the monitoring of its regional kinetics. The measured radioactive concentrations can be translated into colour-coded images and, with an appropriate calibration, it is also possible to quantify the regional tracer concentration at any given time.

Multiple PET tracers have been developed to visualize not only glucose metabolism, but also a wide variety of specific molecular targets such as proteins and specifically receptor systems. Various receptors have been studied in epilepsy: changes in the γ-aminobutyric acid $(GABA)_A$ receptor [4], opioid receptor [5], 5-HT_{1A} serotonin receptor [6], nicotinic acetylcholine receptor systems and others have been described. Of the receptor tracers, ^{11}C- or ^{18}F-labelled flumazenil (FMZ), which binds to the $GABA_A$ receptor, has been studied most often. The use of FMZ in patients with epilepsy, however, has the disadvantage that its binding is affected by several antiepileptic drugs that are often used in clinical practice, such as phenobarbital and benzodiazepines, making it impossible to reliably use this tracer in a large number of patients with refractory partial epilepsy. Although antiepileptic drugs (such as phenobarbital and valproate) cause a depression of glucose metabolism, this drug-induced hypometabolism is fairly uniform and does not affect the degree of asymmetry in FDG metabolism between the ictal onset zone and the contralateral cortex [7]. This is important as FDG-PET can be performed in all patients with refractory partial epilepsy, who usually take one or more antiepileptic drugs at the time of the PET study. Although FDG is available on a daily basis in a nuclear medicine department for especially oncological applications, and the superiority of studying these receptor systems over glucose metabolism in the presurgical evaluation of patients with refractory epilepsy remains to be proven [8,9], their use in clinical practice is limited at the moment. Here, we will, therefore, focus on glucose metabolism. We will also briefly discuss alpha-[^{11}C]methyl-L-tryptophan (AMT) PET, which has been useful mainly in the presurgical evaluation of patients with tuberous sclerosis complex (TSC) [10].

Measurement of glucose consumption using FDG requires an incubation period of 30–45 min after tracer administration before brain scanning (http://www.eanm.org/scientific_info/guidelines/guidelines_intro.php?navId=54). During this time, FDG is trapped and accumulates in cells as a function of glucose transport and hexokinase activity. The FDG scan, therefore, reflects cerebral glucose metabolism during the uptake, weighted towards the beginning of that period, primarily the first 10 min after injection, and may underestimate changes in metabolic rates associated with changes in cerebral function of short duration [11].

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Spatial resolution and partial volume effect

The first tomographs had an in-plane resolution of 15 mm. Current technology has reduced spatial resolution to 3–4 mm. One of the consequences of this limited spatial resolution is the so-called partial volume effect, which can be defined as an averaging of the signal between neighbouring areas. This effect concerns structures smaller than approximately twice the spatial resolution of the system, such as the cortical ribbon of the brain. It results in a blurring of boundaries between adjacent structures and, therefore, in poor definition of anatomical details, as well as in an underestimation of true radioligand concentration for smaller structures. Higher spatial resolution improves the sensitivity of PET studies as, due to partial volume effect, the apparent size of the hypometabolic zone is increased but the degree of hypometabolism is underestimated. Methods to correct for this variable have been designed and implemented (see references in ref. 12). Partial volume correction increases the sensitivity of detecting a lateralizing asymmetry of hippocampal metabolic activity by 15–20% over that without partial volume correction in patients with unilateral hippocampal sclerosis (HS) [13], and improves the detection accuracy of small hypometabolic lesions in FDG-PET images of the brain [14].

PET data analysis

Interpretation of PET images can be achieved through visual inspection alone. Quantification of PET studies may be relative (raw counts) or absolute [after kinetic modelling, to obtain, for example, glucose metabolic rates or receptor densities (B_{max})]. Measurements are obtained in regions of interest (ROI), which are affected by several sources of variations (size, shape, positioning) and biases (partial volume effect). These data are used for comparison with a control population or calculation of asymmetry indices, or normalized to global counts. Quantitative analysis can help validate or negate contradictory or questionable visual interpretation. Automated, non-interactive, voxel-based techniques, such as statistical parametric mapping (http://www.fil.ion.ucl.ac.uk/spm/) or three-dimensional stereotactic surface rendering methods, offer more objective, extensive, rigorous and detailed analysis of brain metabolic activity. Comparisons with a control group may be performed for groups of patients but also for each patient individually. Using SPM analysis of quantitative (CMRGlu) and non-quantitative (radioactive counts) data, Signorini and colleagues [15] obtained the same pattern of results and suggested that it no longer appeared justified to perform invasive arterial catheterization and blood sampling for FDG-PET scans in patients with epilepsy to obtain valuable and reliable functional information in routine clinical practice.

FDG-PET and ictal onset zone in refractory partial epilepsy

Interictal FDG-PET

The vast majority of FDG-PET studies have been carried out during the interictal state. Kuhl and colleagues [11] were the first to demonstrate that interictal FDG scans are characterized by a localized depression in cerebral glucose consumption that correlated anatomically with the EEG spike foci in patients with partial epilepsy. The metabolic defect on PET was larger than atrophic lesions found on CT scan and the structural damage was found at pathological examination. These original findings were later expanded by Engel and colleagues [16] and largely confirmed by many others [4,17–27]. More than 70% of patients with partial epilepsy show a localized area of decreased brain glucose metabolism or hypometabolism on FDG-PET. The hypometabolism may be regional or lobar and usually has a progressive demarcation from the normal cortex. It may also be more widespread and multilobar; in this case, the most hypometabolic lobe is usually the lobe of seizure onset [4]. The hypometabolic region may include an area with more severe hypometabolism and a sharp demarcation from the adjacent cortex. This metabolic pattern often corresponds to a structural lesion. The site of ictal onset usually lies within an area of hypometabolism.

The hypometabolism is usually on the side of the brain with the epileptogenic zone, but in a minority of cases, false lateralizations are possible [4,16–21]. False lateralizations may be due to postictal effects or to unrecognized, subclinical seizure activity during the uptake phase or contralateral propagation of seizures. Following complex partial seizures, the ipsilateral temporal metabolic rate is relatively increased for 48 h before falling significantly later [28].

Patients with extratemporal lobe epilepsy are less likely to have an abnormal PET study than patients with temporal lobe epilepsy (TLE) [29]. Based on a review of the literature, Spencer and colleagues [30] reported that interictal FDG-PET in TLE as judged by EEG criteria had a sensitivity of 84% and a specificity of 86%, whereas in extratemporal epilepsy sensitivity was 33% and specificity 95%. With advanced processing of FDG-PET data, this sensitivity is higher [29]. When a lesion is detected by CT or MRI, FDG-PET tends to be abnormal as well. The hypometabolic zone is larger and more extensive than the lesion itself [4,31].

Cortical dysplasia can present with either hypometabolism or displaced grey matter activity to a white matter area [32]. This latter metabolic pattern is a unique feature of cortical dysplasia and it is highly suggestive of this pathology. It represents glucose metabolism of abnormally located grey matter rather than a subclinical ictal phenomenon.

Prediction of seizure outcome on the basis of PET data is an important issue in patients with uncontrolled partial seizures, as PET results may influence patient selection for surgery. In patients with TLE, temporal hypometabolism on FDG-PET predicts successful temporal lobectomy even when surface electroencephalography and MRI are non-localizing [9,18,23,24,26,33–36]. Multilobar hypometabolism [35], or extratemporal hypometabolism [24], is associated with a higher likelihood of postsurgical seizure activity. Interestingly, it has been found that patients with thalamic hypometabolism ipsilateral to the temporal lobe seizure focus were at higher risk of postoperative seizures than were patients with no thalamic asymmetry. Furthermore, patients with relative contralateral thalamic hypometabolism were not seizure free postoperatively [37]. Normal PET scans are associated with suboptimal surgical outcome [24] and intracranial electroencephalography studies may be less likely to disclose an epileptogenic region when FDG-PET shows no hypometabolism [35]. Nevertheless, these patients without apparent hypometabolism may benefit from surgery but may need further scrutiny [38].

Initial PET studies were performed before MRI scans were available. When high-resolution MR scans became available, the added value of FDG-PET was questioned. Several recent studies, however, have stressed that FDG-PET can give additional information in the presurgical evaluation of patients with refractory partial epilepsy, which is independent of results of other investigations, such as high-resolution MRI. Carne and colleagues [33] reported good surgical results in patients with MR-negative refractory TLE and unilateral temporal hypometabolism, and suggested that MR-negative PET-positive TLE represents a surgically remediable syndrome distinct from mesial temporal lobe epilepsy related to hippocampal sclerosis (mTLE-HS), with focal hypometabolism involving primarily lateral neocortical rather than mesial temporal structures [39] (Plate 65.1). Lee and colleagues [23] reported their experience with FDG-PET in the largest series to date of surgical outcome in 89 patients with refractory partial epilepsy and normal MRI. Overall, 35 had frontal lobe epilepsy, 31 neocortical TLE, 11 occipital lobe epilepsy, 11 parietal lobe epilepsy and one multifocal epilepsy. In total, 47% of patients remained seizure free for more than 2 years after surgery and 80% had a seizure reduction of at least 90%. Diagnostic sensitivity of FDG-PET as analysed by SPM was 44%. FDG-PET localization was greatest in neocortical TLE and significantly related to seizure-free outcome. This study confirmed the usefulness of lateralized hypometabolism in MR-negative TLE. Given that patients with negative MRIs and temporal hypometabolism on FDG-PET have become seizure free following lateral temporal resections [33,40], it may be possible to develop criteria that would permit sparing of mesial temporal structures in some patients based on the results of FDG-PET. Ollenberger and colleagues [41] assessed the role of FDG-PET in the diagnosis and management of children with refractory epilepsy. A majority of their patients had extratemporal lobe epilepsy. In this retrospective study, FDG-PET studies were obtained after all other diagnostic investigations had been performed. FDG-PET provided information additional to that obtained with other investigations regarding the epileptogenic zone in 88 out of 113 patients (77%), and changed management in half of the patients. In the group of patients who were considered good surgical candidates (n = 92), FDG-PET data excluded 36 patients (39%) from surgery. However, it would be impossible to know whether or not these patients might have benefited from surgery and been denied it inappropriately because of the FDG-PET data. In the group of patients who were not considered good surgical candidates (n = 21), FDG-PET data made epilepsy surgery possible in one patient (5%). Ollenberger and colleagues [41] concluded that FDG-PET should be part of a routine work-up in all paediatric patients with refractory epilepsy who are being considered for surgery. Uijl and colleagues [9] reported that FDG-PET was most useful in patients with TLE when MRI was normal or did not show unilateral temporal lobe abnormalities, and when ictal EEG results were not concordant with MRI findings or seizure semiology. O'Brien and colleagues [42] reported that FDG-PET is cost-effective in the presurgical evaluation, particularly when used in patients with a non-localizing or non-concordant video-EEG monitoring or MRI result.

Ictal FDG-PET

In patients with frequent serial seizures or status epilepticus, ictal PET can be obtained and can demonstrate the ictal onset zone as an area of hypermetabolism, even when electroencephalography is not informative [43–45] (Plate 65.2). Occasionally, seizures occur during FDG uptake and produce a hypermetabolic area at the interictal hypometabolic focus [31].

FDG-PET hypometabolism in areas remote from the ictal onset zone

The underlying neurobiology of FDG-PET hypometabolism is not well understood, and has been ascribed to factors such as neuronal loss, diaschisis, inhibitory processes or reduction in synaptic density. The area of FDG-PET hypometabolism is often larger than the ictal onset zone and it has been suggested that this area of hypometabolism represents the functional deficit zone [2,25,46]. In mTLE-HS, the hypometabolism may extend to ipsilateral frontal and parietal cortex, as well as to subcortical structures such as ipsilateral basal ganglia and thalamus, and contralateral cerebellar lobe [20]. mTLE-HS is characterized by neuronal loss and gliosis in the hippocampus. However, there is no relation between the degree of interictal PET hypometabolism and the amount of hippocampal gliosis or cell loss [47]. Furthermore, temporal lobe hypometabolism has been observed in the absence of HS or any other identifiable pathology [23,33], suggesting that hippocampal atrophy is not a major determinant of hypometabolism. Using non-quantitative FDG-PET data normalized for white matter activity only, we correlated interictal FDG-PET metabolism and ictal SPECT perfusion changes in mTLE-HS [25]. Surprisingly, we found that *interictal* hypometabolism was greatest in the ipsilateral frontal lobe, and that this region coincided with the area of greatest *ictal* hypoperfusion, consistent with a seizure-related dynamic process (Plate 65.3). Crossed cerebellar diaschisis suggested that ipsilateral frontal lobe hypoperfusion/metabolism represented strong inhibition during complex partial seizures [48]. We formulated the hypothesis of surround inhibition, which is a dynamic (i.e. seizure-related) process, present in seizure propagation pathways, and which is a defence mechanism against seizure propagation. It is characterized by *interictal* hypometabolism and *ictal* hypoperfusion, and may be responsible for interictal and ictal functional deficits that may be reversible upon cessation of seizure activity. In this hypothesis, some interneurones in the hyperperfused temporal lobe undergo active synaptic inhibition with downstream decreased synaptic activity in the ipsilateral frontal lobe [48], which is the most common route of spread of mesial temporal lobe seizures [49]. This hypothesis might explain why ipsilateral frontal lobe excitability, as measured with transcranial magnetic stimulation, in patients with refractory TLE correlates strongly with time to next seizure [50]. Ictal surround inhibition has been shown to be present in the cortex surrounding an epileptic focus using optical imaging, which is a functional imaging modality based on the same principle of coupling of focal alterations in metabolism and blood flow [51]. A decrease in the optical signal correlated spatially with a decrease in neuronal activity recorded from cortex surrounding an epileptic focus. Witte and colleagues [52] reported PET findings of a patient who had a seizure during PET scanning and documented that the transition from interictal to ictal activity was

accompanied by the development of a hypermetabolic epileptic focus and the dynamic enlargement of surrounding hypometabolism (see also Plate 65.2).

Clinical correlations with FDG hypometabolism in areas remote from the ictal onset zone

FDG-PET hypometabolism has been related to neuropsychological and psychiatric dysfunctioning in epilepsy. McDonald and colleagues [53] correlated interictal FDG-PET with frontal lobe executive function, and found that resting frontal lobe metabolic values were strong predictors of executive functioning in patients with epilepsy. Jokeit and colleagues [54] reported a correlation between prefrontal metabolic asymmetry with frontal lobe cognitive deficits in patients with TLE. Takaya and colleagues [55] compared cognitive functions and interictal cerebral glucose metabolism of 11 patients with mTLE and frequent seizures to those of 10 patients with mTLE and rare seizures. The frequent-seizure group had more set-shifting impairment that correlated with glucose hypometabolism in the prefrontal cortices. These results suggested that frequent seizures in mTLE are associated with hypofunction of the prefrontal cortex. Salzberg and colleagues [56] reported that patients with TLE and a history of depression at any time preoperatively showed focal hypometabolism in ipsilateral orbitofrontal cortex compared with those who did not.

FDG hypometabolism in areas remote from the ictal onset zone is seizure-related and reversible

Several reports provide evidence that hypometabolism at a distance from the seizure focus may disappear on seizure remission. Akimura *et al.* [46] described improvement in hypometabolism of ipsilateral areas remote from the ictal onset zone, mainly the frontal lobe, in patients who underwent temporal lobectomy. Spanaki and colleagues [57] documented increases in metabolism in the ipsilateral inferior frontal lobe and thalamus after temporal lobectomy for intractable TLE. Joo and colleagues [58] compared pre- and postoperative FDG-PET scans in patients with mTLE-HS who were rendered seizure free after surgery. Increases in FDG metabolism after surgery were seen in the propagation pathways of ictal and interictal epileptic discharges, for example temporal stem white matter, inferior precentral gyrus and anterior cingulate gyrus in the ipsilateral hemisphere, suggesting that hypometabolism in these regions was functional, seizure related and reversible. On the other hand, decreases were seen in brain structures with afferents from resected anterior mesial temporal structures.

Clinical correlations of resolution of FDG hypometabolism in areas remote from the ictal onset zone after seizure remission

A key question is whether or not disappearance of FDG-PET hypometabolism at a distance from the ictal onset zone after (postsurgical) seizure remission correlates with neuropsychological and neuropsychiatric improvement, which is common after successful epilepsy surgery [59,60]. In the presurgical assessment, attention is focused on eloquent cortex and loss of function after epilepsy surgery. It is equally important to counsel the patients what they could gain in terms of cerebral functioning after successful epilepsy surgery. Large studies correlating neuropsychological and neuropsychiatric improvements with disappearance of FDG-PET hypometabolism in areas at a distance from the resection site have not been performed and are warranted. To illustrate this point, we provided anecdotal evidence that cognitive impairment associated with frontal lobe hypometabolism due to ongoing parietal lobe seizures recovered over more than 1 year after remission of seizures, and this improvement was associated with resolution of hypometabolism [45] (Plate 65.2).

AMT-PET in refractory partial epilepsy

Tuberous sclerosis complex (TSC) is an autosomal dominant disease in which multiple cortical tubers or focal cortical dysplasias are a primary hallmark. Seizures are the most common symptom of the disease and either infantile spasms or West syndrome is particularly frequent during the first several years of life. Because of the multitude of cortical lesions, however, identifying the epileptogenic tuber(s) is difficult. Chugani and colleagues [10] reported that epileptogenic tubers have an increased AMT uptake and AMT-PET differentiates between epileptogenic and non-epileptogenic tubers in patients with TSC. AMT-PET localization is mostly seen in patients with frequent interictal abnormalities on the EEG [61]. Focal increase of cortical AMT uptake is less sensitive but more specific for the lobe of seizure onset than corresponding FDG-PET hypometabolism, and is often associated with epileptogenic cortical developmental malformations in children without TSC. AMT-PET can assist placement of subdural electrodes even when MRI and FDG-PET fail to provide adequate localizing information [62]. Kagawa and colleagues [63] analysed the surgical outcome of children with TSC in relation to AMT-PET results. Their findings suggested that resection of tubers with increased AMT uptake is highly desirable to achieve seizure-free surgical outcome in children with TSC and intractable epilepsy.

SPECT

Methodology

Ictal SPECT has the potential to localize the ictal onset zone accurately in a non-invasive manner. In order to reliably deliver early ictal SPECT injections, detailed attention should be paid to the logistics of ictal SPECT set-up. Ictal SPECT injections should be performed in the video-EEG suite, with the nursing and review station close to the rooms of the patients. Medical personnel should be educated in handling of radioligands and must be familiar with the electroclinical features of epileptic seizures. The brain perfusion agent should be available in the room and the injection system should allow for fast ictal injections [64,65]. High-resolution SPECT and MR scanners should be available. An excellent cooperation between the neurology and nuclear medicine department is of crucial importance. If the implementation of ictal SPECT is too difficult then referral of selected patients for ictal SPECT should be considered.

SPECT studies in partial epilepsy have been carried out with blood flow tracers, which are $^{99}Tc^{m}$-labelled compounds, such as $^{99}Tc^{m}$ hexamethyl-propyleneamine oxime ($^{99}Tc^{m}$-HMPAO) or $^{99}Tc^{m}$ ethyl cysteinate dimer ($^{99}Tc^{m}$-ECD). These lipophilic amines rapidly cross the blood–brain barrier (up to 85% of brain uptake on the first pass). Once inside the brain they form a hydrophilic compound that is trapped within cells, which prevents washout.

Cerebral uptake is complete within 2 min and less than 5% is redistributed later. The activity in the brain remains essentially constant and proportional to regional perfusion at the time of administration. Its distribution is not affected by subsequent changes in cerebral blood flow (CBF) or pharmacological intervention. Given the long half-life of these radiopharmaceuticals and very slow regional redistribution, static SPECT scans can be acquired up to 4 h after their intravenous administration during a seizure [66]. During the initial ictal studies in epilepsy, $^{99}Tc^{m}$-HMPAO had to be reconstituted rapidly at the bedside during a seizure [67], which made the implementation of ictal injections of $^{99}Tc^{m}$-HMPAO more difficult than with $^{99}Tc^{m}$-ECD, which is a stable ligand, and which allowed for earlier ictal injections. A stabilized form of $^{99}Tc^{m}$-HMPAO is now available. $^{99}Tc^{m}$-ECD is cleared from the body more rapidly than $^{99}Tc^{m}$-HMPAO, giving a higher brain/background ratio of activity and a superior SPECT image quality [68]. These SPECT radiopharmaceuticals can be prepared any time, without the requirement of running a complex cyclotron. The kinetic profile of these tracers with fast uptake and stable retention allows for injecting the patient at distance from the SPECT camera, for example in the epilepsy monitoring unit, during a seizure, which is a major advantage. Scanning is then carried out when the patient has recovered full consciousness and is able to collaborate.

The localizing value of ictal SPECT performed with cerebral perfusion imaging agents in patients with partial epilepsy is based on cerebral metabolic and perfusion coupling, i.e. an increase in neuronal metabolic activity is associated with an increase in CBF, and a decrease in neuronal metabolic activity with a decrease in CBF.

Ictal SPECT is obtained by injecting the ligand during a seizure and an interictal SPECT by injecting the ligand between seizures. The accuracy of ictal SPECT analysis is highest when comparing the ictal with interictal perfusion data. Methodologically, this can be carried out by traditional side-by-side visual evaluation, but computer-aided voxel-based co-registration techniques (such as subtraction ictal SPECT co-registered to MRI (SISCOM) [69,70] and ictal–interictal SPECT difference image (ISAS) [71]) are fast, more accurate and objective, and are routinely available. For SISCOM analysis, interictal and ictal SPECT scans are co-registered using an automatic registration algorithm based on mutual information [72] and the interictal image is then subtracted from the ictal. The difference image is smoothed and transformed into a *z*-score map using the mean and the standard deviation of the differences in all brain voxels. The mean image of the ictal and interictal coregistered images can be used for coregistration to the patient's MRI. The same transformation is then applied to the z-map. For the functional overlay different thresholds can be used to assess most significant differences. Careful quality control of registration (e.g. assessment of acquisition movement artefacts, registration errors) and subtraction is important in order to avoid false-positive and false-negative results, and the result of the SISCOM analysis has to be concordant with the result of visual comparison of the ictal and interictal images, and other data of the presurgical evaluation. Furthermore, SISCOM may be false-negative due to subclinical seizure activity at the moment of tracer injection of interictal SPECT imaging [73]. Electroencephalography monitoring during the interictal injection, therefore, should be routinely performed.

Ictal SPECT in presurgical evaluation

The interpretation of ictal SPECT images should always be undertaken in the context of a full presurgical evaluation. The injection time should be known, as early injections give the best results. The importance of early tracer injection after the beginning of the seizure cannot be overemphasized. It has been shown that an injection delay of less than 20 s is significantly correlated with a correct localization [73]. With early injections, the largest and most intense cluster is more likely to represent the seizure onset zone, and not seizure propagation. Several propagation patterns have been described. Propagation is often from posterior brain regions (parieto-occipital lobes) to anterior brain regions (temporal and frontal lobes) [74]. Noachtar and colleagues [75] reported propagation in 85% of parieto-occipital epilepsy. Another propagation pattern is from the temporal to the frontal lobe. In patients with a temporal lobe lesion on MRI and discordant frontal lobe seizures, ictal SPECT may show propagation from temporal to frontal lobe, obviating the need for invasive monitoring. Propagation from one temporal lobe to the contralateral temporal lobe has been reported in around 1% of cases [21]. Propagation of ictal activity can partly explain why a high SISCOM threshold has a lower sensitivity and higher specificity than a low threshold, which has a higher sensitivity but lower specificity [76]. In clinical practice, using different SISCOM thresholds can help elucidate propagation patterns. In partial epilepsy caused by single MRI-visible focal dysplastic lesions (FDLs), we reported three different ictal perfusion patterns [77]. The first pattern was characterized by the largest and most intense hyperperfusion at the FDL, and was most often seen with very early injections, and represented the ictal onset zone before seizure propagation occurred. The second pattern was characterized by an 'hourglass pattern', with the least intense lobule overlapping with the FDL, and the most intense at a distance, representing propagation (Plate 65.4). Third, a variant of the second pattern showed a more complicated multilobulated propagation pattern that was most often seen in frontal lobe seizures with fast seizure propagation and relatively later ictal injection times.

The injected seizure type and ictal semiology should be known for a correct interpretation of ictal SPECT. In our hands, ictal SPECT during simple partial seizures gave no information in around 40% of cases. For this reason, we have limited the use of self-injection ictal SPECT, as this was often during isolated simple partial seizures [78]. Complex partial seizures give the best results, and secondarily generalized seizures may give multiple regions of hyperperfusion [79].

The duration of the injected seizure is important in the interpretation of ictal SPECT studies. After injection in an arm vein, the tracer takes around 30 s to reach the brain. The postictal switch, i.e. switch from ictal hyperperfusion to postictal hypoperfusion, occurs about 1 to 2 min postictally in temporal lobe seizures [80] but is shorter in extratemporal seizures. It has been estimated that extratemporal seizures should last at least 10 to 15 s after ictal SPECT injection to give localizing information [76].

O'Brien and colleagues [69] reported localization in 39% using side-by-side visual inspection versus 88% localization using SISCOM. A meta-analysis of SPECT brain imaging in patients with TLE showed a sensitivity of ictal SPECT localization of 0.97,

relative to diagnostic evaluation without imaging, while this was only 0.44 for interictal SPECT localization [81]. Interictal SPECT perfusion imaging on its own, therefore, seems to be inefficient in localizing the seizure onset zone and should be used only as a baseline perfusion measure in the comparison of ictal perfusion images. Ictal SPECT studies of complex partial seizures of extratemporal lobe origin also have an excellent localizing value, but may be more difficult to obtain when the seizures are brief in duration [82,83]. The sensitivity of ictal SPECT in extratemporal seizures has been reported to be around 90%. Ictal SPECT, and in particular SISCOM images, are predictive of postsurgical outcome [69] independently of MRI or scalp ictal EEG findings [84].

Multimodality imaging

Several imaging modalities with different spatial and temporal resolutions are available to study the brains of patients with epilepsy *in vivo*. Combinations of these imaging modalities that integrate the strengths of modalities and at the same time eliminate one or more weaknesses of an individual modality may provide new information that is superior to the information provided by each individual imaging modality (Plate 65.5). Although SISCOM is routinely performed, co-registration of ictal perfusion SPECT, interictal FDG-PET, structural MRI, functional MRI, diffusion-tensor imaging (DTI), EEG and magneto-encephalography (MEG) in one multimodality imaging platform could provide a very powerful tool to systematically study the relationships between the epileptic lesion (MRI), irritative zone (MEG and interictal EEG), ictal onset zone (ictal perfusion SPECT, ictal EEG and interictal FDG-PET), functional deficit zone (FDG-PET), eloquent cortex (fMRI and diffusion tensor tractography) and the connectivity between the different cortical regions (diffusion tensor tractography). Knowlton summarized the mounting evidence that multimodality imaging combining FDG-PET, ictal perfusion SPECT, and MEG in combination with MRI is increasing the number of patients being considered for epilepsy surgery without the need for invasive EEG studies [85]. Lee and colleagues [23] investigated patients with cryptogenic neocortical epilepsy with FDG-PET, ictal perfusion SPECT, interictal and ictal EEG, and found that concordance with two or more presurgical evaluations was significantly related to a seizure-free outcome. Chandra and colleagues [86] used the coregistered combination of FDG-PET, MRI and DTI to distinguish epileptogenic tubers and cortex in patients with tuberous sclerosis complex. Compared with non-epileptogenic tubers, epileptogenic tubers had larger volumes of FDG-PET hypometabolism and increased apparent diffusion coefficient.

Introduction

There have been many advances in structural imaging over the last two decades which have greatly enhanced the processes of presurgical evaluation. We have already seen considerable advances in associated functional imaging techniques, such as positron emission tomography (PET), interictal and ictal single photon emission computerized tomography (SPECT) and magnetoencephalography (MEG), described elsewhere. This chapter outlines the principles and current or future potential applications of two specific functional imaging techniques based on computational analysis of the electroencephalogram (EEG) ictal and interictal signals, which are source modelling and EEG-correlated functional MRI (EEG/fMRI).

Source modelling of electroencephalography

More than 50 years ago, Marie Brazier [1] proposed the application of physical and mathematical principles to the localization of EEG sources based on the assumption that an active current source within a finite conductive medium will produce volume currents that lead to potential differences on the surface. In this chapter, we will first review the methodological aspects of EEG source modelling methods then examine the results for interictal spikes, and their relation to other data such as MRI or PET, and invasive recordings. Finally, we will assess the peculiar difficulties encountered in modelling ictal discharges and examine the overall clinical relevance of EEG source modelling results in the presurgical evaluation of epileptic patients. In what follows the term 'generator' refers to the anatomical structure generating the events, whereas the word 'source' refers to the modelled generator.

Methodological aspects

Principle

EEG source modelling is based on an interactive statistical estimation of the locations, orientations and amplitudes of the intracerebral generators from surface signals and this requires models for both generators and conductive media.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Modelling the sources of interictal spikes

The easiest way to represent a current source is with a current dipole, which is produced when an ion flow through the neuronal membrane occurs at the synaptic cleft during postsynaptic excitation or inhibition of pyramidal cell dendrites and this flow is counterbalanced by a current stream along the postsynaptic membrane; this results in a group of negative and a group of positive charges, separated by a small distance along the axis of the pyramidal cell (i.e. a dipole). If a sufficient number of focal neurones are synchronously activated, as occurs during an epileptic spike, currents may be obtained with sufficient amplitude to produce a measurable potential difference at the surface because pyramidal cells are organized in columns orientated perpendicular to the cortical surface. The geometry of neuronal aggregates is of particular importance; 'closed field' configurations (i.e. groups of neurones with radial or random orientations of their dendritic trees (as in amygdala or thalamus) will theoretically give rise to very small or nil equivalent dipoles with no recordable electrical potential outside, but the activity of neurones that are orientated in a parallel way ('open field', as is for most cortex) can be modelled by an equivalent dipole, representing the vectorial sum of each of the unitary dipoles [2].

The potential to detect spikes thus heavily depends on the configuration of the generators, but also on their spatial extent and depth. For instance, the question of whether or not spikes originating solely from mesial temporal structures are detectable on the scalp surface, which is crucial for presurgical evaluation of temporal lobe epilepsies, has been much debated in the literature. A few studies suggested that mesial temporal spikes are detectable on the scalp [3–5], but this was without direct validation by intracranial recordings. Combined depth EEG and surface recordings showed that intracranial spikes involving solely the deepest mesial contacts in TLE are hardly visible on the surface [6,7].

Modelling the conductive volume

The potential differences recorded at the scalp also depend on the different conductivities of the tissues through which neuronal currents are flowing. A model for the head, therefore, has to describe mathematically the physical properties of brain tissues and liquids, i.e. the brain itself, cerebrospinal fluid (CSF), skull and scalp. In order to simplify this calculation, it is usually assumed that all of these properties are purely resistive. The geometry of head models used for dipole modelling is either spherical or realistic.

The spherical model of the human head includes concentric spherical shells of different conductivity, representing the scalp, skull, CSF and brain [8]. Although a sphere is quite well adapted to the shape of the brain over central regions, the real shape of the head is clearly different from a sphere in occipital, frontal or basal regions, which could potentially give rise to localization errors [9]. To improve the localization of intracerebral sources, realistic models of the head have been proposed [10–13], based on the extraction of scalp, skull and brain surfaces from individual MRI data.

The realistic models are generally more computationally demanding and thus less employed in clinical settings. Those realistic models are subdivided into boundary and finite element method (BEM, FEM) models [14]. BEM models use triangulation of the interfaces between compartments of equal isotropic conductivities as a geometric model. In contrast, FEM models tessellate the whole volume and allow the consideration of individual anisotropic conductivities for each element. In practical terms this implies that, in contrast to the BEM model, the FEM model can take anisotropies into account. However, since tissue conductivity is hardly measurable *in vivo*, the advantages of the FEM model are not yet fully exploited. The theoretical benefit of using realistic models instead of spherical models has been shown in recent studies [15,16], showing less localization bias in the anterior frontal lobe. Nevertheless, direct evidence of the clinical relevance of such models is still lacking. In a large study involving 100 patients (46 involving the temporal region and 54 the extratemporal region), Scheler *et al*. [17] demonstrated systematic differences in spike localization using a BEM model compared with a three concentric layers spherical model. Mean localizations were 5.9 mm more caudal and 11.7 mm more inferior with the BEM than with the spherical model. However, the spike sources were equally scattered with both models, showing that the use of the BEM model did not help to delineate a more spatially confined area.

The forward and inverse problems

If, at a given time, the source distributions and configurations within the brain as well as the conductive properties of the tissues are known, the resulting potentials at the scalp surface can be calculated on the basis of physical principles. This is generally referred to as the 'forward problem' and has a unique solution. Conversely, dipole modelling methods search for the location of intracerebral generators whose activity might explain scalp potentials, and this is referred to as the 'inverse problem'. Because each dipole is characterized by three spatial location parameters (Cartesian x, y, z or spherical r, theta, phi, co-ordinates), and three vector parameters (sense, direction and amplitude), the inverse problem is equivalent to an estimation of these parameters in a system involving $6*N$ unknowns for N generators.

As potentials are recorded at only a finite number of sites on the scalp, it is theoretically possible to obtain an infinite number of intracerebral source configurations for a given surface potential distribution. In practice, however, knowledge of the underlying pathology and physiology allows for the definition of some constraints, which considerably help in reducing the number of solutions (for example, sources cannot be located in the ventricles, white matter, eyes, etc.). Dipole inverse solutions are calculated by an iterative process in which the dipole location, orientation and amplitudes are changed step by step to obtain the best fit between the real scalp potential distribution and the theoretical distributions predicted (the solutions of the individual forward problems). The quality of the solution is evaluated by 'goodness-of-fit' or 'residual variance' parameters, respectively reflecting the percentage of data variance explained or left unexplained by the model.

Preprocessing the data

Spike averaging

Interictal spikes usually occur over the background EEG (or MEG) activity, which acts as noise and potentially contaminates the real spike topography. To increase the signal–noise ratio, spikes can be averaged but, since spikes are often polyphasic, averaging has to be triggered from the same time reference so that phases from different polarities are not cancelled. Although spike averaging is used often, this technique has been criticized for the risks of mixing spikes from different generators. The averaging of spikes from different foci gives a composite spike and can falsely suggest a spreading process by blurring the localization process [18,19]. In our experience, however, non-averaged (even filtered) spikes are difficult to model and, in most cases, a dipole solution can be obtained only around the maximal amplitude peak. Another advantage of averaging is that it may reveal small voltage deflections during the paroxysm that would otherwise be indiscernible, but it remains a risky procedure and requires careful checks on the similarities of the spikes selected.

Averaged-spike topography

Averaged spikes are usually characterized by several phases with inverse polarity. The typical deflections observed are an early positive peak, a main negative peak and a late positive peak sometimes followed by a negative wave. Analysis of the temporal sequence of voltage maps during the interictal spike can help to understand better the spatiotemporal dynamics and to formulate hypotheses regarding the underlying generators. For example, a 'dipolar' distribution of voltage fields at the scalp surface, i.e. two maxima of inverse polarity, can be considered to be from a source tangential to the scalp surface, localized approximately under the zero potential line. In a similar way, a topography characterized by a single polarity maximum at the surface suggests a source orientated radial to the scalp surface, localized under the voltage maximum itself. In the example provided in Fig. 66.1, the topographies during the main and late phases of the spike are similar, suggesting that the same generator(s) might be active during both phases. Conversely, during the early peak, as the topography differs, different sources may be active.

The evolution of the topography during the averaged spike has been evaluated with several mathematical parameters (such as the global dissimilarity index) that provide clues to segment statistically the different components of the spike [20]. Other methods using blind source separation such as independent component analysis (ICA) do not need averaging of the spikes. ICA is a technique to separate statistically independent components from a mixture of data. ICA algorithms might be helpful to isolate epileptiform discharges from background EEG [21]. Preliminary clinical studies show that source localization based on ICA

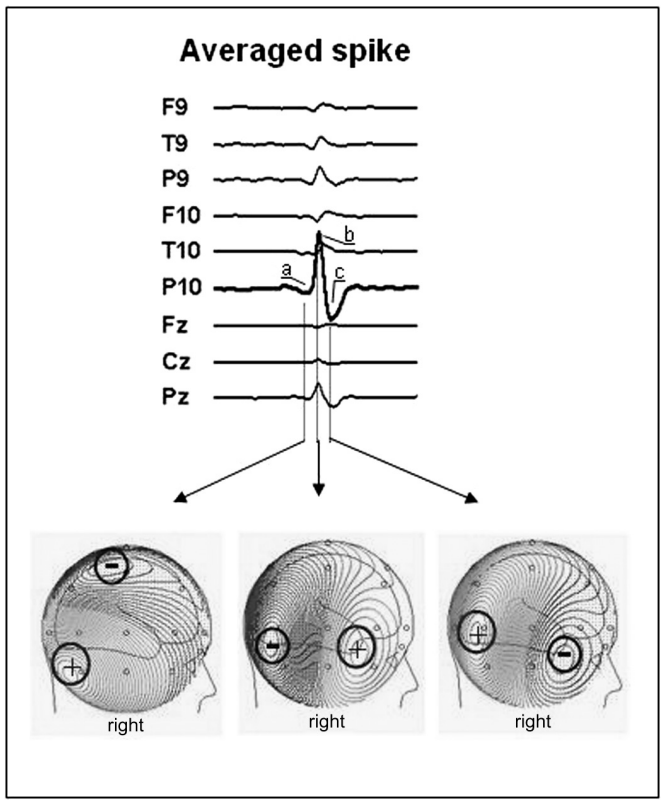

Fig. 66.1 Topographical analysis of an averaged interictal spike. Averaging is time-locked to the main negative peak of interictal spikes. The averaged spike is usually made of three or four phases with inverse polarity: (a) an early positive peak, (b) a high-amplitude negative peak, and (c) a late positive peak, sometimes followed by a negative slow-wave. The scalp voltage distribution observed at these different peaks alludes to the number of underlying generators. In this example, voltage maps at the main and late peaks are almost identical, suggesting that the same source is activated during both phases. In contrast, the early peak voltage map is clearly different, suggesting that another source might be active during this period.

decomposed spatiotemporal components appears promising for the estimation of epileptic sources, with minimal dependence on subjective decisions in the process analysis [22,23].

Dipoles modelling of interictal spikes

Instantaneous dipoles

The most simple dipole modelling approach is to estimate the instantaneous equivalent dipole that best fits the scalp voltage distribution at a single point. This method will have reasonable accuracy only if the actual generator is very focal and simple in space and over time, otherwise the solution will merely estimate the centre of mass for the activated area. The major limitations are (1) to assume that those equivalent sources are well separated, without time overlapping; and (2) to choose the time points within the spike complex of which the sources are to be calculated, ignoring other parts of the signal that might be of physiological interest.

Single equivalent dipole analysis can also be applied to time intervals, producing a pattern of multiple sequential sources (as many as the number of sampling points in the interval), which vary in location and orientation: the 'multiple instantaneous fit', or 'moving dipole' (Plate 66.1). This pattern can be interpreted as reflecting the sequential activation of multiple brain regions, limited in space and time, but the question arises as to whether or not the whole sequence of dipoles is relevant or not with regard to the anatomical propagation of transients.

When a large group of spikes is recorded in a patient, the scattering of sources may be computed mathematically to provide an estimate of the spatial extent of the interictal network. For example, Fischer *et al.* [24] calculated interictal activity extent using an ellipsoidal volume based on principal component analysis of the coordinates of all spikes. Applying this method to MEG data in patients who had undergone surgical resection, these authors demonstrated that a high coverage of this ellipsoidal volume by the resection correlated with a favourable outcome. However, this method does not estimate the extent of each source but rather the scattering of all sources.

Multiple spatiotemporal dipoles

The 'spatiotemporal approach' takes into account the course of the signals as a whole instead of considering each time sample separately. This method, first described by Michael Scherg [25], is based on the assumption that a single spike may reflect the activities overlapping in time of several 'static' dipolar sources, fixed in position and orientation, but varying in magnitude over the time interval of interest. A 'spatiotemporal dipole solution' thus characterizes the position and orientation of the sources, as well as their activation timing during the event (Fig. 66.2). The underlying concept is that if the earliest part of the spike is more likely to reflect the activity of a single source rather than the peak, this early source may also contribute to the genesis of the later time segments of the spike.

Dipole modelling strategy

In practice, it can be useful to combine dipole modelling approaches. The 'single moving dipole' approach provides a pattern of dipolar sources often grouped into 'clusters' for the time interval under consideration. This allows the estimation of both the number of active sources and the timings of their maximal activity. Next, in order to take into account the spatiotemporal evolution of the paroxysms, static dipoles with fixed location and orientation but time-varying activity are useful. In practice, a first source is fitted over the early phase of the spike, then a second is fitted to model the main peak and the residual signal unexplained by the first; this procedure can be repeated at increasing intervals from spike onset until an acceptable fit is achieved with a minimal residual variance (Fig. 66.2).

Projection of sources onto three-dimensional MRI represents the final operation of dipole modelling. The frame of the dipole model is defined by orthogonal axes passing through vertex (Cz electrode, vertical *z*-axis), right ear (T4, lateral *x*-axis) and frontopolar (Fpz, anteroposterior *y*-axis) electrodes. Co-registration of dipole modelling and anatomical data implies that both are in the same frame, which may be done by calculations using external landmarks, or by estimating the mean location of the model centre with respect to anatomy [26]. Most available software packages now allow for automatic registration of dipole modelling results onto individual or averaged MRI data.

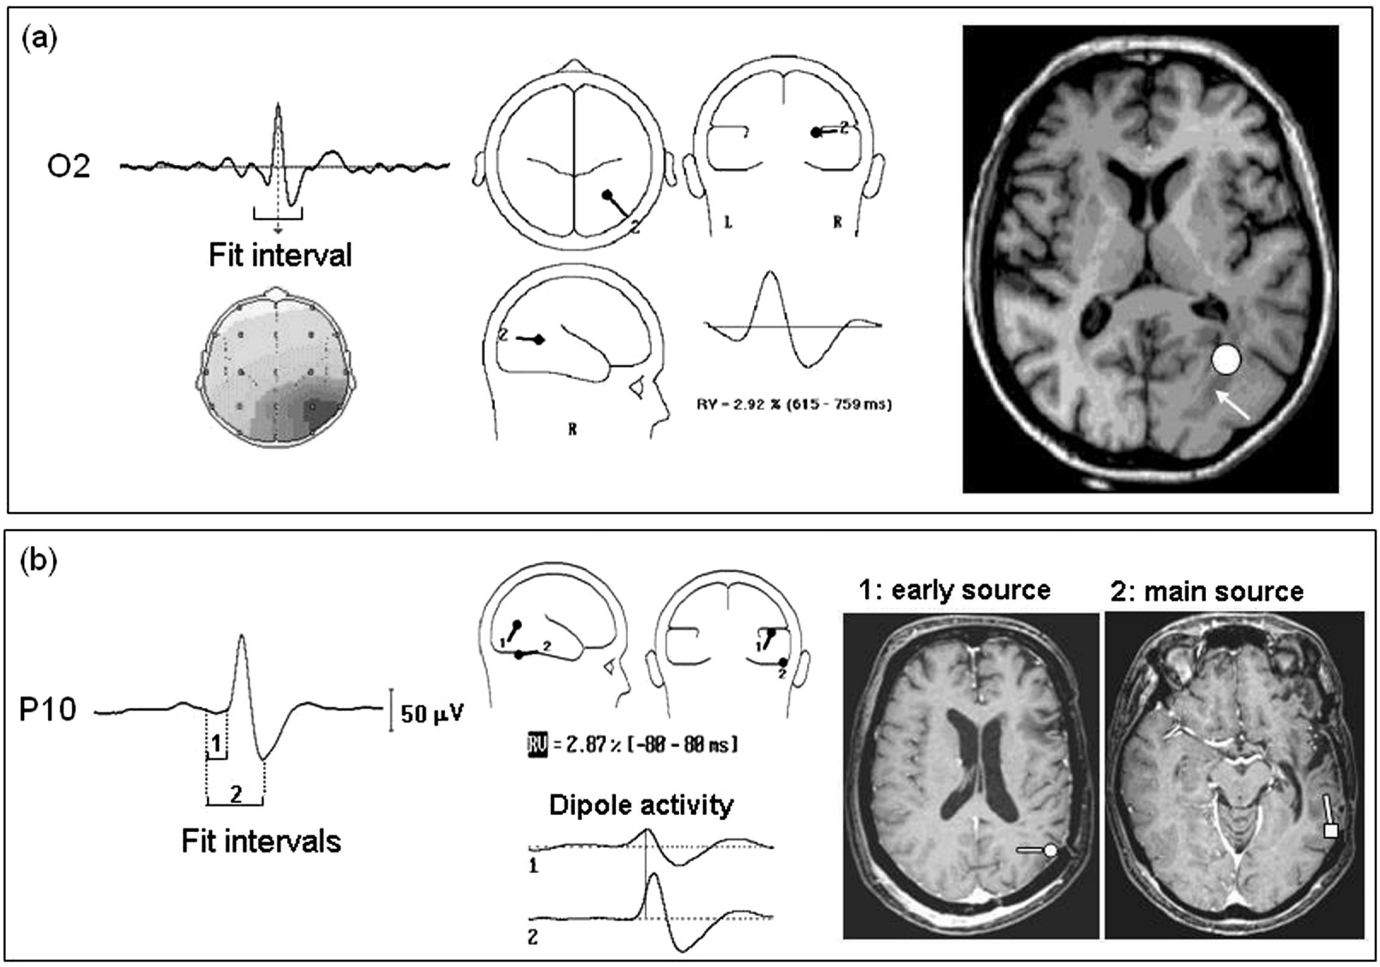

Fig. 66.2 Simple versus complex interictal spikes. In this patient with right parieto-occipital epilepsy, voltage maps at different peaks of the averaged interictal spike show identical scalp distributions. (a) This type of spike can be explained by a single source and adding others does not improve the residual variance. This source was concordant with the MRI, which showed grey matter heterotopia located in the right occipital white matter (arrow). (b) Two distinct sources are necessary to properly explain the spikes in this patient with extensive frontotemporal atrophy of the right hemisphere. They activate sequentially, and suggest early involvement of the temporoparieto-occipital junction, followed by involvement of the posterior temporal neocortex. In this case, when an additional source was added, it always converged towards the main source.

Volumetric methods

The main limitation of the equivalent dipole model is that the neuronal sources of spikes are modelled with a few dipoles that do not provide information on the spatial extent and configuration of the generators.

To overcome this intrinsic limitation, the most basic approach consists of distributing regional dipoles over a predetermined volumetric grid, which usually consists of sources lying on the cortical surface [27,28]. Following segmentation of the MR volume, dipolar sources are regularly placed along the surface of the cortical mantle [27,29]. A realistic representation contains in the region of 10 000–100 000 dipole 'pixels' (Plate 66.1c). Resolution of the inverse problem thus requires the use of either explicit or implicit constraints on the allowed current source distributions. Those constraints can be anatomofunctional (and thus based on known localization priors for the patient) or purely mathematical (based for example on the spatial configuration of the sources). Statistical approaches have been proposed to estimate the probability of sources being at a given location [29].

In the last years, other approaches based on radar applications such a spatial filtering methods (Plate 66.1b) have been proposed [30]. Source reconstruction is achieved by first defining a source space formed by a volumetric grid of target locations. For each target location, a set of beam former weights is then determined, forming an optimum spatial filter for that location and suppressing activity arising from other regions. Computing the beam former output for each location independently allows for the reconstruction of multiple (uncorrelated) sources without making prior assumptions about the total number of active sources [31]. One interesting feature of these methods is that data can be analysed in the time or in the frequency domain [30]. Thus, the spectral characteristics of the spikes can be emphasized to locate their neural sources.

Despite their attractiveness, those alternatives to classical dipole modelling approaches providing a more realistic picture of the spike sources have not yet been formally compared against older methods. Preliminary data show that some distributed source models might have sufficient resolution to delineate precisely epi-

leptic foci [32,33] but validation studies with intracranial recordings are scarce [5]. In the same vein, spatial filtering of spikes seems a promising technique but add-on value over classical approaches needs further evaluation [34].

Very few studies have evaluated exhaustively the extent of the interictal volume determined by the method. However, no gold standard is currently obtainable *in vivo* to validate hypotheses regarding those volumes. Moreover, the 'distributed-ness' of a solution might result both from the effect of the true extent of the source and the inexactness in modelling complex sources. In a simulation study of realistic spikes by Grova *et al.* [35] it was shown that some inverse methods (based on LORETA, 'low resolution brain electromagnetic tomography', or on 'maximum entropy on the mean' [36]) were able to accurately recover sources of different spatial extents, with the exception of sources in temporomesial and frontomesial regions [37]. However, several spurious sources were generated by those methods, whereas methods using MSP (multivariate source prelocalization) [38] always located very accurately the maximum of activity but not its spatial extent.

Quality of solution, accuracy of localization and validation

Quality of solution

The quality of the solution is usually assessed in terms of 'residual variance' or 'goodness of fit', but these are difficult to interpret without a reliability threshold and it is important to use other criteria. For example, the stability of the solution should be systematically taken into account by checking that (1) for one given spike, dipole results are stable as the modelling process is replayed using different starting points prior to fit and (2) for a given patient, different spike averages with similar scalp distributions yield similar dipole configurations. The existence of interactions is another criterion that should be considered. Sources are interacting when they tend to converge on the same location and display a very similar activity waveform during the fitting process, in which case only one is sufficient to explain the data (Fig. 66.2). The limitation of equivalent dipole models for large and geometrically complex spike sources has been shown by a simulation study by Kobayashi *et al.* [39]. The authors showed that a large generator area can be well modelled by a single-dipole source, and also that a small value of residual variance is not appropriate as proof or even an indication that source is small, in the clinical application of dipole modelling.

While determination of 'residual variance' is without doubt useful, it does not reflect the quality of the model used to solve the problem. For instance, the goodness of fit is usually increasing when using more dipole generator sources to model one single spike. The number of real epileptic sources is unknown, so that other estimation parameters are needed to obviate this difficulty. A recently introduced strategy to help quantify the probability of a source solution is the confidence ellipsoid volume calculation [40]. The smaller the confidence interval, the greater is the probability that the dipole resides at the fit location. The confidence volume has been shown to depend on the signal ratio of the spikes and might constitute an index of the reliability of the solution. Unnecessary spike sources in a multiple source solution might therefore lead to large confidence volume.

Accuracy of localization

Error measurements would require reference information as to the actual source locations and this is seldom the case in relation to epileptic paroxysmal transients. In some cases, error may be calculated directly by modelling simulated data from known sources, or alternatively by creating current dipoles between two adjacent intracerebral electrodes *in vivo*. The results of such studies are summarized in Table 66.1. A mean localization error of around 10 mm may be accepted [41–44], but this can vary from a few millimetres to as much as a few centimetres. Indeed it is generally well accepted that the localization error (1) is larger when the source is located deep [44–46]; (2) is smaller when realistic head models are used, compared with spherical models [45–47]; (3) is smaller when the spatial sampling of EEG electrodes or MEG captors is increased [15,48,49]; and (4) decreases when the signal–noise ratio increases. Knowing this, it is reasonable to hold that superficial dipoles calculated from 32-channel data with a good signal–noise ratio, in a realistic head model, can be localized with an error of about 5 mm.

Table 66.1 Localization errors with dipole modelling.

(a) Mean errors or range.

Reference	Localization errors
Smith *et al.* [41]	<20 mm
Cohen *et al.* [42]	10 mm (max 17 mm)
Cuffin *et al.* [43]	11 mm (max 28 mm)
Mosher *et al.* [45]	25 mm
Cuffin [48]	2–17 mm
Yvert *et al.* [46]	5–6 mm
Cuffin [44]	10.6 mm

(b) Mean errors according to mesiolateral localization of sources.

Reference	Error	
	Superficial sources	Mesial sources
Mosher *et al.* [45]	20 mm	35 mm
Yvert *et al.* [46]	5–6 mm	15–25 mm
Cuffin *et al.* [44]	9 mm	13 mm (ns)

(c) Influence of electrode number.

Reference	Number of electrodes	Error improvement
Mosher *et al.* [45]	37 versus 21	10 mm
	121 versus 37	5 mm
Yvert *et al.* [46]	32 versus 19	3 mm
	63 versus 32	1 mm
Krings *et al.* [47]	41 versus 21	5 mm

(d) Improvement in localization error according to the type of head model used.

Reference	Realistic versus spherical: error improvement
Cuffin *et al.* [48]	2.6 mm
Leahy *et al.* (phantom) [49]	0.4 mm
Crouzeix *et al.* [15]	2.5 mm (superficial sources) 12 mm (deep sources)

Validation studies

It is noteworthy that the above estimations are derived from simulated data. For physiological signals such as epileptic spikes, the locations of dipole sources can be validated when scalp and intracerebral signals are recorded simultaneously. Here, intracranial spikes can be used as triggers for averaging the corresponding scalp signal, which in turn can be modelled. Dipole localization can then be compared with intracranial electrodes in which spikes are maximally recorded. Using this technique, Lantz *et al.* [50] could identify different intracranial distributions associated with temporal scalp EEG spikes. Spikes with similar distributions were averaged together with the concomitant scalp EEG activity and the authors showed that the analysis of scalp-averaged activity allowed for the separation of different types of intracranial distributions, and the identification of the temporal regions involved during the paroxysm. Dipole locations, however, were difficult to assess because there was no projection onto MRI. This averaging technique was also used to analyse the scalp EEG signals associated with interictal mesiotemporal spikes recorded from foramen ovale (FO) electrodes [51]. Spikes detected visually on FO traces were used to trigger surface EEG averaging and, although there was initially no paroxysmal activity detectable on surface EEG, a low-voltage EEG transient (5–20 μV) was clearly seen to emerge from the noise post averaging. Dipole modelling of this transient consistently permitted the identification of a source located in the mesial temporal structures, close to the FO electrode where the maximal spike had been recorded. These results show that dipole modelling methods can localize the mesiotemporal sources of interictal spikes with an acceptable spatial accuracy.

Such validation studies, however, focus on specific intracranial signals, but epileptologists would prefer to know whether or not dipole models of scalp data can localize the actual generators of interictal spikes. This question can be indirectly addressed by comparing spike modelling data with results from invasive recordings using subdural electrode grids or depth intracerebral electrodes, or with those of anatomical or of interictal functional imaging. In the following three sections, we review data addressing these points.

Dipole sources of interictal spikes versus intracranial recordings

Since the non-invasive presurgical evaluation techniques reflect different pathophysiological aspects in epilepsy, they are not ideal for validating the localization of dipole sources in epileptic paroxysms. Such validation needs to rely upon more direct tools, such as invasive or semi-invasive recordings, but it is necessary to differentiate studies in which scalp and intracranial data

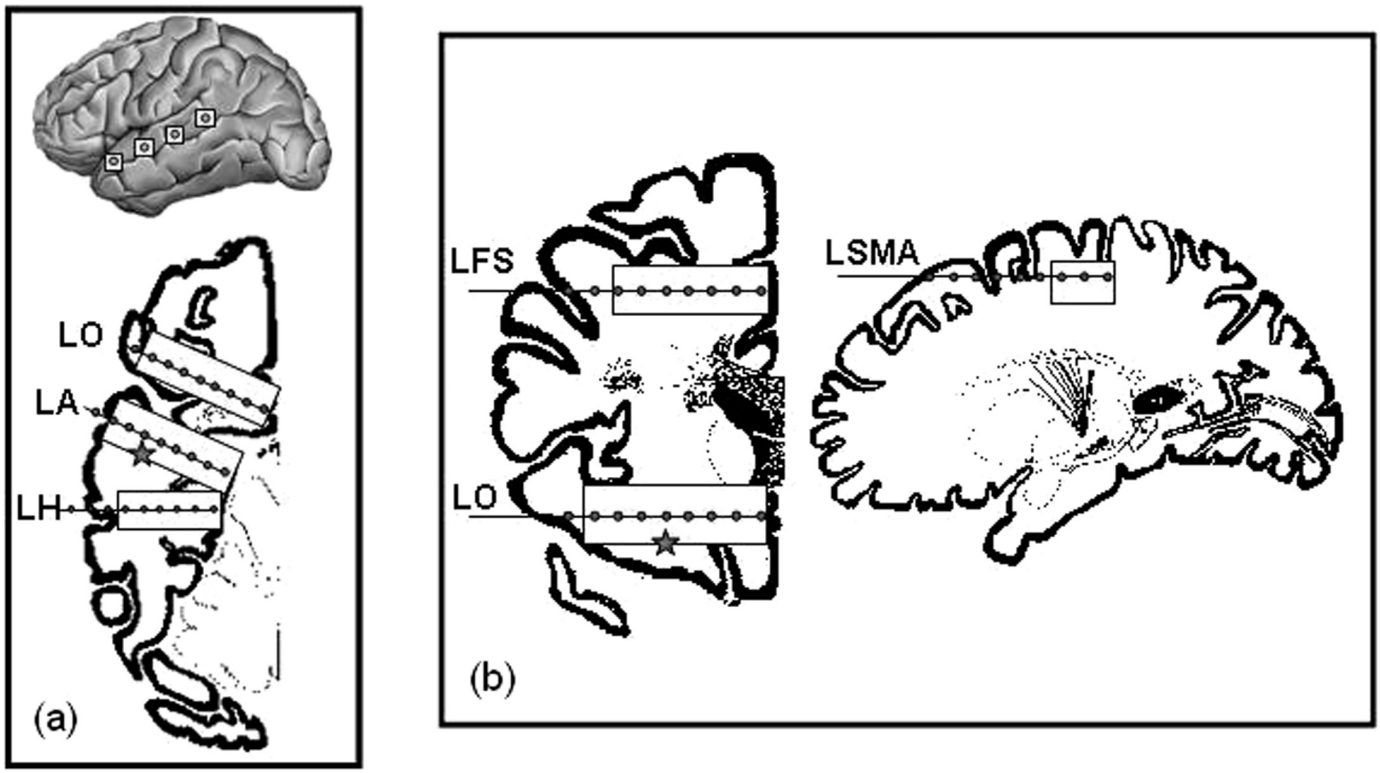

Fig. 66.3 Intracranial correlates of scalp EEG spikes. (a) Scalp spikes were located in the temporal area. (b) Scalp spikes were located in the right frontal area. The figure illustrates the locations of the intracerebral electrode tracks and the position of epidural electrodes in (a). Stars indicate intracerebral contacts in which maximal activity was recorded. Grey rectangles represent the contacts that recorded the spike activity. For example, in (a), contacts 1–8 of the LO electrode, 1–8 of the LA electrode, 1–6 of the LH electrode, as well as the four subdural electrodes on the superior temporal gyrus, are active during the scalp EEG spike. This figure illustrates the fact that generators of a spike restricted to a focal scalp region can be distributed over a large cortical area. LO, left orbitofrontal; LA, left amygdala and anterior middle temporal; LH, left anterior hippocampus and middle temporal gyrus; LSF, left superior frontal; LSMA, left supplementary motor area.

were obtained simultaneously from those obtained otherwise. When EcoG (electrocorticography) or SEEG (stereoelectroencephalography) is not recorded during the scalp EEG session, dipoles are difficult to validate because the risk exists that the scalp and intracranial spikes might not share the same generator.

Several case reports have been published showing a perfect agreement between dipole location and EcoG spikes in lesional cases [52] or in complex cases in which multiple foci are suspected [53,54]. Larger series generally show good concordance between dipole locations and intracranial interictal data. In a group of four patients with focal cortical dysplasia, the localization of MEG spike sources was consistent with interictal intracranial recordings in all cases [55], and Lantz *et al.* showed that, when spike dipoles were spatially stable, their locations were concordant with EcoG recordings [19].

Some studies also demonstrate good concordance between spike dipoles and intracranial ictal onset in mesial temporal lobe epilepsy (TLE) [56,57]. Although some have found that such concordance is higher in TLE than in frontal lobe epilepsy (FLE) [58], spike sources and intracranial ictal data are also reported to have matched in 75% of adults [59] and 90% of children [60] presenting with extratemporal non-lesional epilepsies.

Studies in which simultaneous scalp and intracranial recordings could be achieved are fewer. We have addressed this issue [7,61] to answer the following questions: (1) When a spike is recorded at the surface, what are the spatial characteristics of the underlying activated area? (2) Is the dipole that models a scalp spike located in the region of maximal electric field? (3) When dipole modelling suggests propagation between distinct areas, do intracerebral recordings show spike activity in each of these areas, and are there any intracerebral indices of propagation?

The current finding is that when a spike is recorded at the scalp surface, the intracerebral activity always involves several contacts suggesting the participation of a large cortical area (Fig. 66.3). Conversely, when intracerebral spikes are very focal, either in mesiotemporal structures or even in neocortical regions, no discernible scalp EEG signal is recorded. This result is now widely accepted and was suggested more than 30 years ago from simulated data using a polythene sheet connected to a low-frequency oscillator in an empty skull [62]. These findings have also more recently been confirmed in epileptic patients, in particular by Ebersole's team [57,63,64], using simultaneous EEG and EcoG or SEEG recordings; it is held that a minimal cortical area of 6–8 cm^2 is necessary for a spike to be recorded on scalp EEG. The accuracy of such estimations is, however, limited by the low spatial resolution of intracranial recordings exploring a restricted number of regions. This was confirmed recently by Ray *et al.* [65], who showed that the onset of surface spikes involved between 9 and 15 intracranial electrode contacts. This same study showed that during the rising phase of the surface spike up to the peak, the intracranial generators progressively extended in size. Evaluating the minimal extent of generators leading to a surface spike is thus a challenging issue, since the coverage of intracranial structures is incomplete. Tao *et al.* [66] showed that if 90% of spikes with a source area greater than 10 cm^2 produced scalp EEG potentials, only 10% of spikes with a source surface between 6 and 10 cm^2 and none of those with a source surface <6 cm^2 were detectable on scalp recordings.

A second interesting finding is that in some instances scalp interictal spikes are associated with 'simple' distributions of intracerebral fields (i.e. characterized by a maximum culminating at the time of the surface EEG spikes and by synchronous activity gradually decreasing along the adjacent contacts; see Fig. 66.4a). This does not, however, represent the majority, and in most instances asynchronous activities can be detected in addition to the maximal synchronous peak (Fig. 66.4b) [61]. This complex arrangement of intracerebral fields may be interpreted as reflecting spreading phenomena between regions in which the asynchronous activities are recorded.

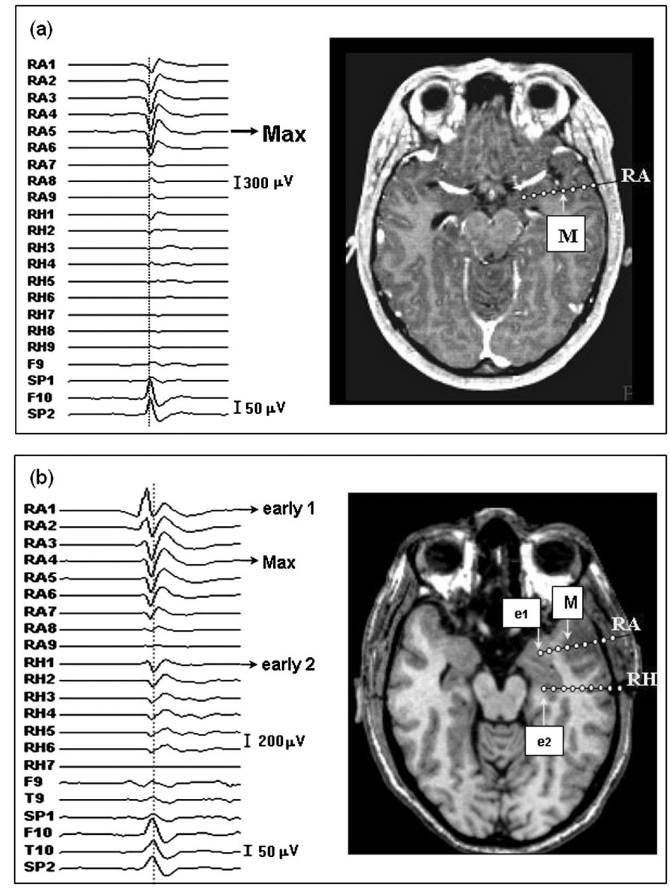

Fig. 66.4 Simple versus complex intracerebral fields associated with surface electroencephalogram (EEG) spikes. (a) Simple spikes. On scalp EEG recordings, the spike is maximal at F10 in the right anterior temporal region. Concomitantly, the maximal intracerebral field is recorded in the right temporal pole (RA5) and gradually decreases along the adjacent intracerebral contacts. No asynchronous activity is recorded elsewhere. (b) Complex spikes. Concomitant with the scalp EEG spike and culminating in the right anterior temporal region (electrode F10), the maximal intracerebral field occurs at the right temporal pole (RA4). Two earlier asynchronous activities can also be detected in the right amygdala (RA1) and hippocampus (RH1). Early intracerebral field(s), e1 and e2. Intracerebral electrodes: contacts 1 are the deepest, and contacts 9 are the most superficial. Scalp electrodes: F9, F10 (anterior low temporal), T9, T10, (middle low temporal) and SP1, SP2 (zygomatic). M, maximal intracerebral field; RA, right amygdala; RH, right anterior hippocampus.

Interestingly, dipole modelling techniques might be able to predict reliably the type of field distribution because, in almost all cases in which intracerebral activity is simple, spikes can be modelled by one source. However, in cases in which intracerebral activity is complex, several dipoles are needed, and when a single model is used, dipoles are usually located at the centre of mass of the intracerebral area activated [67].

Simultaneously combining MEG and EcoG recordings in two patients, Mikuni *et al.* [68] found good concordance when spikes were recorded from the lateral temporal cortex, whereas dipoles were ill-localized when spikes arose from mesiotemporal structures. In our series, no such differences were observed. The main dipole source was located on average 11 mm from the SEEG contact showing the maximal intracerebral potential. In two-thirds of cases good concordance was obtained (1) between main dipole sources and maximal intracerebral fields and (2) between early or late sources and early or late intracerebral fields. In general, they are associated with good temporal concordance, i.e. the delay between the different intracerebral activities was perfectly congruent with the delay between dipole activation curves (Fig. 66.5a). Spatial discordance was found in 16% of cases (Fig. 66.5b), and dipole locations could not be validated in 10% because they were situated in unexplored areas (Fig. 66.5c) [61]. These data confirm that surface EEG spikes are associated with

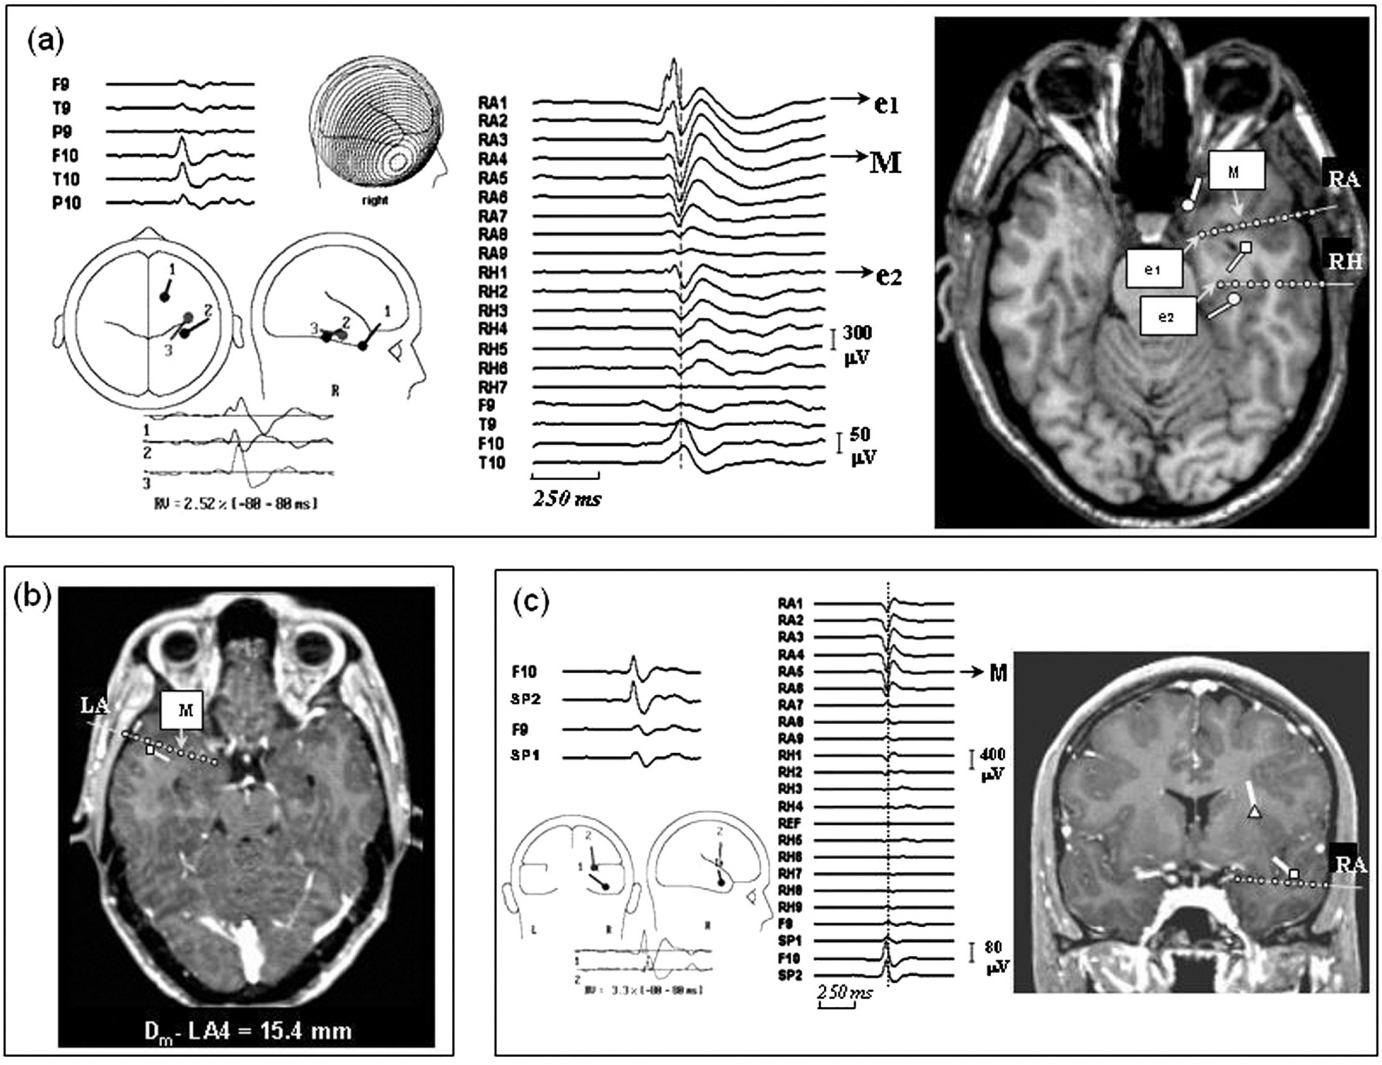

Fig. 66.5 Concordance between spike dipoles and intracerebral fields. (a) Example of spatial and temporal concordance. The two early dipoles (circles) are concordant with the two early intracerebral fields in the amygdala and hippocampus, and the main dipole (square) is concordant with the maximal intracerebral field in the middle temporal gyrus. The dipole activation curves match the sequence of activation observed on intracerebral traces. (b) Example of spatial discordance. The maximal intracerebral field is recorded at LA4 whereas the main source (square) is more lateral and closer to LA6. The distance between the main source and the maximal intracerebral field at LA4 (Dm-LA4) was 15.4 mm. (c) An example of a non-validated source. The late source (triangle) is located in the right insula which was not explored with intracerebral electrodes. In this case the location of this source cannot be confirmed by intracerebral recordings. Early intracerebral fields, e1 and e2. Intracerebral electrodes: contacts 1 are the deepest, and contacts 9 are the most superficial. Scalp electrodes: F9, F10 (anterior low temporal), T9, T10 (middle low temporal), P9, P10 (posterior low temporal) and SP1, SP2 (zygomatic). LA, left amygdala; M, maximal intracerebral field; RA, right amygdala; RH, right anterior hippocampus; circle, early dipoles; square, main dipole; triangle, late dipole.

intracerebral fields distributed over broad cortical areas and rarely occur simultaneously with a focal activity, especially when it is limited to mesiotemporal structures. They imply that modelling the scalp spike by a single source located in the mesial aspect of the temporal lobe may be unreliable.

The aforementioned studies illustrate the difficulties encountered for validating source localization techniques with intracranial data. An essential step towards a better interpretation of source modelling results most likely requires a better understanding of the generation of electrophysiological signals, both from a spatial and from a temporal point of view. We recently made an attempt in that direction by quantitatively investigating the relationship between EEG signals and the spatiotemporal configuration of the underlying neuronal sources [69]. A physiologically plausible model was used to simulate epileptic spikes on scalp EEG and intracerebral EEG signals simultaneously, from a patch of cortex of known location, area and synchronization level. Such a model, in which the ground truth is known, may provide an interesting framework to evaluate source localization methods.

Dipole sources and MRI lesions

Most studies exploring the relationships between MRI abnormalities and the generators of interictal paroxysms conclude fairly good spatial agreement (summarized in Table 66.2). Most have used spherical head models and single instantaneous dipole fits at the maximum of the interictal spike peak. These results come from a series of various sizes (1–16 patients), including epilepsies of different types, and may therefore be contradictory. However, global analysis shows dipole sources to be located within lesions or within 10 mm in about 80% of cases, regardless of the techniques used to record the spikes (EEG or MEG). Thus, both techniques seem to provide a similar degree of accuracy.

Surprisingly, the concordance between dipole locations and MRI lesion was poorer in some studies using realistic head models (58%) [58,70,71] than in others using spherical head models (79%) but the former are fewer. As far as the type of lesion is concerned, the best agreements between dipole results and lesions are found in focal dysplasia or heterotopia (86%), and next in hippocampal atrophies (79%), whereas a dipole is identified close to tumours in only 50% of cases. Using MEG source imaging, Stephan *et al.* [72] reported that in five out of eight cases of cavernous angiomas interictal spikes sources were located less than 20 mm from the lesion itself or from the surgical scar after unsuccessful lesional resection. They suggested that source modelling could be useful to identify the epileptogenic lesion in patients with multiple cavernous angiomas.

Some authors have studied the spatiotemporal relationships between lesions and the activation sequence of spike sources. From a series of five hippocampal atrophies [73], one frontal gliotic lesion [71] and one frontal dysplasia [74], it has been suggested that sources calculated from the first part of the spike (early and main sources) are more concordant. Our own results obtained from a series of 14 patients [75] are less affirmative. Although in heterotopia or tumour cases the best agreement is obtained for early and main sources (Fig. 66.6b and c), for hippocampal atrophies, dipole sources (indifferently early, main or late) may be located in or outside the atrophic hippocampus, in the temporal and in extratemporal neocortical areas (Fig. 66.6a). In some cases, sources may be located in the hippocampus, even in the absence of any atrophic lesion. Results from space-occupying lesions are very similar (Fig. 66.6b).

Table 66.2 Concordance between the location of spike sources and the location of MRI lesions.

Study	Model and approach	Event	Data	Lesion/dipole concordance (<10 mm)				
				Hippocampal atrophies	Tumours	Focal dysplasia or heterotopia	Other	Total (%)

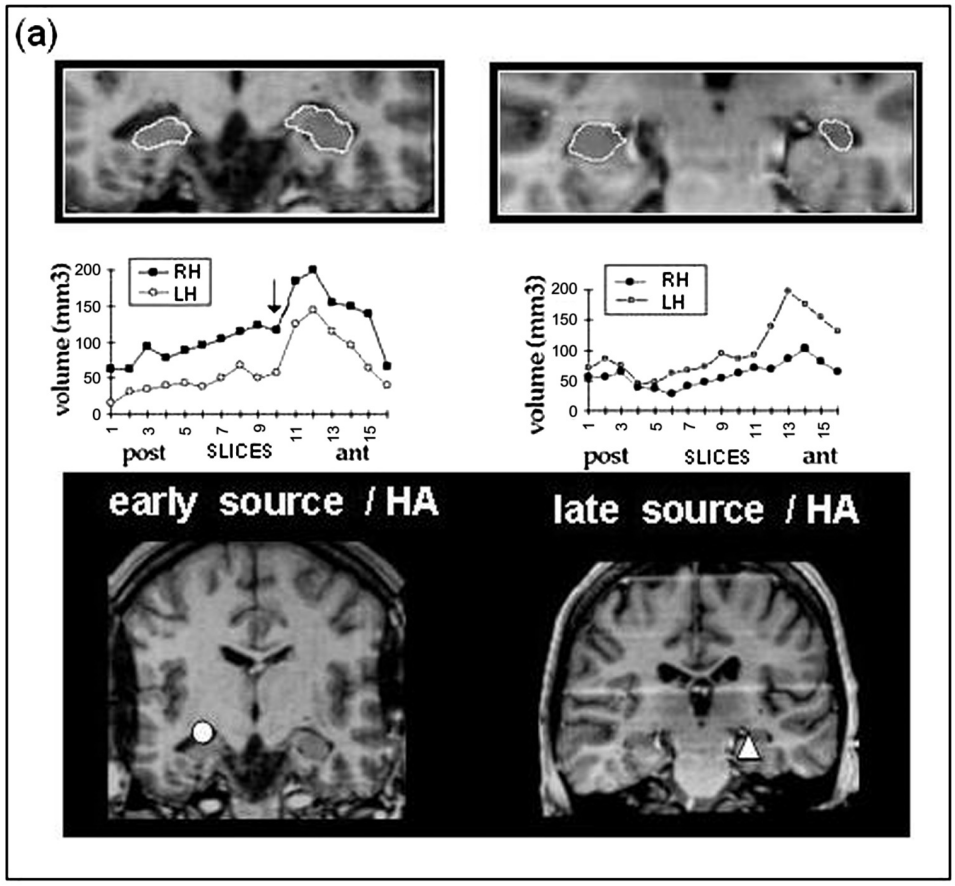

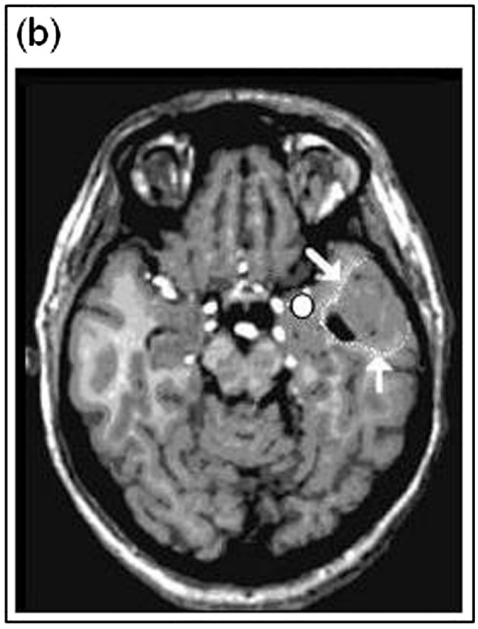

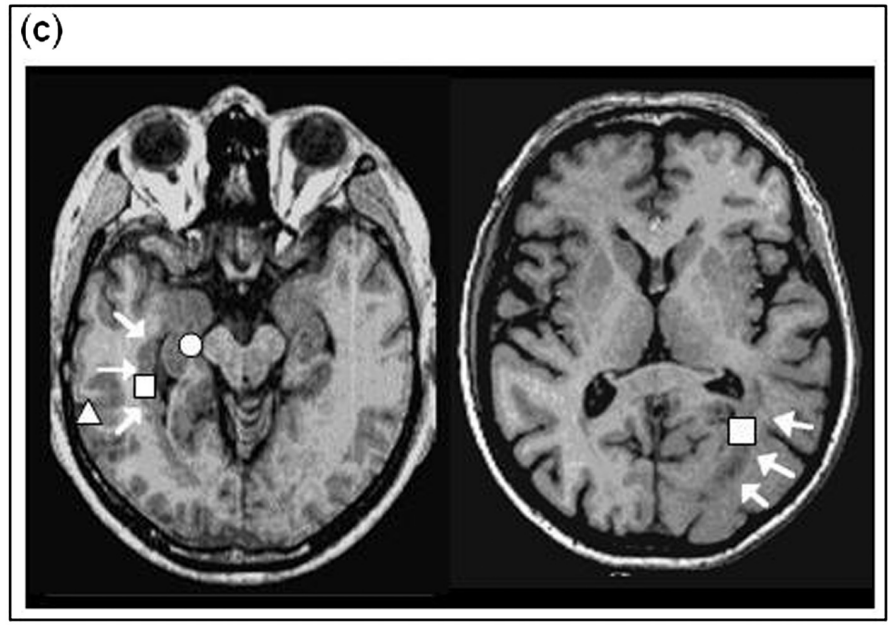

Fig. 66.6 Spike dipoles and MRI lesions. (a) Hippocampal atrophy. Two examples are given. The curves represent the volumes of the right hippocampus (RH) and the left hippocampus (LH) measured on coronal slices between the anterior (ant) and posterior (post) aspects of the hippocampus. The top of the figure illustrates diffuse LH atrophy (on the left), and also atrophy of the anterior aspect of the hippocampus (on the right). In both cases at least one source was located in the atrophic hippocampus, but this source was the early one in the first case (white circle) and the late one in the second case (white triangle). (b) A tumour. In this patient, the early source of interictal spikes is located in the vicinity of a grade III xanthoastrocytoma (arrows and dotted line). (c) Grey matter heterotopia. In these two patients (left: left temporal periventricular heterotopia; right: right occipital heterotopia) the main sources (white squares) of interictal spikes were localized to within the abnormal grey matter in both cases. In the patient with periventricular heterotopia (left), the dipole modelling results suggest that spikes originate from the hippocampus and spread within the lesion, whereas in the other patient (right), they originate from the lesion without involving other regions.

Considering these data, the spatial relationships between lesions and the localization of interictal spikes can vary and seem to depend on the lesion type. In the majority of cases, an overlap exists between the lesional zone and the network involved during interictal spikes, but when timing is considered, dipole results may suggest either origin or propagation within the lesion. Obviously the relationships are complex and echo the relations between electrophysiological and structural abnormalities [76–78].

Dipole sources of interictal spikes and metabolic abnormalities

Most [^{18}F]fluorodeoxyglucose (FDG) PET studies show interictal hypometabolism in 60–80% of partial epilepsies (see ref. 79 for a review). However, the relation between epileptogenesis and glucose hypometabolism is not straightforward. For instance, it appears that the ability of perilesional cortex to generate seizures bears no relation to the presence of perilesional glucose hypometabolism in focal lesions such as cavernous angiomas [80].

Whilst comparing, in the same group of TLE patients, the location of interictal spike sources with that of the FDG-PET hypometabolic zone [81], we found that when spikes are modelled by unilateral temporal sources, the latter were located within the hypometabolic zone. However, glucose hypometabolism was not significantly more pronounced in regions where dipoles were localized. Conversely, in a majority of patients in whom late extratemporal involvement was suggested by interictal spike modelling, hypometabolism was restricted to mesiotemporal areas. In FLE, the spatial relationships between glucose hypometabolism and spike source can be extremely diverse. Dipole sources can be located either within the hypometabolic area when several lobes are involved, or outside the hypometabolic zone in cases in which the metabolic abnormality is very focal.

The above findings are in agreement with those reported by Lantz *et al.* [19] describing the relations between the focal interictal decreases in cerebral blood flow (CBF) on SPECT images, and the localization of spike sources. They found a better concordance between the low CBF zone and sources of interictal spikes when dipoles were localized within one temporal lobe. These results have been corroborated by two similar studies showing a good concordance between FDG-PET abnormalities and dipole sources in both interictal MEG [82] and EEG [83] spikes, when these were unilateral temporal. As with our group of patients, these authors failed to find a correlation between the degree of decrease in glucose uptake and dipole location. They also found less agreement between PET and dipoles when extratemporal involvement was suggested by interictal spike modelling.

Taken together, the above studies converge on the conclusion that, when spike sources are localized to one temporal lobe, FDG images tend to confirm the dipole locations; this could suggest some functional link between the metabolic dysfunction and the processes responsible for spikes. Conversely, when spikes are spread outside the temporal lobe or a frontal origin is suggested by dipole modelling, the metabolic and electrophysiological processes seem partly independent.

Interpretation of dipole modelling of interictal spikes: the concept of 'interictal network'

Are interictal spikes 'simple' or 'distributed' phenomena?

When dipole modelling methods are applied to interictal spikes, several source distributions may be obtained. In rare instances, interictal spikes can be adequately modelled by a single dipole. For example, Fig. 66.2a shows that spikes from a patient with parieto-occipital epilepsy could be modelled by a single source within an occipital grey matter heterotopia. In the majority of cases, however, several dipoles are required. These sources are usually located in distinct anatomical regions, and are activated sequentially but overlap in time, as illustrated in Fig. 66.2b. Such patterns lead to the concept of 'spreading' activity and distributed sources during a single spike. It is historically noteworthy that most of the teams involved in spike dipole modelling have gradually been moving from 'unique source' [84–86] to 'multiple source' activation or volumetric models of interictal paroxysms [87–90].

The interictal network in temporal lobe epilepsy

Modelling spikes in temporal lobe epilepsy (TLE) is helpful to address whether or not mesial, lateral or both temporal cortices are involved in spike generation. In general, the majority of spikes culminating at temporal electrodes can be modelled by dipoles localized to the ipsilateral temporal lobe. However, within this group it is possible to distinguish between 'early mesial' and 'early neocortical' involvement, depending on whether or not early sources localize to mesial or lateral temporal structures. Early mesial involvement seems to be more frequently observed, suggesting that mesiotemporal structures function as a trigger in the interictal network [3,56,81,90–92]. However, the opposite may also be observed and suggests that mesiotemporal structures can also work as a secondary relay in this process [73,81,89].

Whatever the model of sequential activation, interictal spikes appear as distributed phenomena that involve both mesial and neocortical temporal regions, supporting the hypothesis that sustained reciprocal interactions between mesial and neocortical structures exist during interictal temporal spikes. Because of the intrinsic properties of the mesiotemporal regions, particularly the hippocampus, which appears essential to maintaining temporal discharges, results from spike source modelling support the hypothesis that these structures act not only as initial triggers, but also as secondary 'pacemakers' contributing to the amplification, prolongation and spread of ictal discharges.

In certain patients, in addition to the activation of mesial and neocortical temporal regions, it is possible to identify late involvement of extratemporal structures. For example, using dipole modelling techniques, Lantz *et al.* [19] described the combined activation of temporal and orbitofrontal regions during spikes culminating at the temporal scalp electrodes.

In our experience, the most frequently involved extratemporal regions are orbitofrontal, inferior parietal, insular and central opercular regions. Their involvement during ictal propagation is not really surprising, but the fact that they can be recruited during a rapid temporal interictal paroxysm is somewhat more so. Nevertheless, such data are confirmed by electrocorticographic mea-

surements in which the interictal spikes of TLE may be multifocal, often covering a large area of the temporal lobe, and may involve adjacent extratemporal structures such as the inferior parietal lobule or the orbitofrontal cortex [93]. These results favour activation of a distributed network during interictal paroxysms, which not only involves mesial and lateral aspects of temporal lobe but sometimes exceeds temporal lobe limits.

The interictal network in frontal lobe epilepsy

There have been few reports of dipole modelling results in FLE. In general, frontal spikes are recognized as more complex than temporal spikes. They are characterized by a more diverse range of topographies for a given patient (greater number of different types of spikes), requiring more sources to model, and wider spatial extents suggesting interlobar and interhemispheric propagation.

Ito *et al.* [94], correlating the locations of frontal spike dipole sources with ictal semiology, showed frequent orbitofrontal involvement, rapid bilateral involvement and, in some instances, propagation to extrafrontal regions. Accordingly, studies using frequency analysis, in particular coherence and phase measurements [95,96] during bilaterally synchronous spike–wave activity, reported high coherence values between homologous EEG channels on both hemispheres, which favour direct interfrontal connections potentially through the corpus callosum or anterior commissure.

Finally, using principal component analysis (PCA) in a group of 39 children, Rodin *et al.* [97] showed a greater complexity of frontal interictal spikes, compared with temporal and occipital ones. These results are in favour of a caudorostral gradient of complexity reflecting recruitment within the interictal network of an increasing number of structures, as anterior regions are involved in the spiking process. In practice, the high complexity of frontal interictal spikes together with the multifocal distributions of their dipolar sources does cast some doubt on the reliability of such models, in the context of FLE [98].

Dipole modelling of ictal discharges

Studies assessing the spatial relationship between interictal and ictal events give extremely variable results. The concordance between regions generating interictal and ictal paroxysms is generally good depending on the type of epilepsy, the localizing method and its accuracy. In the case of hemispherical lateralization, excellent agreement between interictal and ictal events is observed in partial mono-focal epilepsies, even perfect agreement in certain series [99]. In the case of lobar localization, concordance remains good, especially for TLEs [100,101], but in the case of sublobar localization concordance drops [102]. Using combined scalp and invasive EEGs, Marks *et al.* [103] showed that interictal spikes and ictal discharges originate from the same area in only 58% of TLEs. By means of intracerebral recordings, Rougier estimated that the zones from which interictal spikes and seizures arose were similar in 55% of patients suffering from TLE, but in only 30% of patients suffering from frontal seizures [104].

Seizure modelling is more complex than interictal spike modelling owing to a low signal–noise ratio, the presence of artefacts and the spread of activity which may be extensive and entail rapid changes in the complex source configurations over time. Some authors have demonstrated the feasibility of ictal dipole models [90,105] with good agreement sometimes in the locations of interictal and ictal events [19,56,106,107]. Other studies indicate low yield (30–40% of patients) when dipole modelling is applied directly to ictal signals [7,108].

Interestingly, in cases in which dipole models fail, the intracranial field correlates of the first scalp EEG change are bilateral and maximal in the mesiotemporal regions. This suggests that bilateral involvement at seizure onset may lead to dipoles located at the centre of the head or reaching different locations when initial conditions change. In case reports of one and two patients [109,110], good agreement was also found between the dipole sources of ictal events and ictal onsets as defined on non-simultaneous EcoG recordings.

During simultaneous recordings, ictal dipole sources are usually concordant with ictal onset, provided the latter does not occur in mesiotemporal regions [7]. When maximal activity is located within mesiotemporal structures, dipoles are usually displaced more laterally. Comparisons between ictal dipoles and ictal intracerebral fields are hampered when ictal onsets occur very focally, so that no scalp EEG activity can be simultaneously detected. Finally, additional sources are often found scattered in diverse cortical regions so that, in a majority, their significance cannot be established. It is possible, for example, that, apart from noise, these additional sources reflect spreading to regions beyond the primary epileptic zone.

Clinical relevance of dipole modelling results

Does spike source modelling corroborate epilepsy surgery findings?

This issue has been recently reviewed by Plummer *et al.* [111]. Few studies have examined sensitivity of spike source modelling for localizing the epileptogenic zone and most have compared the location of dipoles with resection margins in good-outcome patients (Engel class I and II). When dipole modelling was performed on ictal signals, concordance rates between ictal sources and resection margins were very poor (only 10% of cases) [108], but concordance was higher for interictal spike sources. Comparing source models of interictal MEG spikes, MRI, interictal/ictal video-EEG and interictal/ictal intracerebral recordings, some found dipole modelling to be the second most sensitive method (57% concordance) for predicting the epileptogenic zone after ictal intracerebral recordings (62%) in TLE [112]. In extratemporal cases this dropped to 44% versus 81% for ictal intracerebral recordings. In another study, sensitivity reached 94% [113]; however, this result is not very conclusive because good concordance between spike dipoles and resection localization was also found in 85% of patients with bad surgical outcome (Engel class III and IV). A recent study by Michel *et al.* [32] using single-source dipolar distributed modelling of 128-channel EEG data reported that in 18 out of 24 patients who underwent epilepsy surgery (17 temporal, seven extratemporal), all but two with lesional focal epilepsy, the source maximum fell within the border of the resection area; 16 of these patients had an Engel class I outcome. However the investigators were not blinded to MRI data during

the source-fitting procedure. In a surgical paediatric study by Sperli *et al.* [114], the authors quantified the concordance between the resected volume and the extent of the statistically thresholded distributed sources solution [114]. A satisfying concordance (>50% overlap) was observed in 27 out of 30 patients, most of them being seizure free after surgery.

The only study that has addressed directly the question of whether or not the spatial extent of the spiking network (as defined by spike modelling) may help in delineating the epileptogenic zone and planning resection is the MEG study by Fischer *et al.* [24] in which a single equivalent dipole model was used in a series of 33 patients who underwent epilepsy surgery. They showed that the concentration of spike sources in a restricted area and a high coverage of this area by the resection volume correlate with a good outcome. In multiple spatiotemporal dipole models, the fact that a single spike may reflect the activation of several sources does not imply that all of them need to be removed to control seizures, and, conversely, seizure spread may include areas uninvolved in interictal spiking. It is likely, for instance, that a number of TLEs remedied by mesial temporal surgery may actually have shown interictal spike sources in the lateral neocortex prior to surgery, and this remains to be demonstrated through a dedicated prospective study.

Does spike source modelling help to lateralize the focus in TLE with bilateral interictal spikes?

In some cases of independent bilateral temporal spiking, early sources for both can be localized to the same side (Fig. 66.7). In our experience, this also corresponds to the side of most frequent spiking, and this is clinically relevant since hemispheric predominance is observed in 80% of TLEs with bilaterally asynchronous spiking [115–117]. The laterality is well correlated with the side from which the seizures originate [99,117] and is associated with better surgical outcome when operating on the same side [118].

Is congruence between spike source modelling and other investigations a reliable predictor of surgery outcome?

The clinical relevance of spike modelling cannot be evaluated without examining concordance between source locations and structural (MRI) or functional neuroimaging data. Stefan *et al.* [119] reported surgical success when dipole sources of MEG spikes were spatially congruent with PET, SPECT and interictal EcoG results. Lamusuo *et al.* [82] have also reported good outcomes in patients in whom dipole modelling results agreed with PET data, whereas the others were not cured by surgery. A good agreement between dipole locations and MRI lesions has likewise been widely reported to predict good surgical outcome [55,107,120,121]. Similarly, Smith *et al.* [59] found concordance between EcoG results and the localization of MEG interictal spikes in 75% of patients, amongst whom surgical results were good in 61%; surgery failed in all discordant cases.

Is source modelling of ictal signals clinically useful?

The largest prospective study of scalp ictal dipole modelling hitherto available is that of Boon *et al.* [122], which evaluated the contribution to the clinical decision making in 100 cases of refractory partial epilepsy, which was mostly lesional (83%). Ictal data were obtained in 93 patients, of whom 62 could not undergo source modelling of ictal events owing to artefact contamination. In 14 out of the 31 remaining patients source localization was considered as clinically useful, mostly by showing spatial incongruence between lesional and ictal EEG abnormalities (10 patients). This study suffers from some methodological deficiencies detailed in the review by Plummer *et al.* [111]; in particular, modelling was limited to the use of a single regional dipole and results were categorized as either vertical (type 1) or radial (type 2) dipoles, according to the early classification first proposed by Ebersole and Wade [123] in which type 1 and type 2 dipoles were considered as equivalent to mesiobasal and lateral temporal sources, respectively. This classification is now viewed as an oversimplification by Ebersole himself [124]. Nevertheless, this study

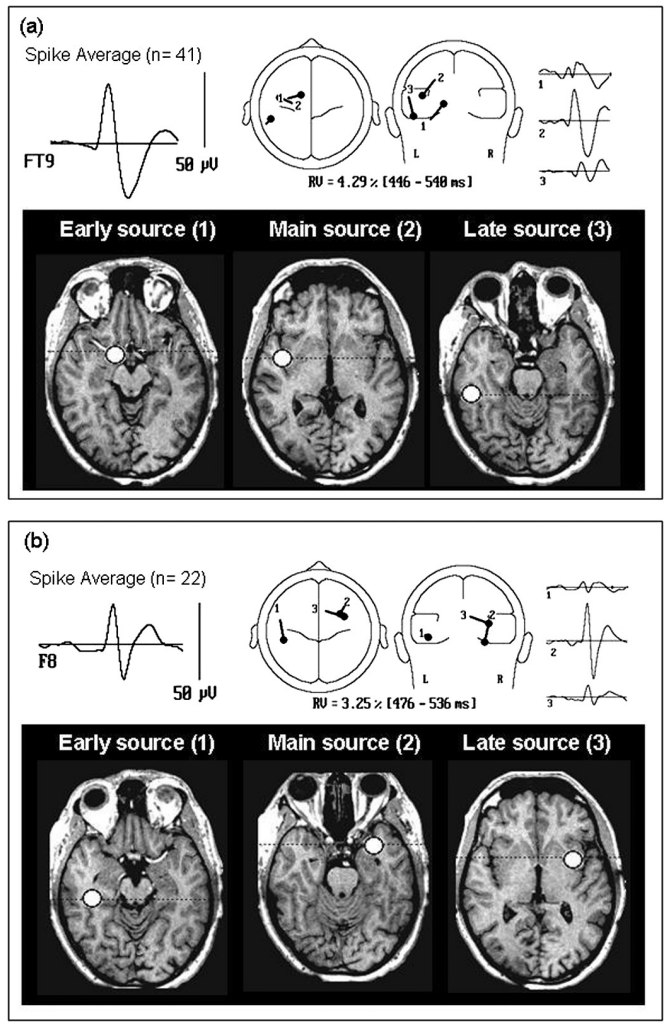

Fig. 66.7 Dipole modelling of bitemporal interictal spikes in TLE**.** In this example, independent bilateral temporal spikes could be averaged. (a) The left-sided (FT9) spikes were the most frequent and could be modelled by three left temporal dipoles, suggesting spread from mesial to lateral temporal regions. (b) The right-sided (F8) spikes were less frequent but had an early source still located in the left mesiotemporal region, as for FT9 spikes. Dipole modelling here suggests spreading from the left mesiotemporal region to the right temporal pole, and later the right insula.

presents the advantage of showing that ictal dipole modelling is a hazardous procedure that has been feasible in less than one-third of patients.

EEG-correlated functional MRI in epilepsy

Functional magnetic resonance imaging has proved over the years to be a powerful non-invasive tool to identify the components of a brain network involved in a sensorimotor or cognitive process, in which the experimental condition differs from the control condition in a way that is controlled by the experimenter [125]. In epilepsy, fMRI has thus been evaluated as an alternative to invasive investigations for localizing language or memory functions. In this chapter, we will exclusively review the applications of EEG-correlated fMRI (EEG/fMRI), with the 'control' condition being that in which the EEG is at baseline and the 'experimental' condition being that in which the EEG shows interictal paroxysmal activity or epileptic discharges.

It is well established that electrophysiological techniques such as EEG and MEG have higher temporal resolution than metabolic- or haemodynamic-based imaging techniques such as fMRI. The millisecond-scale changes of neuronal activity related to seizures or interictal spikes can be tracked online using EEG/MEG. Conversely, as discussed earlier in this chapter in the section 'Methodological aspects', the major drawbacks of those methods is the difficulty in modelling the spatial sources of surface-recorded events. It is therefore generally assumed that the spatial resolution of EEG and MEG modelling is less than that of fMRI. These considerations highlight the theoretically complementary benefits of combining these two approaches to map brain neural events [126,127].

Using fMRI alone, Jackson *et al.* [128] first described concordant areas of activation, based on the visual inspection of subtraction images, in partial motor seizures. Other reports [129–131] have since described concordant fMRI-detectable activation in relation to either assumed seizure activity or overt clinical seizures, but with ever-present risks of motion-related artefact. Using continuous EEG-correlated fMRI, Salek-Haddadi *et al.* [132] were the first to be able to capture a focal subclinical electrographic seizure in its entirety. They reported a cluster of activation concordant with the EEG focus followed by a deep and prolonged undershoot in keeping with ictal physiology data from several other techniques. Although most of the early studies of EEG-correlated fMRI were mainly focused on methodological difficulties, clinical studies have recently flourished (see ref. 133 for a review).

Over the years, the status of EEG/fMRI investigations has progressively changed. With hardware and signal processing improvements, the clinical recording of EEGs inside the MRI scanner is now feasible, and the number of published studies on that topic is increasing rapidly. Some recent studies suggest that it might provide new information for patients being considered for surgery and some clues to understand the neurobiology of epilepsy. Still, the complex pattern of individual signal change for a particular patient is not fully understood and large prospective studies are still lacking for the confirmation of definite use. From a clinical point of view, large prospective studies using EEG/fMRI as a presurgical tool are needed to evaluate whether or not the technique contributes to seizure relief in those patients.

Physiological origin of functional MRI signal

An increase is neural activity is accompanied by an increase in the cerebral rate of oxygen consumption ($CMRO_2$) and a much larger increase in local cerebral blood flow [134]. Owing to this imbalance, local capillary and venous blood are more oxygenated. The magnetic changes associated with the concomitant decrease in local deoxygenated haemoglobin are the basis for the fMRI blood oxygen level-dependent (BOLD) signal [135,136]. Therefore, the complex interplay between blood flow, blood volume and oxygen consumption resulting from the neurovascular coupling is at the origin of the BOLD signal in fMRI studies. The neural activity that gives rise to fMRI BOLD signal is not fully understood, but recent animal studies have shown that 'local field power', as an index of postsynaptic membrane oscillations (and hence local synaptic activity), correlates in time with the BOLD response [137], whereas action potentials, and thus neuronal spiking, are less correlated with BOLD signal. Moreover, dynamic changes in neural synchronization are also possibly involved in the genesis of the BOLD signal [138].

Under a magnetic field strength of 4 tesla (T), it has been shown that BOLD signal is largely dependent on venous contributions [139]. In other words, BOLD changes can reflect a downstream effect, thus reducing spatial resolution of fMRI for the mapping of the underlying neuronal activity [140].

Finally, the sensitivity of fMRI to detect BOLD signal changes related to epileptic activity is not the same across brain regions as a result of non-homogeneous magnetic fields at tissue boundaries. This can be manifest in the orbitofrontal cortex or basal portions of the temporal lobe, in which signal loss may be particularly high [141].

Methodological questions

Is it safe for the patient?

Although rapidly changing magnetic fields inducing a current that might theoretically induce heat from electrodes, safe recordings can be obtained by using non-ferrous electrodes and leads and avoiding current loops involving the patient. Over the years, the recording of EEG during fMRI has proved to be safe for the patient and no incident has been reported to date.

What is the quality of EEG?

The quality of EEG within the MRI scanner is reduced compared with that of the EEG outside, even within a static magnetic field. Immobilization of the head and wires reduces artefacts caused by electrode movements. During scanning, many sources of artefacts are known. Artefacts related to gradient switching have high amplitudes compared with EEG signal, such that EEG is unrecognizable during frame acquisition (Fig. 66.8). This can be avoided by scanning only after the observation of spikes, and it imposes constraints on the paradigm used. This procedure is largely abandoned today. Gradient switching-related

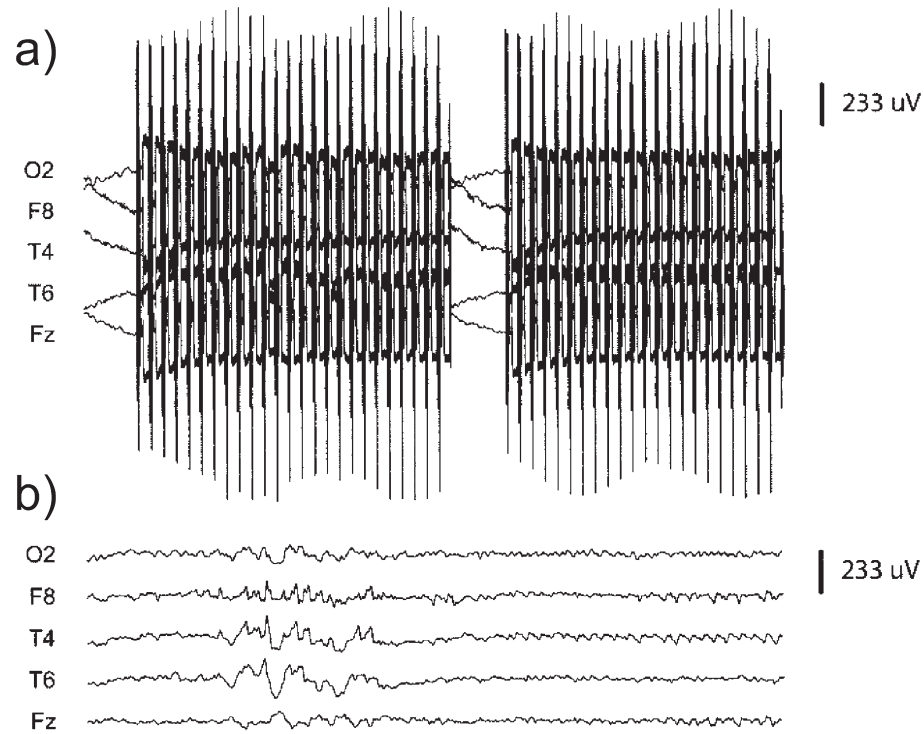

Fig. 66.8 Postprocessing of electroencephalogram (EEG) artefacts during EEG functional MRI (fMRI) acquisitions. (a) EEG trace during scanning. EEG paroxysms are not identifiable because of the switching of the magnetic resonance gradients which induce very large artefacts on the EEG. (b) Artefact removal (subtraction of an average artefact waveform). EEG paroxysms are now visible and enable event-related fMRI analysis. Adapted with permission from ref. 133.

artefacts can be modelled as a linear and time-invariant system. The most widely used method to remove the gradient artefact consists of estimating the artefact and subtracting it from each frame, followed by adaptive noise cancellation [142]. Other methods take advantage of the frequency structure of the artefact [143]. Modern postprocessing techniques permit the identification of epileptiform discharges after gradient artefact removal. Lastly, pulse (or ballistocardiogram) artefacts produced by heartbeats can be removed either by averaging and subtraction [142] or by filtering [144] or independent component analysis [145].

Which is the optimal paradigm of acquisition?

In the early years, the most common paradigm was interleaved acquisition. The acquisition was either aperiodic and triggered by spikes detected during the session [146] or periodic (with a sufficiently long duty cycle to allow for EEG interpretation in between imaging). During the last 5 years, advances in signal processing using the automatic removal of artefacts have enabled the continuous recording of electroencephalography during the session, which is therefore the most common mode of acquisition [127]. These techniques may be used offline but also online, with a direct high-quality visualization of EEG. One advantage of continuous acquisition is that the haemodynamic response function can be calculated, thus permitting a more accurate description of neural events underlying EEG events in the time domain [147].

Which are the principles of statistical analysis?

Despite the well-known high spatial resolution of fMRI, one has to keep in mind that images produced by fMRI depend on modelization of BOLD signal responses related to neural events. In event-related fMRI, the statistical methods most widely used are those developed by Friston *et al.* [148]. In this approach, the signal at each voxel of the brain is statistically compared with a model constructed by convolving impulses corresponding to the timing of the spikes (the events) with one or more basic functions, representing the haemodynamic response function (HRF). A statistical map is constructed and represents the proximity between the model and the data, and therefore the probability that a given region will be activated. One critical step of this approach is therefore to select a valid model, represented here by the HRF. In classical fMRI recordings, it is assumed that the time-course of the HRF to interictal epileptic discharges matches that of the response to brief physiological stimuli with a peak at approximately 2–6 s after onset. This 'canonical' HRF model is widely used but its validity for epileptic events is not definitively established. For example, the HRF associated with a single spike may last 10 to 15 seconds, which may be problematic for temporally overlapping bursts of spikes [149]. Moreover, when measured in epileptic patients, the HRF may exhibit some inter- and even intraindividual variability [149,150], and it was found very recently that responses with shapes that are different from the canonical response may occur at a distance from the suspected generator of epileptic activity, either being a false-positive finding or potentially reflecting propagation effects [151].

Lastly, the constructed map is statistically thresholded so that only voxels above a certain threshold are presumed to be involved in spike generation. Various approaches have been proposed, either parametric or non-parametric, impacting the clinical interpretation of the data.

What is the signification of increased and decreased blood oxygen level-dependent signal?

In EEG/fMRI studies, it is generally considered that the interictal spiking results in a higher level of neuronal activity, and thus an increase in the BOLD signal (so-called *activation*). Increases in postsynaptic activity, whether excitatory or inhibitory, result in an increase in oxidative metabolism and eventually in an increase in the BOLD signal. However, spikes may induce not only BOLD increases but also BOLD decreases (so-called *deactivation*). A BOLD signal decrease can be observed remotely and, more surprisingly, near or within the spiking area. The significance of such deactivations is still unresolved. Deactivation can reflect (1) a decrease in synaptic activity; (2) a GABAergic mediated inhibition resulting in a reduced neuronal firing at low energetic cost; (3) an abnormal vascular coupling or (4) vascular steal in regions surrounding activated areas. While some deactivations are clearly lying in the spiking zone and specific of spike genesis, some others are not directly linked to the epileptogenic process itself. These deactivations can reflect a disruption of ongoing activity in regions that are active in the resting state such as posterior precuneus and frontal mesial cortex. Whether activity changes related to interictal spiking in these so-called 'default mode' brain regions participate in interictal cognitive disturbances is an open and exciting issue.

Clinical studies: EEG/fMRI as a clinical tool

Yield of spike-correlated blood oxygen level-dependent signal changes

In most studies, patients are preselected on the presence of a high rate of interictal spiking. Few systematic studies with large cohorts have evaluated the detection rate of the EEG/fMRI technique. In this case, detection rate is defined as the ratio between the total number of significant spike-related BOLD increases (activation) or decreases (deactivation) and the number of spike groups simultaneously recorded during the study.

Globally, the detection rate of spike-correlated BOLD change varies between 40% and 60% among patients with focal epileptic paroxysms according to studies in adult case series. In the study by Al-Asmi *et al.* [152] involving 38 patients, 39% of the fMRI acquisitions showed spike-correlated BOLD activation. Bagshaw *et al.* [150] showed in a group of 21 patients that the detection yield increased from 45% to 62.5% when using patient-specific HRF. Salek-Haddadi *et al.* [153] reported in a focal epilepsy group that significant haemodynamic correlates were found in 68% of the patients with spikes. Bonaventura *et al.* [154], in a cohort of 43 patients, reported that 49% of the studies showed significant BOLD changes. More recently, Zijlmans *et al.* [155] found a significant BOLD response in 57% of a group of 64 patients. The highest yield of spike-correlated BOLD signal changes (92%) was reported in a recent paediatric cohort that included 37 children; this could possibly be explained by their use of patient-specific HRF and by a high spiking rate in these children [156].

The detection yield of spike-correlated BOLD signal changes also depends on patient characteristics. Thus, the likelihood of a significant response seems to be dependent on the spike rate during the session, but also on spike morphology and temporal distribution of spiking, bursts of spikes being more likely to generate significant results than isolated single spikes [153]. The yield of EEG/fMRI studies in generalized epilepsy is generally higher, for example Aghakhani *et al.* [157] reported significant BOLD changes in 14 out of 15 patients during generalized spike–wave discharges.

Interictal network identification and EEG/fMRI

In the absence of any gold standard it is difficult to assess the reliability of BOLD changes localization to map the area producing interictal spiking. Few studies have compared the spatial distribution of BOLD changes with invasive intracranial data. The largest study investigating the concordance between EEG/fMRI signal and stereotactic EEG comprised only five patients and showed that, if intracranial EEG was sampled from near (within 20–40 mm) a region of BOLD changes, at least one contact presented spikes [158]. However, fMRI was blind to some interictal spiking areas identified by depth recordings, particularly in the basal temporal regions. Interestingly, both activation and deactivation had a localizing value. Moreover, the presence of low-frequency abnormalities such as slow wave was associated more with BOLD activation than with deactivation. Clearly, more studies are needed to confirm the validity of those results in a large cohort with different pathological conditions.

EEG/fMRI and epileptogenic zone mapping

More recent studies have evaluated whether or not EEG/fMRI is a valuable tool to determine the epileptogenic zone, which can be distinct from, or overlapping with, the spiking area. Salek-Haddadi *et al.* [153] brought encouraging results by showing that significant haemodynamic changes on fMRI were highly, but not entirely, concordant with the presumed site(s) of seizure generation (Fig. 66.9). Still, no direct validation by surgical procedure

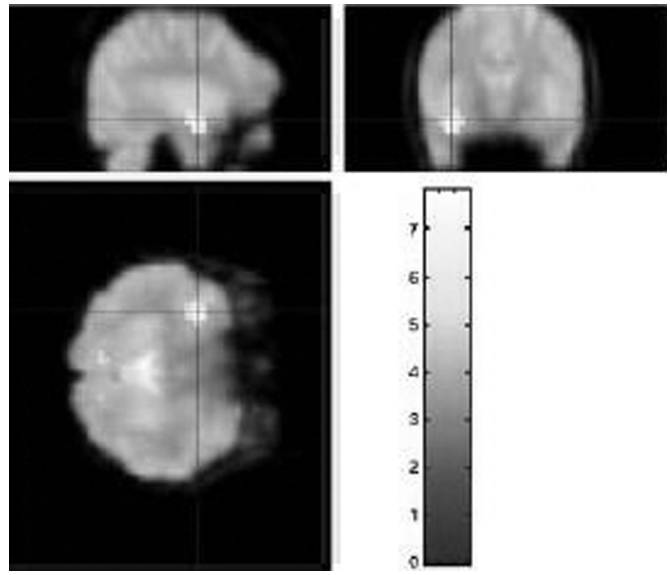

Fig. 66.9 Example of electroencephalogram/functional MRI (EEG/fMRI) study in a patient suffering from left temporal lobe epilepsy. Structural MRI showed left hippocampal sclerosis and scalp EEG revealed left temporal spikes in this patient. EEG/fMRI revealed a highly concordant cluster of temporal lobe activation (local BOLD increase in white pixels). Adapted with permission from ref. 153.

and follow-up is provided in that study. In the study from Bonaventura *et al.* [154], in which focal spike-correlated BOLD changes were seen in 18 out of 21 patients, the haemodynamic foci were congruent with electroclinical data.

Because new physiological tools are mostly needed for complex cases, Ziljmans *et al.* [155] evaluated EEG/fMRI in a cohort of patients rejected for epilepsy surgery because of non-conclusive presurgical seizure onset zone determination. In that difficult group, 8 out of 29 patients presented significant BOLD changes. In four patients, EEG/fMRI brought new localization information, leading to confirmative EEG intracranial recordings and improved localization in four out of six unclear foci. Lastly, in patients with presumed multifocality, EEG/fMRI identified one single focus in one patient and confirmed multifocality in four out of five patients.

Spike-related BOLD changes in different pathologies

During the last years, efforts have been made towards understanding the mechanisms of epileptogenicity of different types of lesions using EEG/fMRI. These studies focused mostly on malformations of cortical development. One study comprised five subjects with focal cortical dysplasia and one with a ganglioma [159], and another study included nine patients with polymicrogyria [160]. Signal changes were found in lesional, near-lesional or possibly subcortical areas, with no specific pattern. The authors speculated that regions exhibiting BOLD variations distant from epileptogenic foci have abnormal functional connections with the lesion area or are parts of the cortical–subcortical circuits involved in the genesis or spread of interictal discharges. Similar findings were found in an EEG/fMRI study of 14 patients with grey matter heterotopia, which showed BOLD activations and deactivations occurring within, near or distant from the lesion [161]. In the case of multiple lesions, EEG/fMRI could theoretically help to determine the most active in the interictal period. Indeed, Jacob *et al.* [162] recently showed in a small group of five patients with tuberous sclerosis that the tuber could be responsible for extensive BOLD changes near or remote from the lesions, suggesting extensive spiking areas in these cases, and that some tubers could be identified as 'active' using this non-invasive method.

Paediatric studies

The feasibility of EEG/fMRI studies has been shown in several papers, even for very young children under 2 years. However, the HFR is different in different age groups, so that modelling strategies should consider using multiple specific HRF in young patients under 2 years old [156]. In a recent study including 13 children who underwent a 20-min EEG/fMRI acquisition at 3 T under sedation-induced sleep, BOLD responses were localized in the lesion or brain area presumably generating spikes in 84% of the cases [162]. In contrast with studies in adults, deactivations in the lesion and the spiking area were more common than activations.

Conclusion

Source modelling of EEG or MEG scalp signals and EEG/fMRI are both based on a modelling of bio-electromagnetic phenomena. As detailed in this chapter, each of them poses multiple methodological questions that have been progressively tackled and, for some of them, solved in the past few years. The question remains as to whether or not these new neurophysiological investigations have reached a sufficient level of reliability to be considered as usable in clinical routine for the management of patients suffering from partial epilepsies who are candidates to surgery, knowing that only those patients may draw an individual benefit from these investigations. The most obvious indication of spike source modelling in everyday practice is represented by lesional focal epilepsies, which have become much more frequent owing to the progresses of anatomical brain MRI, in particular for patients with multiple lesions. In such cases, predicting whether or not the patient will be seizure free after lesion resection is the question at stake, and a good spatial co-extensiveness between the lesion and the spiking area entails a favourable outcome prediction, even although a large scatter of spike sources is less reliable as predictor of a bad outcome. However, we fully adhere to the opinion expressed by Plummer *et al.* [111] in their recent review of EEG source localization that if 'the multimodal imaging technology on offer today for spike and seizure localization has limited value if its results are interpreted without due respect for the patients's electroclinical seizures', it remains that: 'EEG source localization is better regarded as an *underutilized* three-dimensional extension of traditional two-dimensional EEG analysis'. This latter statement is fully justified now that advanced source modelling software packages are commercially available. More advances are still needed to fully understand the coupling between the BOLD haemodynamic response and epileptic EEG transients, and thus to evaluate the reliability of EEG/fMRI data as markers of the epileptogenic zone. Furthermore, the question of whether or not lesional blood–brain barrier changes should be integrated in HRF modelling is still pending. Lastly, both techniques still suffer from the lack of prospective blinded validation studies on large groups of patients.

67 Neuropsychological Testing in Presurgical Evaluation

Marilyn Jones-Gotman and Jelena Djordjevic
McGill University, Montreal Neurological Institute, Montreal, Quebec, Canada

Introduction

Neuropsychological evaluation is an essential part of the comprehensive investigation of patients who are candidates for surgical treatment of epilepsy. The decision as to whether or not a patient is an appropriate surgical candidate is based upon data gathered by a team of professionals. Some of the necessary information is anatomical, derived from neuroimaging, some is physiological (electroencepalography) and some is based on clinical history and seizure pattern. Neuropsychology's contribution is unique in providing data about function through evaluation of a patient's strengths and weaknesses on cognitive tests. An important recent aspect of neuropsychological evaluation is the use of functional neuroimaging to localize critical sites for different cognitive functions in individual patients; this is beyond the scope of this chapter.

The information obtained through traditional neuropsychological testing methods is used in several ways. Interpretation of the pattern of results on neuropsychological tests gives information about the site of epileptic focus, inferred from the pattern of cognitive dysfunction. Although the sophisticated imaging techniques that are now able to evaluate brain structure and function overlap partially with neuropsychological information, they do not supplant it. With respect to localizing dysfunction, neuropsychological findings can reinforce or, if the findings disagree, question data from other sources about the site of seizure focus. When disagreement with other data occurs, those discrepancies can provoke further investigation. An unsuspected atypical representation of language is sometimes exposed in this way, and discrepant or unexpected findings from memory assessment can have a direct impact on surgical management, which will be discussed later.

Because neuropsychological results show the functional effect of a lesion or of abnormally discharging tissue, they allow evaluation of the impact of an individual's epilepsy on his/her life and provide a basis for counselling and making informed decisions. Preoperative neuropsychological measurements also form a basis for evaluating surgical outcome with respect to cognitive function by comparing pre- and postoperative performance on the neuropsychological tests. These objective data identify possible changes that can affect an individual's work, schooling or other activities. Knowledge gained from postoperative studies has also allowed another application of preoperative evaluation: prediction of surgery outcome in terms of seizure control and in terms of postoperative cognitive change/decline.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Determination of site of dysfunction

A thorough neuropsychological evaluation requires 6–8 hours of direct contact between patient and examiner. A basic battery of tests should sample many different cognitive functions. If the battery were tailored for each patient from the outset, evaluations would be skewed to reflect the examiner's expectations. However, after exploring the whole brain with a comprehensive basic battery, the findings for individual patients can be pursued with further tests aimed at delineating that patient's cognitive profile more precisely.

A basic battery includes measures of intelligence, language, attention, memory, fronto-executive skills, visuospatial abilities, and some sensory functions and motor skills. Such an arsenal of tests taps function in the frontal and temporal lobes, and also parietal and more posterior regions. At its most fundamental level, the method underlying neuropsychological evaluation is to determine the dysfunctional *hemisphere* by comparing a patient's performance on verbal tasks with performance on visuospatial or visuoperceptual ones, and within the hemisphere to determine the dysfunctional *region* by comparing performance on various tasks. Results from this thorough, usually standardized, assortment of measures provide a reliable way of characterizing and quantifying the nature and degree of cognitive dysfunction arising from epilepsy. In this chapter, the emphasis will be on testing methods that are useful in focal, surgically treatable epilepsy.

Potential pitfalls in presurgical evaluation

Neuropsychological evaluation of unoperated epilepsy patients can be a challenge for a variety of reasons. Various demographic, medication and seizure-related variables have been shown to exert differential influences on performance. Some examples of demographic factors with a possible mediating role in neuropsychological functioning are gender and age, whereas seizure-related factors include age at onset of epilepsy, duration of disorder, seizure frequency, seizure spread, medications, etc. These factors should be considered when interpreting results from an individual's preoperative evaluation. One should also be aware that some neuro-

psychological tests used in epilepsy may be based on findings from patients with other kinds of brain pathology. Although principles of brain function and dysfunction are the same, different pathological processes can vary from one type of brain disorder to another, and extrapolating findings may not always be appropriate. Traumatic brain injury, neoplasms, vascular disorders, brain damage due to different toxic conditions, degenerative disorders of the nervous system, or infectious processes in the brain have specific features in terms of depth of lesion and involvement of cortical and/or subcortical structures, stability over time, presence of diffuse and/or distance effects, and presence of diseased or dead brain tissue [1].

Furthermore, the pathological substrate of epileptogenic lesions is itself heterogeneous. For example, the most frequent structural abnormality found in temporal lobe epilepsy (TLE) is hippocampal sclerosis. However, other neuropathological processes such as tumours, malformations, cerebrovascular accidents, trauma and infections are associated with epilepsy. It remains unclear whether or not hippocampal sclerosis and other seizure-inducing pathological processes at the same location may affect neuropsychological performance differently. Epileptic patients may or may not have discernible brain damage, and the existence of possible differential effects of lesional versus non-lesional TLE on neuropsychological performance remains an open question.

Another potential problem is that some information underlying neuropsychological clinical practice derives from operated patients, but cognitive effects of surgical lesions are not directly comparable to the effects of brain pathology generating seizures. Deficits are often more difficult to demonstrate in unoperated than in operated patients, possibly owing to such factors as the size of the lesion (larger in the case of surgical lesions) and uniformity of surgical versus heterogeneity of epileptogenic lesions.

A third problem encountered in the field is a relative lack of analogous verbal and non-verbal tests. The concept of hemispheric specialization is widely accepted in neuropsychological practice, and therefore verbal and non-verbal tests are commonly used for assessment of the dominant and non-dominant hemispheres, respectively. However, these tests have often been different in a variety of ways, introducing noise and interfering with direct comparisons of the functional abilities of the two hemispheres, especially in the clinical setting, where it is most important to compare results from the various tests within an individual patient. A strategy of using matched verbal and non-verbal tasks to study analogous brain regions in left and right hemispheres adds power to the neuropsychologist's ability to lateralize dysfunction and to analyse the nature of a patient's deficits. We consider this idea particularly important and will discuss it in more detail later.

Last but not least are the issues of clinical utility of neuropsychological instruments and the development and publication of norms for neuropsychological tests. The number of tests proven to be effective for presurgical evaluation of patients with epilepsy is not large. Tests that have been demonstrated to distinguish among different clinical groups may not be successful on the individual level, and even when a test can distinguish among patient groups with epileptogenic lesions of different locations, the questions of its sensitivity and specificity need to be answered. In addition, the field needs more published norms on its tests, to allow meaningful interpretation of results. Neuropsychological expertise depends on the use of sensitive tests and a solid database about those tests, and, happily, this is an area of growth in recent years.

Despite these caveats, the field has matured well over the past several years and there are many instruments in current use to evaluate patients for epilepsy surgery. We will provide a brief overview of some of these in the sections to follow, organized primarily by brain region.

Evaluation of frontal lobe function

Contemporary characterizations of frontal lobe functioning have shifted the emphasis from anatomically based descriptions (i.e. frontal or prefrontal lobe syndrome or signs) to functional ones, encompassing a variety of psychological constructs, with the concept of 'executive function' being a particularly prevalent descriptor. Definitions of this concept vary among authors, but most agree that some of the known functions of this brain region have to do with planning, initiation, organization, self-monitoring, self-regulation and decision-making. Measures commonly used to explore possible damage in the frontal lobes include tests of problem-solving, fluency, susceptibility to interference, planning and motor skills. Among the earliest objective measures were word fluency tests, which documented the clinically known paucity of spontaneous speech in patients with severe frontal lobe damage, and a card sorting test, which tapped several aspects of frontal lobe damage including problem-solving, impulsivity and inability to use cues to guide behaviour.

Problem-solving: Wisconsin Card Sorting Test

The Wisconsin Card Sorting Test (WCST) is part of the testing arsenal of most neuropsychologists. In the first studies using the WCST with epileptic patients, Milner [2] reported impairment in patients with resection from a frontal lobe, especially the left frontal lobe. The literature has now grown to contain many articles confirming or disputing the sensitivity of this task to frontal lobe dysfunction (for example see ref. 3). Furthermore, several studies have demonstrated that a significant proportion of patients with TLE display deficits on card sorting tests (for example see ref. 4). In a retrospective study [5] of WCST performance in 50 patients with unilateral resection from a frontal lobe (25 left, 25 right) and 40 patients (20 left, 20 right) with unilateral resection from a temporal lobe, we found no group differences before surgery, whereas postoperatively the left frontal lobe group performed worse than the right frontal and left temporal lobe groups but did not differ from the right temporal lobe group. Thus, poor performance on this task can occur in patients with dysfunction in the temporal lobe, in addition to the traditionally expected deficit after left frontal lobe damage. Interpretation of WCST results should be made cautiously, and should be viewed together with results obtained from other tests of frontal lobe function.

Generation of novel responses: word and design fluency

One implication from the card sorting data is that it may be difficult to detect deficits associated with right frontal lobe damage.

One of the rare measures shown to be able to capture dysfunction of the non-dominant frontal lobe is the Design Fluency Test (DFT) [6,7], which is used to measure fluency in the non-verbal mode. The task requirements are to create original abstract designs that do not represent anything and cannot be named, and to produce as many different designs as possible in 5 min. On average, healthy subjects produce about 16 acceptable drawings. Patients with right frontal lobe or right central lesions produce on average five or six acceptable designs, whereas patients with left frontal lesions, or left or right temporal lobe lesions, are not impaired [6]. The performance of patients with damage in the right frontal lobe is manifested in one or more of the following ways: a low overall output, a strong tendency to perseverate (producing many drawings that are essentially the same) and rule breaking (e.g. making representational drawings). Figure 67.1 shows three examples of design fluency: one from a healthy subject (Fig. 67.1a) and two from patients with a right frontal lobe lesion (Fig. 67.1b and c).

Several studies have shown that the DFT is characterized by very good intra- [8] and inter-rater reliability [8–10], and convergent and divergent validity [8]. Normative data for DFT have been published [9].

In contrast with their poor performance on the DFT, patients with a right frontal lobe lesion can do very well on verbal fluency tasks, and patients with a left frontal lobe lesion can perform well on figural fluency but poorly on word fluency. Comparing an individual's performance on paired verbal and visuoperceptual tasks that are as similar as possible except for the actual material of each task (e.g. words versus designs) aids in teasing out subtle deficits. In this case, comparing verbal to figural fluency within an individual patient can help determine whether or not there is frontal lobe abnormality, and can also point to the side of dysfunction. Asymmetry between left and right frontal lobe damage is easier to establish based on both tasks rather than on a verbal fluency task alone.

Susceptibility to interference

Flexibility is another important aspect of frontal lobe function, and it is often explored with Stroop tests [11], which in the 'interference condition' require inhibition of a well-practised response and production instead of a less automated one. The Stroop interference condition is sensitive to the effects of frontal surgical lesions, but does not consistently reveal dysfunction in patients with a frontal lobe seizure origin but no surgery. Lateralized effects on Stroop tests have not been demonstrated in epilepsy patients.

Planning: the Tower of London test

Tests of planning ability are among the staples for assessment of frontal lobe function. A measure that is widely used now is the Tower of London test [12]. It comprises a series of trials in which coloured beads must be moved from an initial position to a goal position in the smallest possible number of moves. For optimum performance, the sequence of moves should be planned before the first move is made. Whereas some studies have shown a clear impairment in patients with frontal lobe resection, and some have suggested a specific role of the left frontal lobe, others have found no differences between unilateral left and right frontal lobe surgery.

Motor tasks: strength: dexterity and coordination

Motor tasks are a useful part of diagnosing frontal lobe function. Among measures used are strength tasks using a hand or pinch dynamometer, manual dexterity tasks such as the Purdue or grooved pegboard tests, finger-tapping tests, and sequential unimanual and bimanual tapping (see ref. 1). Separate norms for men and women should be used when interpreting results from motor tasks, to take into account known significant gender differences. Age should also be considered, as performance declines on various motor tasks with advancing age [13]. Also important is the relationship between hand dominance and side of seizure focus [13], taking into account that the dominant hand is normally superior to the non-dominant hand. In general, an unusually large difference between the hands or a difference in an unexpected direction implicates dysfunction in the contralateral motor and/or premotor and prefrontal cortex.

Parietal lobes

Traditional tests of parietal lobe function have been useful primarily in patients with stroke, tumour or other large lesions. Demonstration of parietal lobe dysfunction in patients with epilepsy is more difficult, and the frank impairments associated with extensive lesions are not seen or are attenuated. Salanova *et al*. [14] described a series of 82 patients with non-tumoral parietal lobe epilepsy treated surgically at the Montreal Neurological Hospital between 1929 and 1988. Neuropsychological results were available in 30 preoperative and 27 postoperative patients from that series. Preoperatively, impairments in reproducing complex pictorial material, constructing block designs and/or left–right discrimination were found in nine (30%) of these patients, and contralateral visuospatial neglect while drawing was observed in two patients with right parietal lesions. After focal parietal resection, some of those patients showed new ($n = 7$) or exacerbated ($n = 2$) deficits that included dressing apraxia and difficulty identifying faces, and disturbances in spatial orientation, visuoconstructive functions and body image. Two patients also showed acalculia, anomia, agraphia and partial auditory and verbal agnosia. Thus, observable deficits occur in a minority of patients with parietal lobe epilepsy.

A retrospective look at our own preoperative and postoperative data on epileptic patients with highly focal damage confined to the left or right parietal lobe (eight left, five right) showed impairment in copying of the Rey–Osterrieth Complex Figure (ROCF) in those with a right parietal focus, whereas we found inefficient reading in those with a left parietal focus [15]. We also found raised thresholds contralateral to seizure focus for two-point discrimination on the palms of the hands in the right parietal group compared with the left. As with many other tasks, the difference was more pronounced after surgery.

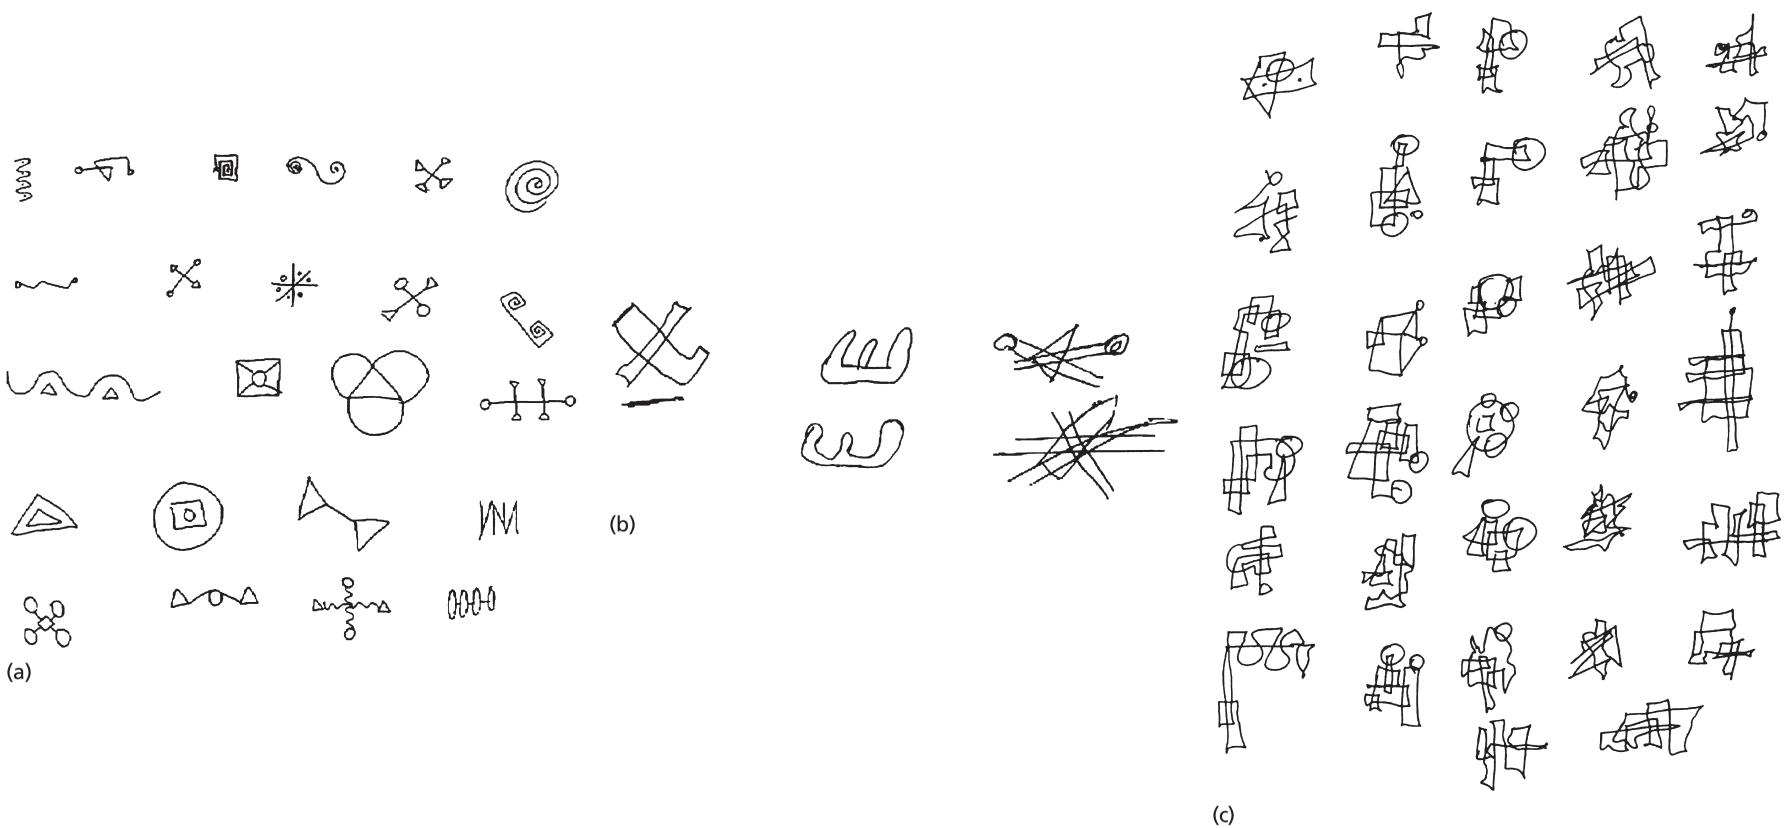

Fig. 67.1 Examples of drawings produced in 5 min in the DFT. (a) Productions made by a healthy control subject. This subject made three drawings that were discounted as perseverative (scoring not shown); producing a few such errors is normal. (b and c) Drawings made by two patients with right frontal lobe resection. (b) The patient, a clerk, had a full-scale IQ of 112. The underlined drawing represented a sculpture in his town, as did the drawing that resembles a rotated 'E'. In addition to these representational drawings, which are not allowed, the patient repeated one of the 'sculptures' (perseverative error), and the two remaining drawings were also highly similar to one another. This illustrates low output, rule-breaking and perseveration. (c) This patient, a geologist, had a full-scale IQ of 128. His output illustrates extreme perseveration: although he made many drawings, they are all alike.

Drawing upon findings from neuroimaging studies, one can expect tests of mathematical abilities to be sensitive to parietal lobe dysfunction, especially on the left side [16], and this avenue is currently largely unexplored. Difficult visuoperceptual tasks may also prove useful [17] and should be tried as part of neuropsychological evaluation.

To summarize, evaluation of parietal lobe function and dysfunction in epilepsy remains a challenge. It may be that most patients with a parietal lobe focus have abnormalities that are too subtle to be detected by existing neuropsychological tests. Among the measures currently available, those that test visuoconstructive and visuospatial functions, reading, and somatosensory functions seem to be the best. A direction for growth in the field is to develop new instruments for evaluation of this brain region based on these best existing measures and on neuroimaging findings.

Occipital lobes

An occipital lobe focus is rare in epilepsy, and therefore little effort has gone into developing special tests of occipital lobe dysfunction for epileptic patients. Tests of visual perception that are available include tests of visual (in)attention and scanning (cancellation and line bisection tests), colour processing (perception, recognition, naming), face recognition and discrimination, visuospatial processing (Benton Judgment of Line Orientation, Hooper Visual Organization test) and visual interference (hidden and overlapping figures tests). These instruments offer evaluation of visual and/or visuospatial functioning with minimal or no engagement of the motor system. Although deficits on some of them have been associated with right posterior cerebral lesions [18], the findings have not always been consistent and cannot be considered specific to the occipital lobe. Furthermore, the clinical utility of these tests in preoperative evaluations of patients with epilepsy remains questionable, given the lack, or inconclusiveness, of published findings.

Temporal neocortex

Although memory is the hallmark of medial temporal lobe function, several other types of measures are also used to assess the temporal neocortex. Among the most important of these are word-finding tests, a very commonly used example of which is the Boston Naming Test (BNT) [19,20], which requires naming pictures. We demonstrated a deficit on the BNT preoperatively in patients with left, but not with right, TLE [21], as did Hermann *et al*. [22], whose patients with left TLE were also impaired on repetition, comprehension and reading. In contrast, Saykin *et al*. [23] also reported a left TLE naming deficit, but verbal fluency, repetition, comprehension and reading were preserved in their patients. A newer test of naming in response to word definitions instead of to pictures, introduced by Hamberger *et al*. [24], approximates the experience of word-finding difficulties more closely than do tests of picture-naming, and it has been shown to tap a more anterior area of the left temporal lobe, making it a more appropriate test of the region to be excised in temporal lobe surgery [25].

One of the most widely used tests of language comprehension is the Token Test [26]. Reports on Token Test results in unoperated epilepsy patients are conflicting. For example, Hermann *et al*. [22] reported impairment of patients with left TLE compared with those with right TLE on this test. However, our analysis of 131 patients with focal cortical resection from a left or right temporal, frontal, parietal or occipital lobe revealed an impairment in all preoperative patients with a left- compared with right-sided focus and no difference among the sites within the left hemisphere (unpublished data). In contrast, Giovagnoli [27] found that patients with left or right temporal or extratemporal epilepsies all performed within a normal range on the Token Test.

For the non-dominant temporal neocortex, tests meant to tap complex visuoperceptual functions are frequently included, as visual association cortex is part of the temporal lobes. The most widely used visuoperceptual tests include the Hooper Visual Organization test, Benton Judgment of Line Orientation test, and Benton Face Recognition test. For these and similar tests, an association with a particular site (lobe) within the brain has not been consistently demonstrated. For example, patients with left versus right TLE do not differ on the Benton Face Recognition test [28], or on the Hooper Visual Organization test or Judgment of Line Orientation test [29]. Thus, the use of existing visuoperceptual tests remains a problem because deficits do not arise exclusively from one site and side within the brain.

Medial temporal lobe function: memory assessment

A thorough evaluation of memory is particularly important in the assessment of epileptic patients because the majority of surgical candidates have a temporal lobe focus, and memory is the most salient of temporal lobe functions. It is well known that bilateral lesions in the medial temporal lobe can result in severe global memory deficits [30], but such profound memory impairment is rare. In contrast, patients with unilateral temporal lobe dysfunction show a more restricted, material-specific deficit. Therefore, a thorough memory assessment should address each hemisphere with tasks appropriate to its specialization.

The fundamental difference between the two temporal lobes is well known. The left (dominant) temporal lobe mediates memory for verbal material, such as names, word lists, stories or number sequences, and the right temporal lobe mediates memory for material that cannot be verbalized readily, such as faces, places, abstract designs or music. Because of this difference in the kind of material each temporal lobe mediates, memory tests ideally should be as purely verbal, or purely non-verbal, as possible. In this way we attempt to maximize differences between the hemispheres by using memory tasks that are polarized into the verbal or non-verbal domain, and in doing so we increase the probability that our tests tax primarily one temporal lobe.

Traditional memory tests

Most neuropsychologists working in epilepsy programmes use memory tests from published batteries [31], especially those in the Wechsler Memory Scales (WMS), and most also use the Rey–Osterrieth Complex Figure test [32,33]. The latter consists of a complex geometric design that patients must copy, followed by a free recall test that may occur immediately and/or after a delay. The copy task provides useful information (see section on the parietal lobe, above) but memory results are at best contradictory. Some group data show impairment after right temporal lobe damage, whereas other group data show no difference between left and right temporal lobe damage. The usefulness of the memory task for individual cases is thus very limited. Several different verbal tasks, usually involving paragraph memory or list learning, are also used widely and will be discussed later in this chapter.

Most of the information available from earlier studies about memory performance of patients with TLE was based on postoperative results in patients who had undergone resection from a temporal lobe. Those results do not necessarily generalize to the unoperated case. We examined the performance of unoperated patients with TLE on several commonly used memory tests, using measured MR scans to group the patients according to side of hippocampal atrophy. The tasks studied were the logical memory (or prose passages), associate learning (word pairs) and visual reproduction (designs) subtests from the WMS and the Rey–Osterrieth Complex Figure test described earlier in the chapter. Figure 67.2 shows the mean recall scores of the two patient groups on the four measures after a 90- (WMS tests) or 45-min (Rey–Osterrieth Complex Figure test) delay. There were no significant differences between the left- and right-sided atrophy groups on any of these measures [34].

As these have been the most widely used memory tests in the evaluation of epilepsy surgery candidates, results from them are frequently reported in the literature. In a meta-analysis of studies reporting memory data in epilepsy, Lee and colleagues [35] were limited to analysing WMS findings because only WMS data were plentiful enough to allow a large analysis. Their findings were clear: the WMS tests did not differentiate left versus right temporal lobe groups. In a combined study by seven epilepsy centres, Barr *et al*. [36] analysed results of 757 left or right temporal lobe presurgical patients on the Visual Reproduction subtests of the WMS and on delayed recall of the Rey–Osterrieth Complex Figure test. Despite their large sample, they also found no differences in these measures between patients with left versus right TLE.

These findings are hardly surprising. Those tests are outdated and psychometrically naive, and not one of them is strongly polarized into the verbal or non-verbal domain. Furthermore, except for the WMS paired-associates test, the recall tests shown in Fig. 67.2 occurred after a single exposure to the material to be remembered. Effects of attention, comprehension and individual strategies are probably most variable on a first trial, or on an only trial, and these effects can confound memory findings.

Matched verbal and non-verbal learning and memory tests

We compared the performance of the patients of Fig. 67.2 with severe left or right hippocampal atrophy on two tasks that tested learning over the course of four trials. The tasks [34,37] were matched in paradigm, differing only in the type of material to be learned: 13 abstract words in one and 13 abstract designs in the other (Fig. 67.3). On each learning trial, subjects copied the 13 items, which were shown one at a time, and immediately upon

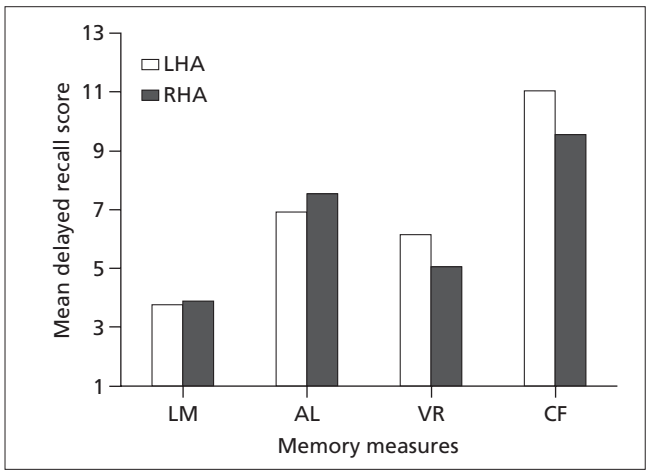

Fig. 67.2 Mean delayed recall scores of patients with left or right hippocampal atrophy on three WMS tasks and on the Rey–Osterrieth Complex Figure (CF). LM, Logical Memory, maximum score 23; AL, Associate Learning, maximum score 10; VR, Visual Reproduction, maximum score 14; CF, Rey–Osterrieth Complex Figure, maximum score 36; LHA, left hippocampal atrophy group; RHA, right hippocampal atrophy group.

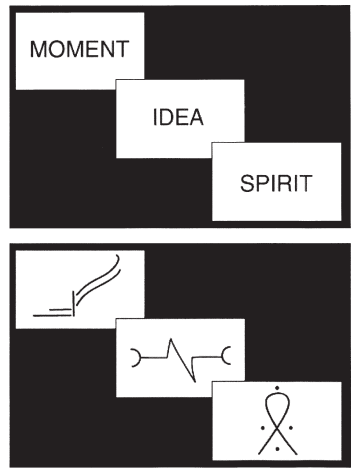

Fig. 67.3 Examples of stimuli from the matched learning tasks: Abstract Word List learning (AWL) and Abstract Design List learning (ADL). The ADL is administered before the AWL. During the learning phase, stimuli are shown one at a time while subjects copy them; each learning trial is followed by a free recall test, and an additional delayed recall test is obtained 24 h later.

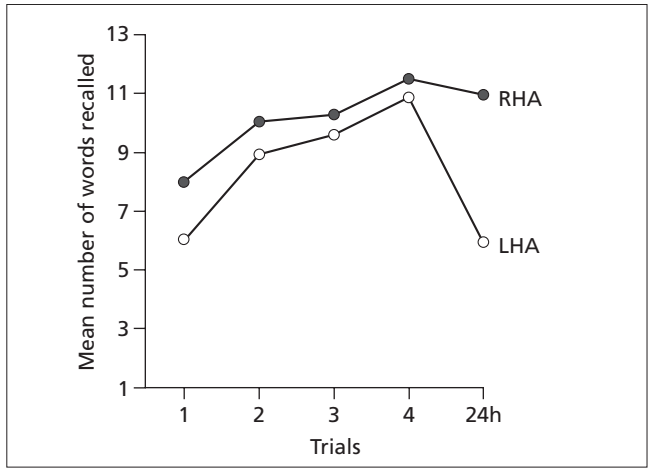
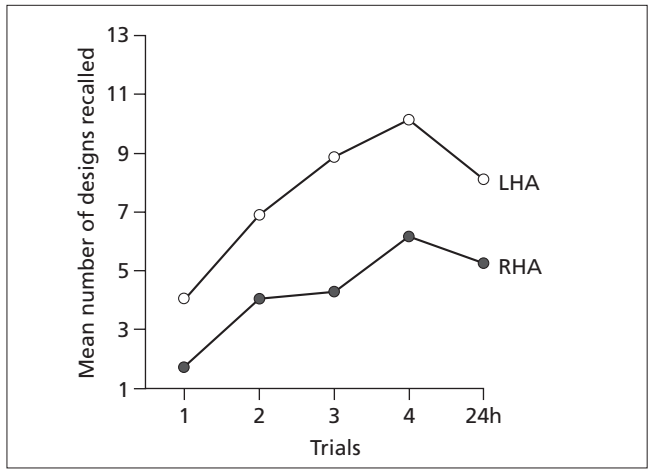
completion of the copy task they wrote as many words or drew as many designs as they could remember. A delayed recall was obtained 24 hours later.

On these tests there was a clear difference between patients with left hippocampal atrophy and those with right in the pattern of results [34]. On the verbal task, the patients with left hippocampal atrophy were worse than those with right hippocampal atrophy, in that they showed severe forgetting of the words after the delay interval (Fig. 67.4a). In contrast, the patients with right hippocampal atrophy were worse than those with left on the non-verbal task, in that they were slow and inefficient during the learning phase (Fig. 67.4b). Thus, patients with left hippocampal atrophy were impaired in *retention* but not learning of words, whereas right hippocampal atrophy patients showed deficient *learning* of designs but they did not forget what they had learned.



(a)



(b)

Fig. 67.4 (a) Learning (four trials) and 24-h delayed recall of abstract words in patients with left or right HA. Maximum score on each trial is 13. (b) Learning and delayed recall of abstract designs in patients with left or right HA. Maximum score on each trial is 13. LHA, left hippocampal atrophy group; RHA, right hippocampal atrophy group.

These results show a double dissociation in unoperated patients for verbal versus non-verbal material in two tasks that were identical except for the nature of the material. This finding contrasts sharply with the lack of effect in the four measures reported above. The critical features of these more sensitive tasks are:

- The material used is polarized: the abstract words are highly verbal and the abstract designs are highly non-verbal.
- These are learning tasks, providing the possibility to improve with additional exposure to the material, increasing the difference between people with a true learning deficit and those who do poorly on a first trial for other reasons.
- They are matched, varying only according to the verbal versus non-verbal nature of the material. This allows direct comparison of the efficiency of the two hemispheres, even within individual patients.

These examples illustrate the importance of the choice of tasks in neuropsychological testing. Several matched memory tasks have been developed in recent years [38,39]; this often represents development of a non-verbal analogue for a previously existing verbal test such as the Rey Auditory Verbal Learning Test (RAVLT) [40,41], the California Verbal Learning Test (CVLT) [42], the Buschke Selective Reminding test [43] or the modified Brown–Peterson paradigm [44,45]. Although some results in presurgical epilepsy patients have been published and may be described as encouraging, these tests await further empirical confirmations.

The Warrington Recognition Memory (WRM) test is a matched pair of tasks using words and faces; it was reported to be sensitive to the effects of temporal lobe lesions in patients with neoplasms and infarctions [46] and in resected patients with TLE [47]. However, other studies showed its clinical utility for presurgical epilepsy patients to be very limited (for an example see ref. 48). Baxendale [48] suggested that temporal lobe lesions that extend beyond hippocampus may be necessary to produce deficits on the WRM. Its modest diagnostic efficiency in focal epilepsy may be due to its use of an incidental memory paradigm with a single exposure to the stimuli and to memory being tested immediately after presentation of the stimuli.

The fact that the WRM does not reliably differentiate left and right temporal lobe dysfunction despite using paired tasks adds emphasis to the utility of the paired learning tasks illustrated above [34,37]. Those tasks alerted us to the difference in pattern as well as in material that distinguishes the left and right temporal lobe memory deficits. Some findings obtained by other authors and using different testing paradigms are consistent with the idea that deficits from unilateral temporal lobe lesions may be both material and process specific. For example, several independent groups reported impaired recall but not impaired learning of words in those with left TLE compared with those with right TLE and healthy control subjects [49,50]. Furthermore, some authors who examined non-verbal learning reported a deficit in the learning of non-verbal material but not in its retention in patients with right TLE [51,52].

Other verbal learning and memory tests

There is a growing literature on single tasks that seem to be sensitive to verbal memory deficits in unoperated epilepsy patients.

Those used most frequently (besides WMS subtests) are the RAVLT and the CVLT, both of which comprise word lists that are presented over several trials, an interference list that is presented once, and recall trials obtained after interference and after a delay. Published results from these tests suggest that they can distinguish between left and right TLE [53].

A promising test that taps a more everyday life aspect of memory is the Story Learning Test developed by Frisk and Milner [54]. It consists of repeated presentation of a story until it is learned to a criterion: therefore it provides measures of learning and of immediate and delayed retention. In the original study, patients with left temporal lobe excisions were impaired compared with those with right temporal lobe excisions and healthy control subjects [54]. We have used the test with unoperated patients for several years, with excellent results that differentiate patients with left TLE from those with right TLE and control subjects [55]. Furthermore, we have developed three alternative test forms and demonstrated their equivalence within two languages (J. Djordjevic, M.L. Smith, V. Sziklas, D. Piper, S. Pénicaud, M. Jones-Gotman, McGill University).

Non-verbal learning and memory tests

Since the old non-verbal memory measures had little success in detecting right temporal lobe damage, there have been a number of attempts to modify the existing tests or develop new procedures to evaluate non-verbal memory. Helmstaedter *et al*. [56] introduced a six-trial learning test in which five line designs had to be reconstructed using wooden sticks. The authors reported learning deficits in patients with right but not left TLE [56]. More recently, Gleissner *et al*. [52] compared performance on this test in patients with right TLE with and without hippocampal sclerosis or atrophy. They found impaired learning only in the patients with right hippocampal atrophy.

Barr [28] reported a deficit in unoperated patients with TLE on the Denman Face Recognition Test. To our knowledge, this finding has not been replicated, and we have been unable to replicate it in our TLE patients. This was not surprising, however, as that task tests memory after a single exposure. We now use a face-learning task ('the Twins Test') [57] consisting of four trials to learn 12 unfamiliar faces, and a delayed recognition test 24 h later. In our original study of patients with a temporal lobe resection we found a learning impairment in the right resection group and no difference between the left resection and normal control groups. The right temporal deficit was specific to learning, with no greater forgetting after a delay than in the other groups, which was similar to our design-learning task as reported earlier in the chapter.

Tests of spatial memory have been shown to be sensitive to right TLE. For example, Baxendale and colleagues [58] and Abrahams and colleagues [59] have both reported deficits in right TLE groups compared with patients with left TLE on spatial memory tasks, confirming findings previously documented in patients with surgical excision.

We have emphasized the usefulness of newer tasks and the importance of using tasks that have been shown to be sensitive to unoperated patients with epilepsy. We maintain that the development and validation of original testing procedures and replacement of old measures with new and more sensitive ones is a desirable activity in the field. Although the existence of a variety of testing procedures prevents direct comparisons of results across centres, we believe that the possible gains outweigh the disadvantages. A search for better tools is more important than uniformity, and the development of efficient instruments will best enable the advancement of the field.

Intracarotid anaesthetic procedures

For some 50 years the intracarotid amobarbital procedure has been an important part of the preoperative evaluation of patients who are candidates for surgical treatment of epilepsy. Its usefulness has come increasingly into question, especially as neuroimaging techniques have improved. Problems with access to amobarbital also led to the use of other anaesthetizing agents and therefore to a change in nomenclature to the more generic intracarotid anaesthetic procedure (IAP).

Description of procedure

Details of the IAP differ among centres, but the basic core is similar across institutions. It consists of the injection of a barbiturate, still usually sodium amobarbital, into one hemisphere, most often through the internal carotid artery; a few centres perform selective and superselective procedures into other vessels for selective inactivation of hippocampal structures [60,61] but these are less common. This anaesthetizes the injected hemisphere and allows one to test the abilities of the awake hemisphere in isolation. The effect is short, and is usually dissipated after about 5–8 min. During the effect, simple speech and memory tests are performed. The injection is made by a radiologist and is preceded by a 3-mL angiogram to verify that there is no serious vascular anomaly and to predict the distribution of the drug. In most institutions an electroencephalogram (EEG) is obtained during the test, and is either read online or recorded on computer for interpretation later by an electroencephalographer.

Before injection, basic speech and memory tests are performed to establish a baseline. Upon injection, more speech and memory tests are carried out while one hemisphere is inactivated. Memory testing consists of showing new material while only one hemisphere is functional, and then testing memory for that material later when the drug is no longer active and both hemispheres are back to baseline functioning. Speech tests are kept simple and usually include naming, serial or automatic speech (such as counting and reciting days of the week), comprehension, reading and repetition [62].

In some institutions all patients undergo an IAP, whereas in others it is performed only if atypical cerebral dominance for language is suspected or if there is evidence of bitemporal dysfunction and consequently a potential risk of significant memory loss after temporal lobe surgery.

Atypical language dominance is suspected in patients who are left-handed, who have a strong family history of left-handedness, who do not show the usual right ear dominance on dichotic listening tests, and/or whose pattern on cognitive tests indicates dysfunction in the hemisphere opposite to a lesion or focus identified by clinical signs, neuroimaging or electroencephalography.

Bitemporal dysfunction may be suspected in several ways. Impairments on both verbal and non-verbal memory tests in the basic, non-invasive clinical memory evaluation suggest bitemporal abnormality. Evidence from electroencephalography or neuroimaging pointing to bitemporal abnormality is also grounds for carrying out an IAP, as are discordant findings about the focus from electroencephalography, MRI and/or neuropsychological assessment.

Interpretation of intracarotid anaesthetic procedure results: language dominance

Interpretation of the speech tests is most often unambiguous: if the dominant hemisphere is injected the patient is aphasic while the drug is active, whereas if the non-dominant hemisphere is injected the patient continues talking without significant errors. Several different patterns may be observed in bilateral speech representation. These include disruption of all speech functions after injection in one hemisphere, with minor but significant disruption after injection in the other; dissociation of type of disruption (for example naming in one hemisphere and comprehension in the other), equal and significant disruption in both hemispheres, and no obvious disruption in either hemisphere [63].

Interpretation of bilateral speech differs among institutions and individuals; consequently, reports of the incidence of this type of atypical language organization vary [64]. This is of considerable theoretical interest but it does not impact significantly on patient management, because the most critical practical question, 'Is there significant language function in the hemisphere destined for surgery?', can almost always be answered.

Interpretation of intracarotid anaesthetic procedure results: memory

A basic assumption underlying the memory application of the IAP is that the patient will have to rely on the awake hemisphere to remember material shown while the drug is active. The patient will not remember the material if the awake, or non-injected, hemisphere is damaged in areas important for memory. The crucial test is after injection of the hemisphere destined for surgery, because it tests the memory function of the hemisphere that will be left intact; thus, results of that injection are expected to predict how well memory will function after resection from the injected temporal lobe. Injection opposite the hemisphere destined for surgery is also important, as the result should confirm or disconfirm an expected dysfunction in that hemisphere. *Good* memory after injection opposite a temporal lobe targeted for surgery is another meaningful result. It shows that the temporal lobe, and presumably the hippocampus planned for resection, functions well, and warns that the deficit after such surgery may be larger than what is typically seen.

It is assumed that passing the IAP memory test requires adequate hippocampal function. Therefore, performance on the test can affect surgical planning. In some centres, patients who show significant forgetting in the critical test receive a limited resection that spares the hippocampus or encroaches only modestly upon it. More rarely, surgery is denied altogether to such patients. There is no current standard for defining failure; some centres have a cutting score and others compare the performance from the two injections, making a relative rather than an absolute judgement [65]. It is important also to take language dominance into account when interpreting IAP memory results, because in most patients there is a bigger drug effect in the dominant than in the non-dominant hemisphere [66]. This results in smaller differences between ipsilateral-to-focus and contralateral-to-focus injections when the focus is in the dominant hemisphere than when it is in the non-dominant hemisphere. As resection from a well-functioning hippocampus can result in a more marked postoperative memory loss than resection from a dysfunctional one [67,68], IAP memory performance, both ipsilateral and contralateral to proposed surgery, should be taken into account in decisions regarding hippocampal excision.

Intracarotid anaesthetic procedure issues

Several controversies and issues have arisen in the past concerning the IAP. They include questions about the extent to which critical memory regions are affected by injection into the internal carotid artery, given that it does not irrigate the posterior hippocampus, and questions about the true risk of amnesia in patients who fail an IAP memory test, given that many of them undergo partial hippocampal resection and do not become amnesic. Other issues involve the timing of presentation of memory stimuli after injection, the number and type of stimuli used, determination of drug dosage and the effect of different dosages, and dealing with fluctuations in attention. These topics are discussed in a special issue of *Brain and Cognition* [volume 33 (1&2), 1997] devoted to the IAP, and in a recent textbook chapter [69].

Around 10 years ago two serious problems occurred with amobarbital. One problem was that in a certain number of procedures injection of this drug produced no effect or a reduced one. According to Bookheimer and colleagues [70], this occurred in patients whose antiepileptic drugs had carbonic anhydrase-inhibiting properties – in particular topiramate and zonisamide. Those authors showed a reduced anaesthetization in one patient even 5 weeks after discontinuation of topiramate, and they therefore recommended discontinuing those drugs for at least 8 weeks before performing an IAP.

The second problem was that there have been recurring shortages of amobarbital over the years, with a particularly long-lasting one that in 2001 resulted in many centres looking for alternatives to this drug. Methohexital had already been used by a few centres for some years [71], and propofol was tried in a small number of patients [72]. Methohexital has the disadvantage that it is very short-acting and usually must be reinjected within a procedure, whereas propofol is contained in an oil-in-water emulsion and is thus also not an ideal choice. At the Montréal Neurological Institute we rejected those possible alternatives and opted to use etomidate, which is an imidazole derivative and a potent non-barbiturate hypnotic agent [73]. With the new drug we also introduced a change in the procedure, which we call the etomidate speech and memory test (*e*SAM); after injecting an initial bolus, we maintain the full hemianaesthesia by infusion of the drug, which is terminated only after all speech tasks have been sampled and all critical memory items

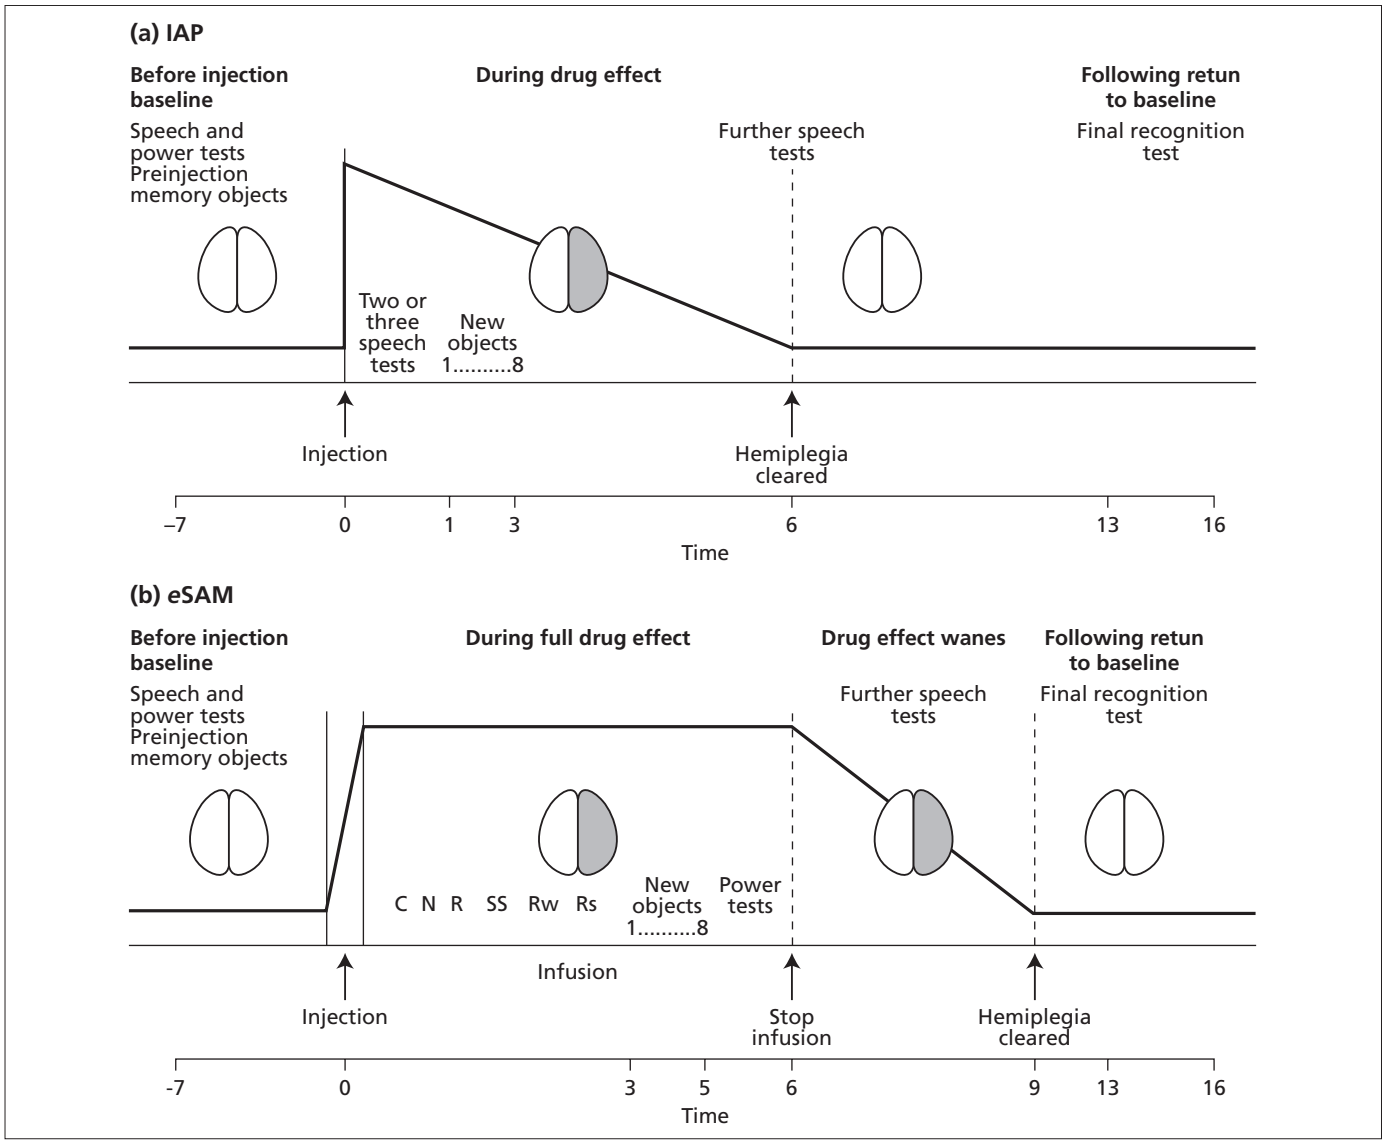


Fig. 67.5 Comparison between the traditional intracarotid anaesthetic procedure (IAP) and etomidate speech and memory (eSAM) procedure. During the IAP, the effect of the drug begins to wane immediately after the initial bolus, so task presentation must be rushed. In contrast, during eSAM maintenance of the drug infusion after the initial bolus over the period of time needed to complete one round of language tests and present all eight memory objects allows well-timed and controlled presentation of the critical cognitive tasks while the drug is fully active. C N R SS Rw Rs denotes the language tests: comprehension, naming, reading, serial speech (counting, reciting days of the week), repetition of words and repetition of sentences.

have been presented (Fig. 67.5). As a result of the changed procedure, we have had no instances of inability to interpret memory results [74], which is frequently a problem in the traditional IAP owing to return of function before all memory items have been shown.

Non-invasive procedures

Non-invasive alternatives to the IAP have been and are still being developed. The most progress has been made in determination of language dominance using positron emission tomography [75] to some extent, and functional magnetic resonance imaging (fMRI) [76,77] to a greater extent. fMRI is used by a growing number of centres to supplement or to replace the IAP in determining cerebral dominance for language [78], but development of a viable alternative to the IAP memory test has been more challenging. However, recently a few paradigms have been reported to produce reliable results [79,80]. These paradigms must be thoroughly validated before one can consider replacing the IAP with them, and once the methodology is considered reliable some patients will still require an IAP instead. Those would be patients

who are not capable of performing the cognitive tasks required in activation neuroimaging, who are unable to go into a scanner because of claustrophobia or metal parts in their bodies, or who are unable to spend the necessary amount of time in the scanner because of frequent seizures. In addition, an important argument against a total replacement of the IAP is that only the IAP mimics, and therefore predicts, the effects of surgery because it transiently disables most of one hemisphere.

Conclusion

Neuropsychological evaluation in epilepsy assesses cerebral function widely to determine dysfunctional regions and also to predict the effect of surgery on postsurgical function. We have described some tests used for this purpose, emphasizing those that we believe are best suited and explaining why. We noted that older tests too often cannot reliably detect a seizure focus in unoperated patients and suggest that such measures were inappropriate because of their lack of sensitivity. However, an increasing number of newer tasks succeed in demonstrating neuropsychological deficits in focal epilepsy. Therefore we recommend that clinicians and researchers attempt to seek and/or develop appropriate instruments specifically for this field, and we have pointed out areas of greatest need for growth. Overall, our appraisal of the current state of neuropsychological assessment in the evaluation of patients with epilepsy is very positive. Results from these evaluations continue to contribute to decisions about patient management in general and with respect to feasibility of surgery, extent of surgery and cognitive outcome after surgery.

Acknowledgements

This work was supported in part by an operating grant, MOP 53274, awarded to M. Jones-Gotman by the Canadian Institutes of Health Research. We thank Andre Olivier for the opportunity to study his patients and Fernando Cendes for volumetric measurements of MR scans.

68 Presurgical Psychiatric Evaluation

Andres M. Kanner
Rush University Medical Center, Chicago, IL, USA

Introduction

In the last three decades, epilepsy surgery has revolutionized the treatment of pharmacoresistant epilepsy, with anterotemporal lobectomy (ATL) constituting the most frequently performed surgical procedure. Postsurgical psychiatric complications have been reported with increasing frequency in the last decade. Yet, in most epilepsy centres, presurgical evaluations rarely include a psychiatric evaluation to identify patients with past and present psychiatric comorbidities, and therefore patients at risk of postsurgical psychiatric complications. Indeed, in a survey sent to the 88 major epilepsy centres in North America, only 21% of the 47 centres (53%) that completed the survey routinely performed a psychiatric evaluation in *every* presurgical candidate. Three centres (6%) perform a psychiatric evaluation only in case of a previous serious psychiatric history, 16% perform a psychiatric evaluation if recommended by the neuropsychologist and 45% follow either of the last two criteria. The purpose of this chapter is to examine whether or not presurgical candidates should undergo a psychiatric evaluation and specifically to assess the impact of presurgical psychiatric disorders on postsurgical psychiatric complications, employment and seizure outcome. The last section of the chapter provides protocols for presurgical psychiatric evaluations.

Are surgical candidates at risk of postsurgical psychiatric complications?

Presurgical psychiatric comorbidity

Compared with seizure-free patients and normal control subjects, patients with medically intractable epilepsy are at risk for mood, anxiety and psychotic disorders, and attention deficit hyperactivity disorder (ADHD). In fact, various case series have found lifetime prevalence rates of depressive disorders ranging between 30% and 50%, those of anxiety disorders between 10% and 30% and those of ADHD between 20% and 30% [1–4]. In a review of the literature Koch-Stoecker found prevalence rates ranging from 43% to 80% among seven case series [5]. In the case series from the Bethel Epilepsy Center, 43% of patients met criteria for a discrete psychiatric disorder (i.e. mood, anxiety or psychotic disorder) according to the *Diagnostic and Statistical Manual of Mental Disorder* (3rd edn, revised; DSM-III-R) criteria, while an additional 29% met criteria for a psychiatric syndrome and personality disorders.

Postsurgical psychiatric complications

Postsurgical psychiatric complications can be the expression of a *de novo* psychiatric disorder, a *recurrence* of psychiatric disorder that had been in remission for a period of time prior to surgery, or an *exacerbation* in severity of a psychiatric disorder of mild severity that had gone unrecognized by patient, family and clinician or that was identified because of a more careful evaluation of the patient.

Postsurgical psychiatric complications of epilepsy surgery were reported initially in 1957 by Hill *et al.* [6], who described depressive episodes occurring independently of seizure outcome and which remitted within 18 months. The most frequent postsurgical psychiatric complications include depressive and anxiety disorders and, less frequently, psychotic disorder. Psychogenic nonepileptic events (PNEEs) and other types of somatoform disorders have also been identified with relatively low frequencies.

Postsurgical depressive and anxiety disorders

The prevalence rates of postsurgical depressive disorders have ranged from 5% up to 63% among various studies. More often than not, these postsurgical complications are an expression of a *recurrence* or *exacerbation* of a presurgical mood disorder, whereas *de novo* depressive disorders are less frequent and are also likely to occur in the first 6 months after surgery. For example, Wrench *et al.* [7] published a study of 62 patients who underwent epilepsy surgery: 43 had an ATL and 19 an extratemporal lobectomy (ETL). Both groups had similar presurgical histories of depression and anxiety (33% and 23%, respectively, for ATL and 53% and 18%, respectively, for ETL). At 1 month after surgery, symptoms of anxiety and/or depression were reported by 66% of ATL patients and 19% of ETL patients; at 3 months, 54% of ATL and 33% of ETL patients were still symptomatic with 30% of ATL and 17% of ETL patients still experiencing a depressive episode. By that time, 13% of ATL patients had developed a *de novo* depressive episode and 15% a *de novo* anxiety disorder, whereas 18% had developed other types of *de novo* psychiatric disorders. In contrast, only 17% of ETL patients had developed *de novo* anxiety, but not depression or other psychopathology. Of note, there was no significant association between postsurgical psychopathology and seizure outcome at the 3 months' follow-up.

In a study of 49 patients who underwent an ATL and were followed for a period of almost 11 years, Altshuler *et al.* [8] found

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

that five patients (10%) developed *de novo* depressive episodes, four within the first postsurgical year. Similar findings were reported by Ring *et al*. [9] in a study of 60 consecutive patients who underwent an ATL and had a psychiatric evaluation prior to surgery and at 6 weeks and 3 months after surgery. At 6 weeks, 45% of all patients experienced emotional lability and anxiety, 22% of whom had not experienced such symptomatology before surgery. By 3 months, symptoms of emotional lability and anxiety had remitted or improved significantly but not so the depressive states.

Blumer *et al*. [10] reported a much higher prevalence rate of *de novo* psychiatric complications in a study of 50 consecutive patients, 44 of whom underwent an ATL and six a frontal lobe resection; 14 patients (32%) developed *de novo* psychiatric disorders presenting as an interictal dysphoric disorder in six patients, depressive episodes in two and a psychotic disorder in six, while only three patients (7%) experienced an *exacerbation* of a presurgical interictal dysphoric disorder. In all but two patients the psychiatric complications occurred within 2 months after surgery. All psychiatric complications remitted with psychotropic treatment. Of note, these investigators associated the development of postsurgical psychiatric complications with persistent seizures. Glosser *et al*. [11] published a study of 44 patients who underwent an ATL; in the first month after surgery 12 patients (31%) developed *de novo* depression and/or anxiety disorders or recurrence of a disorder that had been in remission during the 6 months preceding the surgical procedure. By 6 months they were still symptomatic but significantly improved, and by 1 year all but two patients had become free of symptoms.

A study completed at the Rush Epilepsy Center included 100 consecutive patients, 60 men and 40 women, who had undergone an ATL and were followed for a minimal period of 2 years (median follow-up duration 8.3 ± 3.0 years; range 2–13 years) [12]. Fifty-six patients had a presurgical lifetime psychiatric history, 46 of whom had a mood disorder that consisted of depression alone in 21 patients, and mixed depression and anxiety disorders in 25 patients, while three had in addition ADHD. Forty-four patients met our criteria for postsurgical psychiatric complications: nine patients (11%) experienced a *de novo* depressive/anxiety disorder and four patients (4%) experienced a *de novo* psychotic episode. Thirty-one patients experienced an *exacerbation* in severity of presurgical depressive/anxiety disorders; these complications occurred during the first postsurgical 12 months. In addition, 7 out of these 31 patients developed *de novo* psychogenic non-epileptic events (PNEE). At the last contact, the postsurgical psychiatric complication of 16 patients (16%) had failed to remit, despite multiple pharmacological trials; four of these patients had developed a *de novo* postsurgical depressive disorder. Univariate analyses identified persistent seizures, presurgical psychiatric history and a left temporal seizure focus as predictors of postsurgical psychiatric complications. Multivariate regression models, however, identified a presurgical history of depression and a left-sided seizure focus as predictors of postsurgical psychiatric complications. Interestingly enough, having failed to obtain gainful employment after surgery was not found to be a predictor of postsurgical psychiatric complications.

Other authors have not found a left temporal seizure focus associated with postsurgical psychiatric complications, however. For example, in a study of 107 patients, 90 of whom underwent an ATL and 17 an ETL, and who had a postsurgical follow-up period of 1 year, Quigg *et al*. [13] found that preoperative depressive traits predicted worse postoperative scores on scales measuring symptoms of depression. Although the side of surgery did not predict worse postsurgical symptoms of depression, there was a trend for foci to be right sided. Findings for the ATL subgroup were similar to those of the overall sample. These authors concluded that patients undergoing epilepsy surgery in the right hemisphere, especially those with high presurgical depression-related morbidity, may be particularly susceptible to clinical depression.

Presurgical ictal fear or panic has also been associated with postsurgical psychiatric complications. For example, Kohler *et al*. [14] studied the association of ictal fear with mood and anxiety disorders before and 1 year after ATL in three groups of 20 patients: one with ictal fear, one with other types of auras and a third group with no auras. Evaluations of psychiatric disorders were carried out before surgery, at 1–2 months and 1 year after ATL. The majority of patients in the three groups experienced mood and anxiety disorders before surgery with similar frequencies. Mood and anxiety disorders declined in the two control groups, but not in the ictal fear group after surgery. Postoperative mood and anxiety disorders were more common in patients with persistent seizures and in those in the ictal fear group who were seizure free. Furthermore, a majority of patients with ictal fear required the use of psychotropic medication after surgery.

Presurgical postictal psychosis. Kanemoto *et al*. [15] identified an association between presurgical postictal psychotic episodes (PIPE) and postsurgical mood disorders in a study of 52 patients who underwent an ATL. Postsurgical mood disorders presented as manic and depressive episodes during the first two postsurgical years. In summary, postsurgical depressive and anxiety disorders are relatively common and a presurgical history of depression appears to be a predictor of this complication.

Postsurgical psychosis

The prevalence rates of postsurgical psychotic complications have been estimated to range between 1% and 10% among patients undergoing an ATL. Yet, data regarding postsurgical psychotic episodes are derived from smaller case series and studies that are fraught with serious methodological problems. For example, several case series have included a mixture of patients with presurgical and *de novo* postsurgical psychotic disorders.

De novo postsurgical psychotic episodes may present as schizophreniform-like disorders, manic episodes and postictal psychotic episodes. For example, Shaw *et al*. [16] identified 11 patients who developed *de novo* postsurgical schizophreniform psychosis among 320 consecutive patients (3.2%) who underwent an ATL. Psychotic symptomatology became apparent within the first year in all patients. These 11 patients were compared with a control group of 33 patients. Psychotic patients were more likely to have bilateral epileptiform activity, a smaller amygdala in the non-operated side and pathologies other than MTS. The study carried out at Rush Epilepsy Center cited above yielded

similar prevalence rates, as *de novo* psychotic episodes were identified in four patients within the first 6 months after an ATL, consisting of a manic episode in two and a paranoid episode in the other two patients [12]. Two of these patients had lesional epilepsy, caused by dysembryoplastic neuroepithelioma (DNET) in one and a ganglioglioma in the other. Symptoms remitted in two patients with pharmacotherapy without the need for hospitalization while the other two had to be hospitalized in a psychiatric unit. In one patient, symptoms remitted after the first admission, whereas the second patient had to be hospitalized twice.

In a study of 57 consecutive patients who underwent an ATL, Leinonen *et al*. [17] identified five (8.8%) who developed postoperative psychotic episodes. Two (3.5%) patients had experienced PIPE before surgery, which continued postsurgically. Among the other three patients, two (3.5%) experienced a definite *de novo* schizophreniform psychotic episode, and one patient (1.8%) met the criteria for a probable *de novo* psychotic episode. Among 74 patients who underwent an ATL, Jensen and Larsen [18] identified nine (12.1%) who developed a *de novo* psychotic disorder. Six out of these nine patients began experiencing psychotic symptoms after they became seizure free.

The risk of postsurgical psychotic episodes has been associated with right temporal seizure foci. For example, Mace and Trimble [19] reported seven consecutive patients who developed *de novo* psychotic episodes following an ATL, in six of whom it developed in the right temporal lobe: one developed a delusional depression, four developed a schizophrenic-like psychosis, and one patient was diagnosed with Capgras syndrome. Unfortunately, this relation has been suggested on the basis of these small case series and needs to be confirmed in larger multicentre studies.

The presence of gangliogliomas or DNET has also been associated with the development of *de novo* postsurgical psychotic disorders. Andermann *et al*. [20] reported six patients from four centres who experienced a *de novo* psychotic disorder [20]. The psychotic disorders consisted of schizophreniform-like episodes with paranoid and depressive symptomatology. These investigators estimated a risk of 2.5% for the development of *de novo* psychosis (1 in 39) in patients with this type of lesion who undergo an ATL.

Postsurgical manic episodes can also be psychiatric complications of ATL. For example, from a case series of 415 consecutive patients, Carran *et al*. [21] identified 16 patients (3.8%) who developed a *de novo* manic episode occurring within the first year after the ATL. These episodes were short-lived in all but one patient. Compared with a control group of asymptomatic patients matched for age and gender and a second group of 30 patients who experienced a postsurgical depression, patients with postsurgical mania were more likely to display bilateral electrographic abnormalities and to have a right temporal seizure focus, although this difference did not reach significance when compared with the depressed group. Postsurgical symptomatic patients were more likely to have experienced GTC seizures before surgery and to fail to achieve seizure freedom postsurgically.

Whether or not the development of *de novo* postsurgical psychotic episodes reflects a phenomenon of forced normalization has been the source of significant debate. For example, Stevens [22] identified a *de novo* psychotic disorder in two patients within the first 12 months after surgery from a group of 14 patients who had undergone an ATL and had been followed for a period of 20–30 years. Both patients were seizure free.

De novo postsurgical postictal psychotic episodes

Christodoulou *et al*. [23] reported three cases (1%) among 282 consecutive patients who had undergone an ATL. All three patients had seizures predominantly from the non-surgical side or had bilateral independent seizures; none of the patients who failed surgery but continued to have seizures only from the side of the surgery developed *de novo* PIPE. This supports the conclusion by other authors that patients with PIPE (chronic or *de novo*) have bilateral independent temporal lobe dysfunction [24]. Manchanda *et al*. [25] identified four patients (1.3%) who developed a *de novo* PIPE among a group of 298 consecutive patients who had undergone an ATL. All four patients had a right-sided resection and had no preoperative psychiatric history.

It has been established in several studies that patients with PIPE are at significantly greater risk of having bilateral independent ictal foci [24,26–28]. In a study completed at the Rush Epilepsy Center, the occurrence of PIPE predicted the presence of bilateral independent ictal foci with an 89% probability [24]. By the same token, patients with recurrent PIPE are at significant risk of developing interictal psychosis [29]. To minimize this risk, clinicians must carefully weigh the possibility of offering 'palliative' surgery to patients with PIPE and bilateral ictal foci, particularly those with mesial temporal sclerosis (MTS), provided that most seizures originate from the side of the MTS and the neuropsychological data are concordant with the intended surgical target.

Postsurgical psychogenic non-epileptic events

Ferguson and Rayport were the first authors to describe the occurrence of postsurgical *de novo* PNEE [30]. The prevalencerates of postsurgical PNEEs are relatively low, ranging between 1.8% and 10% among the different case series. For example, in the study carried out at the Rush Epilepsy Center cited above, 7% of the patients developed *de novo* PNEEs [12,31]. The development of a *de novo* postsurgical PNEE has been attributed to the 'stress' associated with a 'seizure-free' life in patients with chronic epilepsy who are not 'emotionally, physically or economically ready' to face their own or their families' increased expectations. Although this 'hypothesis' makes intuitive sense, the available data do not seem to support it. In the Rush Epilepsy Center study, a presurgical lifetime psychiatric history was significantly associated with the development of postictal PNEEs. Interestingly enough, PNEEs were not reported in seizure-free patients; in fact, persistent seizures were significantly associated with the development of *de novo* PNEEs. Furthermore, failure to obtain gainful employment was not associated with the development of PNEEs.

Ney *et al*. [32] identified *de novo* postsurgical PNEEs in 5 out of 96 patients who underwent epilepsy surgery over a period of 11 years [32]. A low full-scale IQ, preoperative psychiatric comorbidity and major surgical complications were identified as risk factors. Glosser *et al*. [33] identified 22 patients with postsurgical *de novo* PNEE corresponding to a prevalence rate just below 10%. Most of these patients were women with primary right hemisphere seizure foci and onset of their epileptic seizures after adolescence. In this study, preoperative psychiatric diagnoses

were not related to increased risk of PNEE. Reuber *et al.* [34] identified 13 patients with both epileptic seizures and PNEE and investigated their postsurgical outcome: 11 out of the 13 patients had significant clinical improvement postsurgically. However, in 2 out of 13 patients the severity of the PNEE (including pseudostatus epilepticus) increased postoperatively despite a significant improvement of their epileptic seizures. Both patients had a presurgical psychiatric history.

Postsurgical somatoform disorder

This type of psychiatric complication is either rare or underrecognized. To date there has been one case series of 10 patients who developed a somatoform disorder (other than PNEE) after ATL [35]. Seven of the 10 patients developed an undifferentiated somatoform disorder, one had pain and body dysmorphia, another had pain disorder and another had body dysmorphia alone. Somatoform disorder was significantly more common among patients who underwent a right ATL ($n = 9$).

Does epilepsy surgery have any impact on presurgical psychiatric disorders?

Anxiety and depressive disorders after anterotemporal lobectomy and extratemporal resections

Epilepsy surgery appears to facilitate the remission of psychiatric comorbidities at follow-up evaluations. In the study carried out at the Rush Epilepsy Center, a lifetime psychiatric history prior to surgery had been identified in 56 patients, of whom 51 were symptomatic at the time of the psychiatric evaluation [12]. At the last contact, 14 continued to be symptomatic despite multiple treatment strategies and an additional 14 patients were symptom free on psychotropic medication. Thus, epilepsy surgery resulted in total remission off psychotropic medication in 45% of the patients. Among the 44 patients reported by Glosser *et al.*, six (15%) were symptomatic before surgery and became asymptomatic postsurgically [11]. Twenty-one patients were unchanged in their psychiatric status: eight who were symptomatic and 13 who were asymptomatic before surgery. Although the overall prevalence of psychiatric disorders had not changed 6 months after surgery, the symptom severity measured with the Brief Psychiatric Rating Scale had improved significantly. In the study reported by Altshuler *et al.* [8], 17 out of 49 patients (35%) had a lifetime history of at least one major depressive episode. Eight of these patients never experienced another major depressive episode postsurgically. In this study, as in our study, the only predictor for postsurgical depressive disorder was a presurgical history of depression. Devinsky *et al.* [36] reported the results of a study of 360 patients from seven epilepsy centres in the USA who underwent epilepsy surgery; 89% had an ATL. Psychiatric syndromes were identified at baseline and 2 years after surgery with a structured interview, the Composite International Diagnostic Interview (CIDI). Presurgically, 75 patients (22%) met criteria for a diagnosis of depression, 59 (18%) of anxiety disorders and 12 (4%) of other psychiatric disorders, including bipolar illness and schizophrenia. At the 2-year postsurgical evaluation, only 26 patients (9%) met diagnostic criteria for depression and 20 (10%) for anxiety, and three patients (1%) met criteria for other psychiatric diagnoses. Thus, epilepsy surgery had resulted in symptom remission in more than 50% of patients. In this study, the presence of an anxiety or depressive disorder postsurgically was not associated with seizure outcome.

Psychotic disorders

The decision to consider epilepsy surgery in patients with refractory epilepsy and comorbid psychotic disorders continues to be the source of much controversy among epilepsy centres, as some exclude automatically these patients from consideration of epilepsy surgery, whereas others do not as long as the patient can cooperate during the presurgical evaluation and has a clear understanding of the therapeutic expectations and risks of the surgical procedure.

The impact of ATL on the postsurgical course of the psychotic disorder has varied from unchanged (in a majority of cases) to improved psychotic status and/or level of functioning. For example, in a study of 74 patients who underwent an ATL, Jensen and Larsen [18] identified 11 with a psychotic disorder *presurgically*. The surgical procedure had no impact on the psychotic disorders postsurgically. In a study of 52 patients, Kanemoto *et al.* [37] reported recurrence of psychosis in more than two-thirds of the patients with a preoperative history of interictal psychosis. Some of the patients (7 out of 12) remained with persistent psychotic symptoms for a long time [37]. In a series of five patients with a chronic psychotic disorder who underwent an ATL, Reutens *et al.* [38] reported an excellent seizure outcome in all patients. The surgical procedure did not modify the psychotic disorder postsurgically, but the absence of seizures facilitated their level of functioning. Marchetti *et al.* [39] reported six patients with presurgical interictal psychosis who underwent an ATL. Five out of the six patients achieved a seizure-free outcome and there was relative improvement in the psychotic disorder of five patients. These same authors reported an additional case of a 45-year-old female patient with a 30-year history of epilepsy and recurrent postictal psychotic episodes since the age of 35, which evolved to a chronic refractory interictal psychosis [40]. After having a right ATL she became seizure free, with remission of the psychotic disorder. All of these case series exemplify that patients with interictal psychosis can successfully complete a presurgical evaluation.

Impact of presurgical psychiatric history on postsurgical psychosocial outcome

Gainful employment

One of the obvious goals of epilepsy surgery is to facilitate gainful employment for unemployed patients or improve the type of job for those who have been able to maintain a job despite their pharmacoresistant epilepsy. Unfortunately, this is not always the case. A review of the literature identified the following variables as predictors of postsurgical employment: (1) reduction of seizures or seizure freedom; (2) presurgical cognitive ability; (3) absence of psychiatric comorbidity; (4) presurgical employment; and (5) improvement of neuropsychological function postsurgically [41]. In a study of 88 adult patients who underwent an

ATL at the Rush Epilepsy Center, the predictors of postsurgical gainful employment included working before surgery, achieving a seizure-free state, a negative lifetime history of depression and female gender [42]. Lendth *et al*. [43] found that a young age at the time of the surgery and improvement of the general neuropsychological functioning and especially attention are associated with employment after the surgery. In another study, Reeves *et al*. [44] found that being a student or working full time within a year before the surgery, driving after the surgery and obtaining further education after the surgery were associated with full-time work postoperatively. Clearly, a psychiatric evaluation is pivotal to identify patients who may have problems seeking and/or obtaining gainful employment.

Family dynamics

With the achievement of seizure freedom, patients have the expectations of becoming more independent, not only as it pertains to their ability to drive but in other areas of their life. Paradoxically, in some cases seizure freedom can have a negative impact on family dynamics. Indeed, some family members become accustomed to the patients' limitations and dependency on others and have difficulties allowing the patient to become more independent and see their role in life (unconsciously) as that of a 'care taker' without which they cannot 'function'. Unfortunately, these dysfunctional family dynamics are not rare in families of patients with a chronic illness like epilepsy, and invariably are bound to lead to conflict when patients try to become more independent. In fact, divorce is not an uncommon 'complication' of successful epilepsy surgery. By the same token, some patients who for a long period of time became too dependent on relatives feel unable to become more independent. Having a clear understanding by the epilepsy team of these family dynamics must be part of any presurgical evaluation and all couples and families need to be evaluated for the eventual risk of this type of family problem.

Impact of presurgical psychiatric illness on postsurgical seizure outcome

Clinicians do not typically associate psychiatric history with a postsurgical seizure outcome. Yet, in December 2000, Anhoury *et al*. [45] published a study of 121 patients who underwent an ATL; those with a lifetime psychiatric history exhibited a worse postsurgical seizure outcome than those without. Likewise, S. Koch-Stocher (Epilepsy Center, Bielefeld, Germany, unpublished data) investigated the postsurgical seizure outcome among 100 consecutive patients who underwent an ATL; 78 had a presurgical lifetime psychiatric history. Among patients without co-morbid psychiatric history, 89% were seizure free after surgery; however, this occurred in only 43% of patients with presurgical psychiatric history. Kanner *et al*. [12] used a logistic regression model to identify predictors of postsurgical seizure outcome in 100 consecutive patients who underwent an ATL and found that a lifetime history of depression and smaller resection of mesial temporal structures were the *sole* predictors of persistent auras in the absence of disabling seizures; a lifetime of psychiatric disorder was a predictor of failure to achieve freedom from disabling seizures. These data raise another question: *Is it possible that a psychiatric history, particularly depression, is an 'indicator' of a more severe form of epilepsy?*

Presurgical psychiatric protocols

Are epilepsy centres concerned about postsurgical psychiatric complications?

In the survey of 47 major epilepsy centres in North America cited in the introduction of this chapter, one question asked whether or not the epileptologists of the centre believe that psychiatric complications following ATL are frequent enough to warrant a presurgical psychiatric evaluation. The data indicated the absence of a consensus on this issue, as 21 centres (45%) considered it to be a problem and 26 (55%) did not.

Are psychiatric evaluations being routinely carried out in epilepsy centres?

Data from the survey revealed that only 10 centres (21%) routinely perform a psychiatric evaluation in *every* patient who is being considered for ATL. The lack of available psychiatric consultants is typically blamed for the failure to carry out psychiatric evaluations in all presurgical patients. Therefore, the survey enquired on the *availability* and *use* of psychiatrists in each centre. Among the 47 centres, only 12 (26%) had a psychiatrist in their epilepsy team. Consultations were provided by the hospital's psychiatry liaison and consultation service (LCS) in the other 35 centres: in 10 (21%) the *same* psychiatrist was always available to do the consultation, whereas in 24 (51%) consultations were carried out by *different* psychiatrists. In one centre, consultations were done by the residents but the attending did not see the patients in person.

The availability of an 'epilepsy team psychiatrist' appears to make a significant difference to the concern of postsurgical psychiatric evaluations in these centres. Thus, 75% of centres with an epilepsy team psychiatrist voiced a concern of frequent postsurgical psychiatric complications, although this was true in one-third of centres in which consultations were carried out by LCS psychiatrists. Of note, there was no difference among centres in which the same (30%) or different (33%) psychiatrists performed the evaluation. These data suggest that psychiatrists with special expertise in psychiatric aspects of epilepsy are more 'attuned' to potential postsurgical psychiatric complications. These data also raise the question of the quality of psychiatric evaluations performed by psychiatrists that lack special expertise in the psychiatric problems of epilepsy patients. In fact, 35 centres (75%) voiced concerns on the failure to obtain in-depth psychiatric evaluations.

It is rather common for centres that lack an epilepsy team psychiatrist to rely on neuropsychological evaluations to identify co-morbid psychopathology. For example, among the 24 centres that get psychiatric support from a different LCS psychiatrist, 23 (96%) based their decisions to order a psychiatric evaluation on the basis of the recommendations of a neuropsychologist or if the patient was known to have a psychiatric history, and this was also the case in 8 of the 10 centres (80%) which had the same LCS psychiatrist available. In contrast, only 4 out of the 12 centres (33%) with an epilepsy team psychiatrist relied on these criteria.

An important question is whether or not neuropsychological evaluations are adequate to identify patients at risk for postsurgical psychiatric complications. After all, most neuropsychological evaluations rely on screening instruments aimed at identifying *current* psychiatric symptoms occurring during the prior 1–4 weeks, depending on the instrument used; thus, these instruments are likely to fail to detect any past psychiatric history that may be in remission at the time of the presurgical evaluation and to capture the complexity of the co-morbid psychiatric disorders that are so common in these patients, as discussed in the previous sections. Indeed, only with a comprehensive psychiatric evaluation that investigates present and *lifetime* histories can clinicians have the necessary information to formulate a correct psychiatric diagnosis, recommend the appropriate treatment and make estimations on the risk for potential postsurgical psychiatric complications. Furthermore, family psychiatric history is one of the leading risk factors of mood, anxiety and ADHD. Unfortunately, these data are rarely investigated in a neuropsychological evaluation. In short, screening instruments do not identify the complexity of such psychiatric comorbidities.

Can epileptologists and neuropsychologists rely on a *patient's self-report* of past or concurrent psychiatric history?

The answer to this question is also 'no'! Indeed, it is a well-established fact that most frequent psychiatric co-morbidities in epilepsy patients (depression, anxiety and ADHD) are very often unrecognized by the treating epileptologist and that only severe forms of these disorders are reported by the patients to the physicians [46]. In addition, some patients may not volunteer information on a co-morbid psychiatric disorder out of misinterpretation of such disorders being 'a normal reaction' to a life with epilepsy, whereas others may hide such history out of fear that such history would disqualify them from consideration for epilepsy surgery. Failure to recognize chronic depressive disorders is illustrated in a study of 97 patients with partial epilepsy with a depressive disorder severe enough to warrant the consideration of pharmacotherapy; 60% had been symptomatic for more than 1 year before any treatment had been suggested [47]. Only one-third of the 97 patients had been treated within 6 months of the onset of their symptoms.

What is the reason behind the failure of most epilepsy programmes to incorporate a psychiatrist in their 'team'? After all, all programmes have one, or more than one, neuropsychologist. The answer is ironically rather simple: lack of financial resources on the part of hospital psychiatry departments to provide a full or part-time staff psychiatrist to a single service. Indeed, a careful analysis of the 12 epilepsy centres with an epilepsy team psychiatrist reveals that the epilepsy programmes pay for part of the salary of their psychiatrist. Thus, epilepsy centres that wish to have a psychiatrist in their team will have to budget a fraction of the psychiatrist's salary in their operating costs.

Suggested protocols

Clearly, the evidence presented in the previous sections suggests that patients who undergo epilepsy surgery are at risk for postsurgical psychiatric complications. Accordingly, presurgical psychiatric evaluations must seek to obtain the following:

- *lifetime* and *current* psychiatric history of mood, anxiety, attention deficit disorders and psychotic disorders, and to identify any evidence of a personality disorder;
- a detailed history of the temporal relation of psychiatric symptoms to seizure occurrence (i.e. to establish if all symptomatology was interictal or if it presented as preictal or postictal episodes solely or in addition to interictal disorders);
- a family psychiatric history, as a genetic predisposition is a pivotal factor in the development of mood, anxiety and attention deficit disorders, the most frequent psychiatric co-morbidities in these patients;
- an assessment of family dynamics and, specifically, the role played by each spouse with respect to the decision-making process in economic and family-related matters as well as an assessment of whether or not the patient's spouse is ready to adjust to a greater independence associated with a postsurgical seizure-free state;
- the patient's and family expectations of the epilepsy surgery, with respect to seizure outcome and changes in the patient's quality of life, employment and potential cognitive risks.

These data can be obtained in a psychiatric interview with the patient and close family members. The evaluation may take 1–3 h, depending on the complexity of the psychiatric history at hand and may require two or three sessions with the psychiatrist. A vocational assessment and the need for referral to a vocational rehabilitation programme should be part of the presurgical evaluation. This type of evaluation can be often obtained from the hospital rehabilitation therapists or from governmental agencies that work with disabled patients.

Presurgical evaluations in research

The data obtained in the survey presented above clearly indicate the need for systematic research on the incidence and types of postsurgical psychiatric complications, and the impact of presurgical risk factors on postsurgical psychiatric seizure and psychosocial outcomes. To that end, any methodologically sound study must include a structured psychiatric interview aimed at identifying lifetime DSM-IV-TR (*Diagnostic and Statistical Manual of Mental Disorders*, 4th edn, Text Revision) psychiatric syndromes and personality disorders. Various diagnostic interviews are available and can be administered by trained research assistants. It should be remembered, however, that these interviews were developed for patients with primary psychiatric disorders and not for patients with epilepsy with psychiatric co-morbidities. The limitations of using these instruments are not known at this time. Furthermore, structured interviews specifically developed for patients with epilepsy will need to be elaborated in the future.

The most frequently structured interviews include: (1) the Structured Clinical Interview for Axis I and II DSM-IV Disorders (DISC) [48]; (2) the Composite International Diagnostic Interview (CIDI) [49]; (3) the Schedule for Affective Disorders and Schizophrenia (SADS) [50]; (4) the Diagnostic Interview Schedule [51]; and (5) the Mini International Neuropsychiatric Inventory (MINI) [52].

It should be said that these psychiatric interviews need not be given in their entirety. Indeed, depending on the question to be addressed by the specific study, special sections of a questionnaire can be administered. For example, in the case of a study on mood

and anxiety disorders, investigators can decide to administer the section of these disorders of the SCID.

Structured interviews have been developed specifically for the identification of psychiatric syndromes in children and adolescents. The most rigorous is the SADS, adapted from the adult version [53]. We cannot emphasize enough the need to include an instrument that investigates the family psychiatric history. The Family History Screen for Epidemiologic Studies (FHE) is a user-friendly screening instrument that can be used in research [54].

Self-rating *screening* instruments are the favourite methods to acquire psychiatric data in research studies of epilepsy patients because of the logistical ease and low costs. Unfortunately, these instruments are designed to detect symptoms and not to establish a DSM-IV diagnosis, let alone the diagnosis of psychiatric entities with all their complexities and atypical manifestations encountered in patients with epilepsy. Thus, the sole use of these instruments represents the most frequent methodological error in psychiatric research studies in epilepsy. The argument for exclusively using screening instruments is that they have been validated to identify conditions such as MDE, some with acceptable levels of sensitivity and specificity, and the severity of the depressive episodes. Thus, proponents of the sole use of these scales might reason 'if a patient has a score of >30 on the Beck Depression Inventory-II, can it be anything other than an MDE?'. Although this statement is probably correct, an MDE may be the expression of more than one type of mood disorder, each with a different prognosis and treatment strategy (see section on depressive symptoms in this chapter).

As in the case of structured interviews, most of the screening instruments were developed for the screening of symptoms in patients with primary psychiatric disorders and not in patients with epilepsy. The only exception is the Neurological Disorders Depression Inventory for Epilepsy (NDDI-E) [55] (see below). In addition, two screening instruments for the identification of symptoms of depression, the Beck Depression Inventory-II (BDI-II) and the Center for Epidemiologic Studies-Depression Scale (CES-D), have been recently validated in patients with epilepsy [56].

Clearly, the use of screening instruments for psychiatric research in epilepsy must be used *in conjunction* with a structured psychiatric interview designed to establish a DSM-IV-TR diagnosis; only then do these screening instruments yield meaningful data, as they permit regular rescreening to measure changes in severity of symptomatology. The most frequently used screening instruments in adults include the screening of general psychiatric, depressive, anxiety and obsessive–compulsive symptoms.

Screening of general psychiatric symptoms

The Adult Self-Report Inventories-4 are symptom inventories that can be used as a guide for conducting clinical interviews [57]. They include the behavioural symptoms of more than two dozen psychiatric disorders described in the DSM-IV. There are parallel versions of the Adult Self-Report Inventories that are designed to obtain information from both patients and significant others. These inventories take approximately 15–20 min to complete. Items are grouped according to diagnostic categories.

The Hopkins Symptom Checklist-90-Revised (SCL-90 R®) is used to evaluate a broad range of psychopathology. It consists of 90 items and can usually be completed in less than 30 min [58]. The scoring system includes nine symptom scales (somatization, obsessive–compulsive behaviour, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation and psychoticism) and three global indexes. This scale has documented validity and has been in many treatment studies of mood disorders and schizophrenia.

The Minnesota Multiphasic Personality Inventory consists of a self-report personality inventory with 10 clinical scales (hypochondriasis, depression, hysteria, psychopathic deviance, male–female, paranoia, psychasthenia, schizophrenia, mania and social introversion) and three validity scales. The administration time is about 40–90 min [59].

Depressive symptoms

The Beck Depression Inventory-II (BDI-II) is the most commonly used self-rating scale for depression [60]. There are 21 items scored on a scale from 0 to 3 according to how the patient feels at the current time. The scale is sensitive to change and has been used in clinical drug trials. As stated above, the BDI-II has been recently tested in 205 patients with epilepsy from five epilepsy centres and was found to have a high sensitivity and specificity as a screening instrument of a major depressive episode [56].

The Center for Epidemiologic Studies-Depression Scale (CES-D) is a composite of 20 items, rated from 0 (rarely) to 4 (most or all of the time). It can yield scores from 0 to 60, with scores >16 being suggestive of depressive illness. This scale has also been recently validated for its use in patients with epilepsy [56].

The Neurological Disorders Depression Inventory for Epilepsy (NDDI-E) is a new self-rating instrument that consists of only six items but which was *specifically* developed to screen for the presence of major depressive episodes in patients with epilepsy, while minimizing the risk of overlap with adverse antiepileptic drug effects or pre-existing cognitive problems [55]. Completing this instrument takes only 3 min or less and a score of >14 is suggestive of the presence of a major depressive episode.

Anxiety symptoms

The Hospital Anxiety and Depression Scale [61] is specifically developed for use in patients with a medical co-morbidity, and consists of seven-item self-rated subscales for both depression and anxiety.

The Beck Anxiety Inventory (BAI) [62] is a 21-item self-report measure of anxiety severity. The scale consists of 21 items, each describing a common symptom of anxiety over the past week on a 4-point scale ranging from 0 (not at all) to 3 (severely – 'I could barely stand it'). The items are summed to obtain a total score that can range from 0 to 63.

Goldberg's Depression and Anxiety Scales [63] consist of nine questions assessing mood and anxiety over the previous month; the full set of nine questions needs to be administered only if there are positive answers to the first four. The scales are devised specifically to be used by non-psychiatrists in clinical investigations. Scores are from 0 to 9.

The Hamilton Anxiety Rating Scale (HAM-A or HARS) [64] is a 14-item clinical interview scale (not self-reported) measuring somatic and psychic anxiety symptoms. The responses include five

degrees of severity ranging from 0 (none) to 4 (frequent and severe symptomatology). This instrument should be used with caution in patients with epilepsy, given the large number of somatic symptoms included in this scale which in patients with epilepsy can result from adverse effects of AEDs, potentially yielding false-positive suggestions of more severe anxiety symptomatology.

Obsessive–compulsive symptoms

The Yale-Brown Obsessive Compulsive Scale (Y-BOCS) is the most widely used scale for rating obsessive–compulsive symptoms. It includes a symptom checklist as well as a 10-item scale that is rated by clinicians. It has been shown to be a highly reliable instrument that is sensitive for measuring changes in the severity of obsessive–compulsive symptoms [65].

Self-report measures for children and adolescents include the following.

- The Child Symptom Inventories (CSI-4) are screening instruments for the behavioural, affective, and cognitive symptoms of more than a dozen DSM-IV childhood disorders. There are Child Symptom Inventories for three different age groups: Early Childhood Inventory-4 (ages 3–5 years), Child Symptom Inventory-4 (ages 5–12 years) and Adolescent Symptom Inventory-4 (ages 12–18 years). There is a self-report measure for adolescent patients: Youth's Inventory-4 (ages 12–18 years) [66].
- The Child Behavior Checklist (CBCL), developed by Thomas M. Achenbach, is a scale that evaluates pathological behaviours and social competence in children from the ages of 4 to 16 years. Forms are available for teachers, parents and children. It is one of the most widely used scales for both clinical use and research [67].
- The Children's Depression Inventory (CDI) is a 27-item self-report questionnaire that can be given to 7- to 17-year-olds. It is currently one of the most widely used instruments for monitoring depression in children. Each question includes three statements of increasing severity [68].
- The Multidimensional Anxiety Scale for Children (MASC) is a scale for children and adolescents designed to assess symptoms of anxiety. The 39 items are scored on a scale from 0 to 3 as follows: 0 = never true about me; 1 = rarely true about me; 2 = sometimes true about me; 3 = often true about me [69].
- The Conners' Parent/Teacher Rating Scales identify behaviour problems through parent and teacher report and particularly symptoms of ADHD. It is available in three versions: a 93-item version, a 48-item version and a 10-item screening version. It is used in children ranging in age from 3 to 17 years [70].
- The Leyton Obsessional Inventory-Child Version (LOI-CV; Short Form) is a 20-item inventory, with 'yes/no' responses adapted from the adult version, to assess obsessive–compulsive symptoms [71].

Impediments for psychiatric evaluations

The second question of the survey enquired about the *availability* and *use* of psychiatrists in each centre. Among the 47 centres, only 12 (26%) had a psychiatrist in their epilepsy team. Consultations were provided by the hospital's psychiatry LCS in the other 35 centres: in 10 (21%) the *same* psychiatrist was always available to do the consultation, whereas in 24 (51%) consultations were carried out by *different* psychiatrists. In one centre, consultations were carried out by psychiatry residents who then staffed the cases with their staff psychiatrist.

Disclosure of postsurgical psychiatric complications

As shown above, epilepsy surgery is associated with postsurgical psychiatric complications which should be openly discussed with patients and family members with as much detail as the other surgical risks. Indeed, patients should be advised of the risk of postsurgical depressive and anxiety episodes occurring within the first 12 months, with a higher symptom incidence in the first 3–6 months and a tendency to remit by 12–24 months. This is especially true when the patient has a previous history of a mood disorder and the symptoms are actually an expression of a recurrence or exacerbation of presurgical depressive and/or anxiety disorders, whereas *de novo* mood/anxiety disorders are significantly less frequent. In patients undergoing ATL, *de novo* depressive and anxiety disorders can be expected in 10–15%, and a risk of 10–15% of persistent mood and anxiety disorders should be disclosed. Patients undergoing extratemporal resections have a lower risk of developing postsurgical psychiatric complications compared with patients undergoing an ATL, although the data available on postsurgical complications after ETL are rather sparse and more studies are needed to establish the actual risk. With respect to the potential risk of postsurgical psychotic complications, patients and family members should be advised that, although *de novo* postsurgical psychotic complications have been estimated to range between 1% and 10% following an ATL, the actual frequency remains to be established.

Conclusion

In summary, the evidence presented in this chapter is indicative of a high prevalence of psychiatric co-morbidity in epilepsy surgery candidates. This psychiatric co-morbidity, whether present at the time of the presurgical evaluation or preceding it, has significant implications in the patients' risks of postsurgical psychiatric complications, psychosocial adjustment as well as seizure outcome. Neuropsychological evaluations complement, but are not a substitute for, psychiatric evaluations.

[2] David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

Modern advances in epilepsy surgery have improved outcomes and reduced complications; however, surgery for epilepsy is not a new practice. As far back as the writings of Hippocrates, focal motor seizure onset was being used as a lateralizing sign for cranial surgery. In the 1500s, Duretus alleviated seizures related to a depressed skull fracture by elevating the impinging skull from the underlying brain [1]. The practice of removing brain tissue for the alleviation of seizures would wait for the late 19th century with the advent of effective anaesthesia techniques. Heyman was the first to report alleviation of seizures by the removal of a brain mass in 1831. The first series of cases involving resective brain surgery for seizures was published by Sir Victor Horsley in 1886 [1]. All of these early surgeries, and those in successive years, were based on pathological substrates with clear physical markers, such as post-traumatic lesions and infections. The surgical technique consisted of removing the lesion (lesionectomy) and sometimes removing the abnormal or damaged surrounding tissue as well.

The next advancement in epilepsy surgery came from the Montreal Neurological Institute, where Penfield and Jasper [1] recorded electrical activity from the brain during surgery under local anaesthesia. The goal was to define the extent of the epileptic zone based on abnormal electroencephalography tracings. This approach fundamentally changed the nature of the operation, from a procedure focused on a structural abnormality to one targeted by electrical pathophysiology. Grossly visible pathologies remained the target of many of the surgeries, but intraoperative electrocorticography (EcoG) was used to determine how far to extend the resection into the cortex surrounding a lesion. Also, for the first time, surgery for seizures with a cortical focus that was not grossly apparent on inspection was possible by directing the cortical resection to the electrophysiologically abnormal region. These procedures predated the advent of magnetic resonance imaging (MRI), which today would reveal some of the previously considered non-lesional seizure foci, and frequently abnormalities were found only postoperatively on pathological examination. Since the time of Penfield, several new modalities for localizing and delimiting the cortical focus of seizure activity for resection have been developed; however, the fundamental principle of using electrocorticography to delineate the margins of the region that should be surgically resected for seizure control remains the same today, albeit with some controversy.

Current practices of medial temporal lobe surgery

As more surgeries were performed based on abnormal electrophysiology and non-lesional cortical resections were performed based on the origin of epileptiform activity, it became clear that many of the non-lesional surgically remediable epilepsies of the temporal lobe represented a distinct pathology. A major advance over the last 20 years has been the identification of surgically remediable syndromes of epilepsy, the chief one being mesial temporal lobe epilepsy.

The original temporal lobe resections for non-lesional epilepsy originating in this area were quite extensive. The temporal lobe removal extended back from the anterior temporal pole for 7–8 cm (almost the entire length), included the medial temporal lobe structures of the hippocampus and amygdala and would sometimes be extended across the Sylvian fissure into the frontal lobe based on electrocorticography [2]. These resections proved fairly effective in controlling seizures, but they were associated with what would be considered unacceptably high morbidity by today's standards. Many of these patients were found to have complete hemianopsia, and there was an approximately 5% risk of hemiparesis or hemiplegia. Early epilepsy surgery programmes were associated with extensive research endeavours, including neuropathology research, that were trying to better elucidate the mechanisms underlying the unique temporal lobe epilepsy phenomenon. It became clear that these 'non-lesional' temporal lobe epilepsies commonly had abnormalities of the hippocampus with profound loss of neurones within the subfields. Pathological examination of surgical specimens from temporal lobectomy patients having electrophysiologically demonstrated medial temporal seizures made possible the determination that these pathological changes within the hippocampus were causing the seizures [3].

Concurrent with the determination of hippocampal sclerosis as an underlying epileptogenic pathology and the observation that removal of a sclerotic hippocampus alone frequently led to a seizure-free outcome, the sclerotic hippocampus became a lesion to be targeted in mesial temporal lobe epilepsy surgery. Early experiences made it clear that bilateral hippocampal pathology could not be addressed by resective surgery. The much studied

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

patient, HM, developed complete and permanent anterograde amnesia following bilateral hippocampus removal [4]. However, targeting a unilateral sclerotic hippocampus made possible more limited temporal lobe resections that were safer than previous surgeries and led to fewer complications. Spencer *et al*. [5] developed a refined, standardized approach to resection of the medial temporal lobe structures that was more conservative in neocortical resection than previous approaches but proved highly effective in controlling seizures. In this approach, only the anterior lateral temporal lobe is resected, followed by entry into the temporal horn of the lateral ventricle, where the hippocampus is then identified and resected. Because of this, the extent of neocortical resection is standardized at 3–3.5 cm from the temporal tip, preserving the entire superior temporal gyrus [6]. This approach allows extensive resection of the hippocampus back to the tectal plate, an important detail given the findings of several studies that indicate there is a greater chance of seizure control as more hippocampus is removed but not with greater neocortical tissue resection in mesial temporal lobe epilepsy surgery [7,8].

Two other approaches to temporal lobe epilepsy surgery have been developed, one potentially more extensive and one more limited. The first of these was developed by Ojemann and colleagues [9,10] and included awake craniotomies with extensive intraoperative cortical mapping and electrocorticography. For temporal lobectomies, the final hippocampal and neocortical resection was tailored based on electrocorticography from the hippocampus and neocortex. Greater knowledge of the neocortical localization of language during surgery enabled more extensive resections based on electrocorticography [9,10]. Some patients with clear lesions in the temporal lobe neocortex also had a seizure focus in the hippocampus, suggesting dual pathology and requiring resection of both the neocortical lesion and the hippocampus for seizure control. It is thought that seizures from the neocortical focus may create a seizure focus in the hippocampus over time, possibly by promoting hippocampal sclerosis. A more limited approach to surgery for medial temporal sclerosis was initially developed in Europe and remains more popular with European neurosurgeons than those in the USA. The selective transcortical, transventricular amygdalohippocampectomy procedure was developed by Niemeyer [11] and further refined with an approach through the Sylvian fissure by Yaşargil [12]. For this approach, a small cortical incision is made through the superior temporal gyrus or by splitting the Sylvian fissure through the circular sulcus into the temporal horn of the lateral ventricle. Once in the ventricle, the hippocampus and part of the amygdala are removed, similar to the other temporal lobectomy procedures, but the temporal neocortex is left almost entirely intact, especially when the approach is transsylvian, although this approach does involve resection in the temporal stem. Amygdalohippocampectomy has demonstrated similar seizure-free outcome rates as the other types of temporal lobe surgeries [13] with some claims of less impairment on some neurocognitive measures, especially in the dominant temporal lobe [14,15]. However, the technique can be more technically challenging and has greater potential for disruption of the middle cerebral artery branches in the Sylvian fissure, possibly resulting in hemiparesis.

Medial temporal lobe resections are also performed for other lesions apart from the syndrome of mesial temporal or hippocampal sclerosis. A variety of neoplastic, vascular and other lesions can involve the medial temporal lobe, and their resection involves complex considerations regarding the risk inherent in the lesional pathology as well as the epileptogenicity of the lesion. These issues are discussed in a separate chapter devoted to lesional epilepsy.

Extratemporal resections and temporal lobe resections outside the medial temporal lobe

Medial temporal lobe surgery has evolved into a standard resection, albeit with some variations, based on the understanding of a fairly uniform pathology defining a surgically remediable syndrome. In contrast, surgical approaches to extratemporal lobar resections rely more on a process of delineation of the epileptogenic network, or 'focus', and do not follow a uniform surgical approach. When there is a lesion that is apparent through MRI, the approach is readily tailored to address the relationship of the lesion to the seizures, and then a surgical approach is developed, often aimed at removal of the lesion and, when appropriate, additional affected brain tissue presumed to be involved in the generation of seizures. Such lesions may be neoplastic, vascular, traumatic, infectious or related to developmental anomalies. Surgical approaches may range from strict lesionectomy to large-scale resection and even hemispherectomy or hemispherotomy for particular syndromes. These approaches are discussed in other chapters in this book.

Most challenging are the non-lesional extratemporal epilepsies, in which a structural substrate is not readily available. A variety of tools are employed in the process of delineating the epileptogenic network responsible for such epilepsies. These modalities include video-electroencephalography monitoring, magnetoencephalography (MEG) and extensive neurobehavioural testing. A variety of advanced and particularly sensitive MRI methods have been developed to reveal subtle brain changes that escape the standard MRI methods. These include magnetic resonance spectroscopy (MRS), diffusion tensor imaging (DTI) and high-tesla (T) imaging with 3-T and stronger magnets. Methods of coupling electroencephalography to MRI have also been developed recently. In a substantial number of cases, these non-invasive methods may not be sufficient and may help only in focusing the work-up process on regions that will need further study using invasive recordings with subdural electrodes and/or parenchymal depth electrodes directed to specific brain targets. Intracranial electrodes are discussed in the section on intracranial studies.

In many extratemporal cases, the epileptogenic network can be localized to a particular lobe, and the surgical work-up and surgical approach then become more focused. In each lobe the existence of an epileptogenic network or focus may warrant special consideration regarding clinical semiology, the details of the work-up, and the surgical approach, taking into account both epileptogenic and functional considerations. Epileptogenic considerations may be based on seizure spread patterns that may vary according to location. For instance, epilepsy of parietal and occipital origin may spread quite fast to the medial temporal lobe and have a clinical and electroencephalographic profile similar to that

of mesial temporal lobe epilepsy. Functional considerations are of particular importance; for example, resection in the occipital lobe may entail very different neurological sequelae than resection in the posterior frontal cortex.

Frontal lobe surgery

The frontal lobe is the largest lobe of the brain, the majority of which is the association cortex or cortex involved in executive functions with significant bilateral representation; therefore, unilateral resection of epileptogenic foci in large areas of the frontal lobe may be feasible. However, there are some characteristics of the frontal lobe that may make surgical resection difficult or impossible. First, proportionate to the size of the frontal lobe, many of the frontal epileptic foci are diffuse and widespread, making it more difficult to achieve complete resection. In addition, the primary motor cortex and Broca's area on the dominant side are in the frontal lobe, making surgical resection unfeasible if these regions are involved. Second, frontal lobe seizure activity is known to spread ipsilaterally and to the contralateral side rapidly, making identification of the specific focus of onset difficult. Frontal lobe seizures can have several characteristic semiologies that may help localize the region of seizure onset [16]. Seizures originating in the primary motor cortex typically present with focal motor activity and may produce the Jacksonian march as they progress, with ipsilateral clonic activity spreading anatomically from the region of onset to involve the entire half of the body. Supplementary motor seizures are characterized by more complex motor activity, including the stereotypical 'fencer posturing' in which the patient's eyes and head deviate to the contralateral side and the contralateral arm is extended and elevated. The other characteristic frontal lobe semiology is a complex partial seizure that may involve motor automatisms such as bicycling of the legs. Although primary motor cortex is not a region in which resection of the seizure focus can occur without significant motor deficits, supplementary motor cortex can be the target of effective and safe resection. Resection of supplementary motor cortex may lead to a postoperative dense contralateral deficit, but this resolves within days or weeks, returning the patient to full motor strength in the affected limb, with little or no residual deficit [17].

Occipital lobe surgery

Occipital lobe epilepsy is typically characterized by visual or oculomotor signs and symptoms, including visual auras that can be complex in nature, transient visual loss, blinking and eye movements [16,18,19]. These seizures are complicated by rapid spread to adjacent lobes, including the parietal and temporal lobes. Rapid temporal lobe spread can make localization by semiology difficult, especially if the visual symptoms are subtle. The seizure can have the characteristics of the typical temporal complex partial seizure with a visual aura. This requires careful monitoring, frequently invasive with widespread electrode coverage, to determine the true location of seizure onset. Occipital lobe seizure foci can be resected, but often at the cost of a visual field deficit. The further the resection is from the primary visual cortex in the calcarine fissure, the less the impact on the visual field; therefore, careful delineation of the margins of the epileptogenic focus is very important.

Parietal lobe surgery

Parietal lobe epilepsy is more difficult to localize by semiology than other lobar epilepsies because of the subtlety or absence of symptoms [16,20]. Abnormal sensations and the sensation of vertigo have been described, but more than one-half of the patients with parietal lobe epilepsy have no symptoms referable to the lobe of seizure origin. As with occipital lobe seizures, parietal lobe seizures spread quickly to adjacent lobes, most commonly the frontal and temporal lobes. For this reason it is not uncommon that seizures with parietal lobe onset are thought to come from the frontal or temporal lobes based on semiology. Surgical resection of a parietal lobe seizure focus is not without effects. Most commonly, the patients will have sensory loss, especially loss of proprioception. Although this may seem fairly insignificant, loss of proprioception can lead to a lack of coordination that may hinder higher-level motor activities, including driving a vehicle. In addition, resection within the dominant parietal lobe can lead to Gerstmann's syndrome, characterized by agraphia, acalculia, an inability to distinguish right from left, and finger agnosia. Resections in the non-dominant parietal lobe may lead to significant deficits, such as contralateral neglect and impairment in spatial orientation and skills [21]. Symptoms that may seem fairly benign can be severely disabling to a person with certain cognitively demanding careers and may lead to job loss.

Multilobar resections

Epileptic networks are not limited by our somewhat arbitrary definitions of lobar anatomy and frequently will overlap lobar borders to involve more than one lobe. Because of this, multilobar resections of seizure foci are not uncommon. Examples include temporo-occipital resections, as well as temporal lobe resections that extend to the orbitofrontal region and parietotemporo-occipital (PTO) resections in some paediatric epilepsy cases such as infantile spasm [22]. However, seizure foci that overlap multiple lobes are more likely to be large and to involve cortical regions that cannot be resected because of their function, and therefore typically have a lower chance of achieving seizure control. This does not eliminate the consideration of surgical intervention in these cases, but it does necessitate more conservative estimates and expectations of seizure control outcomes when discussing surgery with prospective patients.

The remainder of the chapter is devoted to discussion of the work-up, efficacy and potential complications of temporal and other lobar resections for the control of epileptic seizures.

Epilepsy surgery evaluation

Whether for a temporal, extratemporal neocortical or a medial temporal lobe seizure focus, the work-up leading to epilepsy surgery is the same in principle: attempting to localize the epileptogenic network or focus. The goal of epilepsy surgery is to identify an anatomically defined region that once removed will result in the neutralization of the network and cessation of the seizures. This region may be fairly uniform for surgically remediable epilepsy syndromes, such as mesial temporal sclerosis (MTS), or lesional epilepsy associated with tumours, vascular and other lesions. However, for other cases with no apparent lesions,

individually tailored resections span a wide spectrum and require extensive work-up.

The current evaluation for modern epilepsy surgery begins with inpatient video-electroencephalography to determine the general lobar location of seizure onset and to rule out pseudoseizures and other cases that do not fall into the surgically remediable epilepsy syndromes. This stage involves not only the identification of electroencephalogram (EEG) correlates of seizure onset, but also an understanding of the seizure semiology that may sometimes provide a clear clue as to the lobe involved. Such clues may be an early motor event pointing to an origin in the rolandic region, or an early simple visual event in a particular place in the visual field, pointing to a specific occipital lobe as origin. The initial work-up also includes detailed MRI, including special fine cuts in the coronal plane to evaluate for hippocampal sclerosis or other cortical lesions that may account for the seizures [23,24]. Surface MR coils, stronger magnet scanners and various specialized MRI methods (see later section on other magnetic resonance methods) have been developed to detect subtle structural changes, such as those that can be seen in cortical dysplasia. MRI evidence of multilobar abnormalities or no MRI-detectable lesion are associated with poorer postoperative seizure outcome than focal MRI abnormalities limited to one lobe, emphasizing the importance of MRI lesion detection [25,26]. The goal of this first stage of epilepsy surgery evaluation is to limit the region of evaluation for the seizure focus. At this point, if the EEG corresponds to a lesion on the MRI, the patient may be a candidate for resection of the lesion, supplemented by resection of additional epileptogenic brain surrounding it (extended lesionectomy) [27]. This topic is discussed in detail in Chapter 71. This is also the approach for a patient with classic complex partial seizures and unilateral hippocampal changes on MRI, compatible with medial temporal sclerosis that corresponds with the side of temporal lobe seizure activity on video-EEG monitoring. Here the EEG and MRI findings will likely lead to one of the procedures described in the previous section for mesial temporal lobe epilepsy. When there is no MRI apparent lesion, extensive work-up is often required. A variety of diagnostic tools have been developed, some more recently.

Positron emission tomography

Interictal positron emission tomography (PET) scans can be useful in delineating the seizure focus, especially in seizures of medial temporal lobe origin [28,29]. The interictal PET scan shows an area of relative hypometabolism in the region of seizure onset. Ipsilateral medial, but not lateral, temporal lobe hypometabolism on interictal PET is predictive of better postoperative seizure-free outcome after temporal lobectomy [30]. However, a region of hypometabolism can be non-specific and may represent any lesion or abnormality of the cerebral cortex, whether epileptogenic or not. In addition, some epileptogenic pathologies such as post-traumatic gliosis will have hypometabolism throughout the abnormal region, masking the potential localizing properties of the study within the lesion. In conclusion, it is important to understand that the extent of the hypometabolic zone may be considerably larger than the epileptogenic zone; only the latter needs to be removed for control of the seizures.

Single photon emission computed tomography

Ictal single photon emission computed tomography (SPECT) is also useful for seizure onset localization in both medial temporal [31] and neocortical epilepsy, especially when co-registered to MRI (subtraction ictal SPECT co-registered to MRI, or SISCOM) [32]. The extent of resection of the cortical region identified as the seizure focus on the ictal SISCOM is correlated with the rate of seizure control [33]. Ictal SPECT can be more useful than interictal PET in determining seizure onset related to large cortical regions that demonstrate baseline hypometabolism throughout, such as regions of post-traumatic encephalomalacia. To obtain an ideal ictal SPECT scan, the radioisotope should be injected within 45 s of seizure onset [32]. Because of this, it is frequently performed as an inpatient study. The isotope is typically only good for 1 day, and must be administered by someone with appropriate radiation training and authorization. An effective ictal SPECT study requires a dedicated programme as well as set-up and maintenance costs that may be too great for the medium to small programme or hospital.

Other magnetic resonance methods: magnetic resonance spectroscopy, diffusion tensor imaging

Another use of the MRI scanner in the evaluation of the seizure patient is MRS. Postictal MRS shows increased signal from choline-containing compounds as well as creatine and phosphocreatine compounds and decreased signal from *N*-acetylaspartate in the seizure focus, and is effective in lateralizing the epileptic focus [34]. These changes represent dysfunction of neurones and glia rather than neuronal loss [35], demonstrated by their reversal in the contralateral hippocampus following medial temporal lobectomy [36]. The efficacy of MRS in guiding effective epilepsy surgery has not been established, and this imaging technique is not widely used clinically. MRI DTI, a technique used to evaluate the white matter tract projections in the brain, has been investigated as a potential imaging modality for determining seizure focus in non-lesional epilepsy syndromes. DTI has shown changes in both neocortical seizure foci [37,38] and hippocampal sclerosis [39] but does not yet have the reliability to be utilized clinically for determination of the seizure focus except in tuberous sclerosis, in which DTI was more accurate than structural MRI in localizing the epileptogenic cortex [40].

Magnetoencephalography or magnetic source imaging

Magnetoencephalography has been increasingly used in recent years as a tool in the presurgical evaluation of epilepsy patients. It is used mostly in the interictal state, but when it is used during a seizure it can provide useful ictal localizing information [41,42]. The MEG is based on the principle that electrical activities of groups of neurones within the brain create electromagnetic waves, the magnetic component of which can be detected and localized in three dimensions. This is especially useful when co-localized to the patient's MRI scan, resulting in what is termed 'magnetic source imaging' (MSI) [43]. MSI is most useful in neocortical epilepsy [44] and correlates with intracranial recordings in the majority of cases [45]. MEG is not as frequently used as other

studies because of its limited availability. The machine is highly specialized for studying brain magnetic activity and is expensive to purchase, install and staff. For reasons of cost and availability, MEG scanners are typically found associated with active brain research programmes and are most often utilized by affiliated epilepsy surgery programmes.

Functional magnetic resonance imaging

Functional MRI (fMRI) can be utilized to delineate the safety of resecting a seizure focus, especially in areas of motor and speech function [46], and when triggered by EEG spike activity it also holds promise for determining the seizure focus [47,48]. If the seizure focus is thought to be near or in motor or speech areas, the functional MRI will show the regions of the brain that have evidence of activation with movement or verbal tasks like word recognition or speech production. A reliable technique for determining memory function has not yet been developed, so functional MRI cannot currently be utilized in medial temporal seizure onset cases to determine if hippocampus resection will lead to memory deficits. For this, neuropsychological testing and the Wada test, are utilized. In addition, functional MRI shows all regions activated by a given function, but it does not demonstrate the necessity or sufficiency of any given area for the corresponding function. Therefore, it is not clear which of these areas, if inhibited or surgically removed, would lead to loss of function. To adequately investigate function in preparation for resection or disruption of one of these regions, a disruptive test through cortical stimulation is required, for example stimulation mapping using an implanted cortical electrode grid or intraoperative cortical stimulation mapping.

Studies of fMRI triggered by EEG spike activity have shown activity localized to the seizure focus in some patients [48] but not reliably. On EEG–fMRI, blood oxygen level-dependent (BOLD) effect corresponded to the spiking temporal lobe in the majority of temporal lobe epilepsy patients, but there was also activation in other brain regions, thought to represent activation of networks underlying the epileptic activity [49]. Because of the inconsistency in determining the seizure focus, this technology is not currently being used clinically but does show promise for future applications as it is further developed.

Neurocognitive evaluation

Neuropsychological testing can also be useful in preparation for and decision-making concerning epilepsy surgery. Traditionally, such testing has been especially useful in temporal lobe surgery. Material-specific memory deficits have been associated with unilateral hippocampal sclerosis. Although neuropsychological testing alone is not reliable for lateralization of the seizure focus [50] or predicting postoperative seizure outcome [51], it is useful in confirming localization and in determining the risks of surgery to memory function. A patient with good verbal memory function may be more at risk of significant memory deficits following dominant temporal lobe resection. The type of cognitive deficits present may also help in differentiating neocortical versus medial temporal lobe involvement, or a frontal versus temporal lobe focus.

'Wada test' in select cases

The intracarotid amytal test developed by Wada [52] originally for the lateralization of speech function by intracarotid amobarbital injection, has been more recently employed in lateralization of memory function [53]. The patient can be tested for various functions with one side of the brain anaesthetized by unilateral injection of sodium amobarbital into the intracarotid artery via a transfemoral catheter. The angio-Wada test is used particularly in preparation for a medial temporal lobe resection. For a patient to be a candidate for this type of epilepsy surgery, he or she should demonstrate little or no loss of memory function when the side of the proposed surgery is anaesthetized. Retrospective analysis of medial temporal lobe resections following the Wada test has shown that patients with superior memory performance from the non-epileptogenic side had better seizure-free outcomes, giving the Wada test some prognostic significance as well [54]. The Wada test has value in predicting learning and memory abilities in epilepsy patients with temporal lobe epilepsy, which is useful in the decision for surgery and presurgical counselling [53].

Intracranial studies

Once the non-invasive studies have been completed, a small percentage of patients proceed to an intracranial study with surgically implanted electrodes [55]. In these patients the various tests may have yielded non-concordant results, or insufficient information to enable focal resection. Intracranial monitoring is a hypothesis-driven technique used to identify a localized region of epileptogenesis once other non-invasive studies have been used to determine the general region or regions of the brain to be studied. Another potentially useful outcome of intracranial electrode implantation is the ability to use electrical stimulation to delineate brain function in or near regions that may need to be removed to control the seizures. Although helpful in outlining regions of the brain participating in functions such as movement and language, fMRI is limited to being used independently to determine safe regions for cortical resection. This limitation stems from the fact that the neural basis of fMRI BOLD signals is still poorly understood, and that the presence of BOLD changes with function do not mean that these regions are indispensable for the execution of these functions. Electrical stimulation mapping is still the 'gold standard' used to identify critical functions, and it often requires an awake, cooperative patient. Electrical stimulation can be performed either intraoperatively with patients awake or extraoperatively with implanted intracranial electrodes.

For patients suspected of having neocortical onset seizures, subdural cortical electrode grids are typically used to provide adequate coverage for determining the exact region of seizure onset and for stimulation mapping of functional areas such as speech, movement and sensation. Grid studies are typically augmented by cortical strip electrodes that can be extended under the edge of the craniotomy opening to rule out spread or a simultaneous seizure onset from another lobe unappreciated on scalp EEG.

Another type of intracranial electrode is the depth electrode, which is designed to penetrate brain parenchyma. Depth electrodes have the advantage of precisely sampling discrete targets in the brain, and monitoring seizure spread patterns in deep brain structures such as the hippocampus and amygdala [56].

However, depth electrodes do not provide extensive cortical coverage for mapping of seizure onset or function, so they are not as useful in planning resection of a neocortical focus. Intracranial electrode studies may provide valuable information leading to epilepsy surgery, even in patients with scalp EEG demonstrating bilateral seizure onset. A study of patients with bitemporal lobe onset on an EEG showed that the majority of the patients demonstrated onset only or predominantly from a single side and went on to surgery, with 40% being greatly improved and a 29% seizure-free rate [57]. In some cases, depth electrodes can show onset of seizures contralateral to what appeared to be the onset on scalp EEG [58]. This would suggest that medically intractable epilepsy patients, even if not having well-lateralized localization on scalp EEG, could be candidates for an intracranial electrode study.

Epilepsy surgery outcomes

Epilepsy surgery outcomes vary according to the location and pathology of the seizures. The primary goal of epilepsy surgery is to render patients seizure free. Complete seizure control is not always achieved, but postoperative seizure reduction is also used as a measure of success for patients with high preoperative seizure rate. An important factor affecting seizure control rate following epilepsy surgery is the location of the seizure onset; that is, the lobe involved influences the chance of achieving seizure control. This is partly due to the limitations imposed on the area of resection by the neurological function and anatomy of the lobe. Whereas cortical resection within the non-dominant temporal lobe can involve any or all areas of the lobe without loss of function, resection within certain areas of the frontal lobe could lead to motor deficits or aphasia, and resections within the occipital lobe would probably result in some degree of visual field deficit. Depending on the risk for neurological deficit, the surgeon may not be as generous in the resection of the seizure focus. In addition, medial temporal resection represents surgery that is fundamentally different from neocortical epilepsy surgery in that it encompasses a standardized approach based on the understanding of a well-defined syndrome and pathophysiology; therefore it may have a more favourable prognosis. The discussion of seizure outcomes will be organized based on location, with medial temporal lobectomy being discussed separately from the neocortical resection outcomes.

Medial temporal lobectomy has better reported postoperative seizure control rates than the other neocortical surgeries. Probably the most important paper in establishing the role of medial temporal lobe surgery in medically refractory epilepsy patients comes from a prospectively randomized study by Wiebe *et al*. [59]. Over a 1-year period the study found that 58% of the patients with temporal lobectomy were seizure free compared with only 8% of the patients receiving maximal medical therapy. The surgery group also had better mean quality of life and a higher percentage of them were employed or attending school at 1 year post surgery. Adverse events from surgery occurred in 10% of patients and represented problems such as memory difficulties (5%), but there were no mortalities; however, one patient in the medical group suffered sudden unexplained death from epilepsy (SUDEP). The authors of the paper recognized that the seizure-free rate from surgery was lower than in other large series of temporal lobectomy patients, but the study still demonstrated clear benefits of epilepsy surgery over medical management for medically refractory temporal lobe epilepsy.

Another prospective, randomized study evaluated the outcome of temporal lobectomy for seizure control in relation to the extent of hippocampal resection [8]. One group of 34 patients received the more limited hippocampectomy, extending only to the edge of the cerebral peduncle as part of the temporal lobectomy surgery. The other group of 36 patients received a more extensive hippocampal resection back to the superior colliculus. In this study, the patients with the more extensive hippocampal resection had better seizure control rates, with 69% of patients being seizure free compared with 38% being seizure free for the less extensive hippocampal resection. Interestingly, the two groups showed no difference in neuropsychological deficits, indicating that the neuropsychological effect of hippocampectomy is not dependent on the extent of the remaining hippocampal tissue. These findings suggest that patients who are at risk for neuropsychological deficit from hippocampal resection could suffer this deficit in any event. These studies strongly suggest that once the appropriate testing and preoperative evaluation has been performed to verify that the patient will not have a significant deficit from removal of the hippocampus, resection of the hippocampus should be extensive. Conversely, if there is concern about the patient having neurological deficits from hippocampal resection, the hippocampal resection should be avoided altogether, and the epilepsy surgery team should not gain false security about retaining hippocampal function by performing a more limited resection. These findings also agree with the findings of a retrospective analysis of the impact of the extent of temporal lobe resection on seizure outcome in temporal lobectomy patients based on volumetric analysis of postoperative MR images [7]. Overall, 68% of the patients were seizure free, with an average follow-up of 2 years and a minimum follow-up of 1 year. Only 17% of the patients with limited mesiobasal temporal resection were seizure free, whereas 76% of the patients with extensive mesiobasal temporal resection were seizure free. There was no difference in seizure outcome based on the degree of lateral temporal lobe resection. Again, this argues for an extensive medial temporal resection, including a complete hippocampectomy, but gives no support for more neocortical resection than necessary to provide access to the medial temporal structures.

Multicentre analyses of epilepsy surgery outcomes are also more objective and potentially more accurate sources of information about seizure outcomes of the various epilepsy surgeries. A meta-analysis of epilepsy surgeries was performed to determine seizure control outcomes for various surgery types [60]. In this meta-analysis, temporal lobe surgeries are listed as a group without separating out medial temporal resections from temporal neocortical resections. But the majority of temporal lobe epilepsy surgeries performed are medial temporal rather than neocortical, so this sample may be seen as mostly representing medial temporal lobe surgery outcomes. Analysis of 3895 patients in 40 studies showed a 66% seizure-free rate, with a confidence interval from 62% to 70%. In another set of studies of epilepsy surgery that were prospective and multicentre, medial temporal lobe resection surgeries

were analysed separately from neocortical resections. At 1 year, 77% of medial temporal lobectomy patients were seizure free [61]. However, at 2 years the proportion of patients who were seizure free had dropped to 68% [62]. These studies demonstrated both the high rate of seizure control with this surgery and also the low but present risk of relapse to active seizures over time.

Analysis of some of the larger series of medial temporal lobectomy cases may help elucidate some of the factors underlying the seizure-free rates. Analysis of 100 patients who had undergone standard anterior temporal lobectomy for complex partial seizures showed that 63% were seizure free by 2 years, at which point they stabilized and did not tend to have significant change in seizures in the following years [63]. Evaluation of 100 patients who had undergone the selective amygdalo–hippocampectomy demonstrated a 69% seizure-free rate at 1 year and a 58% seizure-free rate at 5 years, again showing a stability of seizure control at around 60% over time [12]. These similar studies using different surgical procedures had similar outcomes in seizure control, indicating equal efficacy of the two procedures. This was supported by a recent study directly comparing the two procedures in a retrospective fashion [13]. The authors of the study compared 50 patients who had cortical amygdalohippocampectomy with 50 patients who had selective amygdalohippocampectomy for intractable epilepsy with hippocampal sclerosis. At 1 year, 73% of the patients were seizure free, but by 5 years of follow-up the proportion of seizure-free patients had dropped to 49%. Most importantly, this study showed no statistically significant difference in seizure control rates between these two procedures, leaving the preference of procedure in the surgeon's hands based on technical complexity and training rather than efficacy.

Based on a review of the literature, the American Academy of Neurology published a practice parameter paper in collaboration with the American Epilepsy Society and the American Association of Neurological Surgeons on temporal lobe and other neocortical resections for medically intractable epilepsy [64]. Concerning temporal lobectomy surgery, their recommendations were largely based on the only class I evidence available, in the Wiebe *et al.* [59] paper discussed earlier in this chapter. In addition, they referenced 24 class IV evidence papers that supported the findings of the class I study. They cited the much higher rate of seizure-free outcome in the surgical group (64%) compared with the medical therapy-only group (8%) at 1 year, as well as the incidence of no surgical mortality and minimal surgical morbidity, when drawing their conclusions that the benefits of anteromesial temporal lobe resection are greater than continued treatment with antiepileptic medications in the medically intractable mesial temporal lobe epilepsy patient. Using the pooled data from the other 24 class IV studies, they found a 66.8% seizure-free rate with a 64–68% confidence interval (CI) and only 14% of patients (CI 12–16%) showing no reduction in their seizure frequency.

A definitive statement concerning extratemporal neocortical resection of a seizure focus could not be made in this practice parameter statement paper because of the lack of class I data within studies of these procedures. The conclusions of the paper are that further study of neocortical resections is necessary to determine if there is a benefit over continuation of medical therapy. However, within the paper, the results from the eight studies of neocortical resections were pooled to show a 49.7% seizure-free rate with a confidence interval of 44–55% [64]. In the six centres reporting patients without improvement, 20.5% (CI 16–25%) had no improvement of their seizure frequency. Given the limitations of these studies, they still show that after surgery approximately one-half of the patients became seizure free, a lower percentage than the medial temporal lobectomy patients but clinically significant nonetheless. However, potentially one-quarter of the patients undergoing neocortical resection do not benefit at all from their surgery. The multicentre study of epilepsy surgery had similar findings, reporting a 56% seizure-free rate after neocortical resection at 1-year follow-up [61] and 50% seizure free at 2-year follow-up, with 19% of the seizure-free patients relapsing after a 2-year period [62]. A recent paper examining the long-term results of 154 extratemporal lobe epilepsy surgery patients, the majority of whom were lesional with 5.8% non-lesional, found a low rate of relapse with 54.5% of patients seizure free at 1 year, 50.3% at 2 years, 52% at 5 years and 51.1% at 14 years [65].

The difficulty in performing standardized analysis of neocortical resections is the variability of outcomes depending on the lobe of resection in the existing retrospective studies. This is probably a result of the variability of neurological function represented in each individual lobe and the comfort level of the surgical team in committing a patient to a specific neurological deficit. Because of this, resections may be more conservative. Unlike medial temporal lobectomy, in which there is evidence that extending the hippocampal resection further posteriorly does not increase the impact on neuropsychological measures, extension of neocortical resection within the extratemporal lobes of the brain will lead to a further neurological deficit if large enough. A meta-analysis of epilepsy surgery outcomes analysed seizure-free rates in several different ways based on the included papers [66]. In the 25 papers that reported temporal and extratemporal resections grouped together, there was a 59% seizure free-rate, but in the two papers that grouped extratemporal resections, there was only a 34% seizure-free rate, showing the disparity of extratemporal versus temporal lobe resections. There were seven papers that looked at frontal lobe resections with a pooled seizure-free rate of 27% and one paper each looking at parietal and occipital lobe resections with 46% seizure-free rate in both. The authors attribute this difference to either the frontal lobe epileptogenic regions being larger and more difficult to completely remove in the largest lobe of the brain or the proximity to the motor regions in the posterior frontal lobe, limiting the feasibility of completely removing these lesions.

Few papers have analysed neocortical resections as a separate group for seizure-free outcomes. One study reports a seizure-free rate for temporal neocortical resections that surpasses the rate of medial temporal lobectomy outcomes, with 78% of patients being long-term seizure free [67]; however, many of these patients had neoplasms or other lesions that may have accounted for these excellent outcomes. This same study reported a 64% seizure-free rate from frontal neocortical resections; again this is probably higher than expected owing to the high number of patients with neoplasms and other lesions. The largest studies of outcomes from neocortical resections have come from the Montreal Neurological Institute. Analysis of 257 patients with frontal lobe resections for non-tumoral epilepsies with 2–49 years' follow-up showed a 26%

seizure-free rate [68]. This group also reported on a series of 79 parietal lobe epilepsy surgeries with a follow-up of 2–50 years [20] and a series of 37 occipital lobe epilepsy surgery outcomes [19] with a follow-up of 1–46 years, both of which had 46% seizure-free rates. One other study of 35 occipital lobe epilepsy surgery outcomes with a 1- to 14-year outcome showed a 46% seizure-free rate as well [18]. These results were represented in the meta-analysis [60] and demonstrate the disparity of outcome between medial temporal lobe resections and extratemporal neocortical resections.

The goal of epilepsy surgery is to make the patient seizure free, so it is appropriate to analyse and report seizure-free outcomes; but this does not tell the whole story about epilepsy surgery impact on patients. Important studies have been conducted to determine the impact of epilepsy surgery on patients' lives in a variety of areas in order to better understand the psychosocial and economic impact. Major surgery involves risk and can be disruptive to routine daily activities, so determining if patients have an overall improvement in quality of life after the surgery is important in assessing whether or not these surgeries are worthwhile. A meta-analysis of psychosocial outcomes from six controlled studies representing 509 medical and 799 surgical patients helps to answer these questions [66]. In five out of the six studies analysing seizure outcome, the surgical group did better than the medical group. In the four studies that looked at social outcomes, two found improvements in the surgical group compared with the medical group and two found the groups to be equivalent. Quality of life measures were improved for surgical patients compared with medical patients in two studies, and were found to be equivalent in one. Depression had a greater improvement in the surgical group than the medical group in the two studies that analysed this factor. Only one group looked at cognition and found that surgical patients did worse than the medical control subjects. Overall mortality was increased in the surgical group in one study but was equivalent to medical control subjects in two studies, probably owing to the low rate of mortality in epilepsy surgery and the risk of death from accidents and SUDEP that can be seen in patients with uncontrolled epilepsy. Although not universally positive, taken together, these results suggest that surgery is more beneficial for refractory epilepsy than the continuation of medical therapy in terms of the psychosocial aspects, with little to no increase in mortality compared with medical therapy, but some evidence of negative impact on cognition that should be accounted for in the decision-making process.

Several papers from the Multicenter Study of Epilepsy Surgery, a prospective observational cohort study, have addressed psychosocial factors. Among 396 patients who had epilepsy surgery, 75.5% said that they would undergo surgery again and 79.1% reported a strong overall impact of surgery on their lives at 2 years; however, only 7% of the patients had improvement in their employment status [69]. Postoperatively, both depression and anxiety levels were decreased at 3, 12 and 24 months after epilepsy surgery in 360 evaluated patients [70]. In both of these studies, patients who were seizure free had much better outcomes than those who continued to have some seizures. In a subset of 68 patients receiving temporal lobe epilepsy surgery, health-care costs were significantly decreased in the 2 years after surgery compared with the 2 years before surgery for those who were seizure free, but there was no difference for those with persisting seizures [71]. These results demonstrate clear patient benefits of epilepsy surgery, but only if the surgery results in a seizure-free outcome.

Epilepsy surgery complications

Epilepsy surgery is not without potential risks, and quantifying those risks is useful in combination with outcome data in counselling patients and assisting them in their decision-making concerning surgery. The epilepsy surgery programme at the University of Bonn in Germany has presented the rate of complications in 429 consecutive surgeries over a 6.5-year period [72]. These surgeries included temporal and extratemporal lobe resections as well as electrode implantations, callosotomies and hemispherectomies. The complications were divided into categories of surgical complications and neurological complications. Overall, there were 7.7% transient surgical complications and 0.7% permanent complications (hydrocephalus in all three permanent cases), and there were 3.0% transient and 2.3% permanent neurological complications. There were no mortalities reported. The most common surgical complications were wound infection at 3.5%, meningitis at 1.4% and deep vein thrombosis at 0.9%. The most common neurological complications were hemi- or tetraparesis at 2.3%, third-nerve palsy at 0.9%, and hemianopsia and dysphasia each at 0.7%. Separate analysis of annual complication rates over the 6-year period showed that surgical complications dropped from 13.2% to 3.7%, with wound infections decreasing from 13.2% to 0%, and neurological complications dropped from 10.5% to 3.7%, with hemi- or tetraparesis decreasing from 5.3% to 0.9%. These statistics show that epilepsy surgery has relatively low risks that are more often transient than permanent, and there is some evidence that risk is mitigated by the level of experience of the epilepsy surgery centre. The practice parameter paper from the American Academy of Neurology discussed the complications reported from seven institutions they reviewed, including mainly temporal lobectomies but also extratemporal resections [64]. From a total of 556 patients, there were only two non-operative deaths, one of which was from a trauma, making the overall procedure-related mortality 0.2%. Six per cent of patients had new neurological deficits including mild aphasias, third- or fourth-nerve palsies, visual field deficits greater than a quadrant, and hemiparesis (2% of patients). One-half of these deficits resolved within 3 months, making the risk of permanent neurological deficit 3%. The most common non-neurological surgical complication by far was postoperative infection, which occurred in 5% of patients.

For epilepsy surgery, each targeted lobe has the potential not only for general surgical complications but also for specific complications related to the neurological functions contained within the lobe and the surrounding anatomy. The randomized, prospective, controlled study comparing temporal lobectomy surgery with best medical management is helpful in establishing the complications specific to the surgery rather than the general complications associated with epilepsy [59]. There were no mortalities within the surgical group, whereas there was one sudden unexplained death in the medical group, emphasizing that epilepsy is

not a benign disease, having its own mortality rate, and that the choice not to proceed with surgery may not necessarily be the safest choice. Four out of the 40 surgery patients had adverse effects including a thalamic infarct causing sensory abnormalities, a wound infection, and two declines in verbal memory. Fifty-five per cent of patients had an expected superior quadrantanopsia as a side-effect of surgery. Depression (18% surgical, 20% medical) and transient psychosis (one patient in each group) occurred in both groups to a similar degree. In the study of corticalamygdalohippocampectomy versus selective amygdalohippocampectomy there were also no operative deaths among the 100 patients studied, and there was only a 4% complication rate, most of which were non-neurological surgical complications [13].

A study of 154 extratemporal, neocortical epilepsy surgeries found a higher rate of complications than seen in the temporal lobectomy studies [65]. There were no mortalities, but there were complications in 8.4% of the patients, with 1.9% having persistent paresis, 3.9% having visual field deficits, 0.6% having a subdural haematoma requiring surgery, and 1.9% with bone infections. In addition, 5.8% had transient neurological deficits that had no long-term impact. In a study of 126 neocortical frontal and temporal lobe epilepsy surgeries there were also no mortalities [67]. Five per cent of patients had surgical complications including meningitis, wound infections, pulmonary embolism and diabetic coma, and 4.5% had neurological complications including dysphasia, hemiparesis, brachial monoparesis and hemihypaesthesia, but all of these complications were temporary and were eventually fully resolved. In a study of 82 patients having parietal lobe resections for epilepsy there was a 52% complication rate with no mortalities; however, the permanent neurological deficit rate was 24% [20]. The permanent neurological deficits included contralateral cortical sensory loss, dysphasia, acalculia, anomia, agraphia, partial auditory and verbal agnosia, contralateral weakness, and disturbances of body image causing apraxia of dressing, hemi-inattention or neglect and contralateral visuospatial defects. Postoperative neurological deficits were also listed in one of the series of occipital lobe epilepsy surgeries, but given the location of the resections, visual field deficits were seen as side-effects of the surgery rather than complications [19]. There were two mortalities among these 42 patients. Fifty-nine per cent of the patients had preoperative visual field deficits. Postoperatively there was a 76% complete homonymous hemianopsia rate, transient aphasia in 4.8% and aseptic meningitis in 7.1%. Clearly, extratemporal lobe epilepsy surgeries have greater side-effects and risks of complications than temporal lobectomies.

Another concern specifically with medial temporal lobectomy is the impact of the surgery on the neurocognitive and language functions. In a retrospective analysis of 47 right-handed patients who underwent left temporal lobectomy for refractory temporal lobe epilepsy, the extent of medial and lateral resection was found not to influence neurocognitive outcomes [73]. These are the patients who would be expected to have the most significant cognitive impacts from surgery because the surgical target was the dominant temporal lobe responsible for verbal learning and memory. Average Wechsler Adult Intelligence Scale scores showed improvements in visuospatial reasoning for all resection types, but verbal reasoning was decreased in two out of the four resection groups. In addition, all groups showed decreases in the memory quotient on the Wechsler Memory Scale and decreases in all measures on the Auditory–Verbal Learning Test. However, a Wada test memory score in the ipsilateral hemisphere can be somewhat predictive of postoperative memory deficits, such that patients with high memory potential are more likely to have postoperative memory deficits [53]. In a randomized, prospective study of limited versus extensive hippocampal resection in medial temporal lobectomy, extent of tissue removal did not influence memory outcome, but left temporal lobectomy without signs of hippocampal sclerosis was associated with a decline in verbal memory, probably because the hippocampus removed was not only anatomically and pathologically normal but was functioning normally as well [8]. A study of verbal function following medial temporal lobectomy of dominant and non-dominant temporal lobes found no overall decrement in language functions in either group [74]. These surgeries were performed with conservative neocortical resection to minimize language impact. Thus, language function can be safely maintained following medial temporal lobectomy provided there is conservative neocortical resection, whether in the dominant or non-dominant temporal lobe.

Conclusion

Temporal lobe and other lobar surgeries for epilepsy have a long history, are well established and have shown better seizure outcome and decreased complication rates over time and with more experience in epilepsy centres. Improved surgical procedures, advances in techniques for preoperative localization of the seizure focus, as well as better understanding of the pathophysiology of distinct surgically remediable syndromes of epilepsy, are responsible for the increasing success of epilepsy surgery over the years. With low risk to the patient and class I evidence of high efficacy in eliminating seizures, with seizure-free rates ranging from 58% to 77%, temporal lobectomy for medial temporal lobe epilepsy represents a good option for the appropriate medically refractory epilepsy patient, a conclusion shared by the American Academy of Neurology in a practice parameter paper [64]. Extratemporal epilepsy or epilepsy involving the lateral structures in the temporal lobe may harbour a favourable surgical prognosis if an apparent lesion is shown by MRI. Neocortical resections for epilepsy, in the absence of structural lesions, are also effective in eliminating seizures in some patients, although less effective than temporal lobectomy or focal lesion-centred resections. However, the difficulty in localization of seizure onset, the functional constraints on resections and lack of class I evidence makes these surgeries a clinical option for medically refractory epilepsy that should be carefully considered on an individual patient basis, although deserving of a full evaluation by a qualified epilepsy surgery centre.

70 Resective Surgery of Neoplasms

Nicholas Wetjen, Mithri R. Junna, Kurupath Radhakrishnan, Aaron Cohen-Gadol and Gregory D. Cascino

Mayo Clinic, Rochester, MN, USA

Introduction

The association of brain tumour with epilepsy has been suspected since ancient times [1]. The occurrence of seizures and epilepsy in the presence of primary brain tumours has been observed for over a century [1–6]. Seizures are the most common presenting symptom in patients with slow-growing or well-differentiated low-grade tumours. Seizures occur in approximately 50% of patients with intracerebral neoplasms [5,6]. There is a direct correlation between the chronicity of the growth of the neoplasm and the incidence of seizures. In the Montreal series of 230 patients with tumours of the central nervous system, the majority were gliomas. Seizures occurred in 70% of patients with astrocytomas, in 92% of patients with oligodendrogliomas and in 37% of patients with glioblastomas [5,6].

In the classic book of William Gowers [2], published in 1881, a clear distinction between focal seizures due to a demonstrable pathological lesion and generalized seizures, constituting idiopathic epilepsies, was emphasized. However, Hughlings Jackson [3] was the first to provide a comprehensive understanding of the significance of focal seizures when he described uncinate seizures in patients with neoplastic and non-neoplastic lesions of the temporal lobe. He emphasized that epilepsy could be the initial and only clinical manifestation of a brain tumour [3]. Victor Horsley [4] reported his three landmark cases in which he surgically cured the patients of their focal epilepsy. More recently, various seizure patterns in patients with structural lesions and their surgical management were described by Penfield and Jasper [7], Spencer *et al.* [8], Boon *et al.* [9], Awad *et al.* [10] and Cascino *et al.* [11].

The remarkable development of neuroimaging during the past 20 years has allowed detection of various types of intracranial abnormalities in patients with medically intractable epilepsy with increasing frequency [8–11]. Primary brain tumours, hamartomas and vascular malformations are the underlying pathology in approximately 20–30% of patients with intractable epilepsy. Magnetic resonance imaging (MRI) is the most sensitive and specific imaging modality to distinguish a mass lesion from other pathological entities in patients with epilepsy [11–13]. If a circumscribed lesion is responsible for intractable seizures and the relationship of the lesion to the seizures can be verified, surgical resection of the lesion and surrounding brain tissue can render the patient seizure free and improve the quality of life [8–13].

With accumulating experience, it has become evident that the neurological examination, electrophysiological studies, seizure types and response to antiepileptic medications may not be useful in predicting the nature of the underlying pathology. Longstanding partial epilepsy may be related to an indolent low-grade glioma with a clinical course indistinguishable from that of a non-neoplastic process. Lesional epilepsy can be associated with simple partial seizures, complex partial seizures or secondary generalized tonic–clonic seizures. It is the purpose of this chapter to elaborate on the current concepts concerning the diagnosis and surgical management of patients with epilepsy associated with neoplastic mass lesions. The lesion associated with epilepsy may warrant neurosurgical intervention because of the mass effect, growth or haemorrhage. In other cases, the lesions are static and benign with the neurosurgical significance being related to the intractable epilepsy only; it is this latter group that is the subject of discussion in this chapter. The results of surgical resection of the lesion with respect to seizure frequency, surgical morbidity and psychosocial outcome will be discussed. Seizures specifically associated with cortical dysplasias and vascular and infective lesions are discussed elsewhere in this textbook.

Partial or localization-related epilepsy

Partial or localization-related epilepsy is the most common seizure disorder in the adult patient, and the most frequently occurring seizure type is a complex partial seizure (CPS) [14–17]. Approximately 45% of patients with partial epilepsy will experience medically refractory seizures that are physically and socially disabling [14,16]. A minority of patients who fail to respond to first-line antiepileptic drug (AED) therapy will be rendered seizure free with newer medical treatments introduced in the past decade [14–16]. Epilepsy surgery is an effective alternative form of therapy for selected patients with intractable partial epilepsy [18–26]. Patients with mesial temporal lobe epilepsy and lesional epilepsy may be favourable candidates for epilepsy surgery and have a surgically remediable epileptic syndrome [19]. The majority of these patients experience a significant reduction in seizure tendency following surgical ablation of the epileptic brain tissue [18–26]. The hallmark pathology of mesial temporal lobe epilepsy is mesial temporal sclerosis (MTS) [27,28]. The surgically excised hippocampus in these patients almost invariably shows focal cell loss and gliosis [27,28]. Patients with lesional epilepsy may have a primary brain tumour, vascular anomaly or a malformation of cortical development (MCD) [10,11]. The common

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

primary brain tumours encountered in patients with partial epilepsy include a low-grade glioma, ganglioglioma, dysembryoplastic neuroepithelial tumour (DNET), and a mixed tumour with features indicating both a neoplasia and an MCD [29–42]. Individuals may also have dual pathology with MTS co-existing with the lesional pathology. Patients with primary intraparenchymal neoplasms almost invariably have an abnormal structural MRI study [10,11]. MRI in these individuals may detect a specific intra-axial structural abnormality that may suggest the likely site of seizure onset and the surgical pathology [10,11]. MRI has a pivotal role in the selection and evaluation of patients for alternative forms of therapy [22]. The rationale for the presurgical evaluation is to identify the site of ictal onset and initial seizure propagation, i.e. epileptogenic zone, and determine the likely pathological findings underlying the epileptic brain tissue [24,43]. In patients with an MRI-identified foreign tissue lesion or unilateral mesial temporal sclerosis, the purpose of the electroclinical correlation is essentially to confirm the epileptogenicity of the structural abnormality [10,11]. The demonstration of concordance between the pathological substrate and the ictal onset zone indicates a highly favourable operative outcome in selected individuals.

Mechanism of epileptogenesis associated with structural mass lesions

The mechanism(s) of epileptogenesis associated with brain tumours is unknown [44]. Hughlings Jackson [3] observed that the pathogenesis of epilepsy in patients with tumours was related to the presence of a slow-growing tumour in the grey matter and the 'sudden excessive and temporary discharge of nerve cells', producing seizure activity [44]. Penfield [44,47] suggested that impaired vascularization of the surrounding cerebral cortex may produce hypoxic–ischaemic neuronal changes. Direct 'irritation' of the cortex by a tumour has also been proposed as the aetiology of seizure activity. In the symptomatic partial epilepsies, a focal structural abnormality is intimately associated with the epileptogenic area, the site of seizure onset [43]. Specific morphological neuronal alterations related to a focal brain lesion, for example tumours, have been observed that are potentially epileptogenic. The pathophysiological mechanisms of ictogenesis associated with intracranial mass lesions are poorly understood. Early proposed mechanisms included impaired vascularization of the surrounding cerebral cortex and direct irritation of the brain and denervation hypersensitivity due to partial isolation and transection of a region of the cerebral cortex [45,46]. There is conflicting evidence regarding the contribution of hereditary predisposition in the development of epilepsy in patients with intracranial structural lesions [9].

The mechanisms of epileptogenesis for different pathological lesions must vary as some are extracerebral and others are intracerebral, some tumours are infiltrative into the brain and others distort it by mass effect. This suggests that the aetiology of seizures in various lesional pathologies is multifactorial involving factors intrinsic to the lesion itself, the location of the tumour and factors unique to the host harbouring the pathology.

Factors unique to a pathological lesion, particularly tumours, may be associated with the expression of various ion channels and receptors, and the relative proportion of different cell types within the tumour. Amino acid disturbances, local metabolic imbalances, cerebral oedema, pH abnormalities, morphological changes in the neuropil, changes in neuronal and glial enzyme and protein expression and immunological activity are all thought to contribute to the pathogenesis of lesional epilepsy syndromes. Future studies from pathological specimens and the development of animal models may further characterize the relative contributions of each of these factors in the development of lesional epilepsy syndromes [28,48–53]. In addition to properties of the tumours themselves, numerous studies have investigated the role of various properties of peritumoral tissue [53]. These investigations have focused on how tumours located in the brain disrupt signal processing. It has been proposed that the tumour either infiltrates into brain tissue or exerts a mass effect, and so transects inhibitory populations of neurones; this upsets the balance of excitatory and inhibitory output in favour of overstimulation, resulting in seizures. In defining the area of resective surgery, Rasmussen [18] identified a primary localization, which is the site of seizure initiation, and a secondary localization, which indicates the volume of tissue adjacent to the site of origin that must be recruited to produce a clinical seizure. The amygdala and hippocampus appear to be critical sites of secondary localization by providing synchronized output and amplifying an ictal discharge [54,55]. Seizures originating as far posteriorly as the occipital lobe may preferentially spread forward through the hippocampus [56]. Anterior temporal lobectomy can result in seizure relief despite the presence of a posteriorly located temporal lobe tumour [57–59]. This suggests that the effect of surgery depends not on the excision of the primary epileptogenic focus, but on the elimination of the recruitment of other cells for full seizure development and interruption of the neuronal pathways required for seizure propagation. Histological studies have demonstrated gliosis or sclerosis of the mesial temporal structures in patients with medically resistant complex partial seizures and small vascular or neoplastic lesions in more posterior parts of the temporal lobe [60–64]. However, in 216 consecutive surgical specimens from patients with chronic, medically intractable temporal lobe epilepsy (TLE), Ammon's horn sclerosis was significantly more common in patients without focal mass lesions than those with focal lesions [49]. Dual pathology, if present, may produce a combination of neocortical and temporolimbic epilepsies (TLME) that necessitate a precise definition of the true epileptogenic area(s) in order to achieve maximum benefit from surgery [65].

Pathology: neoplastic lesions

Seizures occur in approximately 50% of patients with intracerebral neoplasms [6,18]. The incidence of seizures among patients with primary brain tumour is related to the tumour pathology and cortical localization (Table 70.1) [47,66]. Slow-growing, low-grade and well-differentiated gliomas are the most epileptogenic

Table 70.1 Primary brain neoplasms associated with seizures.

	Main characteristics	Neuroimaging characteristics
Pleomorphic xanthoastrocytoma (PXA)	Rare, but common in the epilepsy population Seen in the first three decades of life Two-thirds of cases occur in patients under the age of 18 years Most patients have a long history of seizures	Preferentially involves the peripheral temporal lobes Leptomeningeal attachment or adhesion is common with a base at the meninges and is seen in over 70% of cases Cysts form in one-third to one-half of cases Discrete mural nodule is often seen abutting the meninges Calcification is unusual Mural nodule often enhances May remodel overlying skull
Ganglioglioma	Contain both neuronal and glial elements Rare, accounting for 0.5–1% of all central nervous system neoplasms Common in the epilepsy population Overall 60–80% occur in patients under the age of 30 years Most are symptomatic in the second decade Chronic seizures are the most common symptom Epilepsy is resistant to medication 90% of the time	Most commonly involve the temporal lobe Cyst formation occurs in 38–50% of patients Often associated with a mural nodule Calcifications occur in 30% of cases Surrounding oedema is minimal Enhancement pattern varies from none to striking When peripheral, often associated with bony remodelling of the skull Can be associated with focal cortical dysplasia
Dysembryoplastic neuroepithelial tumour (DNET)	Rare, but common in the epilepsy population Often present in the second and third decades of life Male to female ratio 1 : 1 Usually cause seizures that can be refractory	Most commonly found in the temporal lobes Often wedge-shaped, cortical mass with multiple cysts May extend towards the ventricle Calcification in 20–36% of cases Usually no surrounding oedema Usually no enhancement May remodel overlying bone Over 50% are accompanied by focal cortical dysplasia
Oligodendroglioma	Uncommon, constituting 5–10% of gliomas Minority of tumours are anaplastic Generally occur in the fifth and sixth decades of life Male to female ratio 2 : 1 Most common symptom is seizure owing to cortical involvement	Strong predilection for subcortical white matter in the frontal and temporal lobes Heterogeneous hemispheric mass Foci of cystic degeneration are relatively common, but haemorrhage and necrosis are less frequent Calcification occurs in 70–90% of cases Enhancement pattern can be mild to moderate and inhomogeneous Remodelling of overlying skull can be seen
Low-grade fibrillary astrocytoma	Occur less frequently than high-grade lesions Uncommon with true incidence difficult to determine secondary to sampling and grading variability Represent 10–15% of gliomas Often occur between 20 and 40 years of age Seizures are a common presenting symptom	Focal or diffuse mass May have cystic degeneration, although necrosis/haemorrhage/oedema rare Calcification occurs in 15–20% of cases Enhancement can be absent or mild Erosion of the adjacent skull may occur
Pilocytic astrocytoma	Occur less frequently than high-grade lesions Represent 5–10% of gliomas Often occur in children or young adults with cerebral forms having a peak incidence at age 20 years Seizures are a common presenting symptom	Characteristically located around third and fourth ventricles, though can occur in cerebral hemispheres Solid or cystic mass Calcification occurs in 10% of cases Variable surrounding oedema Enhancement pattern varies

lesions (see Figs 70.1–70.6) [47,66]. In the Montreal series of 230 patients with gliomas, seizures occurred in 70% of those with astrocytomas, in 92% of those with oligodendrogliomas and in 37% of those with glioblastomas [47]. The incidence of epilepsy is lower in patients with glioblastoma, perhaps because of the shorter duration of the disease. These more aggressive lesions, including cerebral metastasis, are associated with a risk of seizures in the range of 20–30% [47].

Tumours located in close proximity to the centrotemporo-parietal region are more frequently associated with epilepsy [18,47,66]. Nearly 75% of the epileptogenic neoplastic lesions are located in or involve the temporal lobe [8,9]. Lesions in the frontal lobe are at least as frequent as lesions in the temporal lobe in patients with neoplasms who do not have seizures [67]. This discrepancy is possibly related to the lower seizure threshold of the temporal lobe, and also to the fact that patients with temporal

lobe partial seizures are more likely to be referred for surgical treatment of epilepsy [9–11]. In a recent series from the Cleveland Clinic consisting of 133 patients who underwent operations for extratemporal epilepsy, tumours were identified in 27.8% of cases; these included, in order of decreasing frequency, astrocytoma, ganglioglioma, dysembryoplastic neuroepithelial tumours (DNETs), glioneuronal hamartomas, oligodendrogliomas and oligoastrocytoma [68].

Brain tumour as a cause of chronic epilepsy

Computed tomography studies in patients with epilepsy have demonstrated a neoplasm in 10–25% of patients with onset of seizures after the age of 40 years and in fewer than 5% of children [69]. During presurgical evaluation of 190 patients with intractable partial epilepsy, Spencer *et al.* [8] detected 15% with a mass lesion, 10% of which were neoplasms. Low-grade gliomas are the most frequent pathological lesions, accounting for nearly 50–70% of all lesions and 70–90% of neoplasms [18,47,66]. Because of differences in the selection and histopathological criteria used in the ascertainment of these lesions, the distributions of the neoplasms according to type have varied widely between series. Nevertheless, indolent or slow-growing glial or neuronal tumours constitute the majority. Although tumours occur more frequently in patients with an onset of epilepsy during adulthood, brain tumours also remain an important cause of intractable epilepsy in children and adolescents as well [32,33]. In a series of 33 children who underwent temporal lobectomy at an average age of 8 years, 48% were diagnosed as having tumours [34].

Gangliogliomas

Gangliogliomas are mixed tumours that are composed of neoplastic glial and neuronal cell types (Figs 70.1 and 70.2) (Table 70.1) [35]. They constitute 10–50% of the neoplasms associated with medically intractable partial epilepsy [35–39]. Seizures are the primary presenting symptom in 80–90% of patients with gangliogliomas [38,39]. Among 11 patients with gangliogliomas, the age at diagnosis ranged between 4 and 69 years [39]. Seizures often occur years before the tumour is detected [37].

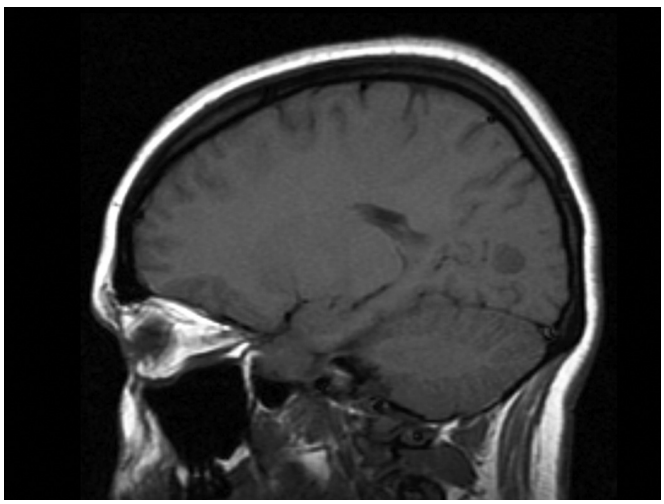

Fig. 70.1 MRI reveals a tumour in the left occipital region in a patient with intractable epilepsy. Pathology revealed a ganglioglioma. There was no recurrence of seizure after resection (sagittal plane T1-weighted image).

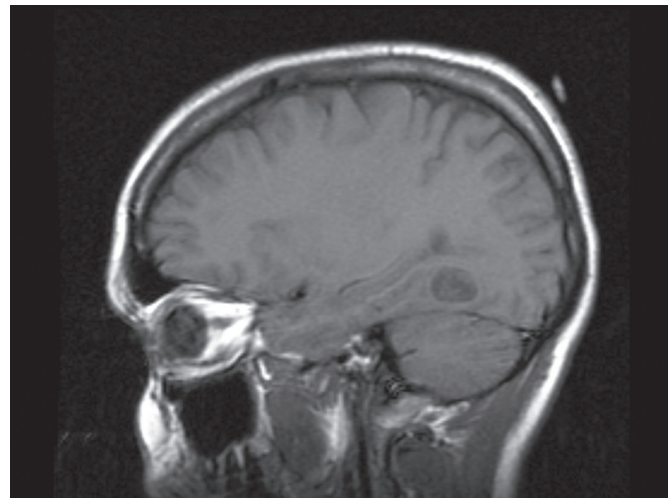
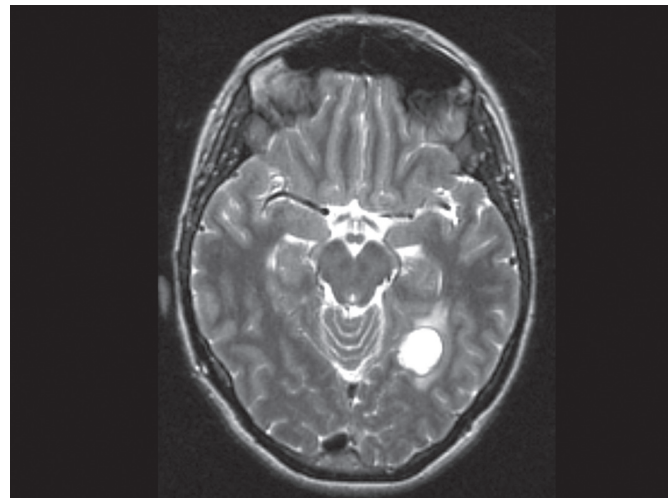
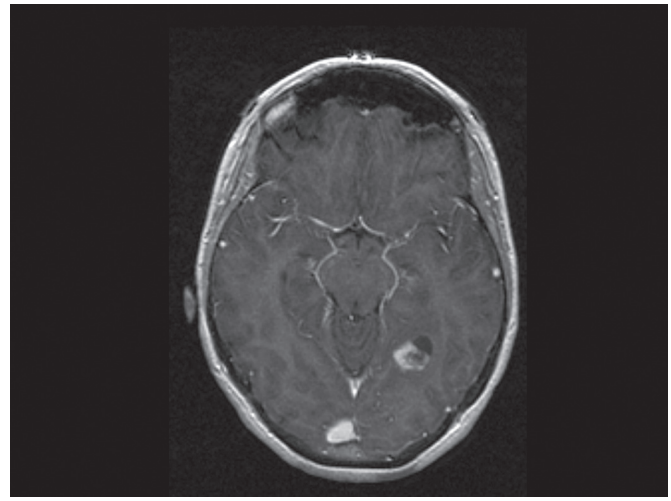


(a)



(b)



(c)

Fig. 70.2 (a and b) MRI in a patient with intractable epilepsy reveals a lesion in the left posterior temporal–occipital region. A lesionectomy was performed. The pathology revealed a ganglioglioma. Partial enhancement of the lesion is noted (c). The patient was rendered seizure free following resection of the tumour. Note: the left side of the brain is on the right side of the figure. (a) Sagittal plane, T1-weighted image. (b) Axial plane, T2-weighted image. (c) Axial plane, T1-weighted image after gadolinium-diethylenetriamine penta-acetic acid.

These tumours are located within the temporal and frontal lobes in most cases [35–39]. Mesial temporal sclerosis was identified in the hippocampus of the excised temporal lobe in 7 out of 13 children with gangliogliomas and intractable seizures [41]. The surgical approach to resect gangliogliomas, therefore, requires careful preoperative evaluation to delineate the extent of the epileptogenic zone.

Dysembryoplastic neuroepithelial tumours

These morphologically unique and surgically curable neuroepithelial tumours are included in the group of neuronal/glial tumours, grade I, in the new World Health Organization (WHO) classification (Table 70.1) [35]. In one recent series, DNET constituted 8% of the lesions in a sizeable number of patients with neoplasms and chronic medically intractable epilepsy (Figs 70.3 and 70.4) [49]. By contrast, in a recent Maudsley Hospital series, 90% of the neoplasms were interpreted as DNET [36].

In a group of 39 patients with DNET, age at onset of seizures ranged from 1 to 19 years (mean 9 years), and the duration of seizure prior to surgery averaged 9 years (range 2–18 years) [58]. The tumour involved the temporal lobe in two-thirds of patients and the frontal lobe in one-third of patients; parietal and particularly occipital involvement was infrequent [51,58].

Presurgical evaluation

Finding an intracerebral lesion in a patient with recurrent seizures does not necessarily mean that this structural abnormality is producing the seizure activity. The main purpose of the presurgical evaluation in patients with intracranial lesions and intractable seizures is to confirm the relationship between the lesion and the seizure foci. In some patients, the epileptogenic focus is contiguous with but extends beyond the structural lesion [8–11]. The lesion may occasionally be incidental and bear no causal

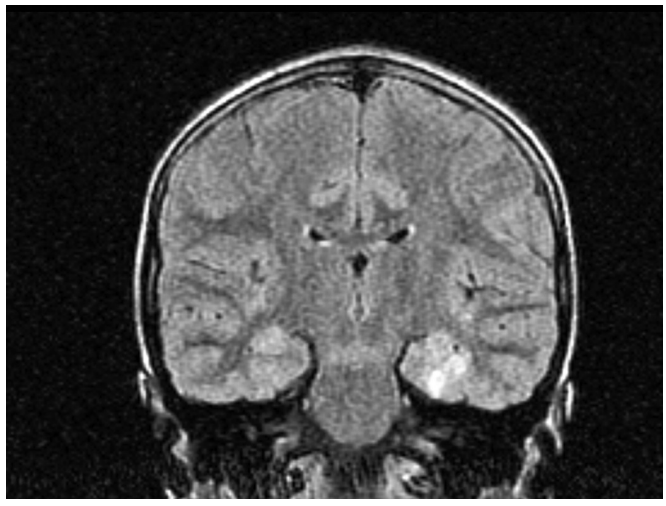


Fig. 70.3 Oblique coronal plane, fluid attenuated inversion recovery sequence. MRI shows a left medial temporal lobe lesion. A lesionectomy and anterior temporal lobectomy was performed. The pathology revealed a dysembryoplastic neuroepithelial tumour. The patient continued to experience recurrent seizures after resection of the tumour. Note: the left side of the brain is on the right side of the figure.

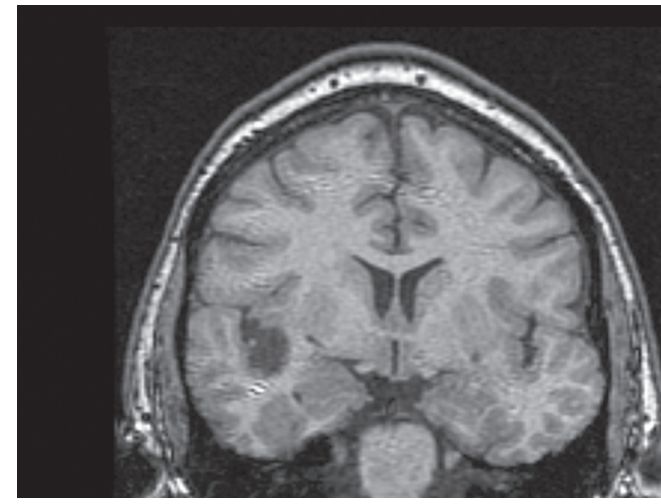
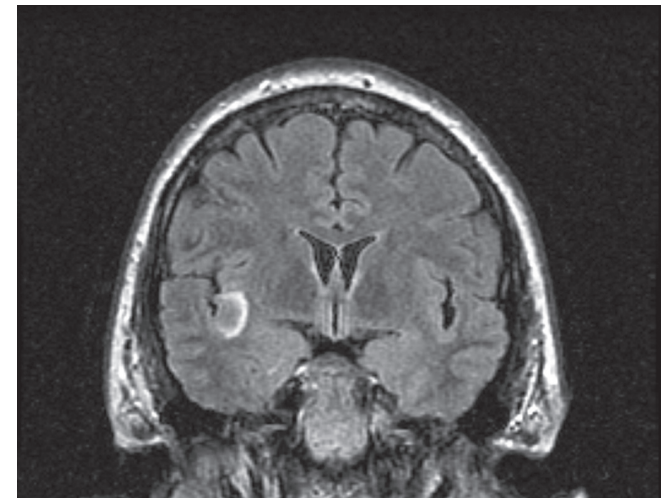
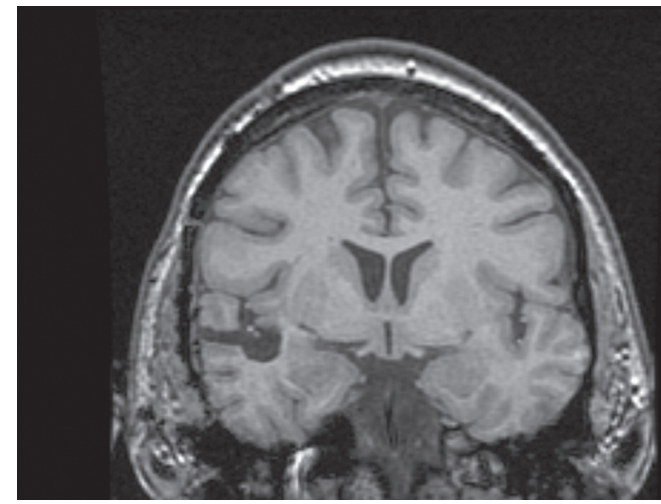


(a)



(b)



(c)

Fig. 70.4 MRI reveals a right insular lesion in a patient with intractable epilepsy (a,b). The patient underwent complete resection of the lesion (c). The pathology was a dysembryoplastic neuroepithelial tumour. The patient was rendered seizure free. Note: the right side of the brain is on the left side of the figure. (a) Oblique coronal plane, T1-weighted image. (b) Oblique coronal plane, fluid attenuated inversion recovery sequence. (c) Oblique coronal plane, T1-weighted image.

relationship to the epileptogenic focus. Therefore, the understanding of spatial and causal relationship between structural lesions of the brain and intractable epilepsy is essential in planning therapeutic strategies. The preoperative evaluation in patients with substrate-directed partial epilepsy is designed to determine the epileptogenicity of structural abnormalities identified by MRI or other imaging modalities.

Duration of epilepsy

Douglas [70] found that the risk of neoplasm declined precipitously with duration of the epilepsy, whereas Vignaedra *et al*. [71] found no differences in epilepsy duration among patients with and without neoplasms. The majority of patients with lesional epilepsy previously considered for surgery have had seizures for more than 10 years [8–10]; however, today, with the availability of MRI, patients with lesional epilepsies are operated on earlier [11]. No significant difference in the duration of seizures has been observed between patients with neoplastic and non-neoplastic lesions [8–11].

Clinical seizure characteristics

Lesional epilepsy may be associated with simple partial, complex partial or secondary generalized tonic–clonic seizures [8–11]. The most frequent seizure type associated with lesional epilepsy is the CPS [72]. Thirty-four of the 50 patients with intractable seizures associated with space-occupying lesions reported by Boon *et al*. [9] had auras, most frequently epigastric sensations. With the exception of visual auras in patients with occipital lesions, the characteristics of the aura did not help in the localization of the lesion [9].

The most frequent seizure type associated with lesional epilepsy is the complex partial seizure. Williamson [72] has described ictal features of CPS arising from different lobes. Among 50 patients with lesional epilepsy, all of them with a temporal lobe lesion had CPS; however, 74% of patients with extratemporal lesions also had CPS [9]. Seventy-five per cent of patients with temporal lobe lesions had typical temporal lobe seizures [9]. An equally good correlation was shown in patients with frontal and occipital lobe lesions but not in patients with parietal lobe lesions [9]. Seizures originating in the parietal lobe can mimic frontal and temporal lobe seizures [72]. A simple partial seizure as a manifestation of a lesional syndrome, either alone or with CPS or tonic–clonic seizures, was found to be nearly always associated with neoplasms by several workers [8,9]. A change in seizure frequency was not found to be a reliable indicator of a cerebral neoplasm [8]. However, after successful treatment, return of seizures has been an indicator of tumour recurrence that may not be detected radiologically for several months [8,9].

History and examination

A careful history should be taken in all patients, with particular attention to a history of febrile seizures, developmental milestones, head trauma and previous neurological problems. Boon *et al*. [9] noted no significant difference in the frequency of febrile seizures in patients with intra-axial space-occupying lesions and intractable seizures when compared with the general population. Sixteen per cent of the patients with space-occupying lesions and intractable epilepsy had a positive family history of epilepsy, which may indicate an increased susceptibility to seizures in these patients [9]. A thorough neurological examination can detect abnormalities such as a mild hemiparesis or visual field defect that may assist in clinically lateralizing the epileptogenic zone. Facial weakness, especially during emotional expression, may occur in patients contralateral to the epileptic temporal lobe and is uncommon in normal subjects [73,74]. However, clinical examination is non-contributory in most of these patients as a majority of the lesions are small and are detected before any gross mass effect appears.

Age at onset of seizures

Although earlier studies found a low incidence of tumours in patients with onset of seizures before the age of 20 years [75,76], more recent data suggest that refractory partial seizures, even before the age of 20, should raise suspicion of an intracranial mass lesion [8,9]. Blume *et al*. [32] found tumours in 46% of patients under the age of 21 who had undergone surgery for chronic uncontrolled seizures. Among a group of 27 patients with intracranial mass lesions and medically refractory partial epilepsy, age at onset of seizures was the same for neoplastic and non-neoplastic lesions [8]. In a selected series of operated cases, Boon *et al*. [9] found that 78% of their patients who had a neoplasm had seizure onset after the age of 20; however, 70% of patients with seizure onset before the age of 20 also had a neoplasm.

Routine electroencephalogram recording

The occurrence of interictal focal sharp and/or focal slow activity in patients with an intracranial space-occupying lesion has been extensively documented [23]. In patients who presented with intractable epileptic seizures as the main feature of an intracerebral mass, nearly two-thirds had an abnormal electroencephalogram (EEG), and epileptiform activity is more common than slow waves [23]. The absence of prominent focal slow-wave activity in this patient population is mainly a result of the limited circumscribed character of most of these lesions. However, when present, a unilateral focal interictal abnormality was a reliable predictor of, at least, the side of the lesion.

The spatial distribution of the focus coincided with the lesion localization in only 30% of the patients, especially with occipital lesions [77,78]. Epileptiform activity localized by scalp electroencephalography distant from the site of a structural lesion is not uncommon. Salanova *et al*. [77] found that, in a group of patients with frontal lobe epilepsy, scalp electroencephalography provided misleading localizing features in nearly one-third of cases. Patients with temporal lobe lesions were not significantly more likely than extratemporal patients to have an ipsilateral temporal spike or sharp wave focus. Extracranial, interictal and ictal EEG changes were found to be unreliable markers of parietal lobe origin of seizure activity [77,78]. Poor interictal scalp localization has been attributed to the fact that the recorded focal abnormality may be only a part of a deeply localized, more extended focus that propagates to the surface.

The occurrence of bilateral independent sharp waves and spikes in patients with epilepsy has been well recognized [79–81]. In the absence of a detectable lesion, this finding can lead to a decision not to operate on a patient with intractable partial seizures. However, it has been demonstrated that this EEG finding does

not correlate with a poor outcome [81,82]. Nearly 20% of the patients with unilateral structural temporal lobe lesions may show this EEG abnormality, and bilateral independent temporal paroxysmal activity has been observed in patients with extratemporal lesions as well [11].

Long-term video-electroencephalogram monitoring

Long-term video-EEG monitoring may reveal interictal focal paroxysmal epileptiform activity but may be normal or show non-specific changes. Continuous video-EEG monitoring with recording of habitual seizures and careful analysis of the recorded seizures and the simultaneous recorded EEG allows good correlation of clinical events with electrical phenomena. Proper classification of seizure type can be made on the basis of specific, stereotyped signs and symptoms during the attack and the findings on the scalp EEG. In most patients with intracranial lesions detected with neuroimaging, the additional information gathered by scalp EEG-video monitoring is sufficient to consider the lesion as the cause of the epilepsy, and those patients can proceed to surgery without invasive monitoring.

Neuroimaging

Advanced neuroimaging is arguably the most important aspect of the presurgical evaluation of patients with lesional epilepsy because it provides information about the exact location and extent of the lesion. Two structural neuroimaging modalities are used in the identification of potential candidates with intractable partial epilepsy for resective surgery: CT and MRI. The diagnostic yield of the neuroimaging studies depends on the underlying pathology and the anatomical localization of the epileptogenic area. The selection of patients for epilepsy surgery, the presurgical evaluation and the surgical strategy will be greatly influenced by the neuroimaging-identified lesion [8–11].

The importance of imaging patients with intractable epilepsy was obvious shortly after the introduction of CT [83]. However, the limitations of CT in detecting small, benign lesions usually associated with long-standing medically intractable epilepsy soon became apparent [84]. A normal CT scan may not exclude a low-grade glioma, cryptic arteriovenous malformation (AVM), hamartoma or focal cortical dysplasia. In the absence of MRI, CT is a valuable part of the presurgical evaluation of patients with partial seizure disorders. CT may complement MRI in selected patients with bony lesions and calcified intracranial abnormalities. In developing countries, where the availability of MRI is very limited, CT remains the radiological investigation of choice in lesional syndromes.

Investigators at Nottingham University first applied MRI to the study of the brain in 1980 [85]. MRI is the structural neuroimaging modality of choice in patients with intractable partial epilepsy. MRI has been shown to be superior in sensitivity and specificity to CT in identifying the intra-axial structural abnormalities that are associated with partial epilepsy [86,87]. Neoplastic, vascular and infective mass lesions are almost always associated with an MRI-identified abnormality [88–91]. In addition, particular MRI characteristics may help identify the underlying pathology and can demonstrate associated features of calvarial moulding, focal atrophy/encephalomalacia or mass effect. In essence, MRI has been the most successful modality in separating patients with intractable partial epilepsy into two groups: those with substrate-directed and those with non-substrate-directed disease [91]. Patients with substrate-directed or lesional disease have one or more potentially epileptogenic structural abnormalities that may be co-existent with the epileptogenic zone [91].

MRI has been demonstrated to be the most sensitive and specific structural neuroimaging procedure in patients with partial or localization-related epilepsy [11,86–91]. Importantly, MRI is a non-invasive technique that has no known biological toxicity and does not involve ionizing radiation. The presence of an MRI-identified structural abnormality, i.e. MRI-positive partial epilepsy, may suggest the localization of the site of seizure onset [86]. The high diagnostic yield of MRI to delineate foreign tissue lesions, e.g. tumour or vascular malformation, has been confirmed (Table 70.2). MRI findings have been used to select favourable candidates for epilepsy surgery, tailor the operative resection, and confirm the extent of corticectomy postoperatively. The optimal technique in adult patients with partial epilepsy must include coronal or oblique-coronal images using T1- and T2-weighted sequences. Gadolinium-enhanced MRI studies may be useful in patients with primary brain tumours (Fig. 70.2). Selected tumours may be more likely to demonstrate pathological enhancement. Fluid attenuated inversion recovery (FLAIR) sequences have also been shown to increase the sensitivity of MRI to indicate a signal change in patients with foreign tissue pathology.

Table 70.2 MRI and primary intraparenchymal neoplasms.

	PXA	Ganglio	DNET	Oligo	Fibrillary astro	Pilocytic astro
T1 image (intensity)	Hypo, iso	Hypo, iso, sometimes hyper	Hypo	Hypo, iso	Hypo, iso	Solid-hypo, iso; cystic-iso, hyper
T2 image and FLAIR (intensity)	Hyper	Hyper	Hyper (bright rim on FLAIR)	Hyper	Hyper	Solid-hyper; cystic-iso, hyper
Enhancement	+/– (rim and nodule enhance)	+/– (variable)	+/– (faint, punctate in 20%)	+ (patchy and moderate)	+/– (inhomogeneous)	+/– (variable)
Unique features	Cystic, peripheral nodule	Partially cystic enhancing mass	Well-demarcated, wedge-shaped, septations	Calcified with cystic changes and enhancement	Enhance = malignant change	Cystic with enhancing mural nodule

DNET, dysembryoplastic neuroepithelial tumour; fibrillary astro, low-grade fibrillary astrocytoma; FLAIR, fluid attenuated inversion recovery; ganglio, ganglioglioma; oligo, oligodendroglioma; pilocytic astro: pilocytic astrocytoma; PXA, pleomorphic xanthoastrocytoma.

In an evaluation of 23 patients who underwent both MRI and CT of the head preceding surgery for medically intractable epilepsy, patients with normal MRI all had non-neoplastic lesions [86]. In contrast, in this selected series, all patients with foci of increased signal on T2-weighted MRI images had neoplasms, even when CT was negative. MRI studies are useful for surgical localization and have variable sensitivity and specificity for the major pathological entities, but both are usually greater than 90%, and the diagnostic yield of these lesions has been confirmed in surgical series [86–93]. MRI studies may also be performed to confirm the extent of corticectomy and lesion resection postoperatively.

As stated above, the most common presenting symptom in patients with low-grade and slow-growing primary brain tumours is epilepsy. MRI will reveal a structural intra-axial abnormality in the majority of these patients [92–95]. Imaging features common to all these tumours include the presence of a cortically based lesion, with sharply defined borders, little or no surrounding oedema and, with the exception of pilocytic astrocytomas or gangliogliomas, little or no contrast enhancement. Some lesions may have characteristic, distinguishing features. For example, gangliogliomas are often associated with a cystic lesion and a mural nodule. Although MRI is highly sensitive in detecting neoplasms, it is not specific to particular histopathology. Primary resection of these MRI-identified lesions is associated with a seizure remission in 80–90% of patients [9,10].

MRI-based volumetric measurement of the hippocampal formation [96,97] may provide additional information about the possible sites of epileptogenesis in patients with mass lesions. In a recent study, MRI-based volumetric measurements of the hippocampal formations were correlated with seizure outcome after temporal lobectomy [98]. Volumetric measurements of the hippocampi should now be routine in lesional epilepsy in order to characterize the possible extent of the epileptogenic zone(s), especially given the possibility of dual pathology.

Several centres have incorporated MRI-compatible implantation frames to provide accurate anatomical information for use with intracranial depth electrodes [99,100]. Quantitative MRI-based techniques to assess the extent of cortical resection, and thereby to correlate the extent of resection and patient outcome, have been developed [101,102].

Neuropsychological assessment

A battery of standard neuropsychological tests, aimed at lateralizing and localizing the area(s) of functional abnormality, is administered during preoperative evaluation of patients with intractable seizures [103,104]. In a recent study of patients with intra-axial space-occupying lesions with intractable partial seizures, lateralized neuropsychological findings were congruent with the lesion in 56% but incongruent in 14%; furthermore, localization corresponded with the lobe of the lesion localization in 26% but did not correspond in 30% [9]. Incorrect localizing findings from neuropsychological testing were more frequent when lesions were extratemporal [9].

Intracranial electroencephalogram monitoring

Patients may require invasive monitoring if the results from all previous procedures are conflicting [105,106]. Invasive monitoring is defined as the long-term recording of EEG from subdural and/or intraparenchymal brain areas using intracranial electrodes. This recording technique is generally required in patients with stereotyped partial seizures in whom no consistent epileptiform focus could be demonstrated during the non-invasive monitoring. In patients with known lesions, a subdural or epidural grid consisting of a thin layer of silastic with numerous embedded electrodes is laid over the cerebral cortex in proximity to the neuroimaging-identified lesion [105,106].

However, in addition to morbidity, the apparent lack of sensitivity in localization, especially when subdural grids are placed directly over the epileptogenic lesion, is well documented [11]. Several authors have reported the poor yield of extracranial and intracranial EEG recordings in patients with an epileptic lesion in the parietal lobes [22,79]. Cascino *et al*. [22] studied a group of 11 patients with seizures associated with lesions in the parietal lobe. Out of five patients with a parietal lesion who underwent intracranial monitoring with depth and/or subdural electrodes in an attempt to localize the region of ictogenesis, parietal lobe origin was documented in only two. MRI detected the lesion in all. The authors recommended lesionectomy without chronic intracranial monitoring as an effective and safe surgical procedure in patients with partial epilepsy related to parietal lobe lesions [22].

Functional mapping

The importance of physiological identification of functionally important areas is being increasingly recognized in neurosurgery. Functional imaging of the brain may provide information which may be complementary to that provided by EEG and structural neuroimaging studies. In addition, when neurosurgical procedures are planned in neocortical sensory, motor or speech areas, functional mapping is performed to circumscribe these areas and avoid an unacceptable neurological deficit post surgery. Functional imaging proves most useful when structural pathology cannot be visualized on MRI.

Single photon emission computerized tomography

Computer-aided subtraction ictal and postictal imaging single photon emission computed tomography (SPECT) co-registered to MRI (SISCOM; subtraction ictal single photon emission computerized tomography co-registered to MRI) is a recently developed neuroimaging technique that localizes cerebral blood flow abnormalities and may identify the epileptogenic region, minimizing some of the inherent limitations of direct side-by-side visual comparison of the SPECT and MRI separately [107–111]. The technique utilized at the Mayo Clinic consists of computer-aided subtraction of the co-registered normalized interictal SPECT from the normalized ictal SPECT, followed by the co-registration of the image difference to the MRI. This provides a more sensitive and specific, semiquantitative map of the cerebral blood flow during a seizure.

In a study by O'Brien *et al*. [110] interictal and ictal side-by-side visual interpretation was compared with SISCOM in 51 patients with intractable epilepsy. SISCOM revealed a localized alteration in cerebral perfusion in 88.2% of patients compared with 39.2% of patients using side-by-side visual interpretation. This method has also been shown to be more specific, as determined by con-

cordance with long-term EEG monitoring. The functional change is concordant with the ictal onset zone in approximately 80% of patients [109–111].

Patients with non-lesional extratemporal seizure disorder have recently been found to have a localized SISCOM alteration in 75%. Many patients with extratemporal epilepsy have inconclusive long-term video-EEG monitoring and no lesion on the MRI. SISCOM has its greatest potential in these more difficult cases for localization of the seizure onset.

Detection of peri-ictal hypo- or hyperperfusion localized abnormalities has been shown to reliably locate an epileptogenic focus and select the patients for operative resection. A localized cerebral blood flow abnormality at this potential epileptogenic focus provides a preliminary map and guides the placement of subdural grids/electrodes. Furthermore, the SISCOM images can be transferred across a computer network to the surgical suite where a frameless stereotactic surgical navigation system can be used to localize the SPECT activation in the surgical field intraoperatively. This technique may potentially play an important role in identifying the optimal amount of cortical resection related to epileptogenic lesions.

A recent study from the Mayo Clinic investigated (a) whether the localization of extratemporal epilepsy with the SISCOM technique is predictive of outcome after resective epilepsy surgery; (b) if the SISCOM images provide prognostically important information in addition to those provided by the standard tests; and (c) whether the area of blood flow change on SISCOM images is useful in determining the site and the extent of the excision required for successful postoperative seizure control [107–111]. The concordance of the SISCOM focus with the site of surgery was predictive of an excellent postoperative outcome. Overall, 38.9% had an excellent postoperative outcome and 72.2% had at least a favourable outcome. All patients with excellent outcome except one were seizure free. The exception was a patient who had rare nocturnal seizures. SISCOM localization was concordant with the site of the surgical excision in 52.8%, non-concordant in 13.9% and non-localizing in 33.3%. The concordant SISCOM group had significantly higher rates of excellent and favourable outcome than the other groups. This study also found that one-half of the patients whose ictal scalp EEG was non-localizing had localizing SISCOM abnormalities. These results strongly argue that SISCOM provides localizing information that is in addition to and not redundant for that provided by the more standard tests.

The importance of SISCOM localization in determining surgical outcome has been confirmed in intractable extratemporal epilepsy. Further analysis of these data revealed that the extent of excision of the SISCOM focus is predictive of the success of the surgery. Concordance of the SISCOM focus with the surgical site and the extent of the excision are the only two predictors of the excellent outcome. Many of the patients in this study had SPECT studies because their seizures were not well localized with more standard tests.

Positron emission tomography

Interictal or peri-ictal positron emission tomography (PET) using 2-[^{18}F]fluoro-2-deoxyglucose (^{18}F-FDG) is included routinely in the presurgical evaluation protocols of many adult and paediatric epilepsy surgery programmes [112,113]. However, PET findings characterized by the increased or decreased uptake of FDG reflect not only the neuronal activity at the site of the ictal onset but also in areas of ictal spread and postictal depression.

Positron emission tomography, when used in the presurgical evaluation of patients with epilepsy, employs either measurements of tissue oxygen consumption (radionuclide ^{18}F-FDG) and/or blood flow [radionuclides $H_2{}^{15}O$ (radioactive water) or ^{15}O]. Tomographic reconstruction locates the sources of gamma ray photons produced after annihilation of the oppositely charged electron and positron that are emitted by the radionuclide. Interictal PET scans may reveal areas of reduced glucose uptake (hypometabolic foci) that correspond to potentially epileptogenic zones.

During a seizure, glucose uptake increases in the area of reduced uptake identified during the interictal scan. The localization of these zones of increased metabolic activity during a seizure is difficult to the point of being impractical. FDG uptake takes place 30–45 min after injection. The seizure must occur early in this period of radionuclide uptake for the focus to be identified. Additionally, FDG has a short half-life. requiring a continuous supply of the isotope during this time. Since seizures are unpredictable, timing limits the utility of ictal PET in localizing seizure foci.

Interictal PET has been shown to be more sensitive than MRI in detecting foci of gliotic tissues with decreased metabolic uptake of FDG. However, gliotic tissue does not necessarily correlate with an epileptogenic region. Only one-third of patients with extratemporal seizures have relevant hypometabolic abnormalities concordant with an abnormal EEG focus [114,115]. These regions of hypometabolic activity are frequently widely distributed and poorly localized [116].

Overall, published clinical series indicate that FDG-PET does not appear to provide additionally clinically useful information in the majority of patients with epilepsy. The continuing development of PET technology may enhance its utility in the evaluation of patients undergoing surgery. The development of receptor-specific ligands (such as ^{11}C-flumazenil) to improve the accuracy of defining seizure foci may lead to future studies relating PET localization to seizure outcome after surgical resection [117–119]. The usefulness of PET in the presurgical evaluation of lesional syndromes will be judged by its sensitivity, specificity and cost compared with other procedures, and how the information provided by PET contrasts with other relatively inexpensive techniques used in presurgical evaluation and in predicting the postsurgical outcome. As PET and other diagnostic technologies are in the process of continuous evolution and improvement, the role of PET in the evaluation of medically intractable lesional epileptic syndromes is unlikely to be settled in the near future.

Magnetic resonance spectroscopic imaging

Whole-brain magnetic resonance spectroscopy imaging (MRSI) is being developed as a functional neuroimaging modality. The usefulness of this imaging technique in the assessment of patients with focal epilepsy is being assessed. In a recent study, phosphorus MRSI correctly lateralized the epileptogenic foci in all eight patients, including a patient with a medial frontal focus [120].

Magnetoencephalography

Magnetoencephalography (MEG) requires complex and costly recording methodology but allows simple interpretation of the field of brain electrical activity [121]. This technique has been shown to map human auditory cortex [122], locations of cortical response to pain and primary and secondary somatosensory cortex [123,124]. With improvement in technology and the availability of simple and less expensive equipment, such localization and quantification of the brain region by non-invasive field measurement may have a major impact in the presurgical evaluation of mass lesions located close to the vital cortical areas.

Invasive cortical mapping

Since the pioneering studies of Penfield and Jasper [7], it has been demonstrated that cortical stimulation of discrete brain areas during neurosurgical procedures is a useful technique for mapping brain areas close to the epileptogenic foci [10,125,126]. Cortical mapping before tumour resection may be required to identify regions involved in critical functions. Because lesions distort the normal topography of the cerebral cortex and vascular landmarks may vary between individuals, cortical mapping may be required to identify regions involved in critical functions. Cortical stimulation techniques have been applied during resection of AVMs and tumours within the language-dominant hemisphere of patients with medically intractable epilepsy [10,125].

Mapping can be done intraoperatively, but this requires that the surgical procedure be carried out under local anaesthetic [125,126]. Alternatively, mapping can be done preoperatively using an implanted subdural electrode array to record both interictal and ictal electroencephalography and to stimulate the cortex at different contact points [10,127]. A major advantage of the grid system is that the patient can fully cooperate in a non-surgical environment and a more elaborate series of functional tasks can be evaluated. Subdural grids of electrodes have also been used for recording cortical somatosensory evoked potentials by stimulating a peripheral nerve to locate the primary somatosensory cortex and to delineate the location of the central fissure.

Electrocorticography

Controversy exists regarding the usefulness of intraoperative electrocorticography (EcoG) to identify and resect the seizure foci versus tumour removal alone. Berger *et al*. [128] analysed 45 patients with low-grade gliomas and intractable epilepsy who underwent EcoG during surgery. Multiple versus single seizure foci were more likely to be associated with a longer preoperative duration of epilepsy. Postoperatively, 41% of the adults and 85% of the children were seizure free without any antiepileptic medication, with a mean postoperative follow-up of over 50 months. Based on their experience, Berger *et al*. [128] advocate EcoG as a useful predictor of seizure outcome in patients with a long-standing seizure disorder. In contrast, among the Maudsley Hospital series of 31 patients who underwent temporal lobectomy for tumour-related epilepsy, postoperative relief of seizures could not be predicted by intraoperative EcoG [36]. The authors routinely perform intraoperative EcoG during resection surgery for epilepsy.

Treatment

Indications for surgery

The widespread and increasing availability of sensitive, non-invasive and neuroimaging techniques means that patients with epilepsy are more likely to be imaged for a structural lesion. The identified lesion may require resective surgery either because of the epileptic seizures refractory to AED or for pathological verification before additional treatment, such as radiotherapy, can be administered.

Patients with medically intractable epilepsy

All patients with medically intractable epilepsy detected by neuroimaging should have 2 years of observation on adequate AED coverage prior to consideration of epilepsy surgery; however, socially disabling seizures, even of 1 year's duration, may necessitate a referral for surgery. Unnecessary AED toxicity and delay in initiating a surgical evaluation may increase a patient's psychosocial debilitation. In contrast, a lesion involving functional cortex may be associated with increased neurosurgical morbidity and surgical management may be deferred.

Patients with well-controlled recent onset or infrequent seizures

Seizure was the first symptom in 164 of 560 patients with a CT diagnosis of supratentorial intra-axial brain tumours [129]. Patients presenting with epilepsy are more likely to have a low-grade tumour associated with a prolonged survival (Fig. 70.5) [8,145]. In these instances, surgery is performed not for the management of epilepsy but to establish a histological diagnosis. It remains controversial whether resection of the tumour either reduces the risk of mortality or improves long-term survival or the control of epilepsy [129]. The controversies in the management of low-grade intracranial neoplasms [130] and the role of radiotherapy [131,132] are beyond the scope of this chapter.

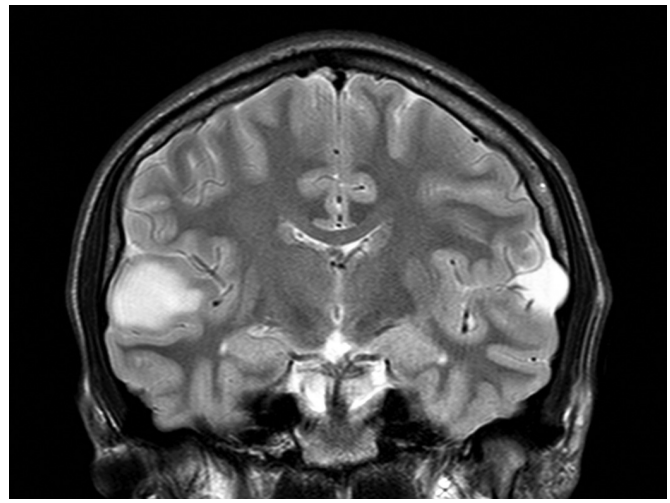


Fig. 70.5 Oblique coronal plane, T2-weighted image. MRI reveals a right temporal lobe lesion in a patient with a chronic seizure disorder that is not disabling. Pathology showed a low grade astrocytoma. Note: the right side of the brain is on the left side of the figure.

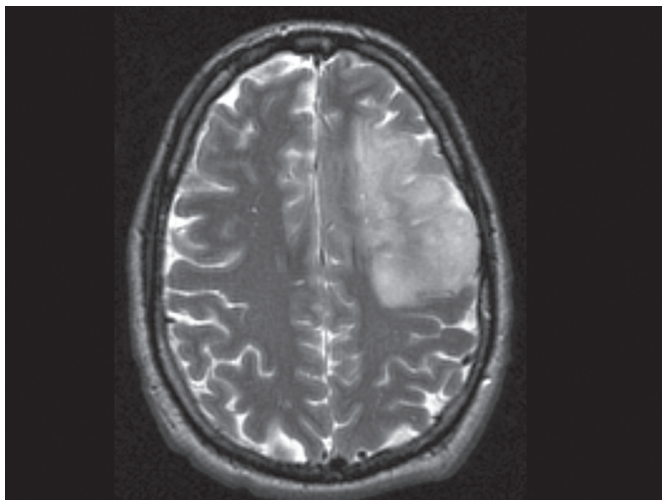
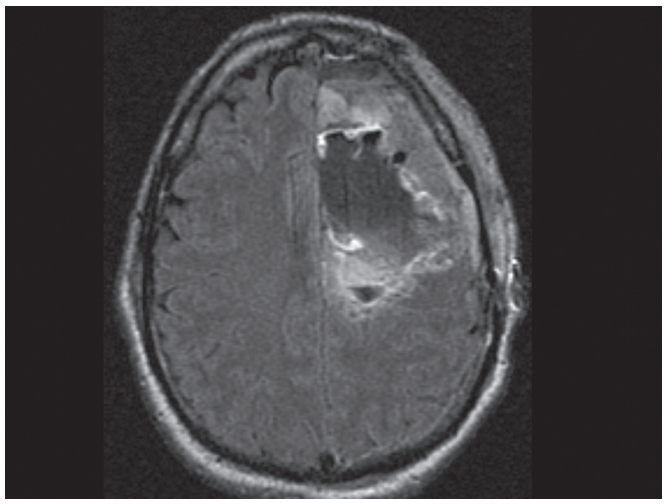
Surgical methods

Resection of the lesion and the surrounding epileptogenic cortex may be carried out by a conventional neurosurgical approach or by stereotactic extirpation of the lesion (Figs 70.4 and 70.6) [92,133,134]. There have been conflicting results regarding the therapeutic efficacy of stereotactic lesionectomy in patients with partial epilepsy [10,92].

A follow-up study of the outcome of stereotactic lesionectomy in 23 patients with mass lesions and intractable partial epilepsy was recently reported [92]. Sixteen lesions involved functional or eloquent cortex as determined by anatomical localization. The mean duration of follow-up was 48.5 months. Out of the 23 patients, 17 (74%) had a significant reduction in seizures and five of them were successfully discontinued from AED therapy.



(a)



(b)

Fig. 70.6 MRI shows a large lesion in the left frontotemporal region (a). A near complete tumour resection was performed (b). The pathology revealed an oligoastrocytoma. The patient had a marked reduction in seizure activity. Note: the left side of the brain is on the right side of the figure. (a) Axial plane, T2-weighted image. (b) Axial plane, fluid attenuated inversion recovery sequence.

Moore *et al*. [135] compared the surgical outcome of anterior temporal lobectomy and stereotactic lesionectomy in 20 and 14 patients, respectively, with intractable seizures operated on at the Mayo Clinic. Seventy-one per cent of lesionectomy patients and 90% of lobectomy patients experienced a worthwhile reduction in seizure tendency.

Outcome

Seizure outcome

The beneficial effect of epilepsy surgery in patients with medically refractory partial seizures associated with structural lesions is well established [7–11]. Postoperative seizure-free rates of up to 83% have been reported, with many of the remaining patients showing a significant improvement in seizure control [11].

The outcome of the surgical treatment of lesional epilepsy is influenced by the nature of the underlying pathology, the completeness of resection of the structural lesion and the extent of the removal of the functionally defined associated epileptic focus [10,11,136]. The relative contributions of these factors and their interactions are difficult to delineate. Moreover, the outcome results from the published series are difficult to compare because of different methods of patient selection, pathological classification, surgical technique and follow-up.

Pathology

LeBlanc and Rasmussen [137] observed in their 108 patients with astrocytomas and other low-grade primary intracranial neoplasms that 70% became seizure free or had a marked reduction in seizures, whereas complete seizure control was unlikely in malignant astrocytomas. Tumour recurrence was often heralded first by a recurrence of seizures after a seizure-free period of variable length [137].

Surgical excision of indolent intra-axial tumours such as gangliogliomas and DNETs is associated with a likelihood of complete or near-complete relief of seizures in nearly 90% of patients (Figs 70.1, 70.2 and 70.4) [36,42]. Out of 15 children, 11 operated on for ganglioglioma and intractable seizures were seizure free over a mean follow-up period of 4 years [138]. These tumours constitute the majority of lesional cases [30]. There is a higher incidence of more benign lesional pathology in intractable temporal rather than extratemporal epilepsy [8].

Completeness of lesion resection

The relationship between outcome and extent of the resection of the lesion is complex and is influenced by the pathology and the extent of the removal of a co-existing epileptic focus. Awad *et al*. [10] studied the effects of the extent of the resection of the structural lesion and the epileptic focus in 47 patients with intractable epilepsy and structural lesions. Complete lesion resection with or without the epileptic focus was associated with a higher chance of a seizure-free outcome than incomplete removal of the lesion [10]. In contrast, despite incomplete tumour removal, 81% of 22 patients from the Maudsley Hospital were completely free of seizures and 10% were almost seizure free during a mean follow-up period of 5.8 years (in this series, DNETs were the most common pathology) [37].

Completeness of epileptic focus resection

Many patients undergoing resective surgery for mass lesions have congruent epileptic foci. Wyllie *et al*. [136] reported better results in those patients in whom the epileptic lesion was fully excised. Extrahippocampal lesions may be associated with cell loss and sclerotic changes in the hippocampus [35,36,39]. Nayel *et al*. [139] reported that the extent of anterior temporal lobe resection may influence the outcome of surgery in patients with posterior temporal and extratemporal lesions.

The factors predictive of a good prognosis in resective surgery for intractable epilepsy guided by subdural electrode arrays and operative EcoG were reported for 64 patients [140]. After 1 year, 70% of the patients with a temporal ictal focus were seizure free compared with 55% of patients with an extratemporal focus. Patients with no postresection spikes had a better prognosis than patients with residual postresection spikes evaluated by operative EcoG. Other factors such as age, gender, duration of epilepsy before surgery, extent of temporal lobe resection and structural abnormalities as determined by MRI were not correlated with a favourable seizure outcome after surgery [140]. However, there are several case reports or small series of patients with congruent epileptogenic foci who became seizure free after surgery limited to the site of structural lesion [10,36].

The goal of epilepsy surgery is to render the individual seizure free without producing surgical morbidity. The primary aim of the treatment should be the removal of the lesion. If complete removal of the lesion cannot be achieved without added risk and morbidity, incomplete lesion removal may provide equally satisfactory results. Many of the tumours associated with medically intractable epilepsy are indolent, with no tendency to progress, and in these cases adjuvant tumour therapy does not appear to be necessary. The relative merits of simple lesionectomy versus additional removal of the epileptic focus in patients with lesional syndromes need further investigation.

Functional outcome

Psychosocial outcomes of epilepsy surgery are a largely neglected field. Little shift in the emphasis of reporting outcome following surgery, other than the seizure frequency, has occurred in recent years. Awad *et al*. [10] reported 47 patients with lesional medically intractable epilepsy showing an association between the extent of the resection of the lesion and seizure control without concomitant indication of whether or how these factors influenced the psychosocial and occupational performance. In a case–control analysis, Gulgvog *et al*. [141] were unable to show any benefit in psychosocial performance in a group of operated patients, despite significant reduction of seizures. In children with intractable epilepsy due to brain tumours treated by surgery, Berger *et al*. [142] reported optimal seizure control in 14 children, but postoperative psychosocial or educational performance was not mentioned.

Psychological outcome

At most epilepsy centres, a comprehensive neurophysiology battery is administered preoperatively and repeated 1 year postoperatively. New material-specific memory deficits are often noted after temporal lobectomy [143]. These abnormalities are usually subtle, asymptomatic and detected only by neuropsychological testing. Dominant temporal lobectomies impair verbal memory, but non-dominant temporal lobectomies impair visuospatial memory [144,145]. This observation indicates that the presence of a contralateral, normal, non-operated temporal lobe is a determinant of the functional outcome. In fact, many patients can show improvement in verbal and visuospatial memory following epilepsy surgery [146,147]. These improvements may be attributed to a significant reduction in postoperative seizure rates and fewer antiepileptic medications.

71 Resective Surgery of Vascular and Infective Lesions for Epilepsy

Christopher E. Uff and Neil D. Kitchen

National Hospital for Neurology and Neurosurgery, London, UK

Introduction

Vascular and infective lesions of the brain have a high propensity to induce seizures, and epilepsy is often the main or only symptom. Debilitating and intractable epilepsy presents a strong case for surgical intervention; however, the risk of haemorrhage, overwhelming infection and neurological deficit must be considered. A multidisciplinary approach is encouraged.

The natural history of any disease is of paramount importance in making decisions regarding its treatment. Although vascular malformations have been recognized for hundreds of years, many aspects of their natural history are still unclear due to new diagnostic and treatment options arresting natural progression. The number of infective lesions of the central nervous system (CNS) diagnosed worldwide has increased in recent decades and it is now recognized that infection is one of the major causes of acquired epilepsy [1]. In a recent study of 100 cases of intractable epilepsy in a low-economy country, CNS infection was found to be the leading aetiological factor [2]. Approximately 75% of the world's 50 million epilepsy sufferers live in developing countries and up to 94% of these cases go untreated, largely due to lack of access to appropriate health services [3]. Despite considerable research, little is known about the causes of epilepsy in developing countries [4].

Increasingly sophisticated neuroimaging has improved detection rates of intracranial abnormalities in patients with epilepsy [5] (see Table 71.1 for classification of vascular and infective lesions associated with intractable epilepsy). In particular, MRI is sensitive and specific in distinguishing mass lesions from other pathological entities in patients with epilepsy [6]. If an operable lesion is considered to be responsible for intractable seizures and the relationship between the lesion and seizures is verified, resective surgery can render the patient seizure free and improve his or her quality of life [7]. Although many infective and vascular lesions require emergency surgery in order to save a life, the scope of this chapter is to discuss selective surgery for epilepsy resulting from these conditions. The intent of epilepsy surgery is to improve the quality of life in a population who do not have life-threatening disease, hence a low complication rate is mandatory. As a consequence of the increasingly widespread availability of non-invasive therapies, surgical results are scrutinized with more candour than ever before, and, in the modern era of patient choice, surgery must be without doubt the better option if it is to be offered. In this chapter, current concepts regarding the diagnosis and management of patients with epilepsy associated with infective and vascular mass lesions will be discussed.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Vascular lesions

Arteriovenous malformations

Arteriovenous malformations (AVMs) are racemose networks of abnormal arteries and veins that communicate directly rather than through a capillary bed, leading to high-flow arteriovenous shunting through one or more fistulae. There is evidence that they are congenital lesions [8,9] although cases of proven *de novo* AVMs have also been described [10].

Although probably first described by William Hunter in 1792, the natural history of AVMs is still not clearly understood. Treatment has traditionally been surgical excision when it is possible to eliminate the risk of future haemorrhage. The natural history in these series is subject to surgical selection and is probably not representative of the natural history of all AVMs. Another confounding factor is a lack of international standards for the diagnosis of AVMs; data from the New York Islands Arteriovenous Malformation Study estimate the incidence at 1.34 per 100 000 person-years, an incidence of first ever AVM-related haemorrhage of 0.51 per 100 000 person-years and a prevalence of haemorrhage in known AVMs of 0.68 per 100 000 [10]. These figures are similar to those of two other major studies [11,12]; in real terms, unruptured AVMs are twice as common as ruptured ones.

It is estimated that between 42% and 50% of AVMs present with haemorrhage [12–14], and that 17–36% [15–17] will present with seizures, with or without associated neurological deficits. The risk of haemorrhage in AVMs has been linked to the epsilon 2 apolipoprotein E genotype [18]. Neurological deficits may occur, and if these are not caused by haemorrhage they can be caused by mass effect on the adjacent brain or by 'steel', in which blood preferentially flows through the shunts in the AVM leading to relatively reduced blood flow in the involved artery's normal distribution [19].

It is generally thought that small AVMs (<3 cm diameter) present more often with haemorrhage than large ones [20,21], possibly because smaller AVMs tend to have higher pressures in the feeding arteries [21]. Several studies between 1970 and 1980 highlight the

benefit of surgical resection for accessible cerebral AVMs in terms of rebleeding and overall morbidity and mortality [22–26]; however, they are, for the most part, in the pre-CT era. This view has more recently been challenged [27] and it has been suggested that a natural history of unruptured AVMs is associated with a significantly lower morbidity than a presentation of haemorrhage. The average bleeding risk is 1.2% per year for unruptured AVMs and 5.6% per year for those with a history of bleeding (at least in the first year following haemorrhage). Subgroup analysis revealed a 0.9% per year bleeding rate for lobar AVMs with superficial drainage [28]. Recent studies suggest that the treatment risk of unruptured AVMs may be higher than the natural history [29], and the morbidity from haemorrhage in those presenting with seizures is less than one-third of that in those who presented with haemorrhage in the first instance [30]. The subject is currently highly controversial and in their 2006 review entitled 'Invasive treatment of unruptured brain arteriovenous malformations is experimental therapy', Stapf *et al.* [31] conclude that 'polar opposites can be found favouring medical or surgical treatment', with 15% differences either way in operative mortality and annual haemorrhage risk between studies. The ARUBA study (A Randomized Trial for Unruptured Brain AVMs), which was started in 2006, is designed to test whether medical management or interventional therapy will reduce the risk of death or stroke by 40% (or about 7.5% per year over 5 years) and aims to randomize 800 patients using intention-to-treat analysis. The outcome of this study is likely to have a significant impact on elective surgery for AVMs.

Seizures are the second most common symptom after haemorrhage. A recent series of 424 patients found increased seizure frequency associated with male sex, temporal lobe AVM, size greater than 3 cm and age less than 65 years [32]; Crawford *et al.* [20] estimated that patients aged between 10 and 19 years had a 44% risk of epilepsy, compared with 31% for patients aged 20–29 years and 6% for patients aged 30–60 years. A significant proportion of patients with cerebral AVMs will develop epilepsy after diagnosis, and the same authors suggested that surgery was the most important risk factor for subsequent development of epilepsy. In their series of 234 patients, the surgically treated group had a 57% risk of seizures compared with 19% for those managed conservatively at 20 years. The 10-year risk was 47% versus 11% for the same groups. No patient with either initial neurological signs or in whom the AVM was a coincidental finding developed epilepsy when treated conservatively [33]. Foy *et al.* [34] found that epilepsy was present in 50% of patients operated on for AVMs after surgery, as compared with an overall incidence of 17% for all patients undergoing supratentorial craniotomies. In earlier series the incidence of postoperative epilepsy has ranged from 4% [22] to 22% [23].

In contrast to these observations, other authors have reported a beneficial effect of surgery on epilepsy associated with cerebral AVMs. Guidetti and Delitala [22] reported that in their series of 130 patients (86 treated surgically versus 44 conservatively) 53% of the surgically treated patients improved, but only 36% of the conservatively managed group improved. Pool [14] found the incidence of epilepsy to range between 30% and 50% in 187 patients who underwent surgical resection, whereas the same incidence was 64% among patients treated conservatively. Trumpy and Eldevik [35] reported that five patients in their series of surgically treated AVMs had no epilepsy following the operation, but five patients developed seizures after surgery. Finally, Murphy found no statistical difference between the percentage of seizure-free patients in the medically treated group and those in the surgical group in his series of 46 patients followed up for a mean of 13 years [16].

Hoh *et al.* [32] report that short seizure history, associated with intracranial haemorrhage, generalized tonic–clonic type, deep and posterior fossa location of the AVM, complete obliteration and surgical resection (as opposed to radiosurgery or embolization) were all associated with a good seizure outcome (Engel class I). Contrasting different treatment modalities, they found an 81% Engel class I result with surgery versus 43% with radiosurgery and 50% with embolization.

The epileptogenic potential is thought to be caused by the tissue adjacent to the AVM, which is characterized by neuronal loss, gliosis, demyelination and haemosiderin deposits [36,37]. Perinidal capillaries have absent basement membranes and this may allow erythrocyte extravasation and subsequent haemosiderin deposition and gliosis in the surrounding tissues [38], which may explain epileptogenesis in the absence of overt haemorrhage. In all the series examined, no mention has been made of any effort by the surgeon to remove surrounding or intervening areas of abnormal brain tissue along with the malformation. Although the importance of preserving normal tissue at surgery is paramount, this approach also has the theoretical disadvantage of leaving the epileptic focus undisturbed. There are as many series reporting good seizure control as there are reporting poor control, and cortical scarring from surgery is a reasonable explanation for postoperative seizures whatever the pathology, so it is unlikely that this will be resolved.

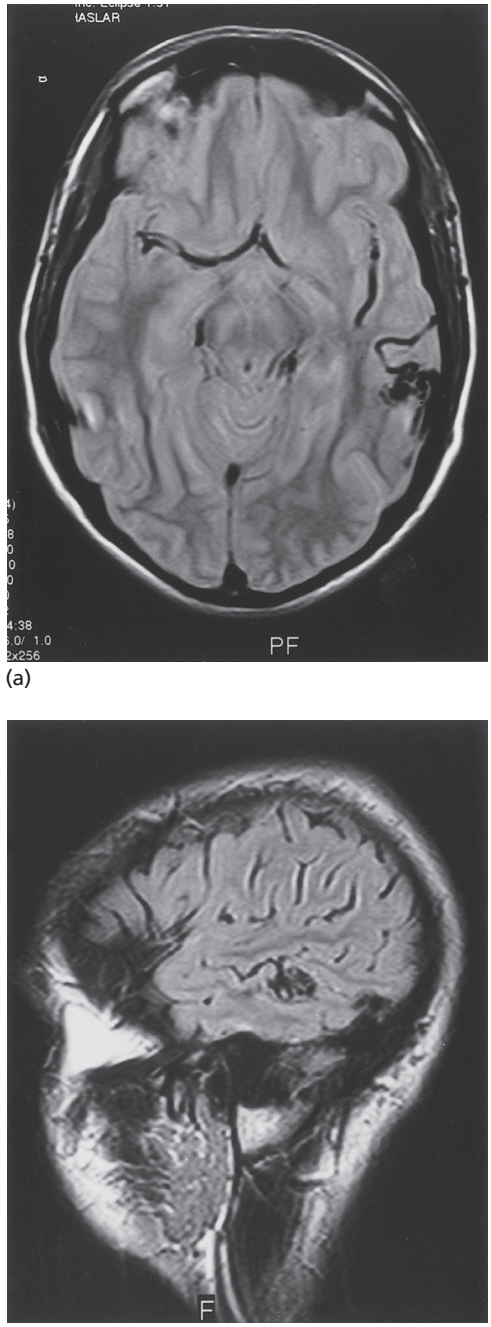
Beside the issue of long-term seizure control, the aim of treatment of AVMs should be to prevent bleeding and reduce long-term morbidity and mortality. It is estimated that the average risk of bleeding from an AVM is around 2–4% per year [39]. For instance, in a study of 166 symptomatic AVMs with 23.7 years' mean follow-up, Ondra *et al.* [30] found that the risk of haemorrhage was constant at 4% irrespective of whether the malformation presented with or without haemorrhage. In the same study, the mortality rate was 1% per year, with a combined major morbidity and mortality of 2.7% per year. In another important contribution, of the patients with cerebral AVMs who survived long enough after the initial haemorrhage to be entered into the Co-operative Study, 53% were reported to have a neurological deficit attributable to the bleeding. Approximately 10% of these patients died as a direct result of their first known haemorrhage

[15]. Twenty-three per cent of the survivors suffered recurrent haemorrhages, with a mortality rate of 12%.

Evaluation

Magnetic resonance imaging followed by cerebral angiography is currently considered to be the gold standard in the evaluation of AVMs. MRI can reveal flow voids on T1- and T2-weighted images, can show the characteristic feeding arteries and draining veins (Fig. 71.1a and b) and can help to differentiate between AVMs and neoplasms, providing the surgeon with vital information in the case of angiographically occult vascular malformations. In nearly all cases, a catheter cerebral angiogram will better outline the characteristics of feeding arteries and draining veins and reveal any associated aneurysms that are present in 7% of AVMs [20] (Fig. 71.2). CT of the brain may show presence of blood around the AVM, as well as possible areas of calcification related to the malformation. It may also reveal pathological contrast enhancement in the area of the AVM itself. With the continuing advances in non-invasive vascular imaging, it is likely that magnetic resonance angiography (MRA) and CT angiography (CTA) will soon supersede catheter angiography.

If surgery is being considered for the treatment of epilepsy associated with an AVM rather than to reduce or abolish the potential for bleeding, every effort should be made to establish the congruence between the area targeted for resection and the epileptic focus. In the majority of patients, scalp EEG alone does not localize or even lateralize the seizure focus. Prolonged EEG monitoring with video correlation of seizures (telemetry), interictal and ictal positron emission tomography (PET), as well as meticulous history-taking and neurological examination, may yield convergent data and therefore augment the accuracy of localization. For obvious reasons, intralesional electrode recordings cannot be made.



(a)

(b)

Fig. 71.1 (a) Coronal view of a MRI scan of a 21-year-old man who presented with generalized seizure activity, showing a left temporal AVM with a large draining vein. There is flow void within the lesion and in the draining vessel. (b) Sagittal view of the same. The scan shows no evidence of previous haemorrhage.

Treatment

Surgery

Epilepsy associated with AVMs can usually be managed with medical therapy, and the presence of seizures in isolation is rarely an indication for surgery. The most attractive feature of surgery for AVMs is that it immediately abolishes the risk of haemorrhage. As has been discussed above, patients presenting solely with epilepsy have a lower risk of haemorrhage than those

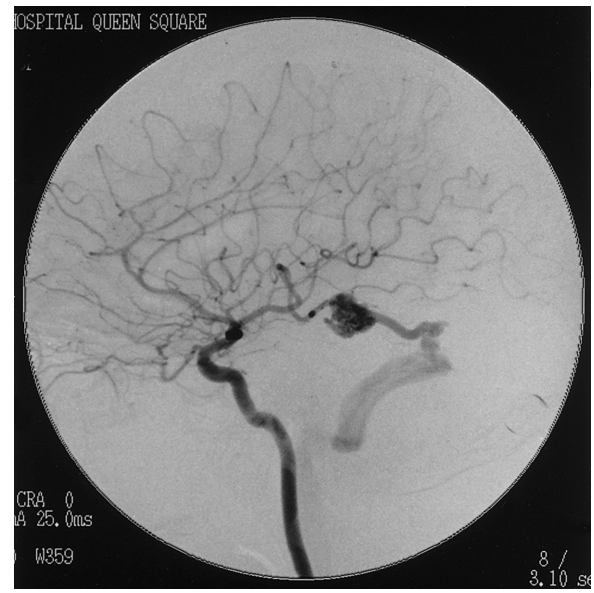


Fig. 71.2 Cerebral angiography of the same AVM (lateral view). The examination shows a single arterial feeder and a single draining vein discharging into the proximal sigmoid sinus. After a failed attempt at embolization the AVM was successfully excised surgically. The patient remains seizure free on phenytoin.

presenting with haemorrhage to the extent that the risk from surgery is greater than the risk of haemorrhage. However, surgery does appear to achieve superior control of seizures compared with other treatment modalities and this may be due to removal of epileptogenic gliosis and blood products during surgery, which does not occur with non-invasive therapies.

The risk of haemorrhage is higher for small AVMs and it has been stated that surgical mortality and morbidity for this group is lower than the projected natural risk [40]. The same authors state that neither seizures nor incipient focal neurological dysfunction alone are indications for surgery, and that the risks of disability or death after the fifth decade of life are probably less than the surgical risks (based on operative mortality of 10% and morbidity of 30%, in 1985). In 1980 a series of 166 consecutive patients found the most favourable operative risk profile as younger than 40 years, absence of neurological deficit, superficial and small AVM in a silent area, female sex and subarachnoid haemorrhage at presentation. The subsequent Spetzler–Martin classification in 1986 reported 100 consecutively operated AVMs and predicted the surgical risk of minor and major neurological deficits based on size, venous drainage and eloquence of involved cortex (small size, superficial drainage and no eloquent cortex predisposes better outcome) [41].

Indications for surgical management of AVMs associated with epilepsy currently include intractable seizures with evidence that the AVM is the cause of the seizures, and seizures associated with an AVM that has previously haemorrhaged. Large or giant (greater than 6 cm) AVMs that are deemed inoperable or an extremely high surgical risk may be transformed into more attractive targets with preoperative embolization.

Radiotherapy

Radiotherapy is an important tool in the treatment of AVMs. Conventional radiotherapy is successful in less than 20% of cases and is therefore not considered effective [42,43]. Stereotactic radiosurgery (SRS) has beneficial effects on both AVM obliteration and seizure control, and photons [X-ray-based linear accelerator (LINAC) systems and gamma knife radiosurgery (GKRS)], heavy charged particles (helium ion Bragg-peak radiation) and proton beam radiotherapy have all been used, although GKRS is the best-established mode of radiotherapy in the treatment of AVMs and is associated with good rates of nidus obliteration and seizure control without the need for fractionation (hence the term 'radiosurgery').

Radiation induces endothelial damage that results in proliferation of smooth muscle cells and the elaboration of extracellular collagen, leading to stenosis of the vessel and ultimately obliteration of the lumen over a period of 1–2 years [44]. SRS is non-invasive in the sense that no craniotomy or brain dissection is required, and it can be administered on an outpatient basis; however, the length of time it takes to work leaves the patient exposed to the risk of rehaemorrhage. Haemorrhages have been documented to occur during the lag period, even in AVMs that had not previously bled, raising the question of whether a partially thrombosed AVM is more likely to bleed because of increased outflow resistance [45]. Several authors suggest that this modality is the best treatment for small malformations located deeply in eloquent areas of the brain [46–48]. It is estimated that between 46% and 61% of AVMs appear obliterated on angiography 1 year after treatment and 86% will be obliterated at 2 years [45]. In a study of 462 patients with cerebral AVM treated with GKRS, 68% of whom presented with haemorrhage and 12.8% with epilepsy, the overall results indicated that seizures improved in 85.5%, were unchanged in 11.6% and deteriorated in 2.9% [49]. In the same study, of the 79 patients (17.1%) who had had a seizure before radiosurgery, 58 presented with seizure as an initial symptom and seizures occurred in the other 21 patients mostly following intracranial haemorrhage. Seizures were either decreased or had disappeared in 91.6% of the former group and in 62.5% of the latter. The authors concluded that radiosurgery is effective not only for the obliteration of the nidus of cerebral AVM, but also for seizure control, even before complete occlusion of the nidus. More recently, a series of 51 patients showed that 51% were seizure free at 3-year follow-up [50]. Another study of 100 patients with AVMs, of whom 33 presented with seizures (11 generalized tonic–clonic, eight simple partial and 14 complex partial), 59% were seizure free and 19% had marked reduction of seizure frequency after radiosurgery [51]. Interestingly, four out of the five patients in this study who had not had obliteration of the AVM on angiography 2 years after SRS also became seizure free, suggesting that structural or biochemical alterations of epileptogenic neurones following radiosurgery may reduce epileptogenicity. Similar results have been reported by other authors [52–54], but new onset of seizures in 1–3% of patients treated with this technique has also been reported [55–57], including one case of acquired mesial temporal sclerosis [58].

The likelihood that radiotherapy will be successful depends on the diameter of the nidus; SRS will obliterate lesions less than 2 cm in diameter 2 years after treatment, although it will obliterate only 50% of lesions with a diameter greater than 2.5 cm. GKRS is less effective for lesions with a volume greater than 10 mL [59]; however, staged GKRS with up to three treatments has been described in patients with larger lesions [60]. Proton beam radiotherapy has been used for lesions greater than 100 mL, with good obliteration rates and seizure control [61]. However, the extreme scarcity of facilities has curtailed its usefulness in clinical practice.

Endovascular treatment

Embolization is also available for the treatment of cerebral AVMs. Although this technique can facilitate surgery, it is generally accepted that it may not achieve permanent obliteration of the malformation because of the high rate of recanalization [62]. It can also induce acute haemodynamic changes in the treated region and multiple procedures may be required to complete the treatment. The complication rate reported by Jafar *et al.* in 1993 [62] for this procedure included a 1.5% risk of severe deficit, a 1–2% risk of death, a 10% risk of haemorrhage and a 3% risk of new-onset seizures. A recent series reported a 90.5% good or excellent outcome but associated with a higher complication risk with a Spetzler–Martin grade III–V [63].

On its own, embolization can achieve a cure in up to 40% of AVMs at best [64], and can also be used as an adjunct to radiosurgery both before [65] and after radiosurgery [66].

Summary

Treatment of epilepsy associated with cerebral AVMs depends on a number of factors, including the size and character of the lesion,

surgical accessibility, locally available expertise and patient choice. Recent studies have demonstrated the comparatively benign course of the many AVMs, and modern antiepileptic pharmaceuticals and advances in radiosurgery have reduced the number of patients in whom surgery is indicated. Close liaison between epileptologists and the neurovascular multidisciplinary team is essential.

Cavernous haemangioma (cavernoma)

Cavernous haemangiomas are well-circumscribed, hamartomatous vascular lesions consisting of irregular-walled sinusoidal vascular channels lined with a single layer of endothelium. They are located within brain parenchyma but do not incorporate intervening neural tissue. There are no large feeding arteries or draining veins. They are thought to grow by a process of vascular cavern proliferation in the setting of repeated haemorrhage [67] and are probably capillary malformations. They have the potential to haemorrhage, calcify or thrombose and are multiple in up to 50% of cases [68]. It is estimated that they constitute 5–13% of vascular malformations of the CNS and they have been found to be present in 0.02–0.13% of autopsy series [69]. The majority present in the third and fourth decades of life; one-quarter to one-third present in the first and second decades [70,71]. Eighty per cent are supratentorial in location [72]. Presentation is most commonly with seizures (79%) and haemorrhage (16%) [72], and the rate of new-onset seizures is 2–4% per year [73].

Autosomal dominant familial clustering can be found in 0.5–0.7% of the population [74] and in 10–30% of cavernous haemangiomas [75]. Sporadic and familial forms are recognized as two distinct conditions, with familial cavernomas associated with a higher rate of haemorrhage and occurring at a younger age [76]. Cavernomas arising in radiation fields following radiotherapy are well documented in children [77]. Other environmental factors, including viral infection, inflammation, immune responses and pregnancy [78], have been reported.

The risk of epilepsy ranges from 4.5% to 11% per year, and this also depends on localization, with greater frequency in the temporal lobes [79]. Relative under-representation in the frontal lobes may be a result of lesions in this area remaining clinically silent; temporal lesions have greater epileptogenicity [72]. Cavernous malformations are twice as likely to be associated with seizures as AVMs or tumours in a similar location, and in a study of 27 vascular lesions associated with intractable epilepsy 74% were cavernous haemangiomas and 14.8% were AVMs [80]. Considering that the prevalence of AVMs is significantly greater than that of cavernous haemangiomas, this finding suggests a greater epileptogenic potential of cavernous malformations. In 1978 Giombini and Morello published a series of 51 cases of cavernous haemangioma and in 19 patients the first symptom was epilepsy whereas haemorrhage was the presenting symptom in 12 [81] (it should be noted that this study was in the pre-CT era). A later (1987) series of 25 cavernous haemangiomas reported that 70% of patients with lesions located within the cerebral hemispheres presented with seizures as the only complaint; 20% had symptoms or signs of raised intracranial pressure and 10% presented with haemorrhage [82].

The haemorrhage rate is estimated at 0.5–3% per year, depending on localization [81], and it is higher in females [83]. In one study of 62 patients with a short follow-up (mean 22.4 months), the haemorrhage risk was estimated to be 1.4% per lesion per annum [84], and in a similar study of 122 patients the bleeding rate was 4.5% for patients with a prior haemorrhage and 0.6% for other presentations [85]. The authors also found that the presence of seizures had no significant association with the risk of haemorrhage.

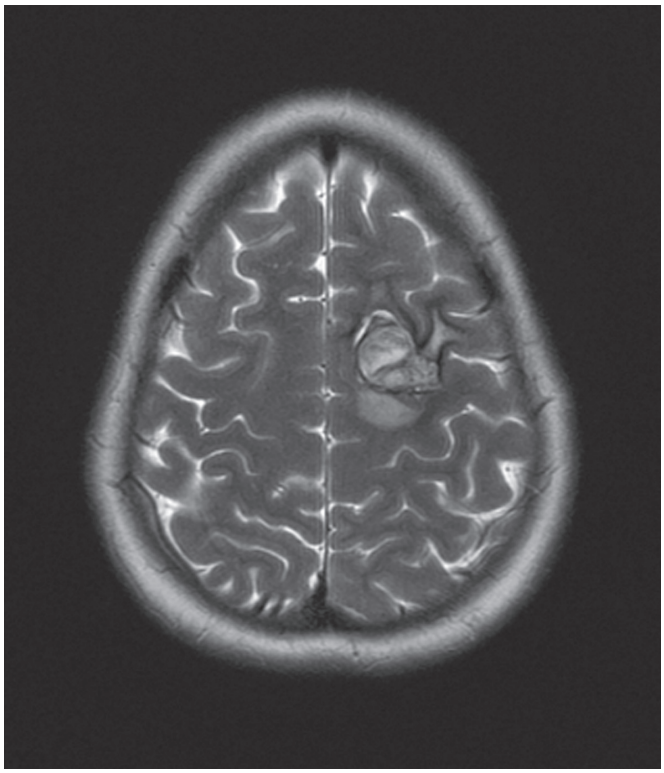
Diagnosis is usually accomplished with CT and more recently and precisely MR scanning. They are the most common angiographically occult vascular malformation and lack large arteries or veins; however, they are commonly associated with developmental venous anomalies (DVAs), which have the characteristic 'caput medusae' appearance on angiography. Typical CT appearances are a well-circumscribed hyperdense lesion. There is usually little or no enhancement [86] but occasionally enhancement is vivid [71]. Forty to sixty per cent are calcified, the surrounding brain appears normal and there is no mass effect unless there is recent haemorrhage; however, CT is negative in 30–50% of cases [86]. MRI is the most sensitive imaging modality and the appearance depends on the age of haemorrhage within the lesion. The most common appearance is a 'popcorn ball' with mixed hyper- and hypointense regions surrounded by a low-intensity haemosiderin ring (Fig. 71.3a). T1- and T2-weighted images have a similar appearance but T2 is more sensitive and may show fluid levels in locules of blood. Contrast-enhanced T1-weighted images demonstrate little or no enhancement [68], unless there is an associated DVA. Gradient echo T2* sequences with a long time to echo (TE) (35 ms) are particularly sensitive to blood products and show 'blooming' of low signal with blood of all ages (Fig. 71.3b). It should be noted that the MRI appearances of cavernous malformations are not 100% specific. The advent of modern neuroimaging has permitted the diagnosis of lesional epilepsy caused by cavernomas which would otherwise have been labelled idiopathic. Lesions presenting solely with epilepsy have probably been under-represented in case series in the pre-CT era.

Pathophysiological mechanisms underlying epileptogenesis include neuronal cell loss, glial proliferation with neuronal death and altered levels of neurotransmitters or secondary messengers [87]. Other mechanisms may include oxygen free radical formation, imbalance of excitatory and inhibitory neurotransmitters, calcium influx and cytotoxicity [88]. The deposition of iron and haemosiderin from blood elicits local gliosis [68,87,89], and iron in particular has been shown to have an epileptogenic effect in animal studies [87,90,91]. A study of low-grade gliomas showed reduced numbers of somatostatin and GABAergic neurones in epileptogenic cortex compared with normal brain [92] but a more recent study using intracellular recording demonstrated different mechanisms of epileptogenesis between cavernomas and neoplasms, with a greater propensity to large spontaneous synaptic events and greater excitation following synaptic stimulation in cavernomas. It is postulated that haemosiderin deposition adjacent to cavernomas can result in impaired glutamate uptake and injury-related synaptic reorganization, allowing focal neuronal hypersynchronization [93]. This may explain the increased incidence of epilepsy in cavernomas compared with other vascular malformations.

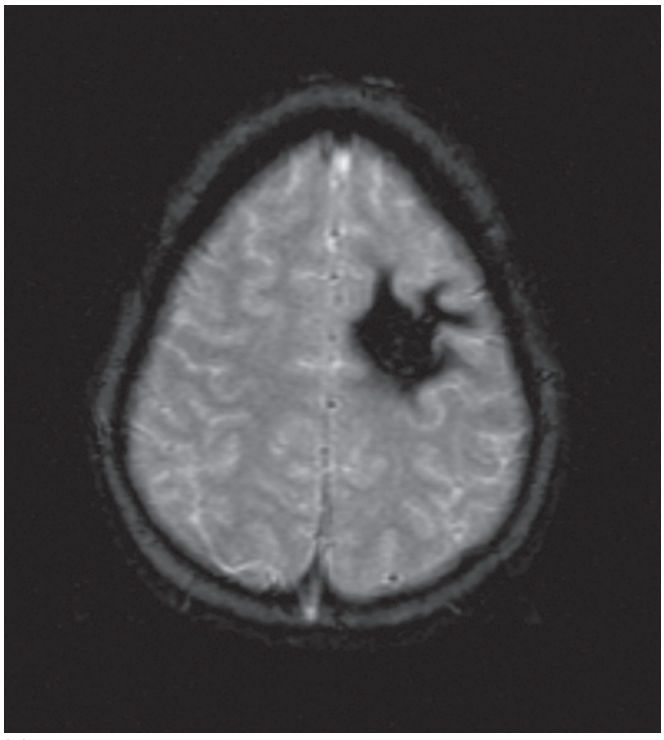
Treatment

Surgery

Although the annual risk of haemorrhage from cavernous haemangiomas is lower than that of AVMs, the cumulative



(a)



(b)

Fig. 71.3 (a) T2-weighted axial MRI showing a cavernoma adjacent to the precentral gyrus in a 28-year-old woman with generalized seizures. (b) The same cavernoma on a T2-weighted gradient echo axial MRI demonstrating low-signal 'blooming' indicating blood products.

lifetime risk for younger patients is still a significant cause of morbidity. It is generally acknowledged that such a risk is higher for patients with documented previous haemorrhage. Several published series show that excisional surgery can be accomplished with low morbidity, with good or excellent results achieved in 82.2–100% of cases [81,82,88]. The results in terms of epilepsy control in surgical series are generally favourable. The meta-analysis of surgical results by Moran *et al* [72] for 268 supratentorial cavernous haemangiomas showed that 84% of patients were seizure free and 8% were improved, with no change in only 6% and with 2% becoming worse. Of the 82% who were seizure free following surgery, 50% were were not taking antiepileptic drugs. In the author's own series of 17 patients, improvement occurred in 13 cases, but four patients remained unchanged with no worsening of seizures. Although seizure control rates in this series are less than in the literature review, this was thought to be a result of the high proportion of patients with intractable epilepsy having been recruited through a formal epilepsy surgery programme, and this illustrates the well-documented finding that intractable seizures are a negative prognosticator for successful seizure surgery [68]. It was also noted that duration of epilepsy negatively affected the outcome of surgery, suggesting that resection should be performed sooner rather than later. A similar suggestion has been made for AVMs [94] and if this is a result of kindling (as has been suggested) then the implication is that seizure surgery should be performed sooner rather than later.

The above review reported that lesionectomy alone yielded seizure control in 92% of cases [72]. Lesionectomy and corticectomy (in which surrounding epileptogenic cortex is also resected) can improve seizure outcome, especially in low-grade gliomas and vascular malformations; however, this may be limited by involvement of eloquent brain. Lesionectomy alone is more likely to be successful in patients with a short and infrequent seizure history that responds to antiepileptic medication, whereas a combined procedure (lesionectomy and corticectomy) may be required for truly intractable epilepsy [67]. Potential functional deficit must be considered when deciding which surgical procedure to offer and individual vocational requirements may guide this. Follow-up in the first year appears to be a good prognosticator of long-term seizure control following surgery [95].

As an alternative to resective surgery, disconnection procedures can offer seizure control in which the epileptogenic focus lies within or involves eloquent areas. Such indirect surgery is not commonly described in the treatment of vascular malformations and, excepting a single case report in which multiple subpial transactions were used in conjunction with excision of a cavernous malformations [96], current literature is devoid of reports.

Vagus nerve stimulation and deep brain stimulation are both neuroaugmentative palliative techniques that are well established in the treatment of intractable epilepsy. However, their role in the treatment of epilepsy arising from vascular lesions has not been described in the current literature.

Radiosurgery

The treatment of cavernous malformations by radiotherapy has been largely focused on brainstem and basal ganglia lesions, and

this is because the morbidity associated with surgical approaches to intrinsic brainstem lesions makes them an attractive target for non-invasive therapies. Histological studies have shown vascular and connective tissue stromal changes, similar to those found in AVMs treated with GKRS, and they have been described in cavernous malformations following GKRS [97]. LINAC-based radiotherapy has produced results similar to surgery in treating epilepsy caused by cavernous malformations [98], but GKRS is used more commonly. GKRS has been shown to be useful in the treatment (decrease in size) of surgically inaccessible lesions in the brainstem and basal ganglia, and has been shown to reduce the annual haemorrhage rate from 33.9% to 12.9% per year in high-risk patients following GKRS [99]. It has also been shown to reduce seizure frequency [100]. Some authors have found rebleed rates to be as high as 33%, with a particularly significant incidence of radiation-related complications [101–103]. However, more recent series show that GKRS can reduce the haemorrhage risk with a 70% cure rate [104]. A multicentre study on the use of a gamma knife for cavernous malformations suggested that, despite the failure of this treatment to protect against risk of rehaemorrhage, there was a beneficial effect on epilepsy, with 53% becoming seizure free, 4% with occasional auras and 20% with a significant decrease in the number of seizures; the remaining 26% were unchanged [105]. The authors found that sex, age and duration of epilepsy had no prognostic value, but that the outcome was better for patients with simple partial seizures than for those with complex partial seizures. Location in the mesiotemporal region was associated with a poor outcome, whereas location in the laterotemporal and central regions was associated with significantly better results. Recent series have reported similar epilepsy cure rates (53% Engel class I or II), combined with effective reduction in the rebleed rate and few complications [106]. Two reviews from 2007 suggest that a benefit of radiosurgery over conventional surgery is unproven for epilepsy. They noted the lack of prospective randomized controlled studies and found higher complication rates in cavernomas treated with GKRS than with radiotherapy for other lesions in similar locations [106,107]. It was also noted that, although GKRS can reduce the haemorrhage risk from cavernous malformations, its superiority over conservative management is not proven.

Modern dose planning targeting the lesion only (and not the adjacent brain) with lower doses has reduced the complication rate; whether this has altered clinical outcome is not yet known. Excellent results have been reported for the treatment of mesial temporal lobe epilepsy associated with hippocampal sclerosis by a gamma knife [108,109]. Although further evaluation of effects of radiosurgery on seizures associated with CMs is necessary, ideally with a prospective study, this form of treatment may be useful for intractable epilepsy related to lesions situated in eloquent and/or inaccessible areas of the brain.

Intracranial aneurysms

Epilepsy is an extremely uncommon presentation of intracranial aneurysm. Although seizures are a well-recognized presentation of subarachnoid haemorrhage, we refer specifically to unruptured intracranial aneurysms causing epilepsy through mass effect on adjacent brain. This is not a well recognized phenomenon; however, it is described in case reports with cessation of seizures coinciding with aneurysm ablation. Aneurysms presenting in this way are likely to involve the middle cerebral artery and/or exert mass effect on the medial temporal structures, giving rise to complex partial seizures [110,111].

Venous malformations

Venous malformations, also known as developmental venous anomalies (DVAs), are best thought of as congenital variations of normal venous drainage. They represent the most commonly documented intracranial vascular malformation by either brain imaging or autopsy, with a prevalence as high as 3% [112]. They can be associated with CMs or, more rarely, with AVMs. On MRI they appear as a stellate vascular or contrast-enhancing mass [113]. Angiography typically shows a caput medusae appearance in the late venous phase [114].

The haemorrhage risk associated with venous malformations is exceedingly low. In a prospective study of 80 patients the bleeding rate per year was calculated to be 0.61%, although the risk of symptomatic haemorrhage was considerably lower (0.34%) [115]. In an older retrospective MRI study, the risk of haemorrhage was estimated to be 0.22% [116].

The risk of epilepsy associated with venous malformation is uncertain. In a retrospective review of MR scanning performed on 1020 epileptic patients, only four had venous malformations [117]. It is also interesting to note that in only two of these cases was there concordance between the vascular lesion and the electroencephalogram (EEG) focus. In another study, by Topper *et al.* [118], of 67 patients with venous angiomas, the concordance was even lower. In their analysis, in only one patient out of 15 who presented with seizures was the EEG found to be congruent with the topography of the lesion. In fact, none of the 67 patients showed an association between the complaints that led to the MR scan and the location of the venous malformation, supporting the view that these are a congenital abnormality of venous drainage of no clinical significance.

Resection of these lesions is generally associated with high morbidity and mortality [119–121], probably because the venous anomaly is a functioning venous channel that drains normal parenchyma, and surgical removal of such channels can thus lead to venous infarction [115]. Similarly, radiosurgery is thought to carry a 30% risk of radiation complications or venous infarctions and may not achieve total obliteration [122].

Capillary telangiectasias

Capillary telangiectasias are often detected as incidental findings at autopsy. They appear as poorly demarcated pink or reddish discoloured lesions with dilated capillaries and may look like a petechial haemorrhage. The intervening parenchyma between the vessels is usually normal and gliosis and microhaemorrhages are absent, distinguishing these anomalies from other vascular malformations [123]. These lesions are extremely rare. In a series of 30 000 autopsies capillary telangiectasias were identified in 0.06% of cases [124]; they represent less than 4% of all angiographically occult vascular lesions [120]. These malformations are usually seen in hereditary haemorrhagic telangiectasias (including Osler–Weber–Rendu syndrome), or associated with other vascular anomalies such as cavernous angiomas. Non-hereditary cases are rare and usually remain asymptomatic [125]. The usual

presentation of symptomatic lesions is haemorrhage or epilepsy, and in a study of 21 patients, seizures occurred in nine cases and haemorrhage in eight [126]. Increasing numbers of capillary telangiectasias are now being diagnosed with more widespread use of MR scanning. Typical appearances include a variable T1 appearance, high signal intensity on T2-weighted images, contrast enhancement and a lack of mass effect. Haemorrhage and calcifications are rare, suggesting that the findings on T2-weighted images are probably related to the presence of deoxyhaemoglobin in slow-flowing blood. They enhance faintly in a 'brush-like' or 'stipple' pattern [127]. The presence of an enlarged vessel in about two-thirds of capillary telangiectasias is thought to represent a draining vein and has led some authors to consider these lesions to be 'transitional malformations' [128]. The brainstem is the most common location [127].

Although seizures may be present in a high percentage of these [120], the number of reported cases is so small that it is likely that these are incidental findings during epilepsy investigation. The absence of cases reported in the literature does not allow us to draw any firm conclusions as to the epileptogenic or bleeding potential of capillary malformations and, on the strength of currently available medical evidence, the discovery of one or more of these lesions during investigations for epilepsy or haemorrhage should not alter the routine surgical or medical management of the underlying pathology.

Infective lesions

In this section, current concepts regarding the diagnosis and surgical management of patients with epilepsy associated with infective mass lesions will be discussed. Emphasis will be on pyogenic brain abscesses, neurocysticercosis (NCC), cerebral hydatid disease and cerebral tuberculoma. Discussion of schistosomiasis, toxocariasis, toxoplasmosis, paragonomiasis and gnathostomiasis is beyond the scope of this chapter.

Pyogenic cerebral abscess

A brain abscess is a focal suppurative lesion within the brain parenchyma. Between 30% and 50% of patients will have a seizure prior to surgical intervention; however, the primary aim of surgery for abscess is not the relief of epilepsy but to save the patient's life by draining the abscess for microbiological diagnosis and reduction of mass effect. A brain abscess may come to the attention of the epilepsy surgeon after resolution of the abscess with an area of cortical scar causing epilepsy. Treatment is then similar to other forms of lesional epilepsy.

Brain abscesses range in size from microscopic foci of inflammatory cells to major encapsulated necrotic areas exerting significant mass effect. Brain abscesses can result in major morbidity and mortality through suppuration alone as well as the effects of raised intracranial pressure from the abscess and associated cerebral oedema. Recent advances in the diagnosis and management of brain abscesses have led to improved survival rates: in the 1950s, the mortality rate associated with brain abscess in the USA was estimated to be 38%. By the 1980s this had fallen to 25%, and the current figure is between 5% and 10% [129]. This reduction has been attributed to improvements in diagnostic imaging (especially CT), neuroanaesthesia and critical care, the evolution of neurosurgical techniques, a better understanding of the pathophysiology and management of raised intracranial pressure and the development of new and more effective antibiotics [130]. Despite these advances, however, brain abscess remains a serious and potentially fatal condition.

The estimated annual incidence of brain abscess in the USA is 1 in 10 000 hospital admissions. Its frequency is one-sixth that of bacterial meningitis and it accounts for 0.7% of all neurosurgical operations. Large postmortem series report brain abscess occurrence rates of 0.18–1.3%. Although historical studies have suggested a male predominance, it is currently thought that there is no difference between the sexes [131]. The median age of presentation is between 30 and 45 years, and this is related to the aetiology; brain abscess due to otitis media has a bimodal age distribution with peaks in childhood and above 40 years. Abscess secondary to paranasal sinusitis commonly occurs between 10 and 30 years of age, 25% occurring in children below the age of 15 years.

Predisposing factors

Brain abscess can develop by direct extension of infection into the brain (this includes trauma and surgery) or by haematogenous spread from remote regions of the body. The most common cause was previously direct extension from the paranasal sinuses or ear. However, with more effective antibiotic treatment of sinus infections, haematogenous spread is now the most common cause. Patients who are severely immunocompromised following organ transplantation or those with HIV are not commonly afflicted by pyogenic abscess, but they are predisposed to cerebral toxoplasmosis, cryptococcal abscess and other atypical organisms.

Direct spread

Chronic middle ear infection is the most common cause of direct intracranial spread (acute infection rarely spreads intracranially). Cholesteatoma is an additional risk factor, increasing the incidence of intracranial extension from 23.2% to 74%. Brain abscesses related to middle ear infection are usually solitary, arising in the inferior temporal lobe adjacent to the petrous temporal bone. Abscess formation may be a result of direct invasion through the dura, bacterial transmission through diploic or emissary veins, or by spread through existing channels, including the internal auditory meatus, cochlear and vestibular aqueducts and temporal suture lines. In contrast to middle ear infections, mastoid infections typically result in abscess formation in the cerebellum.

The majority of abscesses complicating infection in frontal, ethmoidal or maxillary sinuses occur in the frontal lobe, and frontal lobe abscesses are almost always the result of a complication of underlying sinus infection. Sphenoid sinusitis is the least common of the paranasal infections but must be treated with great caution as its complications tend to be more frequent and more severe. Cocaine abuse has been suggested as a risk factor for sphenoidal sinusitis and subsequent brain abscess development [132]. Intracranial abscesses resulting from sphenoid sinusitis tend to occur in either the pituitary fossa or the adjacent temporal lobe.

Periodontal infection is implicated in 6–13% of cases of brain abscess [133]. Organisms spread by either direct extension

through the skull foraminae or by haematogenous seeding. Infection of a molar tooth is more likely to metastasize as it can spread between the muscles of mastication along fascial planes to the skull base. Unlike abscesses that complicate ear infections, most odontogenic cranial abscesses occur following acute rather than chronic infections [134].

Brain abscess is a rare complication of bacterial meningitis in adults; however, it is more common in infants, particularly those with Gram-negative meningitis, and cerebral abscesses have been associated with over 70% of cases of *Citrobacter koseri* (formerly *diversus*) in infants. On this basis it is arguable that all those from whom this organism is isolated from blood or cerebrospinal fluid (CSF) should undergo neuroimaging to exclude an intracranial abscess.

Haematogenous spread

The metastatic spread from distant parts of the body frequently leads to development of brain abscesses. The most common site of origin is pyogenic lung infection, including abscess, bronchiectasis, empyema and cystic fibrosis. Acute bacterial endocarditis is another important cause. Other potential primary foci include osteomyelitis, wound and skin infections, cholecystitis, pelvic infection and intra-abdominal sepsis. In the normal brain, the frontal and parietal lobe receive the majority of cerebral blood flow and bacterial emboli are more likely to be delivered to these areas, lodging at the grey–white junction where cerebral vessels decrease in calibre. They are less well encapsulated, multiple in up to 50% of cases (or multiloculated) and are associated with a higher mortality than those that arise from direct spread (although this may be due to the condition giving rise to the parent infection). The formation of these abscesses appears to depend on the combination of bacteraemia and the presence of an appropriate environment. Areas of infarction, ischaemia and contusion provide a fertile territory for bacterial seeding and abscess formation.

Postoperative abscess

Infection of cranial wounds can lead to formation of a brain abscess. Although it was previously thought that bacterial contamination occurred at the time of surgery, a recent study of paediatric shunt infections suggests that the window of infection extends throughout the postoperative course [135]. Factors influencing infection include CSF leak, implantation of prostheses (including CSF shunts or deep brain stimulation electrodes), systemic steroids (most neuro-oncological patients take steroids during the perioperative period) and the use of intraoperative chemotherapy (Gliadel® wafers, which release carmustine into the tumour bed). If the surgeon has opened the paranasal sinuses or mastoid air cells, the operative site may be contaminated by sinus flora and there is also a potential route for introduction of infection during the postoperative period. If the bone flap becomes infected after a craniotomy, then removal of the bone flap is almost invariably required for resolution of the infection.

Trauma

Brain abscess complicates approximately 3% of penetrating head injuries, especially gunshot wounds. Metal fragments do not pose a significant risk of abscess and do not usually require removal; however, bone fragments have consistently been recognized as an important factor in brain abscess development and should be removed. Several studies of penetrating head injury (combat related) reveal a brain abscess incidence of 3–17% [136] with a mortality rate of 54% [137]. Post-traumatic abscess development can occasionally be significantly delayed: one report describes a brain abscess due to *Clostridium bifermentans* as a result of a metal fragment from a Vietnam War mortar that had been in place for 15 years [138]. In another case, a brain abscess was formed 10 years following a traumatic head injury with retained glass fragments [139].

Microbiology

The species of bacteria responsible for brain abscess depends on the pathogenic mechanism involved. Commonly isolated organisms are streptococci, including aerobic, anaerobic and microaerophilic types. These are found in 60–70% of non-traumatic brain abscesses and many, particularly *Streptococcus milleri*, are part of the normal bacterial flora of the oral cavity, appendix and female genital tract. *Strep. pneumoniae* is a rarer cause of brain abscesses, which are often the sequel to occult CSF rhinorrhoea and also to pneumococcal pneumonia in elderly patients. Enteric bacteria and *Bacteroides* are isolated in 20–40% of cases and often in mixed culture. Anaerobic organisms have become increasingly important organisms, and in many instances multiple species are involved. Gram-negative organisms rarely occur alone. Staphylococcal abscesses account for 10–15% of cases and are usually caused by penetrating head injury or bacteraemia secondary to endocarditis. Clostridial infections are most often post-traumatic. Rarely *Actinomyces* or *Nocardia* species are found to be the causative agent in a brain abscess. Actinomycotic abscess can occur secondary to distant infection, particularly in the chest or oropharynx. *Nocardia asteroides* is an unusual cause of multiple and multilobar thick-walled brain abscess. They are almost invariably associated with pulmonary infection and are often seen in patients with defects in cell-mediated immunity.

Diagnosis

The clinical presentation, laboratory findings and neuroimaging all contribute useful diagnostic information. The clinical presentation of patients with brain abscess depends on the size, location and number of lesions, the virulence of the micro-organism, the host response and the amount of cerebral oedema. There are no pathognomonic features. Parenchymal destruction combined with oedema often results in signs of raised intracranial pressure and focal neurological deficit, but the classical clinical triad of headache, fever and focal neurological deficit is present in fewer than 50% of patients. A constant progressive headache which is refractory to treatment is the most common symptom, occurring in 70–97% of patients [140]. It may be localized to the side of the abscess, but it is often generalized, increasing in severity as the abscess expands. If the abscess is adjacent to the brain surface it may provoke meningeal irritation.

Symptoms of acute infection can be lacking unless there is an active systemic focus. Only 50% of adult patients are febrile at the time of diagnosis and the fever is usually low grade [141]. In children fever occurs in up to 80%, but a high-grade temperature of 38.6°C or more is less common and frequently indicates the presence of systemic infection or meningitis [142]. A reduced Glasgow Coma Scale score is seen in up to two-thirds of patients and presentation ranges from mild confusion and drowsiness to

coma [140]. A relatively late event is papilloedema, which is seen in approximately 50% of patients, and third and sixth cranial nerve palsies may likewise reflect raised intracranial pressure. In most large series, over 60% of patients present with focal neurological deficit [140] and, in a recent analysis of the clinical features of 20 patients with streptococcal brain abscess, nine presented with hemiparesis [143]. Although the majority of supratentorial abscesses (especially parietal) tend to result in hemiparesis, those in temporal lobe cause varying degrees of dysphasia, and visual field deficit and cerebellar abscesses lead to ataxia and nystagmus. Seizures occur in 30–80% of patients preoperatively in larger series, but were a clinical manifestation in only one in 20 streptococcal brain abscesses in one series [143]. Occasionally, brain abscess may mimic a cerebrovascular event; Shintani *et al.* [144] reported a patient in whom sudden-onset homonymous hemianopia was later found to be caused by bacterial brain abscess.

Adults with a normal immune response frequently show a rapid onset and progression of symptoms. Conversely, patients with immunodeficiency may have an insidious onset of symptoms, in which case a high index of suspicion is necessary to make an early diagnosis. Children under the age of 18 months (prior to fusion of the cranial sutures) present with a bulging fontanelle, enlarging head circumference and suture separation, seizures, irritability, nausea and vomiting. Untreated, a brain abscess is usually fulminant, resulting in death in 5–15 days. If the initial picture is suggestive of a focal lesion and rapid deterioration occurs with fever, headache and stiff neck, rupture of an abscess into the ventricle or subarachnoid space should be considered. Abscess rupture is a true neurosurgical emergency and, despite diagnostic and treatment advances, the mortality associated with intraventricular rupture exceeds 80% [144].

Laboratory diagnosis

Routine laboratory studies are of limited value in establishing a diagnosis of brain abscess. The peripheral white blood cell (WBC) count is normal or mildly elevated in 60–70% of patients [145] and blood cultures are likely to be negative unless the abscess is associated with septic embolization from infective endocarditis or a mycotic aneurysm. The erythrocyte sedimentation rate (ESR) is raised in approximately 90% of patients but is non-specific. Serum C-reactive protein (CRP) has some use in differentiating brain abscesses from other intracranial mass lesions [146] and CRP levels have been shown to remain elevated with incomplete treatment, returning to normal after successful treatment. Based on these observations, it is suggested that the return of the CRP to normal coupled with improved clinical condition and CT evidence of abscess resolution should be used as guidelines for discontinuation of antibiotics.

Cerebrospinal fluid analysis is non-specific. There is generally a mild pleocytosis with a WBC count of less than 100/cm^3 unless there is concomitant meningitis [145], and in another study one-third of patients with well-established abscesses had no evidence of pleocytosis. CSF protein is mildly elevated (usually below 100 mg/dL) and cultures are often sterile, especially in patients who are already on antibiotics. Given the limited use of CSF analysis and the presence of an intracranial mass, lumbar puncture is not recommended if the diagnosis of abscess is suspected.

Radiological diagnosis

Advances in neuroimaging, particularly CT scanning, have dramatically improved diagnosis and treatment of brain abscesses. More recently, MRI, magnetic resonance spectroscopy (MRS) and diffusion-weighted imaging (DWI) have emerged as useful tools in the evaluation of patients with suspected brain abscess.

Computed tomography

Computed tomography allows early diagnosis, localization and staging of the abscess according to criteria developed by Enzmann *et al.* [147], who classified abscesses as cerebritis or capsule stage according to patterns of contrast enhancement. Furthermore, they showed that CT classification corresponds well with histopathological stage as confirmed at surgery or postmortem. They noted that the early and late cerebritis phase is characterized by a poorly defined area of low density on non-contrast scans, indicating development of the necrotic centre of the abscess. As the early capsule phase is reached, non-contrast scans demonstrate a faint ring of slightly higher density compared with the necrotic lucent centre and the surrounding oedematous brain. This ring correlates histologically with the developing collagen capsule. Use of corticosteroids significantly reduces peripheral enhancement during the cerebritis stage but has little effect on a mature encapsulated lesion [147]. The characteristic features of the capsule help distinguish ring enhancement due to abscess from that caused by neoplasm. Other features indicative of brain abscess include multiplicity, multiloculation and location at the grey–white junction. Ependymal or leptomeningeal enhancement also favours a diagnosis of brain abscess. With no history of penetrating head injury or craniotomy, the finding of gas within an intracranial lesion is highly suspicious of an abscess involving a gas-forming organism.

These CT findings are not pathognomonic of brain abscess. The differential diagnosis of a ring-enhancing lesion includes tumour, infarction, radiation necrosis and resolving haematoma. With an increasing population of immunocompromised patients, there has been a corresponding increase in the number of abscesses caused by opportunistic infections. Parasites, fungi and atypical bacteria cause a variety of diseases, such as brain abscess (Fig. 71.4), meningitis, meningoencephalitis and granuloma. Because of compromised host defence mechanisms, parenchymal infections may be poorly localized and may fail to become encapsulated [148].

Magnetic resonance imaging

Magnetic resonance imaging is a more powerful tool than CT for the identification of brain abscesses. It has greater sensitivity than CT and is capable of detecting brain abscesses in the earliest stages of development [149]. Some investigators have suggested that, even without the benefit of contrast enhancement, the MRI characteristics of brain abscess are specific enough to make an accurate diagnosis [150]. In addition, MRI can better demonstrate anatomical detail and multiple imaging planes. The MRI features of brain abscess, like CT features, are related to the pathological phase of the abscess. On T1-weighted images, a peripheral zone of mild hypointensity relative to adjacent brain is seen, representing oedema formation. This surrounds a core of more marked signal hypointensity, which equates to the necrotic centre of the abscess. Between the two regions is the capsule,

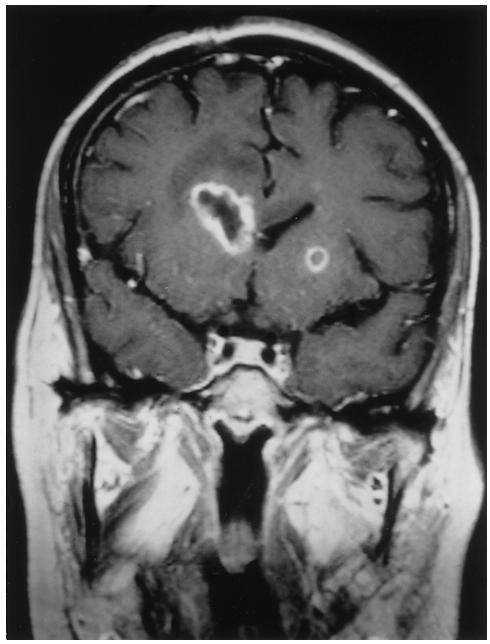


Fig. 71.4 *Aspergillus* abscesses in a 38-year-old immunocompromised man.

which appears as a discrete rim that is isointense to mildly hyperintense, and enhances vividly with gadolinium. This enhancement is frequently the most reliable diagnostic criterion in the acute setting (Fig. 71.5). On T2-weighted images, the signal intensity of the oedematous region increases markedly compared with the adjacent brain, and the centre is isointense to hyperintense compared with grey matter. The capsule has better definition and is seen as a hypointense rim at the margin of the abscess. Finally, one author has suggested that MRI is more specific than CT in differentiating oedema from liquefactive necrosis, which is valuable for planning the timing of aspiration [151].

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy has emerged as a useful technique for the differentiation of a brain abscess from neoplasm [152]. It is non-invasive and can be added to routine MRI examinations with only a minimal increase in cost and time [153]. *In vivo* MRS, when combined with MRI, can help to characterize cystic intracranial mass lesions [154]. Lesion-specific spectral patterns may assist in tissue characterization, for example they permit differentiation of brain abscess from necrotic or cystic tumours [155]. Compounds seen in MRS spectra of abscesses are often absent from tumour spectra. Intracranial tumours demonstrate resonance lines from lactate, choline and lipid, whereas abscesses demonstrate resonance lines from succinate, acetate and several amino acids derived from extracellular proteolysis or bacterial metabolism.

Diffusion-weighted imaging

Diffusion-weighted imaging can differentiate between abscess and tumour or infarct when the diagnosis is uncertain, despite CT or MRI. Ebisu *et al.* [156] examined the diagnostic ability of DWI to differentiate brain abscess from necrotic or cystic tumours. In previous studies, necrotic or cystic tumours showed low signal intensity on DWI, indicating a high apparent diffusion coefficient (ADC). Ebisu *et al.*, in contrast, observed high signal intensity in abscess fluid, associated with low ADC.

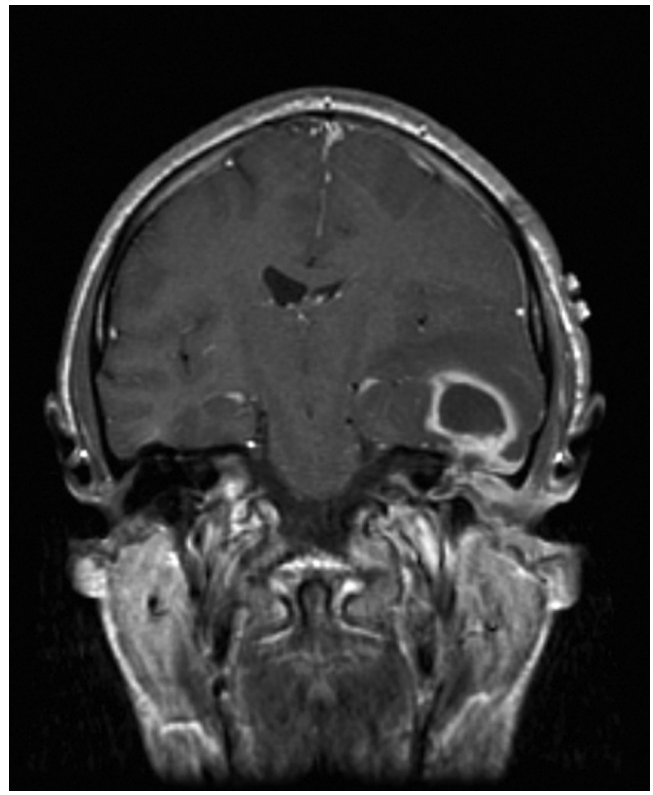

Fig. 71.5 Gadolinium-enhanced T1-weighted coronal MRI showing ring-enhancement of an abscess in the inferior temporal lobe on the left. There is associated enhancement of the middle ear cavity adjacent to the abscess.

Surgical management

Until the early 1970s, surgery (aspiration, drainage, excision) was considered the method of choice in the management of brain abscess. Later evidence, however, suggested that selected patients, especially those in the early cerebritis stages, could be managed successfully with antibiotics alone [156,157]. Heineman and Braude [158] were the first to suggest that a brain abscess could be treated successfully without surgery, reporting six patients with brain abscesses who were cured with antibiotics alone. Rosenblum *et al.* [157] reviewed five large series concerning non-operative management of brain abscess. Overall success rate was 74%, with a mortality rate of 4% among a total of 50 patients.

Although non-surgical management can be effective, the ease and safety with which abscesses can be aspirated through a single burr hole using modern image guidance techniques means that it is usually preferable to obtain cultures and confirm the diagnosis. Rosenblum *et al.* [157] found that no abscesses over 2.5 cm in diameter resolved without surgical intervention, and Black *et al.* [159] found complete failure of antibiotic therapy alone for large abscesses despite adequate concentrations of antibiotics in the abscess cavity. This is of particular relevance to immunocompromised patients, who may harbour opportunistic infections not responsive to conventional antibiotic therapy. Removal of

purulent matter provides the additional benefits of immediate reduction in mass effect and intracranial pressure and a more favourable environment in which antibiotics can work (many antibiotics are rendered ineffective by the acidic environment within an abscess cavity). Non-operative management without an attempt to culture abscess material directly, therefore, has a limited role, especially given that there are few instances in which aspiration of a suspected abscess for culture is not feasible or possible.

The optimal definitive surgical management of brain abscess, in terms of its aims and techniques, remains a subject of controversy. Various procedures have been utilized, the most common being continuous tube drainage, stereotactic or open aspiration, open drainage and washout [160], marsupialization of the abscess and craniotomy with complete excision [161]. At present, drainage either open or via a tube and marsupialization are rarely used. Aspiration and excision are the mainstay of surgical treatment; however, controversy continues regarding optimal treatment. Although many surgeons have particular preferred methods, choice of one procedure over another may be influenced by patient factors, such as age, neurological and general medical condition, stage and type of abscess and whether multiple lesions are present. Aspiration alone has led to excellent outcomes in several reports [162,163] and in combination with appropriate antibiotics is considered by many to be the procedure of choice [145]. In the majority of cases aspiration establishes the diagnosis and provides culture material for antibiotic sensitivities. Large abscesses can be completely decompressed with minimal trauma and immediate reduction in mass effect. CT- or MRI-directed stereotaxis and ultrasound guidance (particularly useful for supratentorial lesions over 15 mm in diameter and in infants through an open fontanelle) [164] have all been described. Stereotactic aspiration is particularly suited to deep-seated or multiple abscesses and abscesses situated in eloquent areas of the brain where open operation would cause neurological damage. Factors shown to be related to failure of this approach include inadequate aspiration, lack of catheter drainage of larger abscesses, chronic immunodeficiency and insufficient antibiotic therapy.

Direct instillation of antibiotics into the abscess cavity during aspiration has frequently been employed, but the benefits of this practice are ill defined. Although there is as yet no direct evidence that this practice hastens abscess resolution, it has been shown to reduce wound infection rates [165], and it is argued to be a useful adjunct in cases of recurrent or refractory abscesses. Instillation during the early cerebritis phase may be deleterious in that the irrigating fluid can promote spread of infection to surrounding tissues [159]. Also, high local concentrations of some antibiotics (especially β-lactams) can cause seizures.

The most common complication of aspiration is intracranial haemorrhage. This occurs in the region of the developing collagen capsule, which contains friable vessels. Haemorrhage is a more common event in patients with cyanotic congenital heart disease.

Although aspiration has clearly proved successful, some surgeons favour excision via formal craniotomy, especially for cerebellar abscesses. Formal excision is inappropriate for lesions in the cerebritis phase, for deep abscesses and for those located in eloquent region when aspiration can be performed with relative ease. Multiple lesions are generally not amenable to excision. If the abscess is associated with a foreign body (especially bone fragments from penetrating trauma) surgery is often required to remove the foreign body, otherwise recurrence of the abscess may occur [166]. Fungal abscesses usually require excision as hyphae tend to aggregate within the capsule, making eradication difficult. Abscesses caused by mould are generally limited to severely immunocompromised patients. They require excision but are associated with a very high mortality.

Some authors recommend that all gas-containing abscesses be excised on the basis that, although gas-forming bacteria are occasionally responsible, the gas is more often a result of a fistula into the paranasal sinuses or middle ear. One study examined five patients in whom gas was found in the abscess cavity, all of which were eventually found to have an extracranial communication that required repair [167].

The role of surgery differs in the case of multiple abscesses. These are most commonly encountered in patients with cyanotic heart disease and other forms of haematogenous spread. In one series the incidence was said to approach 50% [168] with a mortality of 32%, failure to control intracranial and systemic infection being the main source of mortality. Because multiple abscesses tend to be smaller, the role of surgery is primarily diagnostic rather than curative. If there is one large abscess causing significant mass effect then this may be considered for operation, and in some patients with multiple abscesses aspiration of pus can be a life-saving measure [168]. Mamelak *et al.* [131] suggest that the combined approach of appropriate antibiotics, elimination of the primary septic focus and liberal use of CT to anticipate intracranial complications should yield cure rates of over 90% – a result similar to that expected when treating patients with solitary lesions.

As an adjunct to surgery, corticosteroids have been used to attempt to reduce cerebral oedema; however, steroids have been shown to inhibit leucocyte migration and impair host defence mechanisms that help to contain the infection. In experimental animal models of brain abscess, the collagen capsule in dexamethasone-treated animals did not develop [169] or development was delayed [170]. In addition to this, corticosteroids appear to reduce the degree of contrast enhancement on CT scan, especially in the early cerebritis stage [171], hence those treated with corticosteroids cannot reliably be assessed on the basis of reduced contrast enhancement. In most hospitals steroids are currently used only in those patients in whom significant mass effect is thought to be responsible for neurological deficit. Steroid treatment should be continued until the neurological condition stabilizes and then it should be tapered.

Despite the reported success with non-operative management as well as various forms of surgery, there is no consensus as to what constitutes optimal management of brain abscesses. No strict protocols can be devised; each case must be treated individually on its own merits, taking account of the factors described above. However, the general aim in the acute situation is elimination of active suppuration. Consideration of long-term effect on seizures is less of a priority.

Outcome

Thus, despite the best efforts, even successfully treated brain abscesses can result in long-term neurological morbidity [172,173], and this is most frequently related to seizures, cognitive dysfunction and focal neurological deficit, with up to 50% of patients suffering permanent neurological deficit [174]. The single most

important factor influencing mortality is the neurological condition of the patient at the time of diagnosis [145]. Patients who are alert with minimal deficits tend to have a good outcome, whereas mortality rates are much higher in patients who present in obtunded or comatose states.

The reported incidence of epilepsy following brain abscess is between 30% and 80%. One study in which 72% of patients developed late epilepsy also showed that all the patients who had seizures preoperatively went on to develop late epilepsy. The mean onset time of seizures for patients in this group was 3.5 years, although this was age dependent: in the 20- to 40-year age group, seizures began on average 1.7 years after diagnosis, compared with 4.4 years for patients below 20 years of age. In fact, 50% of patients in the older group had their first seizure during the first year after diagnosis compared with only 20% in the younger group. Analysis of seizure frequency showed that the maximum frequency occurred during the fourth and fifth years post diagnosis, and this peak correlated well with the occurrence of epileptogenic EEG patterns [175]. It has been suggested that the risk of developing late seizures is related to the location of the abscess. Nielsen *et al.* [173] found a higher incidence of seizures with frontal lobe abscesses, but other authors report no such relationship [130]. There is some evidence that there is a reduction in seizures among patients treated with aspiration as opposed to excision [146,176].

Summary

The majority of seizure disorders occurring after a brain abscess are relatively well controlled with AEDs. For those that remain intractable to maximal medical therapy, seizure focus resection may be considered [145]. Given the high likelihood of developing seizures, all patients with supratentorial brain abscesses should routinely be placed on prophylactic AEDs to continue for 1–2 years as directed. They may then be tapered, providing that the EEG shows no epileptogenic activity.

Neurocysticercosis

Background

Despite voluminous literature on neurocysticercosis (NCC), it is a disease that is unlikely to be familiar to most clinicians in the UK and Western Europe [177]. Worldwide it is the most common parasitic disease of the central nervous system (CNS) and a major cause of epilepsy and death in endemic areas, including Mexico, India and China [178]. Epilepsy is the most common clinical manifestation and presenting feature of NCC [179]. With the exception of south-west USA, it is very rare in industrialized nations [180], and prevalence is highest in Latin America and South-East Asia. It may be endemic in sub-Saharan Africa, although few studies have been carried out [181]. Reports show that NCC is still a significant cause of epilepsy in Ecuador [182], Honduras [183], Brazil [184], Cuba [185], Colombia [186] and Peru [187] and a resurgence of cases of epileptic seizures associated with NCC has been reported in Indonesia [188]. It is being diagnosed more frequently in developed countries as a result of tourism to countries where the disease is endemic [189]. NCC causes enormous human and economic cost owing to medical resources, AEDs and lost production. It has been proposed that NCC should be an internationally reportable disease [190].

Neurocysticercosis is a helminthiasis caused by the encysted larval stage, *Cysticercus cellulosae*, of the pork tapeworm *Taenia solium*. In the first stage, a human (the definitive host) ingests undercooked pork containing viable cysticerci, from within which the scolex hatches in the gut and attaches to the intestinal mucosa. Over 3 months, the tapeworm matures to a length of 2–7 m and gravid segments are released into the faeces. Following ingestion by a pig (the intermediate host), the eggs hatch in the small intestine, burrow through the wall and enter the CNS and the striated muscle, where they develop. When humans become intermediate hosts by accidental ingestion of eggs (faecal–oral spread), the life cycle is completed in a similar way in the CNS, skin and muscle of the human [177]. Postmortem studies of expatriates from endemic zones have improved our knowledge of natural human infection and it is now known that parenchymal cysts usually lie dormant for many years, and symptoms usually coincide with larval death and an intense inflammatory response caused by the release of larval antigens. A solitary parenchymal lesion is the most common form and seizures are the most common symptom, presenting in 70–90% of patients. Lesions may be multiple and can cause significant mass effect, hydrocephalus, basal arachnoiditis and cerebral infarction. In time, cysts tend to shrink, resulting in granulomata, which either calcify or disappear completely [180]. This pattern of spontaneous resolution has important implications for the correct diagnosis and treatment of the disease.

Diagnosis

A thorough history and neurological examination may yield clues, but there is a wide variation in the clinical manifestation of NCC. Seizures are the most common symptom and may occur when a cyst is degenerating or around a chronic, calcified lesion [179]. Other common presentations include symptoms of raised intracranial pressure. CSF usually shows increased protein and pleocytosis (eosinophils are not always raised). Electroencephalography is unreliable and may show generalized, focal or no abnormalities. A study of interictal EEGs in 50 patients with epilepsy and evidence of NCC showed that the EEG was normal in patients with inactive forms of NCC but was abnormal in 50% of patients with active and mixed forms, and in 48% of patients with active forms only [191]. EEG abnormality was independent of multiple lesions.

Ten to twenty per cent of patients will have intraventricular cysts. These may cause hydrocephalus and can be accompanied by nausea and vomiting, headache, ataxia and confusion. Focal neurological deficits are uncommon. Cysts within the basal cisterns can present with signs of meningeal irritation, hydrocephalus, vasculitis and stroke. Rarer neurological manifestations, such as altered mental state, spinal NCC with radicular pain, paraesthesiae or cord compression, migraine, ophthalmic cysticercosis and neurocognitive deficits have all been reported. Cysticercal encephalitis with multiple parenchymal inflammatory cysts and diffuse cerebral oedema has been described in young girls and such patients are at risk of severe neurological sequelae. In India, solitary enhancing CT lesions are particularly common but meningeal NCC has a much lower frequency [192]. The reasons behind this are unclear.

Cerebral tuberculoma is the main differential diagnosis and criteria for differentiation are described by Rajshekar *et al.* [193].

In a series of histopathologically diagnosed cases, intracranial hypertension and progressive neurological deficit were not seen with NCC. NCC lesions were well circumscribed, less than 20 mm in size and not associated with midline shift. Tuberculomas are, by contrast, usually irregular, solid, greater than 20 mm in size and present with a progressive deficit. This distinction is very significant for management; parenchymal cysticercosis is a benign and mostly self-limiting condition, but a tuberculoma is an active infection that requires prolonged therapy with potentially toxic drugs.

Neuroimaging is crucial to diagnosis, CT being particularly useful for showing calcified inactive lesions. MRI is superior for demonstrating subarachnoid or intraventricular cysts and for showing inflammation around a cyst [194]. Cysts may be single or multiple and at different stages at any given time. A classification system that corresponds to parasite viability has been proposed by Carpio *et al.* [195]: active, transitional and inactive. In the active stage (cyst asymptomatic) the CT appearance is a rounded hypodense area, or there may be a CSF-like signal on MRI. The 'starry night' effect (the presence of multiple eccentric mural nodules) is characteristic of NCC, although it may also be seen in cases of *Toxoplasma* infection. The transitional stage is a result of cystic degeneration. This appears on CT as a diffuse hypodense area with an irregular border that enhances with contrast. They appear as low-signal areas on T2-weighted MRI. Lastly, with the death of the scrolexes within the cyst, it either disappears or becomes a calcified inactive nodule of low intensity visible by proton-weighted MRI or homogeneous high density on CT scans.

Standard enzyme-linked immunosorbent assay (ELISA) techniques have proved less useful than hoped because of high false-negative and false-positive rates. Newer enzyme-linked immunoelectron transfer blot (EITB) assays on CSF or serum appear to have higher sensitivity (98%) and specificity (100%) in Latin American samples [196] but are less accurate for solitary enhancing CT lesions in India [197], Ecuador [198] and Honduras [182]. Its superiority to ELISA is a result of its ability to detect up to seven glycoproteins specific to *Taenia solium*. It is visualized like a Western blot, so that non-specific bands can be ignored, thereby ruling out cross-reactivity. More recently, an antigen detection 'capture' assay specific for viable metacestodes in CSF has been designed [199] and so far this has proved to be the most reliable method of detecting active cases of NCC.

A satisfactory international diagnostic protocol has yet to be agreed upon [200], although this was addressed recently by a panel led by Del Brutto *et al.* [201], who have summarized diagnostic criteria and degrees of diagnostic certainty (Tables 71.2 and 71.3). Criteria are divided into categories based on the weight attached to each feature: absolute, major, minor or epidemiological. Data interpretation allows the calculation of three degrees of diagnostic certainty – definitive, probable and possible. Since spontaneous cyst resolution is typical of NCC, it has been suggested by another group that this is also included as a minor criterion [177]. The most effective approach to NCC infection is prevention and this should be a primary public health focus for all developing countries [195].

If NCC is suspected clinically then antihelminthic drugs should be started without biopsy, and if seizures occur then these should be treated medically. It is not general policy to use albendazole and praziquantel with single enhancing lesions because the cysticerci are, by definition, dying away and will resolve spontaneously [180]. Good seizure control is usually achievable with a single lesion.

The management of NCC depends on the degree of neurological impairment, location, size and viability of the cysticerci, and the extent of the immune response [202]. Treatment of individual cases is based on anatomical location (parenchymal, subarachnoid, intraventricular, ocular or spinal) and mixed forms of NCC constitute more than 50% of cases. Therapy for mixed forms should address the most serious or life-threatening lesion first, including lesions causing raised intracranial pressure, hydrocephalus (of any mechanism), meningitis caused by subarachnoid NCC, cysticercal encephalitis and spinal NCC with myelopathy. These have been labelled 'malignant' because of their high morbidity and mortality rates. Benign forms of NCC include parenchymal cysts or calcifications without associated hydrocephalus, and chronic meningitis. Surgical excision is occasionally indicated for large solitary parenchymal cysts that exert local mass effect or cause raised intracranial pressure [203]. It is also indicated in cases of focal, medically intractable epilepsy that can be localized on an electroencephalogram of a parenchymal cyst or granuloma.

Table 71.2 Diagnostic criteria.

Absolute
Histological demonstration of parasite
Fundoscopic visualization of parasite
Cystic lesions with scolex on CT or MRI
Major
Lesions suggestive of neurocysticercosis on CT or MRI
Positive anticysticercal antibodies in serum or CSF
Calcifications on plain X-rays of thigh
Minor
Subcutaneous nodules
Clinical manifestations suggestive of cysticercosis
Disappearance of brain lesions with anticysticercal therapy
Epidemiological
Immigration from or living in endemic area
Travel to endemic area
Household contact with *Taenia solium* infection

Giant convexity NCC cysts have frequently been treated surgically because of a misdiagnosis as arachnoid cysts or subdural haemorrhages on CT scans. Surgical intervention was advocated for subarachnoid cysts owing to poor CSF penetration of praziquantel and its lack of effect on these cysts [204], but reports since 1990 describe successful treatment of subarachnoid cysts with albendazole [205]. Although surgery may still be indicated for subarachnoid cysts refractory to albendazole, anticysticercal therapy is now the initial treatment of choice. Some lesions, however, still require surgical resection as first-line treatment; cysts adjacent to blood vessels and cranial nerves can cause an intense inflammatory reaction in response to cysticidal drugs, hence cysts in the parasellar region may cause optichiasmatic arachnoiditis and endarteritis of the supraclinoid internal carotid artery (leading to occlusion), and complex cysts within the Sylvian fissure may occlude the middle cerebral artery [206]. Skull base cysts should be treated surgically if there is symptomatic brainstem compression.

Surgical resection has been suggested as the treatment of choice for intraventricular lesions by several authors [207]; this is based on evidence of cases of sudden death related to CSF obstruction. Although standard open procedures provide acceptable access to most cysts, recent advances in neuroendoscopy have made removal of freely mobile, lateral and third ventricle cysts preferable to open craniotomy [208]. Cysts within the fourth ventricle may be associated with hydrocephalus and this should be treated before any decision is made regarding the cyst [207]. Excision may be warranted owing to potential cyst expansion, with brainstem compression, cyst migration or formation of granular ependymitis. Two surgical series showed good or excellent clinical outcomes in 81% and 71% of patients, with 15% and 26% morbidity, respectively [209,210]. A study of 10 patients treated with praziquantel and albendazole showed complete disappearance of 80% of fourth ventricular cysts. Of the other two cysts, one decreased significantly in size and the other remained unchanged. Six out of the 10 patients presented with hydrocephalus and underwent shunting before anticysticercal therapy [211].

A paper describing the experience of eight patients with NCC in the UK has demonstrated the value of a general conservative approach to treatment [177] and the development of a useful management protocol, in part based on the diagnostic criteria of Del Brutto *et al.* [201]. Seven of these patients presented with epilepsy and single or multiple small enhancing parenchymal lesions and one with hydrocephalus caused by a midbrain lesion. One lesion was stereotactically excised but five other lesions spontaneously resolved with patients receiving expectant management and AED therapy. Two patients with multiple lesions were free of active infection. The authors' view was that small cortical granulomas should not be biopsied or removed because the parasite is dying and will disappear spontaneously; this view is corroborated by other authors [193,201]. A conservative approach is also beneficial in that a stereotactic biopsy may be complicated by a haemorrhage owing to the toughness and mobility of the cysticercus and fragile blood vessels at the grey–white junction [212]. In the unlikely event of a cyst enlarging or causing increasing neurological deficit, treatment with anticysticercal therapy should be initiated in the first instance. However, if the lesion remains refractory to treatment, then surgery is inevitable [177]. In all cases in the series of eight described by Wadley *et al.* [177] a definitive diagnosis was made as per the diagnostic criteria outlined in Tables 62.2 and 62.3. During the course of treatment and observation of these patients, a coherent management strategy for patients presenting with epilepsy was produced (Fig. 71.6). It is recommended that for patients with a definitive or probable diagnosis after investigation, management should be expectant with AEDs alone and imaging should be repeated at 8–10 weeks. Surgery should be reserved for lesions that enlarge or persist despite additional anticysticercal treatment or when there is diagnostic uncertainty. This conservative approach is corroborated by other authors. Proano *et al.* [211] described their treatment of 33 patients with large subarachnoid cysticercal cysts, for whom the usual recommendation would be surgical treatment. All of the patients in this series improved with albendazole and dexamethasone at 59-month follow-up. In most patients, improvement was rapid after the initiation of treatment [211]. Reports such as these may change the standard of care for patients with NCC. NCC with a solitary or small number of cerebral lesions is a self-limiting infestation with a pattern of spontaneous resolution. Unnecessary surgery or therapy with potentially toxic drugs should be avoided.

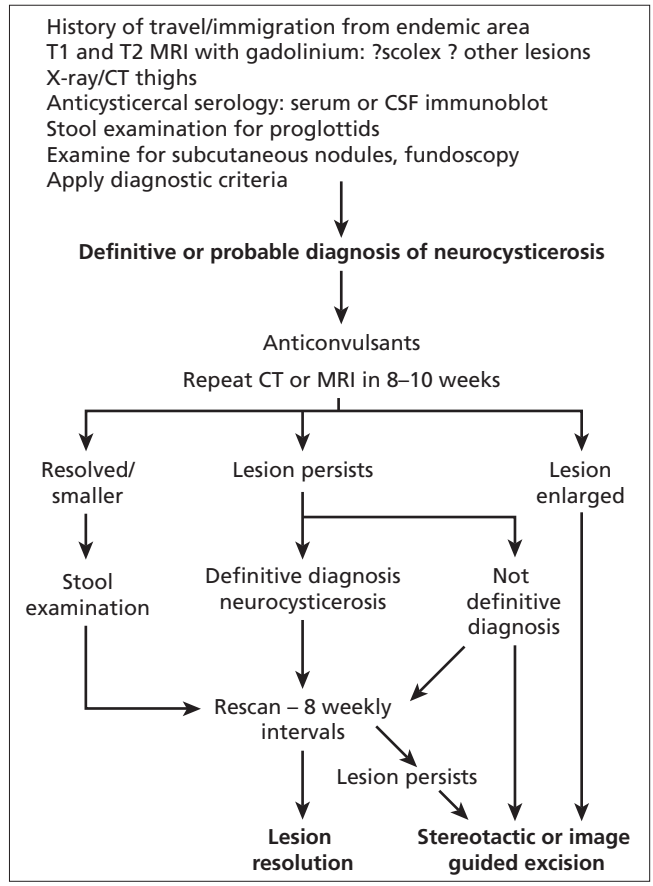

Fig. 71.6 Management protocol of a patient presenting with epilepsy and small enhancing lesions.

Cerebral tuberculoma

Background

Tuberculosis remains a major problem in developing countries and the incidence is rising in many industrialized countries owing to migration and HIV. Although the most common form of tuberculosis is pulmonary infection, CNS involvement is one of the most serious manifestations of the disease. The incidence of intracranial tuberculoma is decreasing, particularly in Western countries, and this is mainly due to the bacillus Calmette–Guérin (BCG) vaccination. In an autopsy study of intracranial space-occupying lesions (SOLs) conducted early in the 20th century (published in 1933), Garland and Armitage [213] found that tuberculomas represented 34% of all the SOLs, and in 1940 tuberculomas were said to account for 3.6% of 2190 brain tumours [214]. In 1959, Obrador [215] showed that cerebral tuberculoma accounted for 20–40% of all intracranial masses. In 1972, the incidence was put at 0.15% of 2200 intracranial masses [216]. In 1987, a study in Saudi Arabia showed that tuberculoma constitutes approximately 5% of intracranial SOLs [217], and a further report in 1993 estimated that cerebral tuberculoma in children constitutes 5–10% of intracranial SOLs in developing countries [218]. Reports of brain tuberculoma have appeared in the developed countries among immigrants [219] and patients with HIV [220]. In a recent study of 455 HIV cases in India, 23 patients had new-onset seizures, and 13% of these were caused by cerebral tuberculoma [2]. Gulati *et al.* studied 170 Indian children with chronic seizures and a high index of suspicion of an underlying SOL, and MRI indicated tuberculoma in 64 of them [221]. A study by Rebai *et al.* [222] over 16 years examined 1015 cases of intracranial SOLs; 24 of these (2.4%) were found to be tuberculomas. Because of their rarity, tuberculomas are not always considered in the differential diagnosis of intracranial SOLs. Furthermore, the exact pathophysiology is still not clear, partly because of the impossibility of reproducing tuberculoma in animals.

Tuberculomas are typically firm, lobulated masses of granulomatous inflammation with central caseous necrosis up to several centimetres in diameter and walled off by fibrous tissue. Lesions can occur within the cerebellum but are most common in the cerebral hemispheres [222].

Diagnosis

The diagnosis of intracranial tuberculoma should rest on the proper integration of data from clinical manifestations, CSF analysis and neuroimaging studies [223]. Tuberculoma should be distinguished from tuberculous meningitis, although the two may coexist. Rupture of a parenchymal lesion into the CSF has been implicated in the formation of tuberculous meningitis [224].

Computed tomography and MRI were directly compared in a study of six patients [223]. Although both were equally sensitive in visualizing the intracranial tuberculoma in every patient, MRI was superior in demonstrating the extent and maturity of the lesion, especially for brainstem lesions. Nevertheless, the diagnostic role for MRI in intracranial tuberculomas is limited by its inability to differentiate between other infections or neoplasms. In the developing world, CT remains the radiological investigation of choice.

The identification of a target lesion on an enhanced CT scan is characteristic of tuberculoma, although it is also seen with toxoplasmosis. It is difficult to distinguish tuberculoma from NCC; the criteria for differentiation using CT were described by Rajshekar *et al.* [193], and this difficulty was also highlighted by Garg *et al.* [225], who described an NCC-like presentation in a case of CNS tuberculosis in India. A clinical picture of seizures, multiple non-tender subcutaneous nodules and multiple ring-enhancing lesions on brain CT, was seen in a patient in an area endemic for NCC. Serological tests and histopathology established tuberculosis as the cause.

Diagnosis is further complicated by the fact that many patients with tuberculoma have no preceding history of tuberculosis infection. In the series of Rebai *et al.* [222], only 29% of patients with tuberculoma had a history of tuberculous infection (although bacterial examination is not conclusive even if negative). Although solitary lesions are generally more common, the diagnosis has been stated to be easier in cases with multiple intracerebral lesions. Boucetta *et al.* [226] reported solitary lesions in 84% of their patients, and 19% of the patients in the series by Rodat *et al.* [227] had multiple tuberculomas.

Management

Historically, tuberculomas were managed surgically; however, the development of antituberculous chemotherapy has reversed this [228]. Surgery may still be indicated, if the diagnosis is in doubt, for intractable epilepsy or mass effect causing intracranial hypertension, and there are reports of paradoxical expansion of intracranial tuberculomas during chemotherapy [229]. Two years of medical therapy is deemed suitable prior to consideration of epilepsy surgery; occasional debilitating seizures may warrant earlier referral. Delay in definitive treatment can be devastating; in one patient [230], rupture of the parenchymal lesion into the CSF led to the fulminating and fatal intracranial spread of the tuberculosis. Conversely, lesions involving eloquent cortex are likely to lead to increased neurological morbidity, and it may be prudent in such cases to defer surgical referral. It has been argued that, if diagnosis is likely, a trial of antituberculous therapy should be begun without biopsy confirmation [209]. Others [229] favour early open brain biopsy as soon as intracranial tuberculoma is suspected, especially in rapidly progressing cases. Primary medical treatment with frequent monitoring is reserved for lesions in the pons and brainstem or for multiple forms that are impossible to approach surgically. Cerebral tuberculomas with co-existent extracranial disease should also have primary medical treatment. Cerebral tuberculomas usually decrease in size within 8 weeks of starting medical therapy and this is accompanied by improved neurological status. Diagnosis should be reviewed if the anticipated improvement in clinical condition and radiological appearance is not forthcoming [217]. Furthermore, corticosteroids should be avoided during the therapeutic trial as regression of an underlying lymphoma can be misinterpreted as a favourable response to antituberculous chemotherapy [231]. With early diagnosis and a balanced combination of surgical and medical management, cerebral tuberculoma is curable.

Hydatid disease

Background

Echinococcus is a parasite that is endemic to Eastern Europe, the Middle East, Argentina, Chile, Uruguay, South Africa, Australia

and New Zealand, although its distribution is worldwide. Hydatid (meaning 'drop of water') describes the fluid-filled cysts created by the parasite. The dog tapeworm, *Echinococcus granulosus*, accounts for the majority of hydatid disease and tends to cause cystic brain lesions. *E. multilocularis* is a rarer cause of hydatid disease, which produces alveolar brain lesions. Domesticated dogs are the definitive hosts for the parasite and acquire the tapeworm when ingesting parasite-infested viscera of sheep and cattle (the intermediate host). The adult worm resides in the intestine and has a lifespan of approximately 6 months. Sheep typically become intermediate hosts by ingesting parasite ova in dog faeces; humans may interrupt the cycle, becoming intermediate hosts also by ingesting parasite ova originating in dog faeces. On ingestion of the ova, the larvae hatch and penetrate the intestinal mucosa. Haematogenous dissemination leads to the formation of cysts in the brain and spinal cord.

Two different histological types of cerebral hydatid cyst have been described: embryonal (primary) and scolical (metastatic or secondary) [191]. Primary cerebral hydatidosis is caused by embryos that escape filtration by the liver and lungs and become implanted in the brain parenchyma. Owing to their embryonal origin, primary cysts are usually fertile, as they contain many scolices. Primary cysts are almost always solitary, reports of multiple primary cerebral hydatid cysts being very rare [230]. In contrast, secondary metastatic cerebral hydatid cysts originate from infertile scolices of ruptured fertile cysts and are therefore usually infertile. Cerebral cysts have a variable rate of growth of 1–5 cm/year but may expand relatively quickly due to the immunological quiescence of the brain and a scant fibroblastic response. Cystic expansion may lead to compression and necrosis of surrounding tissues. In a series of 120 patients, 6% of the cysts measured between 6 and 10 cm in diameter and six cysts measured more than 20 cm in diameter [232].

Diagnosis

Cerebral hydatid cysts can occur at any age, but are most common in children. In a series of 155 cases, 117 were children, with a mean age of 7.2 years and a slight male predominance [233]. The most common mode of presentation in children is raised intracranial pressure. In adults, focal motor deficits are the more common, with signs of raised intracranial pressure occurring later. The presenting symptoms and signs in reducing order of frequency in a group of 120 patients with cerebral hydatid disease were headache (80%), papilloedema (74%), vomiting (70%), hemiparesis (60%), facial paresis (42%), cerebellar dysfunction (42%), hemianopia (40%), seizures (36%), reduced visual acuity (35%), ataxia (20%), somnolence (20%) and speech disturbance (15%) [232].

Laboratory tests are not particularly helpful in establishing the diagnosis. Serological tests can be useful, and ELISA, latex fixation and haemagglutination are acceptably sensitive and specific; however, all are limited by cross-reactivity with *Taeniidae solium* and are not sufficient on their own to establish the diagnosis [234]. Immunoglobulin G (IgG) ELISA, however, is useful as it has a sensitivity of up to 94% and a specificity of up to 99%. Radiological examination is important; lesions can remain undetected on CT scanning when they are visible on MRI [235]. Lack of rim enhancement, absence of perilesional oedema and, occasionally, calcification of the cyst rim are seen. Studies have shown significant variability in CT and MRI features of these cysts, such as irregularity in shape and contour of the cyst wall, cyst contents isodense to brain, heterogeneity of cyst fluid density, enhancement of the rim, surrounding brain oedema and globular calcification of the cyst margin [236].

Differential diagnosis should include NCC, arachnoid cysts, cerebral abscess and cystic tumours, such as metastasis, haemangioblastoma and glioma. Features distinguishing NCC from a hydatid cyst include size of the lesion and the presence of calcifications. Most parenchymal cysts of NCC are less than 2 cm in diameter, whereas hydatid cysts are usually much larger. Calcified parenchymal granulomas are seen in 58% of NCC patients, whereas calcification of the cyst rim is seen in fewer than 20% of hydatid cyst cases [232]. Brain abscesses and many neoplasms may produce perilesional oedema and also demonstrate significant contrast enhancement and a case report of solid cerebral *Echinococcus* mimicking primary brain tumour has been described [237]. Arachnoid cysts are probably the most difficult lesions to differentiate from hydatid cysts; arachnoid cysts are typically less spherical than hydatid cysts, but this is not always the case.

Management

Establishing the diagnosis preoperatively is crucial, as this guides surgical technique. Resective surgery remains the primary treatment of the disease. The standard surgical technique used for excision of large tumours containing cysts, i.e. aspiration and deflation of the cyst before resection of the tumour itself, is absolutely contraindicated as this risks turning a potentially curable condition into a chronic ongoing disease characterized by repetitive cyst recurrence. If the primary cyst ruptures, the enclosed protoscolices spill into the surrounding parenchyma and each protoscolex is able to transform into a secondary cyst. Most hydatid cysts are located at the grey–white matter junction as a result of haematogenous spread, typically in the distribution of the middle cerebral arteries. However, deep brain or intraventricular lesions are virtually impossible to resect without them rupturing. One accepted method of cyst removal is the Dowling technique [238]. Rather than using sharp dissection, this method relies on gravity to deliver the cyst from the surrounding brain. The patient is positioned on the operating table such that the cyst is in a dependent position. A large bone and dural flap are reflected and a cortical incision is made over the thinnest area overlying the cyst. Saline irrigation is used to dissect a tissue plane between the cyst and surrounding parenchyma. If the lesion is deep to the cortical surface and complete resection is not feasible, careful cyst aspiration is recommended, with hypertonic saline or silver nitrate solution used to destroy protoscolices [238].

The antihelminthic drug albendazole is effective in the treatment of cerebral *Echinococcus* [239]. Its success in a limited number of patients suggests that it may be preferred to surgery in certain clinical settings. Albendazole can achieve cyst concentrations of up to 40% of serum concentrations, causing disruption of the cyst wall and death of the protoscolices. It could be used adjunctively to shrink large superficial cortical cysts, as this would facilitate removal and reduce risk of rupture during resective surgery. Furthermore, albendazole prevents the formation of secondary cysts in case of inadvertent rupture. For cysts in eloquent brain or those in deep areas, the risks of surgery may be substantial. In such cases, albendazole alone may be able to resolve the cyst and obviate the need for surgery. It is also useful

in the treatment of secondary cysts that recur after surgery at the original site. Hepatotoxicity is a major limitation of albendazole use and hepatic enzyme levels must be monitored closely. Surgery remains the best option for large lesions; it produces immediate clinical improvement, unlike drug therapy, through which cyst resolution may take months or years.

Cyst rupture during attempted resection significantly affects prognosis. This is because the cyst contents are highly antigenic and rupture may lead to severe anaphylaxis with circulatory shock and death [240,241]. In a 1992 study, 10 (24%) of 41 patients in whom cyst rupture occurred during surgery died within 36 days of surgery. However, no deaths occurred among the 79 patients without cyst rupture.

Cyst rupture has also been seen to occur spontaneously in some patients. A rapid clinical deterioration is seen and severe pericystic oedema is seen on CT. This is a surgical emergency: removal of cyst contents must be carried out immediately, with copious saline irrigation and administration of antihelminthic drugs.

72 Surgery of Developmental Anomalies Causing Epilepsy

Joshua Chern and Youssef G. Comair
Baylor College of Medicine, Houston, TX, USA

Introduction

Malformations of cortical development (MCDs) consist of a group of brain developmental anomalies (for a comprehensive discussion and classification scheme, see ref. 1). These disorders were originally named according to their gross anatomical appearances: polymicrogyria (PMG), schizencephaly, lissencephaly (LIS), hemimegalencephaly, grey matter heterotopia and focal cortical dysplasia (FCD). Various classifications were introduced with different emphasis. For example, the classification by Barkovich *et al*. in 1996 [2] subdivided these disorders based mostly on stages of development: disorders of neuronal and glial proliferation, abnormal neuronal migration and/or cortical organization. Further categorization could be made based on location, extent of disease and histological findings. The classification by Palmini *et al*. in 2004 [3] was exclusively based on histology. More recently, information from genetics, molecular biology and neuroimaging has been included in some of the newer classification schemes [1].

This chapter will consider surgical treatment of refractory epilepsy due to various types of MCD. Tumours such as dysembryoplastic neuroepithelial tumour and ganglioglioma were sometimes labelled as 'developmental' and were categorized under MCD in some classification schemes, but this is the subject of Chapter 70 and will not be discussed here. The most common and distinct disorders will be considered separately, highlighting surgical results. A particular emphasis is placed on FCD, which is the most common type of MCD diagnosed in surgical series. Advancement in various presurgical assessments, including imaging technique and EEG monitoring, will be discussed here briefly although covered elsewhere in detail (Chapters 60–65).

Epidemiology

The prevalence of MCD in the general population and in various patient groups is not precisely known, the reason being that the presentation of MCD could vary widely. Patients with mild forms of MCD (i.e. FCD) might have no symptoms at all or mild symptoms that were undiagnosed. In an autopsy series of 7374 brains of healthy individuals that was published in the early 1990s, FCD was found in 1.7% of subjects [4]. In the era of modern imaging, however, more MCD disorders have been identified in asymptomatic subjects. In a report of 100 consecutive patients with a neuroimaging diagnosis of MCD it was found that 33 presented with a normal neurological examination, 61 presented with partial epileptic syndromes and 13 with secondary generalized syndrome [5]. In patients with severe signs and symptoms, i.e. developmental delay and/or epilepsy, increased incidence and severity of MCD might be expected. For example, in a series of 98 mentally retarded children with epilepsy, 60% were found to have generalized MCD on MRI [6].

The prevalence of MCD in epilepsy patients is estimated via surgical series or imaging. In a study published in 1995, 12% of 341 patients with refractory epilepsy had MRI diagnoses of MCD [7]. Before the era of imaging, 3% of patients who underwent surgery at Montreal Neurological Institute for epilepsy were found to have some type of MCD (YGC's experience). A case series of 133 consecutive resections for extratemporal intractable epilepsy at Cleveland Clinic established MCD as the histological diagnosis in 37.6% of cases [8]. MCD is particularly common in the paediatric epilepsy surgery population. In the paediatric UCLA surgical cohort from 1986 to 2005, MCD was identified in 45.5% of operated patients from age 2 months to 19 years [9]. In another study published in 1998 based on patients under 20 years old, MCD was found in 31 out of 120 patients (26%) [10]. Moreover, the diagnosis of MCD was found to be an independent prognostic factor for seizure intractability [11], and patients with MCD often have drug-resistant epilepsies [12].

Selection of surgical candidates

Although Taylor *et al*. [13] demonstrated more than 30 years ago that intractable epilepsy associated with cortical dysplasia could be successfully treated with surgery, surgery for MCD was performed on a small scale with poor results. Palmini *et al*. in 1991 [14] reported on a series of 30 patients from the Montreal Neurological Institute; surgical outcome in the series was not optimal, with only 11% achieving a seizure-free outcome. This report and the demonstration in the early 1990s by the UCLA epilepsy programme that children with catastrophic epilepsy secondary to severe MCD, including hemimegalencephaly, could be successfully treated with surgery rekindled interest in MCD. Subsequently, several reports confirmed the findings of the UCLA group. Furthermore, improvement in imaging and surgical strategies for the management of this group of disorders led to better detection and dramatically improved surgical outcomes.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Patients with drug-resistant intractable epilepsy are selected for surgical treatment. Infants with MCDs frequently have catastrophic epilepsy with heavy seizure burden and progressive developmental delay. The extent of reversibility of this delay has been the subject of several studies. All candidates with suspected MCDs should undergo an extensive presurgical evaluation that seeks to determine the presence and extent of the MCDs, the extent of the epileptogenic zone, and the relationship of the proposed resection to functional brain areas. This task is particularly complicated in children because of the presence of wide epileptogenic zones and the difficulty with localizing functional brain areas.

Presurgical evaluation: to determine the extent of the epileptogenic zone

The goal of presurgical evaluation is to determine the extent of the epileptogenic zone. The determination of the epileptogenic zone relies on data obtained from clinical examination, seizure semiology, imaging and electrophysiology. An essential first step is a demonstration of a MCD by MRI. Although the epileptogenic zone frequently extends beyond the MRI abnormality when demonstrated, the finding of an abnormality on the MRI greatly facilitates the presurgical evaluation and is considered an essential first step in the delineation of the extent of the epileptogenic zone. However, in a significant number of cases MRI is negative despite the acquisition of the sophisticated sequences and techniques described below. These patients are still considered for surgery with a heavier reliance on invasive electrodes.

History, physical examination and seizure semiology

The importance of careful history, physical examination and seizure semiology cannot be understated. In the presence of a family history of seizures, genetic counselling and testing is recommended. This is common in familial polymicrogyrias, schizencephaly and periventricular nodular heterotopia. Febrile convulsions are associated with hippocampal sclerosis and in the presence of a MCD a dual pathology should be considered [15]. Neurocutaneous syndromes associated with MCDs are noted on physical examination. Paresis is indicative of involvement of the central area. Neuropsychology testing is performed to establish a baseline; a developmental delay ranging from mild to severe is common.

Seizure semiology is related to the location of the epileptogenic zone; however, infantile spasms can be generated in children by MCDs in any brain location – a higher incidence of left hemispheric lesions associated with infantile spasms has been reported [16], although this has not been our experience. In infants, false localizing signs are related to the immaturity of the white matter tracts.

The clinical characteristics of 120 patients with a focal cortical dysplasia have been reported by Fauser *et al.* [17]. Seizure onset was before the age of 5 years in the majority of patients, although it could occur until the age of 60 years. Patients with mild FCD (type Ia of Palmini) had significantly later epilepsy onset. Age of seizure onset was unrelated to FCD localization; a change in seizure semiology occurred between the ages of 1 and 14 years – 17% of patients showed transient responsiveness to AED either at initial treatment (50%) or later (50%).

Auras carry a very important localizing value and together with seizure semiology contribute to developing a hypothesis on the location of the epileptogenic zone. The hypothesis is then confirmed by MRI and other presurgical tools. A discrepancy between semiology and imaging is suggestive of dual pathology. Multiple seizure generators are noted in dual pathology, with rapid seizure propagation. This condition is usually associated with poor seizure outcome. Status epilepticus is noted in 15% of patients.

Role of imaging

MRI

The critical importance of MRI in the diagnosis of MCD and treatment of epilepsy due to MCD has already been noted. It has a direct impact on the establishment of diagnosis, which in turn influences the surgeon's and clinician's decisions on treatment selections. Furthermore, a recent systematic review of the literature confirmed that an abnormal MRI was among the strongest predictors of seizure outcome after surgery [18].

The MRI evaluation is age dependent and is modified depending on the extent of the brain myelination. Before the age of 10 months, heavily T2-weighted spin-echo images are obtained. In older individuals, 1–2 mm thin section, T1- and T2-weighted images are necessary. There are expert recommendations on MRI acquisition techniques and sequences for MCD in general, with a particular emphasis on the importance of fluid attenuation inversion recovery and T2-weighted sequences [19]. Many reports have described typical MRI features of FCD: gyration anomalies, focal thickenings of the cortex, blurring of the grey–white junction, and abnormal cortical and subcortical signal intensity [20,21].

Malformations of cortical development lead frequently to abnormal gyral and sulcal development of the brain. Therefore, knowledge of the normal sulcal anatomy is essential for the detection of subtle anomalies. If the initial MRI investigation is negative, subtle anomalies can be detected by using advanced techniques that include phased-array surface coils, three-dimensional curvilinear reconstruction with postprocessing morphometry [22,23]. MRI (3-tesla) has demonstrated an increased capability in detection of dysplasia, particularly of the transmantle type.

Magnetic resonance spectroscopy

The sensitivity and specificity of magnetic resonance spectroscopy in the detection of MCD has not been assessed in a systematic fashion. Previously, spectroscopy has suffered from a limited spatial resolution and limited sampling of the region of interest. Several studies have demonstrated a decrease in NAA/Cho ratio and NAA/Cr ratio in FCD [15,24,25]. These findings are nonspecific for cortical dysplasia and have been reported in temporal lobe epilepsy [26,27]. In general, the extent of spectroscopic abnormality is larger than the structural imaging abnormality and the utility of magnetic resonance spectroscopy in MCD is being

assessed in patients whose initial MRI yielded unremarkable results.

Tractography and diffusion tensor imaging

Abnormalities of proliferation, migration and layering theoretically should result in anomalies of the white matter tracts of the brain. Diffusion tensor imaging (DTI) techniques have demonstrated increased diffusion in a high proportion of MCDs, and tractography has shown decreased and aberrant fibre connections with brain areas outside the structural abnormality. This technique is promising and contributes to a better assessment of the extent of the lesion. The abnormal white matter tracts associated with MCD could provide an explanation of the unusual propagation patterns and unexpected interactions between non-contiguous cortical and subcortical sites that has been reported by Duchowny [28,29] using subdural electrodes.

PET scanning

PET scanning has been used in the detection of MCDs before the development of high-resolution MRI [30]. The FDG-PET hypometabolism demonstrated reflects the functional deficit zones, therefore it includes but is wider than the epileptogenic zone [31]. PET scanning can be very useful in MRI-negative temporal and extratemporal cases [32,33]. Several new ligands are expanding the applications of PET scanning.

[^{11}C]-Flumazenil (FMZ) PET binding with the GABA receptor and [^{11}C]-α-methyl-L-tryptophan (AMT) improves the visualization of neocortical epilepsy in MRI-negative patients [34–41]. Decreased flumazenil binding appears to correlate better with the epileptogenic zone than glucose hypometabolism. FMZ may demonstrate secondary epileptogenic foci remote from the primary epileptogenic zone. Other ligands are being developed (for review see ref. 42).

SPECT scanning

Ictal SPECT scanning with substraction techniques appears as a highly sensitive method in the presurgical evaluation of a patient with cortical dysplasias. It is especially useful in MRI-negative cases, ranging from 56% [43] to 80%) [44]. The yield depends on early administration of the radiotracer at the onset of the seizure followed by sophisticated analysis methods [45–47]. These requirements have limited the use of ictal SPECT to centres which have developed a specific expertise in its administration and data analysis.

EEG/fMRI

EEG/fMRI is a new investigation modality that combines the high temporal resolution of EEG with the exquisite anatomical resolution of MRI. This allows a precise localization of the cortical and subcortical sources of paroxysmal EEG changes. Although reports of this technique are preliminary and have not been applied on a large scale to the study of cortical dysplasia, recent reports have provided important insights into the epileptogenicity of MCDs and interaction between MCD and surrounding cerebral structures in the genesis of epileptic activity [48–53]. These findings are discussed in conjunction with the role of invasive electrodes.

Role of electrophysiology

Long-term electroencephalography monitoring

The value of surface electroencephalography in the presurgical evaluation of MCD has not been investigated. Dubeau and Palmini [54] reported that two-thirds of patients with FCD have lateralized interictal findings on EEG corresponding to the localization of the malformation. However, bilateral independent interictal activity is not infrequent in children and should not lead to exclusion from presurgical evaluation. Widdess-Walsh [55], in a series of 48 patients, showed that 64% of patients had a regional surface ictal EEG pattern, 25% had a lateralized onset, and 11% had a non-localizable ictal pattern. Foldvary *et al*. [56] demonstrated that false localization occurs in high frequency in mesial frontal (75%) and mesial parieto-occipital locations (36%). Ictal beta rhythms, when present, are an excellent prognostic factor in frontal lobe epilepsy [57].

Invasive recordings

The value of invasive electroencephalography recordings in the delineation of the extent of the epileptogenic zone has not been completely settled. In most centres, some form of electroencephalography recording is used to delineate the extent of resection. We will discuss the benefits and limitations of each method.

Electrocorticography

In 1991 Palmini *et al*. [14] described distinctive electrocorticography (EcoG) patterns over dysplastic cortex consisting of frequent ictal trains of continuous spikes. This pattern was present in 67% of patients and correlated well with the anatomical extent of the lesion. This EEG pattern was not present in controlled patients and was more restricted than diffuse interictal discharges recorded in 82% of patients. These findings were confirmed by several authors. Ferrier *et al*. [58] demonstrated that the continuous ECOG spiking activity of Palmini was also noted in 12% of patients with glioneural tumours. In their series, only 55% of patients with FCD demonstrated continuous spiking. The discharge pattern did not correlate with the presence or absence of balloon cells on pathology. These studies and others demonstrate that, when present, epileptiform discharges can delineate the extent of the epileptogenic zone and provide the surgeon with an excellent tool in determining the extent of resection. Their persistence post resection would indicate residual dysplastic epileptogenic tissue and, therefore, a poor outcome. However, it has been our experience that EcoG is non-informative in approximately 50% of patients with FCD.

Invasive electrodes

Two types of invasive electrodes are used in the investigation of MCD: subdural grid electrodes and stereo EEG using depth electrodes. These both allow mapping of cortical function, therefore correlating ictal discharges with adjacent cortical function. The choice of electrodes is influenced by the centre preference and the location of the malformation. Periventricular nodular dysplasias, given their location, are more amenable to depth electrode investigation. At times, a combination of subdural and depth electrodes is indicated.

Subdural electrodes The efficacy of subdural electrodes in detecting an ictal onset area in MCD is still controversial. Despite the widespread use of these electrodes in MCD, results have not been adequately reported. A study from the Cleveland Clinic on 48 patients who received subdural electrodes demonstrated a diffuse ictal onset zone in 35% of the patients despite wide coverage. An ictal onset involving the edge of the subdural electrode was noted 49% of the time, and two or more separate ictal onset areas were detected in 41% of patients. Complete resection of the ictal onset zone led to a 65% seizure-free outcome. Incomplete resection of the ictal onset zone was associated with an 8% seizure-free outcome [55].

Recent advances in EEG are providing clues that could improve the ability of invasive recordings to demonstrate the ictal onset zone in some patients with MCD. Classical recording techniques have used a 200-Hz sampling rate and filtered EEG signal to around 70 Hz. High-frequency oscillation (HFO) above 70 Hz, although reported in animal models [59] and in patients with FCDs, was not initially perceived as clinically relevant [60]. Several centres have now demonstrated that HFO can be recorded using subdural and depth electrodes and that their depiction appears to approximate closely with the ictal onset area [61]. In 2007 Ochi *et al*. [62] reported that resection of areas associated with ictal HFO resulted in good surgical seizure-free outcomes [62].

Depth electrodes and SEEG The results of depth electrode investigations of the major types of MCD have been reported and have improved our understanding of the epileptogenicity of these malformations [49,63–70]. Depth electrodes appear to be superior to subdural electrodes in detecting a focal ictal onset area, with 93% efficacy in a large series [63]. This is explained by the ability of depth electrodes to sample tissue that is inaccessible to subdural electrode investigation.

Intralesional SEEG recordings from focal cortical dysplasia, in Taylor type and also non-Taylor type, have demonstrated a characteristic interictal pattern of repetitive and rhythmic spikes and polyspike waves [64]. This therefore confirms the high intrinsic epileptogenicity of FCDs noted in Palmini's reports using EcoG.

Depth electrode investigations are also particularly informative in periventricular nodular heterotopias, and several authors consider them to be necessary before resective surgery [65]. Epileptogenicity in these lesions involves a complex network that includes the ectopic grey matter, the overlying cortex and, not infrequently, the hippocampal formation. Identifying a focal generator is a good predictor for resective surgery in this MCD subtype.

Electrode recordings from nodular heterotopias have shown independent epileptiform discharges occurring in the heterotopia and the overlying cortex. In the temporal lobe, epileptiform activity can come from heterotopia, the overlying cortex and/or mesial temporal structures independently. In some cases, activations are recorded from the heterotopia and surrounding cortex with concomitant activation of a distant cortical area that bears no clear relationship to the lesion. In band heterotopias, wide activation from both the lesion and surrounding cortex were noted, confirming the diffuse nature of this lesion. Interestingly, fMRI activation rarely involved the entire heterotopia but was confined to restricted areas within the lesion [67]. These data appear to contradict findings using invasive recordings using SEEG [65].

Focal polymicrogyria has also been investigated using depth electrodes. In this pathology, the ictal onset zone is frequently outside the polymicrogyric cortex and involves the mesial temporal structures. As previously described by Silbergeld and Miller [71], wide resections that include the epileptogenic zone and the polymicrogyric cortex, when possible, are recommended [66].

EEG/fMRI has clarified the epileptogenicity of polymicrogyria. Previously, invasive recordings had failed to confirm intrinsic epileptogenicity within PMG. fMRI activation was noted within the polymicrogyria in 65% of patients. It also involved a focal area within the PMG in 61% of patients [67].

Magnetoencephalography

Magnetoencephalography (MEG) offers several advantages over EEG in the determination of the extent of the epileptogenic zone and its relationship to eloquent cortex in MCD. As MCDs are frequently deep and assume complex configurations, MEG-source modelling allows better determination of the location and time activities of the dysplastic neurones compared with EEG. It also allows the display of these activities on MRI imaging facilitation the surgical planning [72].

Several studies using MEG have confirmed intrinsic epileptogenicity of FCD previously reported by surface EEG recordings [73–75]. In one study comparing MEG with invasive EEG recordings in patients with cortical dysplasia it was revealed that MEG and EEG are complementary, as EEG is mostly sensitive to superficial currents and MEG detects preferentially tangential current within fissures [76].

In MRI-negative patients with cortical dysplasia, MEG investigation reveals subtle abnormalities that are verifiable pathologically [77].

Magnetoencephalography plays a role in the localization of essential cortex. Localization of the central sulcus is possible with an accuracy of a few millimetres [78]. In addition, various language paradigms allow mapping of speech areas [77,79–81].

Magnetoencephalography therefore can add critical information to the decision-making in the presurgical assessment of patients with MCD.

Surgical outcome

Surgical outcome in grey matter heterotopia

Heterotopia of grey matter is classified into three types: laminar, band and nodular. Nodular heterotopia is further classified according to the location: periventricular or subcortical. Heterotopia may be focal or multifocal, and it may or may not be associated with other cortical malformations.

Not surprisingly, patients with nodular heterotopia without other cortical malformations had a more benign clinical course. Seizure type tended to be partial, with onset in early adulthood, and susceptible to antiepileptic drug treatment, and the number of seizures decreased with time [68,82]. Occasionally, if the heterotopia is unilateral and localized, and its epileptogenicity confirmed (usually by invasive monitoring), seizure-free outcome may be obtained after surgery (9 out of 16 patients from refs 65 and 83 combined). In these cases, resection of additional areas adja-

cent to the heterotopic nodules and/or other remote epileptogenic area was almost always necessary.

A bigger proportion of patients, however, had heterotopias that were either diffuse or were associated with other MCD disorders, and surgical resection was often not an option. The most frequently associated MCD disorder was mesial temporal sclerosis [84,85]. These patients had a higher prevalence of epilepsy, developmental delay and neurological deficit [82,86]. When they did undergo resection, whether it was directed at the heterotopia or the mesial temporal sclerosis, the result was generally poor [87]. Stereotactic radiosurgery for heterotopia has been considered as a surgical option but a literature search did not reveal any published references.

Surgical outcome in lissencephaly

Lissencephaly consists of a paucity of gyri and sulci. Depending on the extent of involvement, agyria and pachygyria are also included in this disorder. Correspondingly, clinical manifestations are also quite variable. A PubMed search did not identify surgical series based solely on patients with lissencephaly. In case series on corpus callosotomy, some patients, whose underlying abnormality were bilateral lissencephaly with clinical manifestations of drop attacks and generalized tonic seizure, did benefit from surgical intervention [88,89].

Surgical outcome in hemimegalencephaly

Hemimegalencephaly arises from a global abnormal proliferation of neurones and glia that tends to affect an entire hemisphere. Traditionally, hemimegalencephaly is treated with hemispherectomy with limited success. An excellent review of recent surgical series was published by Di Rocco *et al.* [90]. In a total of 78 patients published in 11 reports since 1994, 31 patients achieved Engel class I outcome. There was a general improvement in cognitive and psychomotor development. Surgical technique included anatomical hemispherectomy or hemicorticectomy or functional techniques that all seemed to be equally efficacious. The authors speculated that the lack of complete success was due to the possibility of disease in the 'healthy' hemisphere that escaped imaging detection, and the difficulties in performing the surgery due to the severe anatomical distortion. However, surgical complications, including hydrocephalus, infection, fever and death, could affect up to 50% of patients.

Surgical outcome in polymicrogyria, schizencephaly and porencephaly

Polymicrogyria consists of abnormally small gyri that could be focal, bilateral, perisylvian or diffuse. Histologically, there is a decreased number of neurones, which is most pronounced at layer V. The normal-appearing neurones in adjacent layers suggest that the proliferation and migration of the neurones are grossly intact, and it is the late process of cortical organization that is interrupted [1]. Thus, it is generally believed that polymicrogyria is an acquired lesion due to intrauterine insults, which is mimicked by the rat freeze lesion model.

There are few case reports of surgical treatment of polymicrogyria and no surgical series were identified [91–93]. All emphasized that the malformation was more extensive than that which was indicated by MRI.

Schizencephaly is characterized by a cleft extending through the thickness of the cortex lined by polymicrogyria; therefore, it is often included in the same category of cortical organization disorder as polymicrogyria [1]. One of the difficulties associated with these cases comes from the fact that the cortex within the cleft is not easily accessible for recording. Surgical techniques used in case reports include partial or total resection of the walls of schizencephalic cleft, resection of surrounding regions and multiple subpial transections of the cleft wall [71, 94–96].

Surgical outcomes in porencephaly

Continuing with the theme of prenatal and perinatal insult, porencephaly is sometimes associated with epilepsy. Patients usually present with hemiparesis and intellectual impairment in addition to intractable epilepsy [97]. Hemispherectomy of various degrees is often the only surgical option, but in selected cases focused cortical resection is possible [98].

Surgical outcome in focal cortical dysplasia

Focal cortical dysplasia is localized by definition and therefore affords the possibility of surgical resection as a treatment option. As a result, many more patients with FCD than with other types of MCD have undergone surgery. A greater availability of surgical specimens enables histological, molecular and genetic studies, which then make possible correlations with clinical and imaging findings.

Classifications

The term 'cortical dysplasia' was first proposed in 1971 by Taylor *et al*. [13] to describe the histology of epileptogenic neocortex. In the simplest terms, FCD is the 'subtype of MCD in which the developmental abnormality is strictly or mostly intracortical' [3]. Additional subdivisions include the following: type 1A, cortical architectural abnormalities; type 1B, architectural abnormalities with giant cells (meganeurones), but no dysmorphic neurones or balloon cells; type 2A, dysmorphic neurones in the setting of architectural abnormalities; and type 2B, the presence of balloon cells intermixed with dysmorphic neurones in the setting of architectural abnormalities [3]. This is the most widely used histological classification today.

The majority of FCD patients experience onset of epilepsy by 5 years of age; however, seizure onset can also occur in the second or third decade. Patients can present with generalized or partial seizure or in status epilepticus. Even although some show transient responsiveness to antiepileptic drug therapy, this group of patients often has intractable seizures [17]. Most studies found that the presence of dysmorphic and balloon cells was positively correlated with younger age of seizure onset, more frequent seizures and more severe cognitive disability [17,99,100]. However, the correlation between histology and surgical outcome is much less well defined (see below).

Imaging

Approximately 90% of patients who were selected for surgery and had a histologically confirmed FCD had an identifiable lesion on preoperative MRI (see below). This percentage did not reflect the sensitivity of MRI at detecting FCD, but merely indicated that patients with normal MRI were less likely to be offered surgery.

Two clinically relevant questions can be asked concerning the role of MRI. First, can one accurately predict histological subtypes based on MRI findings, which may provide prognostic information and influence patient management, without subjecting patients to surgical biopsy or resection? Few studies directly answered this question. Studies by Colombo *et al*. [101] and Matsuda *et al*. [102] showed that even although different histological subtypes can be distinguished with MRI to some extent, enough overlap existed such that the clinical usefulness of this information was limited [101,102]. A second relevant question concerns whether or not MRI displays the real extent of the cortical dysplasia. Because a significant proportion of patients who underwent complete resection per imaging criteria still suffer from seizures (see next section), the answer is probably 'no'. As MRI technique continues to advance, one would expect that more and more patients will be offered surgery and better outcome will be obtained, but there will always be a small number of patients whose lesions escape imaging and who will thus stimulate further technical progress.

Surgical outcome

Focal cortical dysplasia is by far the most common MCD identified in surgical specimens. The focal nature of the disease means that patients are more often selected for surgery than those with more diffuse types of MCD. We have reviewed surgical series based on patients who underwent resective surgery and whose histological diagnosis was focal cortical dysplasia [69,103–119]. All 18 series were published since 2000 and all with a follow-up period of at least 1 year. All patients had preoperative MRI with 1.5-T magnet or better. Studies were included only if seizure-free outcome was reported explicitly.

A total of 469 patients and their surgical outcome were available for review: 59.7% of patients (280 out of 469) achieved seizure-free status 1 year postoperatively. This rate of success does not differ between patients who were older than 18 years (60.3%) or younger (59.8%). Overall, 89.4% of the patients had a lesion that was detectable by MRI, but a considerable percentage of patients who had a normal preoperative MRI were seizure free after the surgery (20 out of 36).

The one variable that most significantly correlates with a seizure-free result was the extent of lesion resection. In total, 71 out of 87 patients (81.6%) were seizure free after complete resection, compared with 23 out of 94 patients (24.5%) whose resection was incomplete. The difference was statistically significant ($P < 0.001$). Temporal lobe location was more favourable than extratemporal location. Of 82 patients (68.3%) who underwent temporal resection within the temporal lobe, 56 were seizure free, in contrast to 102 out of 204 patients (50.0%) whose resection was extratemporal. The difference was relatively small but statistically significant ($P = 0.019$). The use of either invasive monitoring or intraoperative EcoG did not affect the surgical results.

The most visible and easily classified lesion was the balloon cell. As a result, a large number of the studies focused on whether the presence of balloon cells predicts surgical outcome. Conflicting results were found in these surgical series. Although some found that the presence of balloon cells was correlated with better outcome [106,107,119], others found the opposite relation [110], or no relation at all [105,115]. As a whole, data from a pool of 210 patients indicate that the presence of balloon cells is not a reliable prognosticator of seizure-free surgical outcome.

Conclusion

Intractable epilepsy is frequently associated with MCD; however, it is amenable to surgical treatment. Surgical outcome with this pathology relies on a precise identification of an epileptogenic zone and its complete resection. This task is complicated by the frequent occurrence of MCD in eloquent areas and the persistence of essential cortical function within the epileptogenic zone in some types of MCD. Despite the challenging nature of this pathology, surgical outcome has steadily improved owing to important insights into this group of pathologies brought on by genetics, imaging, electrophysiology and refinements in surgical techniques.

73 Hemispherectomy for Epilepsy

Georg Dorfmüller[1,2], *Christine Bulteau*[1,2] *and Olivier Delalande*[1]

[1] Fondation Ophtalmologique Rothschild, Paris, France
[2] University Paris Descartes, Paris, France

Introduction

When congenital or acquired unilateral extensive brain pathology is associated with medically intractable hemispheric epilepsy, the only successful treatment in terms of seizure control will be a complete removal of this hemisphere or a functionally complete disconnection of all its afferent and efferent fibres (hemispherectomy or hemispherotomy; in this chapter, both terms will be synonymously referred to as HS if not otherwise specified).

Following the pioneering work of Walter Dandy [1], who performed the first documented hemispherectomies in man between 1923 and 1928 in five patients with infiltrating gliomas of the right cerebral hemisphere, and the concomitant theoretical work of the French neurologist Jean Lhermitte [2], the Canadian Neurosurgeon Kenneth McKenzie was the first to perform (in 1936) an anatomically complete right-sided hemispherectomy for disabling epilepsy in a 16-year-old girl with infantile hemiplegia following head trauma. The procedure was successful and the patient remained seizure free from then on [3]. However, relatively little notice was taken of his report and the procedure became popular only after the published work of R.A. Krynauw in 1950 on a series of 12 young patients with infantile hemiplegia who underwent hemispherectomy for drug-resistant epilepsy, with successful seizure control achieved in 10 of them [4].

Since then, anatomical hemispherectomies have been performed worldwide, with extensive discussions and several proposals as to whether, and to what degree, the basal ganglia should be included in the brain volume to be resected. Over the subsequent 10 years, more than 260 such procedures for epilepsy patients with infantile hemiplegia were performed worldwide [5]. Following the first reports of superficial cerebral haemosiderosis (SCH) as a late and potentially lethal complication of anatomical hemispherectomy, due to chronic repetitive bleeding into the huge subdural cavity and into the remaining ventricles [6–8], several essential modifications have been proposed in the last 40 years, such as the hemidecortication procedure [9], the Oxford modification, which consisted of obliterating the subdural cavity and excluding this space from the ventricular system [10], or Rasmussen's functional hemispherectomy [11]. More recently, different surgical techniques with a minimum amount of cerebral tissue resection but functionally complete disconnection of the affected cerebral hemisphere have been developed. In 1992, Delalande [12–14] proposed the vertical parasagittal approach in order to disconnect the hemisphere in a vertical plane from within the lateral ventricle and coined the term 'hemispherotomy'. Other disconnection techniques were developed [15,16], such as Villemure's peri-insular hemispherotomy. This technique is derived from the classical concept of functional hemispherectomy, using a lateral approach above and below the insular cortex and through the lateral ventricle in order to proceed to the hemispheric disconnection [15]. The transsylvian keyhole functional hemispherectomy is a similar technique which allows the temporomesial resection and hemispheric disconnection through a transsylvian approach to the lateral ventricle across the circular sulcus of the insula [17]. At present, all of the above-mentioned techniques are applied by epilepsy surgeons around the world with apparently similar results on seizure control, although depending on the underlying pathology; however, there is variation with regard to perioperative risk and hospital course. Until now, very few publications have been able to address this issue of comparing different existing techniques [18,19].

Indications

Congenital or acquired unilateral brain lesions of different pathologies are capable of triggering severe, intractable epilepsy, originating from the entire or from major parts of the damaged hemisphere. The underlying aetiologies are infantile hemiplegia seizure syndrome, which includes pre- and postnatal injuries and vascular accidents that have formed large porencephalic cysts and which, historically, was the first hemispheric seizure disorder to be treated by hemispherectomy; Sturge–Weber syndrome, a phacomatosis associated with a more or less extensive unilateral leptomeningeal angiomatosis; the group of extensive malformations of cortical development with unilateral manifestation, including hemimegalencephaly; and Rasmussen's syndrome, a chronic unilateral encephalitis, which is unique among the seizure disorders considered for hemispheric surgery in that the first clinical manifestations, i.e. generalized or partial seizures followed by a progressive hemiparesis and hemispheric atrophy, will appear after an initial period of normal childhood development, with a median age of onset of about 5 years (14 months to 14 years) [20].

The time of prenatal injury with regard to brain development will determine if migrational and maturational disorders of cortical development will occur in addition: when injury happens before the 26th week of gestation, dysplastic grey matter adjacent to the porencephalic cavity and overlying polymicrogyria can be associated [21].

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

A distinct pathology which can develop into a seizure disorder of hemispheric origin is the hemiconvulsion hemiplegia epilepsy (HHE) syndrome. Systematically described by Gastaut in 1957 [22], the HHE syndrome usually follows one or several initial prolonged febrile hemiconvulsions, with or without deficit, in early childhood and evolves, after a free interval of variable duration, into an intractable epilepsy, probably due to ischaemic damage from prolonged seizure activity. The epilepsy may be of focal origin, usually of the temporal lobe, but it may have a larger extension, with diffuse cortical and subcortical atrophy of the affected hemisphere.

Other pathologies that are less frequently encountered in the presurgical evaluation setting for HS are due to sequelae of cerebral inflammatory processes of bacterial or viral origin.

Patients who are considered for hemispheric epilepsy surgery have several clinical characteristics in common: they initially present or will progress with a contralateral hemiparesis, which is usually predominant in the upper limb and is associated with a hemisensory deficit which is difficult to assess. Most children will present with a fixed or progressive homonymous hemianopsia, dependent on the underlying pathology, but the extent is difficult to assess in younger children. When the dominant cerebral hemisphere is affected, language development may be impaired to a certain degree or, as in Rasmussen's encephalitis, will eventually deteriorate in a progressive manner. The frequent contralateral seizure spread will interfere with early childhood development, with a deleterious effect on cognitive and behavioural functions over time. This may lead to severe epileptic encephalopathy, particularly in pathologies with very early seizure onset, as is frequently the case in extensive malformations of cortical development.

Diagnostic evaluations

Clinical findings

When children with refractory hemispheric seizure disorders are being considered for hemispheric surgery, they already present with a contralateral neurological deficit (motor, sensory, visual) and, to a variable degree, impairment of cognitive and language functions, particularly when the left hemisphere is affected. Severe cognitive impairment may also indicate continuous subclinical epileptic discharges, as in continuous spike waves during slow-wave sleep, clinically manifesting in significant language and behaviour disturbances [23,24] or involvement of the opposite 'healthy' hemisphere in the disease process.

On the other hand, children who eventually develop Rasmussen's syndrome will have had a normal development before the seizure onset and, from the time the chronic encephalitis is suspected, neurological and subsequently higher cortical function decline will parallel the progressively disabling seizures. The decision of when to propose hemispheric surgery in these patients will therefore depend on the actual degree of the deficits and severity of epilepsy, particularly in left hemispheric pathology.

Motor function

Preoperatively, all children will present with a certain degree of contralateral motor impairment (muscle strength, range of motion, muscle tone). After HS, muscle strength in the proximal upper limb and in the lower limb will eventually return to the preoperative level, whether in the distal arm and hand, muscle tone is increased and strength remains decreased compared with the preoperative level, with permanent loss of finger dexterity [25,26]. This phenomenon might be explained by the fact that hand movements are more under the control of the corticospinal pathways, whereas the locomotor task of the lower limbs is more under the control of the spinal neuronal circuits [27]. Furthermore, subcortical regions, such as the cerebellum and the mesencephalic locomotor region of the brainstem or ipsilateral corticospinal pathways, might contribute to the ability to ambulate following HS [28]. In general, patients who are ambulatory prior to HS remain so thereafter, independent of the underlying pathology [18]. In a retrospective study including 111 patients undergoing hemidecortication, 89% were able to walk without assistance after surgery [29]. Those who where unable to walk had prior immobility due to the underlying process, major postoperative complications or persisting seizures. On the other hand, it has been shown that children with a better cognitive development before surgery had more improvement in global motor function after hemispherectomy than children with a lower cognitive level [25].

Visual pathways

Contralateral homonymous hemianopsia will either remain unaltered if already present before surgery or will result following HS [25]. Recently, the capacity to process visual information in the blind visual field (blindsight) has been demonstrated in hemianopic patients following hemispherectomy by means of functional MRI (fMRI) and diffusion tensor imaging tractography [30–32]. The possible capability of the retinocollicular pathway, which does not degenerate completely as a result of cortical hemispherectomy in the same hemisphere, in processing visual inputs (projecting to the contralateral cortex) has been hypothesized in this phenomenon [30,31,33].

Language

When left or dominant hemispheric disconnection is carried out before the age of about 5 years (a period considered critical for language lateralization) postoperative language outcome is in general excellent. Thus, homologous language zones in the right (minor) hemisphere are capable of taking over receptive as well as expressive language functions. In contrast, in acquired pathologies (such as Rasmussen's syndrome) with a later seizure onset following an initial period of normal development preoperative language skills will be impaired in most cases and postoperative recovery may well improve but never return to normal. Hertz-Pannier *et al.* [34] described a 9-year-old boy who underwent left hemispherotomy for epilepsy with Rasmussen's encephalitis, with disease onset at age 5.5 years after normal language acquisition [34]. At 1.5 years post surgery, language function had considerably improved and fMRI during word generation demonstrated activation in the right inferior frontal, temporal and parietal regions, homologous to the preoperative left-sided fMRI activation pattern. On the other hand, Voets *et al.* [35] described a pre- and postoperative language fMRI study of a similar case of a boy with Rasmussen's encephalitis who underwent left

hemispherectomy at the age of 14. The postoperative fMRI revealed right inferior frontal as well as anterior insular activation, whereas the preoperative study had shown engagement of a bilateral frontotemporal network for the same language task. More recently, in a fMRI study involving six patients undergoing hemispherectomy (three left and three right), the patients showed a variable pattern of language activation in the inferior frontal region (Broca's area and its right homologue) along with consistent and typical activation in the temporal and precentral regions [36]. The extent of the activated right inferior frontal region seems to determine language outcome in children after left hemispherectomy.

In general, recovery of expressive language functions lags behind recovery of receptive functions. This was confirmed in a study by Boatman *et al*. [37] on six children aged 7–14 years with Rasmussen's encephalitis undergoing left hemispheric decorticectomy [37]. By 1 year after surgery, receptive functions were similar to, or surpassed, the presurgical performance, whereas expressive functions, such as naming and spontaneous speech, were still impaired. These authors did not find other factors to influence language outcome, such as the time interval from seizure onset to surgery or the patient's presurgical IQ.

In our retrospective study [14], including 83 patients with different underlying aetiologies who underwent hemispherotomy, language function was evaluated in 58 French native speakers with the Vineland Adaptive Behavior Scale [38]. In general, children showed a better communication score after right hemispherotomy than after left hemispherotomy, independent of the underlying pathology, and children in the Rasmussen group performed best in all the four skill domains. The time interval from onset of seizures to surgery was inversely correlated with the Vineland scores in three out of the four domains – socialization, daily living skills and communication – in right as well as in left hemispherotomy patients and for all aetiology groups [14].

Special considerations in Rasmussen's encephalitis

Children with Rasmussen's encephalitis who are considered for HS are in a different clinical situation from those with refractory epilepsy from other aetiology groups, and controversy exists as to whether HS should be performed early in the disease course or if it should be delayed in order to await spontanous progressive impairment, similar to what would be inflicted by early surgery. Neurocognitive development is normal before seizure onset and the functional pattern of deterioration will follow partial seizure activity. At the time of the first presentation for presurgical evaluation, motor hemideficit will be at most mild and, particularly, the hand function preserved. Successive motor deterioration will depend on the intensity of seizure activity and progressive focal cortical atrophy. Language and intellectual capacities are initially unimpaired, even in left hemisphere involvement, but will later on decline to a certain degree, although not always with a predictable time course. Steroid therapy can lead to a transitory remission, thereby further delaying the decision to operate.

Therefore, decline and eventual reorganization of cortical functions within the contralateral hemisphere will show an evolutionary but variable course, depending on factors such as age at seizure onset, the intensity and frequency of seizures, and the child's age at surgery.

After HS, children with Rasmussen's encephalitis show the most pronounced postoperative motor deficits compared with all other aetiologies [14], particularly concerning distal arm and hand function, which will necessitate an intensive and long-lasting rehabilitation programme.

HS of the left hemisphere might further worsen pre-existing language impairment, especially for expressive capacities. The degree of deficit and its long-term recovery will depend on the age at surgery, but the variability in hemispheric language shift and the participation of the healthy contralateral hemisphere in the language network before surgery are probably due to other factors as well.

Pulsifer *et al.* [39], in a pre- and postoperative cognitive study including 71 children who underwent hemispherectomy for different aetiologies, found a significantly lower general IQ score as well as receptive and expressive language performance scores in children with left hemispheric Rasmussen's syndrome than in those with right hemispheric, whereas they did not confirm such a side difference for cognitive outcome in children operated for cortical dysplasia or vascular aetiologies.

In our own patient cohort, as mentioned below, children with Rasmussen's encephalitis and left hemispherotomy fared better in language performance when surgery was performed at a younger age and when there was a shorter delay between onset of epilepsy and time of surgery. These results are in favour of an early decision towards surgery, as interhemispheric language shift caused by the disease process itself is obviously not a sufficient precondition for a good postoperative language outcome. On the contrary, our observation rather corroborates the hypothesis of a reinforced new language network after early HS.

Evolution of the surgical techniques

Since anatomical hemispherectomy for intractable epilepsy was applied for the first time in 1938, several fundamental modifications have been proposed, The classical procedure of anatomical hemispherectomy [1,4] was progressively abandoned in order to avoid early and late complications, such as intraoperative blood loss [19,40] or the incidence of fatal brainstem shift towards the resected side [41]. This process was accelerated from the late 1960s onwards, when the first reports of SCH as a severe late complication in as many as one-third of the patients undergoing hemispherectomy were published [8,42].

Functional hemispherectomy

In 1983 Theodore Rasmussen [11] published his experience of eight patients in what he called a 'functionally complete but anatomically subtotal procedure' – the *functional hemispherectomy*. This novel technique evolved from his observation that none of the patients who had previously been operated with a subtotal hemispherectomy suffered SCH in the long term, implying that the retention of a substantial cerebral volume on the operated side would reduce the size of the subdural cavity and could thus prevent brainstem shift and repetitive subdural bleeding with SCH formation. The success rate in controlling seizures, however, was disappointing and he therefore sought to develop an

anatomically subtotal but functionally total hemispherectomy. Functional hemispherectomy is based on a combination of a temporal lobectomy, including removal of the mesial structures, and extensive excision of the central region, while performing a complete subpial disconnection of the frontal, posterior parietal and occipital lobes, which are left in place together with their blood supply (Fig. 73.1). Epileptogenic insular cortex may additionally be resected. Indeed, in a published series of 34 patients who underwent functional hemispherectomy, none developed SCH after a median follow-up of 8 years [43].

The *modified hemispherectomy* originated at Oxford and was popularized by Adams [10,44]. In order to prevent the formation of chronic subdural haematoma membranes, this modification consisted in creating a wide dural detachment which is then sutured down to the falx tentorium and the dura of the skull base, thus turning the large subdural into an epidural space. Adams added to this technique the separation of the remaining subdural cavity from the ventricular system by obstructing the foramen of Monro with a plug of muscle, in order to avoid the chronic exposure of the ventricular system to blood products and subsequent hydrocephalus formation.

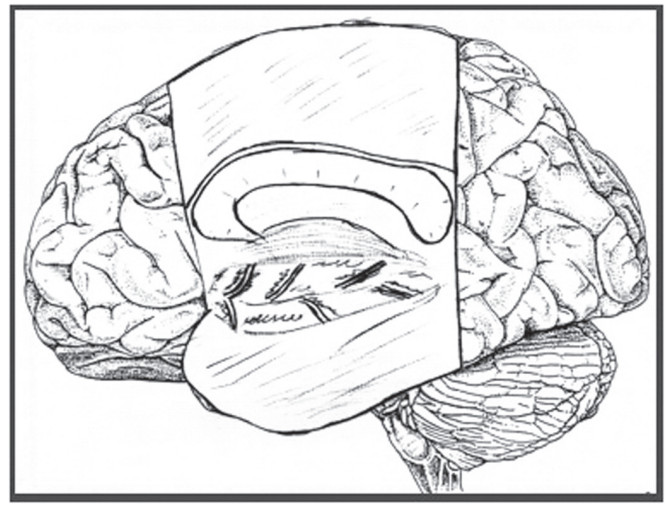
Hemidecortication was proposed by Ignelzi and Bucy in 1968 [9,45–47] and consisted in a hemispheric excision of the grey matter only, thereby sparing as much as possible of the white matter and avoiding opening of the lateral ventricle. This suggestion was based on the idea that removal of the entire epileptogenic cortex would be sufficient to stop seizure activity. Particularly in the case of Sturge–Weber syndrome, the cortical removal would include all areas with pial angiomatosis, but could spare cortical regions not affected, as is frequently seen in temporomesial cortex. The effectiveness of this technique in seizure control, however, was diminished in children with diffuse cortical dysplasia and hemimegalencephaly, as deeper-seated epileptogenic tissue can be at the origin of persisting seizures.

In order to further decrease complication rates due to the volume of brain tissue removal, intraoperative blood loss and duration of surgery, less invasive techniques have been developed, further increasing the ratio of disconnection to resection and requiring a smaller skin incision and bone flap.

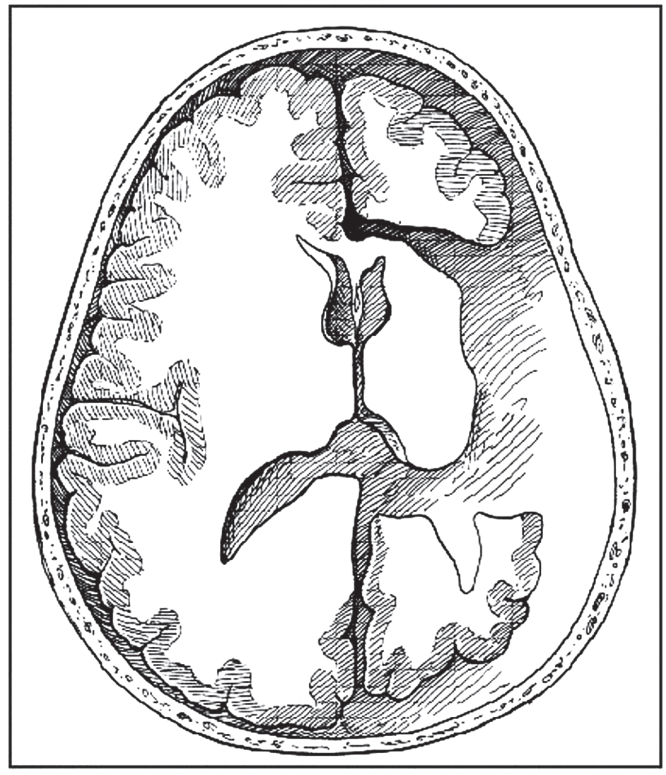
This concept turned out to replace the term hemispherectomy with that of *hemispherotomy*, proposed for the first time by Delalande in 1992 [12,13,48]. He described a vertical approach by opening the roof of the lateral ventricle below the frontocentral region and performing a vertically oriented hemispheric disconnection from within the ventricle. This technique is described in more detail below. The authors' experience with this *vertical parasagittal hemispherotomy* amounts to 200 such procedures to date. The technique and its results have been recently published for a part of this population [14].

Other hemispherotomy techniques have since been proposed, through a lateral peri-insular or transsylvian approach.

The *peri-insular hemispherotomy* described by Villemure and Mascott [15], which is derived from the concept of functional hemispherectomy, uses a small lateral supra- and infrainsular window through the frontoparietal and temporal opercula in order to reach the lateral ventricle. From here, resection of the amygdala and anterior hippocampus, as well as callosotomy and complete hemispheric disconnection, are performed. The insular cortex may additionally be excised.



(a)



(b)

Fig. 73.1 Drawings of a functional hemispherectomy as developed by Th. Rasmussen: lateral (a) and axial (b) plane, demonstrating resection of the temporal lobe, the central region and the insular cortex, with disconnection of the remaining frontal and parieto-occipital lobes. Both images reproduced with permission from Villemure JG. Cerebral hemispherectomy for epilepsy. In: *Operative Neurosurgical Techniques*, 3rd edn. Schmidek HH, Sweet WH (eds). Philadelphia: WB Saunders, 1995.

A generally similar technique, the transsylvian transventricular functional hemispherectomy, was proposed by Schramm *et al.* [17]. After resection of the anterior temporomesial structures and transsylvian exposition of the insular cortex, the lateral ventricle

is accessed through the circular sulcus of the insula and a callosotomy and hemispheric disconnection can be then carried out.

Shimizu and Maehara [49] have described another modification of the peri-insular hemispherotomy, beginning with a resection of the frontoparietal operculum and performing the different steps of complete hemispheric disconnection through this opercular resection cavity.

The lateral disconnection techniques are more difficult to perform in pathologies with minimal cerebral atrophy or even hypertrophic forms of cortical malformations, such as in hemimegalencephaly. In this pathology, the situation can be further complicated by a distorted anatomy of the lateral ventricle, the callosal body and other midline structures. The authors of the lateral approaches therefore recommend adapting the technique in these cases by enlarging the volume of excision, which also provides more space for postoperative brain swelling, which can particularly occur in hemimegalencephaly.

Vertical parasagittal hemispherotomy

At our institution, hemispheric surgery for epilepsy has been performed with one single technique, the vertical parasagittal hemispherotomy, which was first described by Delalande in 1992. To date, our personal experience with this technique amounts to 200 hemispherotomies over a period of 18 years. The distribution of the different underlying pathologies in our population is listed in Table 73.1. We recently reported the surgical technique in detail, as well as the postoperative results for a part of our patient population [14].

The technique can be described as follows. Through a small parasagittal frontoparietal craniotomy, a limited cortical resection of approximately 3 cm × 2 cm is performed and pursued, until the central part of the lateral ventricle is unroofed and its anatomical landmarks exposed (see Plate 73.1a). The corpus callosum is identified by following the roof of the lateral ventricle mesially. As for the whole hemispheric disconnection, the ultrasonic aspirator is used at a low level of vibration. The first step of the hemispherotomy will be a posterior callosotomy through this parasagittal approach. Resecting the splenium to the midline will expose the roof of the third ventricle and the arachnoid over the ambient cistern. From here, the dissection is pursued laterally to the choroidal fissure behind the pulvinar, thereby disconnecting the posterior column of the fornix at the level of the ventricular trigone (see Plate 73.1b). A strictly vertical incision lateral to the thalamus is then performed from this point anteriorly, by opening the roof of the temporal horn up to its most anterior part. This step will interrupt all fibres from the insular cortex as well.

Next, the callosotomy will be completed anteriorly. As for its posterior part, the ultrasonic dissection is performed intracallosally up to the interhemispheric cistern, with the exposed pericallosal arteries serving as a guide. This is followed by a limited resection of the most posterior part of the gyrus rectus. This resection allows one to visualize, across the arachnoid, the first segment of the anterior cerebral artery and the optic nerve, and provides space for the following straight incision oriented laterally through the caudate nucleus, in order to finally join the dissection line at the anterior point of the lateral incision. This last dissection will cut all the connections from the anterior temporal lobe, the amygdala and the frontal lobe. The hemispherotomy is now complete, having isolated the entire epileptic cortex from the subcortical structures.

The surgeon's vertical perspective allows a relatively clear identification of the anatomical key landmarks adjacent to the ventricle and facilitates the hemispheric dissection around these core structures, even in anatomically difficult pathologies, such as extreme forms of hemimegalencephaly or extensive post-ischaemic/-traumatic sequelae.

Furthermore, the vertical hemispherotomy allows us to perform, from within the ventricle, the whole tissue dissection subpially, thus avoiding manipulation of important vascular structures, such as the perforating branches from the anterior and middle cerebral artery or the densely packed insular branches.

On postoperative axial and coronal MRI, the line of the hemispheric disconnection can be easily identified (see Plate 73.1c).

Table 73.1 The different pathologies underlying unilateral hemispheric epilepsy.

Number of patients operated on by vertical parasagittal hemispherotomy for each category at our institution (total number of hemispherotomies from April 1990 to April 2008, n = 200) (right hemisphere 89, left hemisphere:111)

Malformations of cortical development
n = 87 (hemimegalencephaly: 40) (43.5%)

Rasmussen's encephalitis
n = 46 (23%)

Infantile hemiplegia (including perinatal stroke, brain haemorrhage, post-traumatic and post-infectious sequelae, miscellaneous)
n = 43 (21.5%)

Sturge–Weber syndrome
n = 24 (12%)

Seizure outcome

Once an appropriate patient selection for HS has been conducted, the postoperative outcome in terms of seizure control will be among the best in epilepsy surgery. In 90–95% of the patients, surgery leads to a worthwhile improvement from seizure reduction, and between 65% and 80% of the patients (all pathologies included) will be seizure free [14,18,19,29,50]. Devlin *et al*. [25] reported a somewhat lower rate of seizure-free children in their hemispherectomy series (52%). However, children with migrational disorders and hemimegalencephaly, who have the lowest seizure-free rates in all published series, were predominant in their reported population.

In all series to date, patients with migrational disorders, in particular with hemimegalencephaly, had a lower chance of being seizure free following HS (51–63%) than all other aetiologies [14,18,29,50].

Long-term outcome (>5 years) has been reported to be less effective with an overall decrease in seizure freedom from 76% at 1 year postoperatively to 58% at 5 years' follow-up [50]. Long-term follow-up in our own population (mean: 4.4 years) does not support this finding, with no decrease in seizure-free rates during the entire observation period [14].

Another important issue is whether the type of HS technique has an influence on seizure outcome. This has been adressed by

only a few authors, as most epilepsy surgeons who perform hemispheric surgery use only one single technique, and all but one published reports to date are from single centres. Cook *et al.* [19] compared three different hemispherectomy techniques (anatomical hemispherectomy, Rasmussen's functional hemispherectomy and a modified lateral hemispherotomy technique), applied in 115 patients over a 16-year period at a single centre by three neurosurgeons. They found perioperative risk and hospital course varied significantly depending on the techniques as well as the underlying pathology; there were significantly fewer perioperative problems related to blood loss, shorter times spent in the intensive care unit and shorter total hospital stays in patients undergoing hemispherotomy [19]. Differences in seizure control were not significant when comparing the three techniques, although there was a trend towards better outcome for all pathologies following hemispherotomy.

Holthausen *et al.* [18] conducted the largest retrospective and the only multicentric study to date, including 333 patients who were operated by one out of five different hemispherectomy or hemispherotomy techniques in 13 participating centres. Overall, 70.4% became seizure free, with a minimum follow-up of 6 months.

Regarding the different techniques, the best results were achieved with hemispherotomy and with Adam's modification (81.9% patients seizure free) compared with anatomical hemispherectomy, functional hemispherectomy and hemidecortication (64.1% patients seizure free). However, this difference did not reach statistical significance. In none of the pathology subgroups did the patient's age at surgery and the duration of the epilepsy correlate with a less favourable outcome.

The lowest seizure-free score was achieved in patients with malformations of cortical development (56.6%) and the best score in patients with Sturge–Weber syndrome (82.1% seizure free), followed by hemiatrophy (77.3%), Rasmussen's encephalitis (77.1%), vascular insults (76.1%) and 'others' (67.9%).

In our own published series, 74% of patients were seizure free following vertical parasagittal hemispherotomy, with no seizure recurrence after long-term follow-up and there was no necessity to reoperate children [14].

Postoperative seizures

Overall, approximately 5–10% of the patients undergoing HS will eventually not benefit from this surgery in terms of seizure control, with even higher failure rates being reported in children with migrational disorders, in particular those with hemimegalencephaly.

Theoretically, persistent or recurrent seizures might be explained by one of the following mechanisms:

- The epileptogenic tissue within the affected hemisphere has not been completely removed or disconnected.
- The epileptogenic tissue includes deeper subcortical structures, such as the basal ganglia, that were not included in the tissue volume to be resected or disconnected.
- Independent seizures arise from the contralateral hemisphere which was judged 'normal' in the presurgical evaluation.

The first point relates to the surgeon's experience and familiarity with the applied surgical technique. In our own patient population, we have performed 'second-look' surgery in two children with persisting seizures, after postoperative high-resolution MRI indicated a possible incomplete disconnection, and this proved to be the case in one child.

The second point is rather hypothetical but may be the reason for surgical failure in patients with cortical migration disorders, with a higher probability of finding dysplastic tissue within the subcortical structures. This is particularly the case in children with hemimegalencephaly.

The third point can never be completely excluded but emphasizes the requirement of a thorough presurgical evaluation of the contralateral hemisphere as well, by means of EEG analysis, structural and – if possible – functional imaging. In this respect, Rintahaka *et al.* [51] found a higher incidence of contralateral hypometabolism on FDG-PET studies in children with hemimegalencephaly and surgical failure following hemispherectomy, indicating structural abnormalities at the microscopic level [51]. On the other hand, Soufflet *et al.* [52], in a study including 13 patients with hemimegalencephaly who were evaluated with prolonged EEG recording and ^{133}Xe-SPECT measuring cereberal blood flow (CBF) pre- and postoperatively, found pathologically elevated CBF values in the hemisphere contralateral to the hemimegalencephaly [52]. This finding correlated with diffuse interictal spike activity and normalized soon after hemispherotomy, indicating that normal CBF function contralateral to the pathology can be restored. In hemimegalencephaly, some bilateral neuropathological changes have been proved following autopsy [53,54].

Early and late complications

Intraoperative complications in HS will determine the intraoperative and early postoperative morbidity and are mainly due to excessive blood loss, as may be particularly the case in children with hemimegalencephaly, a disorder associated with very early and severe seizure onset. Together with the group of extensive unilateral cortical dysplasias, these are the youngest patients to be operated on, frequently in early infancy. Significantly higher blood loss, which can reach an entire blood volume or more, and longer duration of surgery in children with hemimegalencephaly compared with all other aetiology groups (from authors' personal experience: see also ref. 50) have been related to young age, a more difficult anatomical situation with extensive cortical and subcortical hypertrophy, an anatomically distorted ipsilateral ventricle and corpus callosum, an increased blood flow to the megalencephalic hemisphere and a presumably abnormal venous drainage, which has been described in several cases with excessive bleeding [40,55,56]. Abnormal venous drainage can in turn be the reason for considerable postoperative brain swelling. In young infants in particular, possible problems from hypothermia, volume derangement, electrolyte imbalances and coagulative impairment during long surgery, and blood loss have to be taken into account.

Besides the specific anatomical features of each hemispherectomy/-otomy technique, operative blood loss seems to be a critical distinguishing parameter. The only comparative study addressing this issue to date has demonstrated a significantly reduced intraoperative blood loss and associated parameters, as well as a reduced postoperative intensive care stay in children operated by hemispherotomy as compared to anatomical or functional

hemispherectomy for all aetiology groups, including hemimegalencephaly [19]. These authors demonstrated that modified lateral hemispherotomy had the significantly lowest overall complication rate (11% vs. 35% and 34% for anatomical and functional hemispherectomy, respectively) and a reduced necessity of postoperative shunting (22% vs. 78% for anatomical hemispherectomy), although the shunt rate was even lower following functional hemispherectomy (9.4%).

Among the surgery-related morbidities, the development of internal and/or external hydrocephalus is relatively frequent, occurring several days to several months after HS but rarely as a late complication beyond the first postoperative year, and which will necessitate the placement of a ventriculoperitoneal or subduroperitoneal shunt. The incidence of postoperative hydrocephalus varies from 5% to 39% as reported in several recent series using different techniques of hemispherotomy [19,14,25,29,50,57]. Note that some authors do not consider hydrocephalus to be a postoperative complication [50]. The incidence seems to be elevated in children with hemimegalencephaly [14,25,57], although other authors have not found significant differences among the different pathologies [50].

Unexplained high fever early in the postoperative course, probably related to aseptic meningeal reaction, is a common observation and has been described by several groups [25,58].

In general, postoperative wound infections and haemorrhages seem to have the same low incidence as with other neurosurgical procedures of similar extent and duration and will deserve the same prophylactic and therapeutic measures.

The above-mentioned SCH as a severe late complication after anatomical hemispherectomy has led to newer, less invasive techniques with virtually no cases reported in the more recent larger series with sufficiently long follow-up. Nevertheless, some authors report the absence of SCH in more recent anatomical hemispherectomy series, relating this improvement to a meticulous haemostasis [19,59].

Conclusion

When unilateral hemispheric refractory epilepsy has been well documented, including a meticulous analysis of the integrity of the contralateral hemisphere by means of structural and functional imaging, ictal EEG and clinical seizure semiology, in order to rule out bilateral pathology, HS is a very effective surgical procedure, with a rate of seizure control that approaches the success rates in surgery for mesial temporal lobe epilepsy. Seizure outcome will depend primarily on the underlying pathology and is inferior in patients with extensive malformations of cortical development, including hemimegalencephaly. Intellectual and behavioural development will, in addition, be influenced by the age at seizure onset and the age at surgery, with a better chance for higher cortical function recovery when HS has been performed in earlier childhood.

Hemispherotomy is the logical continuation of the functional hemispherectomy, by further reducing the amount of excision in favour of disconnection, with the same indications and the same effect on seizure control. In our own experience with the vertical parasagittal hemispherotomy, as well as that of other neurosurgeons with the lateral approach hemispherotomy, overall surgery-related morbidity and hospital stay are significantly reduced, due to a very limited amount of cerebral tissue removal, a shorter length of the surgical procedure and a reduced amount of blood loss. Moreover, the incidence of shunt-dependent hydrocephalus seems to be improved by the disconnective techniques or other functional hemispherectomy techniques compared with anatomical hemispherectomy.

Once the hemispheric resection or disconnection is supposed to be complete, a failure to control seizures is most probably due to epileptogenic tissue within the remaining opposite hemisphere. On the other hand, when abnormal interictal and ictal EEG activity is recorded over both hemispheres during the preoperative assessment it should not necessarily preclude the therapeutic option of hemispheric surgery, as it may be due to rapid discharge propagation from the epileptogenic hemisphere.

The timing of surgery depends primarily on factors such as duration and severity of the seizure disorder, dynamic evolution of the disease, and actual neurological and cognitive state. Particularly in children with malformations of cortical development and with Rasmussen's encephalitis of the language-dominant hemisphere the decision when to operate remains a challenge, in order to achieve the best possible long-term cognitive development, degree of autonomy and quality of life.

74 Corpus Callosotomy

David W. Roberts
Dartmouth Medical School, Lebanon, NH, USA

Introduction

Surgical section of the corpus callosum has attracted enormous attention since its earliest reports, in large part the result of fascination with its neuropsychological consequences and implications. It was first performed nearly 70 years ago by Van Wagenen and Herren [1], who had observed that patients sustaining stroke or tumour progression destroying the corpus callosum often had improvement in an associated seizure disorder. There was laboratory evidence supporting the rationale for this procedure, notably that of Erickson [2], who in non-human primates demonstrated prevention of the spread of the epileptic discharge to the opposite hemisphere when the corpus callosum had been divided [2]. Following this early work, a small number of clinical series were reported [3–25], but it was not until the late 1980s that the procedure was widely adopted as a surgical option in medically intractable epilepsy patients who were not candidates for resective procedures. Today, most epilepsy centres perform commissurotomy and it retains an important role in the armamentarium of interventions for intractable epilepsy.

Indications

Resection of an epileptogenic region with the goal of surgical cure has always been the surgical procedure of choice, but in those patients with generalized seizures in whom a discrete epileptogenic region cannot be identified or resected, surgical disruption of secondary generalization is a reasonable option. Other palliative procedures, including multiple subpial transection, vagal nerve stimulation and deep brain stimulation, have also been developed and the strategy for optimal utilization or prioritization of these various non-ablative strategies remains to be determined.

From the earliest days of callosotomy it has been appreciated that drop attacks (variously classified as atonic and akinetic seizures) are among the most likely of seizure types to benefit from disconnection; tonic and tonic–clonic generalized seizures similarly have been shown to be significantly reduced [8–13,15–20,22–106]. Given the difficult evaluation in this patient population, it is both understandable and reasonable that many patients have undergone callosal section largely on the basis of their seizure semiology.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

The pathological substrate of the seizure disorder historically has played a secondary role in patient selection for this procedure. A spectrum of disease has been encompassed in clinical series. Williamson [92] looked at surgical outcomes in terms of clinical diagnoses and classified patients into groups of infantile hemiplegia, *forme fruste* infantile hemiplegia, Rasmussen's syndrome, Lennox–Gastaut syndrome, frontal lobe epilepsy and other secondarily generalized epileptics. Slightly better outcomes were found in the first two groups but there was sufficient improvement in all categories to justify surgical intervention.

Electroencephalography and video-electroencephalogram (EEG) monitoring have influenced patient selection principally in demonstrating the presence or absence of a resectable seizure focus. EEG findings in patients selected for callosotomy have been analysed by a number of investigators [50,107–113]. Correlating EEGs with surgical results, Geoffroy *et al*. [37], Spencer *et al*. [23] and Matsuzaka *et al*. [114] all reported better results in patients with lateralized EEG abnormalities. The majority of patients have evidence of bilaterally synchronous epileptiform activity and this does not necessarily represent a bad prognostic sign. The significance of bilateral, independent foci remains undetermined.

Demonstration on neuroimaging of lateralized structural lesions has been believed to be associated with a better surgical outcome [10,23], but in the selection process their presence or absence has always been secondary to clinical and electrophysiological information. The impact of neuroimaging on the callosotomy experience has been limited. As imaging technologies continue to evolve with increasing sensitivity and specificity, they are directing such aspects of the seizure evaluation as intracranial recording electrode placement, and this will obviously affect patient selection and perhaps the surgery itself.

Candidates for callosal section are patients who have medically intractable epilepsy in whom a resectable seizure focus cannot be identified and whose generalized seizures are believed likely to be ameliorated by disruption of seizure propagation. Patients in whom seizure semiology, electrophysiological studies, neuroimaging and neuropsychological testing have shown localized disease amenable to resection are excluded. The remaining candidate pool will be heterogeneous, including patients with infantile hemiplegia, *forme fruste* infantile hemiplegia, Rasmussen's syndrome, Lennox–Gastaut syndrome, frontal lobe epilepsy and other secondarily generalized epilepsies.

At our institution, selection criteria include (1) medical intractability of at least 2 years' duration (and typically longer), with exhaustive anticonvulsant regimens and documented adequate serum anticonvulsant levels; (2) generalized seizures, usually but

not necessarily major motor or atonic in type; (3) exclusion of a resectable seizure focus; and (4) potential functional benefit if improvement in the seizure disorder is achieved. We have not automatically excluded patients from surgery because of retardation, age, mixed hemisphere dominance [54,81], lack of demonstrable partial seizure onset or bilaterally independent EEG abnormalities, although it is recognized that the likelihood of success may be less in certain instances. Although the outcome of a seizure-free patient is always hoped for, this is achieved in only 5–10% of cases [115,116]. The goal of surgery with callosal section is distinguished from that of other epilepsy surgeries as it is usually palliative rather than curative.

Surgical technique

Early clinical series often included division of the corpus callosum, the underlying hippocampal commissure and additional structures, including the anterior commissure and, in some instances, one fornix [1,3,5–9,11]. Nearly all series today restrict division to the corpus callosum and, in posterior or complete callosal section, to the hippocampal commissure that is immediately apposed to the ventral aspect of the posterior portion of the callosum. There remains variation, however, with regard to which part or how much of the structure is divided. Seizure outcome appears to have some correlation with the extent of section [79,88]. As neuropsychological consequences of callosal section are encountered primarily with complete section [117,118], most centres today usually divide the anterior three-quarters and spare the splenium at initial surgery. Completion of the section can then be performed in those patients who fail to obtain an adequate response to such surgery. Exceptions to this approach are division of a smaller, select portion of the callosum, division of the posterior half as an initial procedure and division of the entire callosum in one operation. The presurgical evaluation and preoperative substrate may influence the consideration of these alternatives.

Diffuse or bilateral disease for which commissurotomy may be an appropriate strategy may be suggested by the history, neurological examination and cognitive evaluation, and these may contribute in the consideration of the risk–benefit ratio for partial or complete section. The sensory dissociation whereby visual, auditory or tactile information received by the non-dominant hemisphere may not be accessible to the speech-dominant hemisphere is of diminished consequence in the severely impaired individual, and in such a setting complete section may be a reasonable surgical approach. This is especially true if drop attacks, which usually respond to anterior section, are not the predominant seizure pattern. If presurgical evaluation, including electrophysiological studies, demonstrates predominantly parietal–occipital disease, it may be appropriate to consider posterior partial section as the first stage.

Consideration of the epileptogenic substrate may be important for reasons similar to those in the preoperative evaluation. A more discrete pathology may direct one towards an appropriate partial section [16], and diffuse disease may render any partial section futile. The correlation between extent of disease and successful section, however, is insufficient to place great reliance on these factors. Lateralized pathology does have a modest but worthwhile role in determining the side of the interhemispheric approach; this is usually on the non-dominant right side, but in the setting of an atrophic left hemisphere or right hemisphere language dominance, surgery from the left side of the falx may be indicated.

The patient is usually placed under general anaesthesia; intraoperative electroencephalographic recording, when performed, has been primarily for investigative purposes. Tailoring of the length of resection based on intraoperative EEG information has been advocated by at least one centre [55,56,119]. However, given the reality of often insufficient abnormal interictal EEG findings intraoperatively, as well as the observation that subsequent seizure propagation may occur across remaining, adjacent callosal fibres, most have not adopted this practice. The patient is placed in a supine position on the operating table, with the head unturned and secured in a three-point pin fixation. For the anterior division, the neck is kept in neutral position; for the posterior division, flexion of approximately 20° facilitates exposure. Alternatively, one may position the head parallel to the floor such that the hemisphere to be retracted is dependent, thereby allowing gravity to help provide the exposure [35,53]. This has the appeal of minimizing any retracting force placed interhemispherically, although whether this retraction is significant enough to warrant the perhaps less comfortable and differently oriented horizontal positioning is open to discussion.

The incision and type of craniotomy used is a matter of the surgeon's personal preference. We have used linear incisions and 5-cm trephinations [11,120], but the actual type and extent of craniotomy is relatively unimportant. A 9-cm transverse incision with one-third of its length across the midline and placed 2 cm in front of the coronal suture is used for the anterior procedure. A similar incision and trephination at the level of the parietal eminence is employed for the posterior procedure. The placement of the craniotomy across the sagittal sinus requires caution but facilitates exposure down the interhemispheric fissure with minimal retraction, and this is important.

Determination of the location of parasagittal draining veins prior to transcallosal procedures has been advocated, but this has not been a routine step for most centres, including ours. It has always been possible to work on either or both sides of such a vein without requiring its sacrifice using a microsurgical technique. Nevertheless, Apuzzo's observation [121] that in 42 out of 100 angiographic studies significant veins were noted to enter the sagittal sinus within 2 cm of the coronal suture, with 70% of these posterior to the suture, is of interest. Such angiographic information may be available in those patients who have previously undergone amytal testing or in whom MRA techniques have delineated parasagittal venous structures.

The dura is opened in the conventional manner, with a curvilinear incision and reflection on the sagittal sinus. Dissection begins down the interhemispheric fissure under loupe magnification, and retraction is aided by the earlier administration of mannitol (1 g/kg). Pressed Gelfoam (Upjohn, Kalamazoo, MI, USA) is used to protect the exposed cortex, and a Greenberg self-retaining retractor is placed before use of the operating microscope. Gentle retraction is accomplished with a single retractor blade on the ipsilateral hemisphere and, very occasionally, an additional blade retracts the inferior aspect of the falx or contralateral cingulate gyrus.

Adhesions between the hemispheres may make initial exposure difficult, especially when there is a history of previous infection or trauma. With patient microsurgical technique, one can generally obtain good exposure; approaching the callosum more posteriorly and utilizing the deeper extension of the falx can prove helpful in this situation. The corpus callosum is distinguished from the more superficial cingulate gyrus by its glistening white appearance, and exposure along the length of callosum to be divided is obtained prior to entering the commissure. The pericallosal arteries are identified overlying the callosum and care is taken to avoid their injury. Actual sectioning of callosal fibres is usually carried out between these arteries, although division lateral to these vessels can be performed if more convenient.

It is standard practice today to use the operating microscope, whose superior magnification and illumination have proven invaluable during the exposure and actual sectioning. Bipolar cautery is used for coagulation of small vessels supplying only the callosum itself. The actual division of callosal fibres is carried out with a microseptal or microsuction tip. The ultrasonic aspirator may prove to be of greater utility in this step as it becomes more refined and thinner.

The slightly darker, bluish appearance of the underlying ventricular ependymal surface, described in early reports of callosal section recommending its use as the limit of division [11], will indicate the approach to the ventral aspect of the callosum. The alternative of identifying the midline, however, offers numerous advantages increasingly evident over the course of our series. These include unequivocal assurance of completeness of fibre division, elimination of possible lateral deviation (especially in the frontal region), decreased likelihood of entering the lateral ventricle, and less operative time. A blunt microinstrument is gently swept from side to side as the callosum is nearly traversed, and this will usually expose the midline cleft between lateral ventricles. This is usually easiest at the most posterior portion of the genu or the anterior portion of the body. Once this cleft has been identified, the remainder of the section is easily accomplished.

The actual direction of subsequent section is not particularly important. Division around the genu and down the rostrum is performed extraventricularly as far as possible. The rostrum at this point is nearly paper thin, and any remaining fibres are insignificant. No attempt is made to divide blindly the anterior commissure.

Division posteriorly is readily performed following the midline cleft. If an attempt is being made to achieve success with a partial division, it is reasonable to carry the division through approximately the anterior three-quarters. A number of methods have been employed to assure accomplishment of the desired length of section. These include physical measurement of the exposed callosum to be sectioned, identification of structural features (such as the thinning of commissure generally seen in the posterior body or the appearance of the fornices), intraoperative radiographs [122] and, more recently, the image guidance of frameless stereotactic navigational systems. When assurance of section and haemostasis is complete, a metal clip attached to a small piece of Gelfoam may be placed at the posterior extent of the divided callosum; at subsequent surgery, such a marker has often been greatly appreciated when gliosis may obscure the extent of previous resection. It has not created an undesirable, excessive MRI artefact.

Division of the posterior portion of the corpus callosum, either as a second or as an initial procedure, is accomplished in a similar manner. Exposure down the interhemispheric fissure is in this instance facilitated by the deeper falx cerebri. The fibres of the splenium are divided with similar instrumentation, and under magnification the completeness of the section is certain. The underlying arachnoid, beneath which lie the pineal and quadrigeminal cistern, is preserved. The posterior hippocampal commissure may be difficult to distinguish from the overlying callosal fibres, but this is of no practical significance as it is divided as well. If an anterior section has already been performed, the previously placed clip is retrieved. If the posterior section is the initial commissurotomy procedure, a clip is left as a marker at the anteriormost extent of the section.

Closing is performed in the conventional manner. The dura is closed over Gelfilm (Upjohn, Kalamazoo, MI, USA) using 4–0 Vicryl (Ethicon, Inc., Johnson & Johnson, Somerville, NJ, USA) after confirmation of haemostasis. The bone flap is secured with a bone-plating system, the galea aponeurosis is reapproximated using 3–0 Vicryl, and the skin is closed with either 4–0 Prolene (Ethicon, Inc., Johnson & Johnson, Somerville, NJ, USA) or staples. The patient is observed in the neurosurgical observation unit overnight and transferred to the neurosurgical ward the following morning. Mobilization begins immediately, and the patient is typically discharged 3 or 4 days after surgery; in anterior section alone, or in children, hospitalization may be shorter. Anticonvulsant medication is generally left unaltered until at least subsequent follow-up. A decision regarding completion of the callosotomy is usually deferred 6 months or more after the initial procedure.

There are alternative techniques that have been occasionally proposed. Endoscopy [123], stereotactic lesioning [124] and radiosurgery [125–133] have been described, but experience with these techniques for this specific purpose is very limited. Any such technique must be assured of not inadvertently sparing commissural fibres, as suboptimal seizure outcomes have been attributed to such sparing during open procedures. Such techniques must also match the low morbidity and mortality of today's microsurgical procedure.

The utilization of image guidance (neuronavigation) for this surgery has paralleled its increasing incorporation into the majority of neurosurgical operating room environments. Image guidance is routinely used in microsurgery, particularly in epilepsy, and as alluded to earlier it can be a useful aid in callosal section as well. With respect to intraoperative MRI, CT or other updated imaging, the role for these more resource-intensive techniques has not been demonstrated for this procedure. Intraoperative brain shift or deformation is less an issue in either such a central location or in a non-resective procedure.

Refinement of surgical technique has been accompanied by a decrease in the morbidity associated with the procedure. Complications of corpus callosotomy can be considered as surgical or functional in nature [134]. Frontal lobe swelling or infarction with resultant hemiparesis or hemiplegia can result from excessive retraction or sacrifice of bridging veins, and hydrocephalus requiring shunting has been seen with larger surgeries in which there may have been soiling of the ventricular system with surgical debris and blood [10,11]. Current microsurgical technique, with reduced retraction and extraventricular callosal sectioning, has

greatly reduced the incidence of these sequelae. The risk of infection at this time is similar to that of standard neurosurgical procedures.

Transient mutism or decreased spontaneity of speech, with or without mild hemiparesis, has sometimes been noted following anterior callosal section and is presumed to result from either medial frontal retraction or perhaps disconnection [12,135,136]. When it does occur, it almost always resolves within days and is rarely problematic. Posterior section, on the other hand, disrupts interhemispheric transfer of visual, tactile and auditory information, and is responsible for the long-term disconnection syndromes associated with this operation [117,137–141]. Objects presented solely to the hemisphere that is not dominant for language may not be verbally reported by the patient, but as isolation of such stimuli to one hemisphere usually requires a fairly constrained, laboratory environment (e.g. tachistoscopic hemifield visual presentation) it is unusual for this to cause disability. Most patients, as well as many early investigators, have been unaware of the deficit.

Independent and sometimes conflicting behaviours generated by the two hemispheres have been associated with complete callosal section [16]. Anecdotal reports of uncooperative or antagonistic action of the two hands while getting dressed or repeated hesitation about whether or not to enter a room are certainly true, but over time such behaviours generally abate.

The deficit that may arise when an interhemispheric compensatory mechanism that has developed after an earlier hemispheric insult is disrupted by callosal surgery is of greater concern. Mixed dominance, in which language resides in the hemisphere ipsilateral to the dominant hand, may predispose to postoperative language difficulty [142], but this has not been a consistent finding. By a similar mechanism, a pre-existent hemiparesis might worsen following commissurotomy. Fortunately, such deficits are relatively uncommon. The nature of an occasionally observed postoperative memory disturbance remains incompletely understood [117,143].

Conclusion

Commissurotomy may successfully reduce seizure frequency and severity for certain patients who have failed medical management, who are not eligible for resective seizure surgery and who have either preferred not to undergo vagal nerve stimulation or failed to respond to that procedure. Atonic seizures (drop attacks) and secondarily generalized major motor seizures are most likely to be improved, but other seizure types may also respond.

Although early surgeries had often included other anatomical structure, standard commissurotomy today includes only the corpus callosum. Complete callosotomy may not be required in all patients, and anterior three-quarter section, followed by completion of the section if needed, remains a reasonable approach in most patients. As a microsurgical procedure, extraventricular division of the corpus callosum can be safely and assuredly performed. Although there are always numerous variations in surgical technique, the procedure of corpus callosum section is probably less variable than that of most other, longer established surgical interventions for the treatment of epilepsy.

The psychological aspects of commissurotomy have received extraordinary attention in the past [30,81,117,118,136–168], but it is uncommon to encounter permanent disabilities. For the great majority of patients, the benefits resulting from the procedure outweigh any such effects.

75 Hypothalamic Hamartoma and Multiple Subpial Transection

Michael C. Smith, Richard Byrne and Andres M. Kanner
Rush University Medical Center, Chicago, IL, USA

Hypothalamic hamartomas

Hypothalamic hamartomas (HHs) are congenital lesions of the hypothalamus often associated with gelastic epilepsy, precocious puberty and behaviour and developmental abnormalities [1–7]. Most cases of HHs are non-familial and sporadic in nature; however, HHs have been reported to be associated with Pallister–Hall syndrome and other congenital syndromes [8,9]. Because HHs are usually small, their presence was often not detected in patients before the advent of magnetic resonance imaging (MRI) [1]. In addition, ictal discharges from HHs are difficult to detect without depth electrodes [2,3,5]. As a result, until recently it was not clear whether HH represented an epiphenomenon of a developmental epilepsy condition or if it was a causal lesion in gelastic epilepsy. Patients with HHs may be asymptomatic, may have gelastic seizures (characterized by brief episodes of laughter) or may have severe generalized epilepsy. The generalized seizures include GTC (generalized tonic–clonic), atypical absence tonic and atonic seizures. With the appearance of these seizure types comes developmental delays and cognitive dysfunction consistent with the Lennox–Gastaut syndrome. Thus, the clinical syndromes of HHs associated with gelastic seizures create a spectrum from occasional gelastic seizures and normal development to severe epilepsy syndromes with developmental delay and precocious puberty. Early attempts to remove HH lesions were disappointing, both in efficacy and from the standpoint of postoperative complications [10–12].

Theories of the aetiology of HHs and their causal role in gelastic and generalized epilepsy and precocious puberty have recently been put forth. Based on genetic findings in Pallister–Hall syndrome, Craig *et al.* [8] reported a possible link between sporadic cases of HHs and somatic mutations in the *GL13* gene. Links between HHs and epilepsy have been proposed by several authors based upon the proximity of HHs to the mammilothalamic tract [2,5,13–16]. Based on combined depth electrode and cortical electrode recordings, Kahane *et al.* [17] proposed a possible mechanism of propagation of seizures in HHs. In their series of five patients, depth electrode recording of gelastic seizures alone showed no activity in the cortical electrodes. Generalized seizures were typically recorded as starting in the hemisphere on the side of the largest portion of the HHs. These generalized seizures did not affect the HHs. These authors and others raise the possibility that this could represent a model for secondary epileptogenesis [2,17]. Although a clear link exists between HHs and gelastic seizures, gelastic seizures are not exclusively linked to HHs. Gelastic epilepsy rarely has been reported to occur secondary to temporal cortical dysplasia [18] and cingulate gyrus lesions [19].

Anatomical classifications of HHs have been proposed based on MRI characteristics and location. Arita *et al.* [20] divided 11 cases into 'parahypothalamic' and 'intrahypothalamic'. This classification was then tested on 61 cases reported in the literature in which an anatomical description was clearly given. The parahypothalamic type described by Arita *et al.* [21] is suspended from the floor of the hypothalamus, may be pedunculated and is more likely to be associated with precocious puberty than with epilepsy. Endocrinological changes leading to precocious puberty have been linked to bioactive substances released by the HHs accelerating the onset of puberty [4]. The intrahypothalamic type, which arises within the hypothalamus itself and may be visible within the third ventricle, is more likely to be associated with epilepsy. MRI characteristics were reported in a series of 72 patients by Freeman *et al.* [22]. They found that HHs were hyperintense to grey matter on T1 in 93% of cases and hypointense on T2 in 74% of cases. MR spectroscopy showed increased myoinositol and reduced *N*-acetylaspartate. HHs always involved the mammillary bodies in their review. Intrahypothalamic involvement was almost always seen and usually pushed the fornix anterolaterally. Larger size was more commonly associated with precocious puberty, as was seen in the series reported by Arita *et al.* [20].

Metabolic imaging of HHs gave further evidence of the causal role HHs play in epilepsy. Positron emission tomography (PET) findings in HHs have been reported by Shahar *et al.* [23]. Ictal PET findings in HHs show increased activity in the region of the hypothalamus. Single photon emission computed tomography (SPECT) findings were reported by Kuzniecky *et al.* [5], and later duplicated by Castro *et al.* [24]. In a series of six patients, Castro *et al.* found all seizure types beginning in the region of the HHs. The mounting evidence of the epileptogenic nature of HHs led to the development of new surgical approaches that have proven safer and more effective in controlling epilepsy related to HHs [5,13,24].

Surgical approaches

Anterior and lateral approaches

The earliest attempts to remove HHs were via the traditional pterional or subfrontal approaches, which gave good exposure

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

to any exophytic or pedunculated portions of the HHs, but gave little exposure through lamina terminalis to the intraventricular portion of the HHs and their attachments to the mammilothalamic tracts. It has been proposed that this lack of exposure to the hamartomas' attachments to the circuitry of the mammilothalamic tract accounts for the lack of consistent efficacy of these early surgical attempts. As these approaches must expose and involve critical structures, such as the pituitary gland and infundibulum, cranial nerves and vascular perforating vessels, reports of significant operative morbidity are not surprising. Fohlen *et al.* [25] have suggested a two-stage procedure in which the subventricular portion of the HH is removed via pterional approach and the intraventricular portion is removed at a second stage.

Stereotactic radiofrequency thermocoagulation

Stereotactic techniques have been widely applied to many conditions in neurosurgery, including movement disorders, brain tumour, cyst aspiration, epilepsy depth electrodes, vascular lesions and other functional disorders. Radiofrequency lesioning has been applied to movement disorders, functional disorders and pain conditions such as trigeminal neuralgia [26]. Stereotactic placement of depth electrodes followed by radiofrequency lesioning was reported by Kuzniecky *et al.* [5] in 1997. Radiofrequency lesioning by thermocoagulation was reported by Kuzniecky *et al.* [27] in 2003 in a series of nine patients. Although six patients required repeat lesioning, the authors reported that three patients were seizure free and another four had at least an 80% reduction in seizure frequency. Complications included cranial neuropathy, appetite stimulation and short-term memory disturbance.

Transcallosal approaches

Because of the limited intraventricular view afforded by the pterional and subfrontal approaches, a midline transcallosal approach was proposed by Rosenfeld *et al.* [28]. In their series of HHs, the transcallosal, interforniceal, and the later transcallosal, interforniceal, trans-septal approach was used [29]. In their initial report of five patients, Rosenfeld *et al.* [28] reported >95% resection in all cases with no neurological complications. With a mean reported follow-up of 24 months, three patients were seizure free and two patients had only rare gelastic seizures. Behavioural improvements were also noted. Endocrinological complications of transient diabetes insipidus and enhanced appetite were noted in two patients each. Follow-up reports with larger series were reported by this group [29–31]. Harvey *et al.* [30] reported a series of 29 patients operated on via a transcallosal, interforniceal approach. Greater than 95% resection was achieved in 18 out of 29 patients. With at least 12 months' follow-up and a mean follow-up of 30 months, 15 out of 29 patients were seizure free, with another seven patients achieving Engel's class III or >90% reduction in seizure frequency. Behavioural improvements were seen in most patients. Temporary complications were frequent, with two cases of transient hemiparesis and memory deficits and endocrinological complications noted in one-half of the cases. Permanent complications of short-term memory loss in four, weight gain in five hypothyroidism in five and need for growth hormone supplementation in six patients were reported. Concern for hypothalamic injury leading to hypothalamic syndromes, along with concern for short-term memory deficits, replaced concerns for cranial neuropathy and stroke. A more anterior trajectory approach was developed to avoid forniceal or deep central venous manipulation. This transcallosal, interforniceal, trans-septal approach was reported in 45 patients with reduction in complications related to memory and stroke. Rosenfeld *et al.* [29] suggested that because of possible concern for memory function in some higher-functioning patients, radiosurgery may be preferable.

Success with open surgery for HHs in relieving epilepsy was also reported in a series by Fohlen *et al.* [32]. Twenty-six operations were reported in 18 patients with the primary goal of surgery being disconnection rather than complete removal. In 10 patients, surgery was performed with surgical endoscopy. Hemiparesis was reported in two patients, in one case permanent. The endoscopic frameless stereotactic assisted approach has been reported as the favoured approach by Procaccini *et al.* [33] and Ng and Rekate [6].

Another large HHs surgical series has been reported with both transcallosal resection by Ng *et al.* [34] and endoscopic resection [6]. The transcallosal resection series reported 26 patients with an average follow-up of 20.3 months. Fifty-four per cent of patients were seizure free, with another 35% improved by at least 90%. The majority of patients had improvements in behaviour and cognition. Two patients had permanent memory loss, and two had permanent endocrinological deficits. Patients who were seizure free were more likely to be younger, have smaller HHs, and undergo a total resection. The endoscopic approach was reported in 2007 by Ng in 44 patients [6]. They recommended the endoscopic approach assisted by frameless stereotaxis for cases in which the HH is less than 1 cm, is unilateral and is at least 6 mm below the roof of the third ventricle.

Stereotactic radiosurgery

Steroetactic radiosurgery (SRS) has been successfully applied to a wide variety of intracranial pathologies, including benign tumours, vascular malformations and functional pathologies. SRS uses the same stereotactic principles used in radiofrequency lesioning, but also uses highly conformal radiotherapy. Because of the small size and deep location of HHs and the critical nature of the surrounding anatomy, stereotactic radiosurgery has come to play a role in the treatment of HHs. Initial reports of SRS treatment of HHs involved the use of a gamma knife. The gamma knife uses cobalt-201 source beams of radiation focused on an MRI-targeted lesion. Another technology that may be applied to HHs is linear accelerator based. The linear accelerator uses photons to deliver highly conformal radiation to the lesion. Stereotactic radiosurgery requires the application of a fixed cranial frame and lesion targeting based on MRI localization.

The potential for SRS treatment of epilepsy has been noted based on treatment of epileptogenic lesions with successful control of epilepsy, despite the continued presence of the target lesion [35]. Experimental treatment of epilepsy has shown the potential of SRS to control seizures.

Regis *et al.* [36] reported a prospective multicentre study of gamma knife radiosurgery for mesial temporal lobe epilepsy. Using a dose of 24 Gy at the margin of the mesial temporal lobe target in 21 patients, they reported a 65% seizure-free rate at 2 years' follow-up. Transient complications were commonly reported, but permanent complications were limited to visual field

defects. Several groups have now reported gamma knife treatment of HHs [35,37–41]. Treatment doses averaged at 15 Gy at the 50% isodose line over these series. Regis *et al.* [39,40] have reported the largest series of gamma knife treatment of HHs. In 27 patients treated with at least a 3-year follow-up, they reported a 37% seizure-free rate with an additional 22.2% having only rare seizures. They reported no permanent complications. Based on anatomical classifications, they recommended gamma knife as the primary treatment modality for HHs located primarily in the hypothalamus.

Summary

The understanding of the intrinsic epileptogenic nature of HHs has led to direct and indirect focal surgical treatment. These surgical treatments are evolving with reports of multiple open surgical approaches, stereotactic thermocoagulation and SRS approaches as current options. As hypothalamic hamartomas are variable in their size and location, each of these options will likely have a role in the surgical treatment of medically intractable cases of gelastic and generalized seizures related to HHs. Based upon anatomical factors, a treatment paradigm of surgical resection or disconnection for larger or pedunculated lesions and SRS or endoscopic treatment for lesions located exclusively within the hypothalamus has been offered. Lesions expanding into the third ventricle but limited to one side of the hypothalamus may be reached by the endoscopic approach. Surgical treatment paradigms for HHs will continue to evolve with more surgical experience and longer follow-up with previously treated patients.

Multiple subpial transection

Focal-onset medically intractable epilepsy has been surgically treated for 70 years by location of the seizure focus and resection of the involved cortex. A certain proportion of patients who undergo evaluation for possible surgical resection are found to have an epileptogenic zone originating in, or overlapping with, eloquent cortex. These patients traditionally have been denied surgery because resection of the primary speech, motor, sensory or visual cortex would result in unacceptable deficits. Multiple subpial transection (MST) was developed specifically to address this problem. The purpose of this technique is to disrupt the intracortical horizontal fibre system while preserving the columnar organization of the cortex (i.e. its vertically oriented input and output systems and vascular supply) [42]. The transection of horizontal fibres is aimed at preventing the propagation of epileptic discharges, thus averting the synchronous neuronal activation that ultimately results in the development of clinical seizures. The preservation of the columnar organization of the cortex prevents or minimizes the disruption of the functional state of the transected cortex.

The development of this technique was derived from three sets of experiments, each unrelated to the others or to the field of epilepsy surgery. The first set of experiments by Asanuma and Sakata [43], by Hubel and Wiesel [44] and Mountcastle [45] demonstrated that the vertically oriented micro and macro columns (with their vertically oriented input, output and vascular supply) are the organizational unit of functional cortical architecture. However, the functional role of the intracortical horizontal fibre system is yet to be firmly established. This system is composed of fibres responsible for recurrent inhibition and excitation underlying neuronal plasticity. In the second set of experiments, Sperry [46] demonstrated that surgical disruption of the horizontal fibre system in the visual cortex of the cat, while sparing its columnar organization, does not affect its testable functional status. The third set of experiments was related to the importance of the horizontal fibre system as a 'critical component in cortical circuit necessary for generation and elaboration of paroxysmal discharges' [47]. Epileptic activity in the form of spikes or sharp waves requires a synchronous neuronal activation of a contiguous cortical surface of at least 12–25 mm^2 [47–49]. Tharp [47] found that epileptic foci would synchronize their activity if the distance between them was 5 mm or less, and disrupting the neuropil between the foci would desynchronize the epileptic activity.

With this information, Morrell and colleagues [50] hypothesized that sectioning of the intracortical horizontal fibres at 5-mm intervals, while preserving the columnar organization of the cortex, could abolish epileptic activity yet preserve the functional status of the transected cortex. Testing this hypothesis in the monkey, Morrell produced an epileptic focus with aluminium gel lesions in the left precentral motor cortex, which resulted in the development of focal motor seizures. Using a small wire, he disconnected the horizontal fibres at 5-mm intervals throughout the epileptogenic zone. This procedure, the first subpial transaction for epilepsy, stopped the seizures and no motor deficits were suffered by the monkey from the procedure. To confirm that what he had transected was motor cortex, 1 year later Morrell surgically removed the transected area, resulting in the expected hemiparesis. With this experimental evidence, Morrell and colleagues moved forward into the treatment of intractable human neocortical epilepsy arising in or overlapping eloquent cortex.

Indications for multiple subpial transection

Multiple subpial transection is indicated in any patient in whom the epileptic zone arises from or overlaps with eloquent cortex. The procedure is performed after a detailed presurgical evaluation, which includes closed-circuit television/electroencephalographic recording of habitual seizures using scalp and intracranial electrodes, mainly subdural grids. In addition, detailed functional mapping to identify eloquent cortex by electrical cortical stimulation and evoked potentials is performed. Neuropsychological testing and intracarotid amobarbital tests, as well as functional neuroimaging studies, all assist in defining the baseline function and risks of the procedure. Magnetoencephalography studies have also been very useful in the evaluation of children with an acquired epileptic aphasia of childhood or Landau–Kleffner syndrome (LKS) [51]. It allows more accurate identification of the source of the dipole, especially its depth within a sulcus.

Multiple subpial transection can be performed as the sole procedure or in conjunction with resection of non-eloquent cortex, depending on the extent to which the epileptogenic zone involves eloquent cortex. Most cases of MST occur in conjunction with a cortical resection. Candidates are typically patients with dominant temporal neocortical epilepsy, dominant frontal lobe epilepsy, or primary sensory, motor or visual cortex involvement. In patients

undergoing resection/transection, resection of non-eloquent cortex is performed to within 1.5 cm of the identified eloquent cortex. We recognize that this patient group is problematic for the evaluation of the clinical effectiveness of MST.

Cortical surgical anatomy

Human cortex is arranged in a gyral pattern, which is fairly constant between individuals. However, the microgyral patterns of individual gyri may be considerably variable. These cortical variations must be taken into account in a procedure in which transections are being made perpendicular to the long axis of a gyrus. Thus, careful inspection of each gyrus prior to the procedure is important. Grey matter is, on average, 5 mm thick over the crown of a gyrus. However, the depth of each sulcus is variable.

These points are critical in subpial transection procedures because the objective is to divide the neuropil at 5-mm intervals perpendicular to the long axis of the gyrus while preserving the overlying pia with its blood vessels and the underlying white matter tracts and U-fibres.

About one-quarter of our patients have undergone MST as their primary procedure. These patients mainly had epilepsia partialis continua due to Rasmussen's encephalitis or Landau–Kleffner syndrome. In the patients with Rasmussen's syndrome, the epileptogenic zone arose from primary language and/or motor cortex, whereas in patients with Landau–Kleffner syndrome, it involved posterior language cortex.

Operative procedure

Patients are given preoperative antibiotics and steroids and are positioned so that the surgical site is at the highest point in the operative field. This makes intraoperative electrocorticography (ECoG), resection and transection easier. The head is held in Mayfield head fixation and all pressure points are padded. If the operation is done with the patient awake, the patient's comfort is especially important.

Anaesthesia is accomplished with intravenous methohexital and a generous amount of local anaesthesia. Although methohexital has been shown to activate interictal epileptiform activity, such activation does not extend beyond the epileptogenic zone [52]. Furthermore, the degree of activation of epileptiform activity can be minimized by lowering the infusion rate of methohexital. At our centre, we perform intraoperative ECoG in all cases, even when mapping with subdural grids has been done, to ensure that the initial transections result in the desired abolition of epileptic activity.

Transections

Before performing the transections, careful inspection of the gyri, microgyral pattern, sulci and vascular supply is carried out. Transections are first performed in the more dependent areas to avoid the problem of subarachnoid blood obscuring the other areas. At the edge of the visible gyrus, in an avascular area, a 20-gauge needle is used to open a hole in the pia. The tip of the subpial transection hook is introduced into the grey matter layer and advanced to the next sulcus in a direction perpendicular to the long axis of the gyrus. The tip of the hook is held upward and is visible immediately beneath the pia. It is important that the pia be left undisturbed to minimize vascular injury and scarring. The transection hook is designed with a handle, a malleable shaft and a tip that is 4 mm long (parallel to the cortical width) and 1 mm wide. If the 4-mm tip is introduced just below the pia, it should remain in the grey matter layer, leaving the white matter undisturbed. The tip is angled at 105° and is blunt. These two features make snagging or injuring a vessel less likely. However, it is important to avoid crossing a sulcus where buried vessels are unprotected. While this procedure is simple in principle, we have found that to master it requires considerable experience.

After the first transection is completed, bleeding from the pial opening is controlled with small pieces of Gelfoam and a Cottonoid®. The 4-mm tip is then placed up against the cortex next to the transection so as to select the next transection site, 5 mm from the first. This is repeated until the identified epileptogenic zone is transected. Over a few minutes, the lines take on a striped appearance from the petechial haemorrhages along the lines. Minimal bleeding is encountered if the transections are done properly. EcoG is repeated at the conclusion of the transections. The transected area displays a significant attenuation of the background activity with elimination of the spikes. In cases of persistent epileptiform activity, the possibility that activity is coming from the depth of a sulcus or from remote areas must be considered. On rare occasions, when persistent activity is clearly identified as originating in an area that has been transected, transecting down into the sulcus may be done. To do this safely, the tip of the probe should be turned away from the sulcus as the instrument is advanced.

Favourable outcomes using alternative instruments and methods of transection have been described by other neurosurgeons [53,54].

Seizure outcome

Evaluation of seizure outcome should be carried out in patients who underwent MST without additional cortical resection. We have previously reported our series of patients with partial epilepsy, with 37.5% of patients becoming seizure free at 2 years' follow-up and an additional 37.5% having a worthwhile outcome (classes II and III). However, as has been reported by other centres, there is a late recurrence rate in seizures following MST [54]. Orbach *et al.* [55] reported a relapse rate of 18.6% over several years. Schramm *et al.* (2002) reported on the efficacy of MST alone in 20 patients with drug-resistant epilepsy. One patient had a previous temporal resection; there were two cases each of LKS and electrical status epilepticus of sleep (ESES). In this series, 10% had a class I outcome and 45% had a class II–III outcome. They also noted the relapse in seizures over time [56]. In 2005, Zhao *et al.* [57] treated 80 patients with MST alone as part of their larger series. They reported a 51.7% seizure-free rate in patients with at least 1-year follow-up.

In a meta-analysis of MST with or without additional cortical resection, Spencer *et al.* [58] reviewed 211 patients who underwent MST for intractable epilepsy and found an excellent outcome (greater than 95% reduction in seizure frequency) in 87% of patients with generalized seizures and 68% of patients with simple and complex partial seizures. Zhao *et al.* [57], in the largest series reported to date, reported on 200 patients (80 with MST alone) treated with multiple subpial transection for

intractable partial epilepsy involving eloquent cortex between 1991 and 2000. They reported complete control of seizures in 62.5%, with another 20% of patients having a significant reduction (>75%), with 160 patients having at least a 1-year follow-up [57].

In paediatric patients, Shimizu *et al*. [59] reported on 25 cases in which MST was utilized, with 10 out of 25 having an Engel class I or II outcome. In 2006, Benifla *et al*. [60] reviewed two studies of MST efficacy that included 60 patients (10 with MST alone). They found that between 33% and 46% of patients in each series had Engel class I or II outcomes [60].

Multiple subpial transection had been used to treat Landau–Kleffner syndrome for the past 15 years at our institution. In reviewing 24 patients with classic LKS, Kanner *et al*. [61] found that 13 out of the 24 patients had MST alone and seven had resection and MST. All had continuous spike–wave in slow-wave sleep from a unilateral perisylvian source. All had been followed for at least 2 years. After MST of the perisylvian epileptic abnormality, follow-up revealed that two-thirds of the children could speak in complex sentences at their last formal speech evaluation, with significant improvement of language coming within the first 6 months postoperatively [61].

In 2001, Irwin *et al*. [62] reported five patients presenting with classic LKS who underwent MST. All had ESES clinical seizures, severe language dysfunction or no language and a behavioural disorder. The frequency of seizures and behavioural characteristics were significantly improved in all; however, improvement in language function was not dramatic. This might be related to the duration of the epileptic abnormality prior to surgery [22]. The mean duration was 4.6 years and studies have suggested that a duration of over 3 years is a predictor of the severity of chronic language disturbance [22].

Multiple subpial transection with cortical resection has also been used in patients with multifocal multilobar epileptic foci with clinical seizures and developmental regression. Devinsky *et al*. [63] reported a moderate improvement in language, social and behavioural function with a significant improvement in seizure frequency in this diverse population.

Multiple subpial transection had been used in Rasmussen's encephalitis in seven patients from Morrell's series. In four patients, the targeted seizures were eliminated but the progression of the disease continued. In three out of seven patients, MST did not eliminate the epileptic process due to the fact that it arose from the depth of the sulcus. MST had also been used in patients with refractory status epilepticus that involved eloquent cortex. In both cases, MST successfully stopped the status epilepticus [64].

Surgical morbidity

Acute postoperative morbidity

Cerebral oedema is expected after MST, peaking on the third to the fourth postoperative day. Consequently, patients are expected to experience transient dysfunction of transected cortex, with ensuing neurological deficits lasting for 2–3 weeks. Sometimes mild deficits may persist for several months. Similar observations have been made at the other centres in which MST is performed (see next section on chronic morbidity).

Chronic morbidity

The incidence of chronic morbidity varies, in part, with the experience of the neurosurgeon with the MST procedure. We have reported previously a neurological complication rate of 15%, with 7% suffering a permanent deficit. These deficits included foot drop in 2%, language deficit in 2% and a parietal sensory loss in 1%. Mild but clear diminution in rapid skilled movements was seen in the majority of those undergoing MST of the parietal sensory cortex.

Spencer *et al*. [58], in the meta-analysis of 211 patients, reported the highest morbidity with new neurological deficits found in 19% of those with pure MST, including four with memory decline, five with hemiparesis and one with a partial visual field defect, a total of 23% of the patients with resection and MST had persistent neurological deficit. Schramm *et al*. [56], in the 20 cases of pure MST, reported transient neurological deficit in 29% but all deficits resolved to the point that they would not be noted on a standard clinical examination. In Zhao *et al*.'s [57] larger series of 200 patients, 80 MST alone, transient neurological deficits were reported in just 3%. Likewise, in a review of paediatric MST, Benifla *et al*. [60] reported no permanent language or motor disabilities after MST.

Summary

Multiple subpial transection is successful in the treatment of epilepsy arising or extending into eloquent cortex, both alone or in combination with cortical resection. Its morbidity is low given the area of operation. This procedure allows successful treatment in patients who would otherwise be inoperable. Further refinement and experience with MST will bring additional benefit for patients with medically intractable epilepsy.

76 Awake Surgery for Epilepsy

Christian B. Kaufman and Webster H. Pilcher
University of Rochester Medical Center, Rochester, NY, USA

Introduction

Awake craniotomy has been a fundamental surgical technique since the advent of modern neurosurgery. Harvey Cushing [1] performed awake craniotomies for tumour removal using only local anaesthetic. Awake craniotomy, with functional brain mapping and intraoperative electrocorticography (ECoG) recordings, was also fundamental to the pioneering work of Penfield and Jasper [2] as they defined the early neurosurgical interventions for intractable epilepsy. Although advances in anaesthetic and surgical techniques have improved the safety of awake surgery for epilepsy and other neurosurgical disorders, the utility of awake surgery for the majority of patients with intractable epilepsy has been challenged. Improved structural and functional brain imaging, video electroencephalography (VEEG) monitoring, neuropsychological assessments, and outcome measures have led to the delineation of surgically remediable epileptic syndromes [3]. This taxonomic and pathobiological context allows epilepsy surgeons to define operative approaches in advance and to predict more accurately the likelihood of a favourable outcome, in terms of both seizure control and functional status. Contemporary neurosurgeons now have access to preoperative electrographic and semiological (e.g. VEEG) as well as functional data, which have made them less reliant upon intraoperative ECoG and brain mapping than was the case in Penfield's era. These and other advances have prompted a convergence of operative approaches in temporal lobe surgery that emphasize the anatomical resection of mesial structures, with the result that ECoG and brain mapping are used less frequently than in the early days of epilepsy surgery. The challenge is to define the clinical circumstances in which awake surgery may provide value and to use this unique context to optimize the outcome of surgery for each patient.

The two principal goals of surgical intervention for medically refractory epilepsy include the improvement or elimination of seizures and the preservation of neurocognitive functions. These goals have the intention of conferring measurable improvements in the quality of life upon each patient. Assuming proper preoperative patient selection, the resection volume should incorporate the maximum epileptogenic tissue required to produce the elimination or improvement in seizures without the resection of functional or eloquent brain tissue that might create neurocognitive deficits [4]. In the ideal setting, awake surgery techniques allow tailored resections on the basis of intraoperative electrographic and functional data from brain mapping to better achieve these goals.

Contemporaneous with the trend away from awake surgery, advances in anaesthetic and surgical techniques have actually made awake surgery easier and safer. There has also been a continued evolution of functional diagnostic studies that offer more in the way of non-invasive localization of both epileptogenic and eloquent cortices and which may contribute to the utility and efficacy of awake surgery for medically refractory temporal lobe epilepsy (TLE).

In this chapter, we will examine the advances in functional imaging, neuroanaesthesia and neurosurgical technique that have contributed to the utility and efficacy of awake surgery for medically refractory TLE.

Functional assessment

The delineation of eloquent cortex (i.e. language cortex and primary motor and sensory cortex) and the preservation of memory (particularly material-specific verbal memory) are important goals in epilepsy surgery. Over the past 50 years, epilepsy surgeons have relied primarily upon direct cortical stimulation mapping (intraoperative or extraoperative), neuropsychological assessments, and the Wada test to pursue these objectives. The recent introduction of functional imaging and electrographic localization modalities, however, offers surgeons new tools that promise to transform both the preoperative functional analysis and the ultimate execution of the resective surgery.

The traditional assessment of language functions often begins with the intracarotid amobarbital procedure (IAP) or Wada test, developed by Dr Juhn A. Wada in 1949 [5]. Although the Wada test is useful in language *lateralization,* it is insufficient to *localize* language function, which is a prerequisite for surgical intervention. The Wada test is an invasive procedure with definable risks, including carotid artery dissection (0.7%) [6], cerebral vasospasm leading to stroke, hemiplegia, hemisensory loss and unilateral blindness or hemianopsia, as well as femoral neuropathy or haematoma. Additionally, untoward alterations of behavioural and emotional status may occur following amobarbital administration [7–10] during dominant hemisphere injections in patients with frontal lobe pathology or in those with a history of significant emotional trauma. The Wada test has been routinely used to

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

assess the risk of material-specific memory losses [11,12], although the efficacy of the Wada test in predicting global memory losses in all patients has been questioned [13,14]. In a few centres, in patients felt to be at risk for memory losses, memory mapping intraoperatively has been used to limit the resection of essential cortex [15] and direct hippocampal ECoG has been performed to limit hippocampal removal [16].

Multiple non-invasive modalities of functional localization have been utilized in recent years, including functional magnetic resonance imaging (fMRI), single photon emission computerized tomography (SPECT), and positron emission tomography (PET) scanning. Although the evolution of these techniques is exciting and each makes important contributions, none, as yet, localizes the epileptogenic zone or eloquent memory and language functions with sufficient clarity to support a surgical approach in all cases.

Although PET imaging has been available for several decades, its utility for the imaging of eloquent brain functions has remained limited in most centres. Radioisotopes such as ^{18}FDG and ^{15}O-water can elucidate regions of altered cerebral blood flow in order to create functional maps of cortical activity. At least two studies [17,18] have directly compared ^{15}O-water PET with Wada testing. Both studies revealed concordance with or even superiority to the language lateralization achieved with the Wada test. PET approaches offer both lateralization and localization and ^{15}O-water PET in both studies provided superior evidence of language localization based on the resulting postoperative deficits. Unfortunately, PET is not available in all centres and ^{15}O-water, in particular, requires the close proximity of a cyclotron.

Functional magnetic resonance imaging has developed as the most promising alternative to Wada testing, both for the assessment of language lateralization and for the prediction of risk for postsurgical global or material-specific memory losses. The superior spatial resolution of fMRI and the lack of radiation exposure are obvious advantages of this technique. Detection of localized changes in cerebral blood oxygen content due to regional brain activations during memory encoding or during the performance of language tasks forms the basis for fMRI assessments of these functions. Comparisons of fMRI and Wada testing have generally demonstrated high concordance between the two modalities [19] and initial studies suggest the possible future utility of fMRI for the prediction of global and material-specific memory losses postoperatively. Localization of essential language cortex is also possible with fMRI. In many studies, similar but non-identical cortical regions are identified by fMRI and direct electrocortical stimulation techniques. fMRI localization of language may vary according to different language testing paradigms that may differentially localize 'language cortex' across the frontal, temporal or parietal cortices. The use of tasks involving object naming based on visually presented definitions [20] has been shown to activate temporal regions better than previously studied paradigms that resulted primarily in frontal activation with poor temporal lateralization. The correlation of these patterns of fMRI task-specific language localization to a practical understanding of the effect of tissue resection in these areas, tantamount to Ojemann's '1 cm rule' [15,21], will be required for these data to provide operative utility equivalent to direct cortical stimulation mapping at surgery.

Other current limitations of fMRI are notable. 'Spurious activations' are not easily distinguished from 'actual activations', as any given activation may or may not be related to the language task being assessed [19]. Also, fMRI signal quality is highly susceptible to motion artefact in patients who cannot remain still. Additionally, fMRI testing is also limited in patients with cranial metal implants (i.e. aneurysm clips, previous craniotomy), pacemakers, claustrophobia and morbid obesity. Finally, patients with high-flow vascular lesions may cause false activation and localization [22]. In patients requiring an extended neocortical resection beyond 'standard' resection volumes, intraoperative brain shift looms as a disadvantage of relying purely upon preoperatively acquired data.

Studies comparing PET versus fMRI [23] and scalp electroencephalography versus fMRI [24] suggest that discrepancies in functional localization are unavoidable with techniques that measure different physiological phenomena during functional testing. These discrepancies may be mitigated when combination modalities are utilized.

An example of a multiple modality assessment used to localize the epileptogenic zone is subtraction ictal single photon emission computerized tomography (SPECT) coregistered to MRI (SISCOM). In a study of 49 patients with medically refractory epilepsy, Anhilde *et al*. [25] used SISCOM in patients with non-lesional epilepsy or poorly circumscribed lesional epilepsy in which VEEG, neurocognitive testing and seizure semiology were non-concordant in the localization of seizure foci for reliable placement of subdural electrodes. In their study, for all patients with favourable outcomes (Engel I–II) at 1 year, SISCOM localization was either prerequisite, or at least in agreement with, other localizing assessments.

Anaesthesia for awake craniotomy

The surgeon's ability to safely and successfully perform awake craniotomies is predicated on a well-controlled anaesthetic technique. Patients must feel minimal pain and discomfort if they are to fully cooperate with functional assessments. Likewise, patients who are oversedated run the risk of respiratory depression, aspiration and airway compromise, which complicates both the surgical approach and attempts at brain mapping.

Proper attention to patient positioning at the start of the assessment is vital to its success and should not be overlooked. Patients should be well padded to avoid compression of neurovascular structures, maximize comfort and limit the urge to move during the procedure. Patient positioning should facilitate communication with the operative team, and frequent reassurances and explanations of the procedure by the operative team enhance patient compliance [26,27].

Awake craniotomy for epilepsy surgery generally incorporates a large scalp incision and craniotomy. This requires a generous scalp and muscle infiltration with local anaesthetic as well as specific nerve blocks, including the lesser and greater occipital, the supraorbital, supratrochlear and auriculotemporal nerves. If Mayfield pin fixation is used then the volume of anaesthetic agent is increased, raising concerns about toxicity [28]. Use of long-acting agents, such as ropivacaine and levobupivacaine, has been

recommended [28] owing to better safety profiles over bupivacaine or lidocaine.

The most commonly used intravenous anaesthetic agent in epilepsy surgery is propofol. It provides rapid anaesthesia and is quickly metabolized, allowing patients to be readily aroused. This is important in awake craniotomies, as the asleep–awake–asleep paradigm is most commonly used, by which patients are kept asleep for the opening of the cranium and dura and are awakened for testing and cortical stimulation. Continuous propofol infusion has been shown to be safe, even with an unprotected airway, as is done in the asleep–awake–asleep model for awake craniotomies for epilepsy surgery [29]. Propofol has a strong antiepileptic effect [30] and may interfere with ECoG; therefore, the anaesthesiologist needs to be aware that the propofol infusion should be discontinued 15–20 min before ECoG [28]. Note that propofol infusion alone does not provide analgesia and manipulation of pain-sensitive structures, such as the dura or cerebral vessels, may cause patient discomfort and poor compliance if an intravenous narcotic agent is not co-administered.

Among the short-acting intravenous narcotic agents, remifentanil appears to be the best suited for awake craniotomies, principally because it allows rapid changes in sedation [28] and is not sequestered in tissues, allowing for very predictable emergence regardless of the duration of infusion [31]. Although it may cause bradycardia in rare patients, one study of 135 patients [32] has shown that the combination of remifentanil plus propofol causes cause less haemodynamic instability than other short-acting narcotics, such as fentanyl.

Dexmedetomidine (DEX), a relatively new, novel intravenous agent, has been gaining acceptance as an alternative (or preferred) choice for neurosurgical procedures that require an awake and cooperative patient. DEX acts as a highly selective α_2-adrenoreceptor agonist, causing effective patient sedation, analgesia and also anxiolysis, but does not depress respiratory function [33]. Unlike other anaesthetic and sedative agents, DEX does not work on the cerebral cortex directly, and provides 'cooperative sedation', with patients easily aroused by verbal command [28,33] and remaining cooperative [33] and cognitively sharp [34,35]. Propofol infusion, in contrast, may leave some patients cognitively blunted or disinhibited with diminished cooperativeness [36,37].

Unlike propofol, DEX incorporates an analgesic effect, thought to be mediated by α_2-receptors in the spinal cord dorsal horn, which inhibit nociceptive signal transmission [38].

Although the degree of analgesia is not on par with intravenous opioids [39], DEX does seem to accentuate the effects of opioids [40] and has been shown to decrease opioid requirements in patients by one-third to one-half [41].

Dexmedetomidine has been demonstrated in adult patients to be particularly effective for use during awake craniotomies for epilepsy [42–46] and may be used as the only agent during the awake portion of the craniotomy [44], without the need for multiple drugs to provide anxiolysis, analgesia and sedation. Limited studies in adolescents for awake craniotomies [47] and for paediatric patients undergoing radiographic testing exist [48,49], suggesting that DEX maybe both safe and effective in these populations, but FDA approval for use of DEX in paediatric patients is still pending.

Dexmedetomidine does not interfere with evoked potential monitoring [50]. Although DEX may minimally alter electroencephalography and ECoG recordings [35,44], it does not significantly affect intraoperative ECoG or cortical stimulation [45] or interfere with ECoG spike activity [46] during awake craniotomy.

Given the positive neurosurgical profile of DEX this novel agent is emerging as highly useful either as an adjunct agent that allows reduction in both narcotic [51,52] and anaesthetic dosing [33] or as the primary agent [45] in awake craniotomies for epilepsy surgeries.

Indications for awake tailored resection for medically refractory epilepsy versus anatomically guided resection

There is little debate regarding the comparative efficacy of surgical intervention for medically intractable epilepsy versus best medical management. The few prospective studies available [53,54], along with multiple retrospective studies, have demonstrated the superiority of surgical treatment in achieving seizure control and improvements in quality of life of treated patients.

However, less is known about the comparative outcomes of various resective approaches, including awake tailored resections versus anatomical resections including standard *en bloc* temporal lobe resection, restricted anterior temporal lobe resection [55] and selective amygdalohippocampectomy [56]. Retrospective comparisons in the 'modern era' [3] suggest that these approaches achieve similar results in terms of seizure freedom postoperatively and do not define the superiority of any particular approach with regard to preservation of neurological and/or language and neuropsychological (especially memory) functions. Many of these studies combine patient subpopulations (i.e. mesial temporal sclerosis, regional and lateral neocortical temporal lobe epilepsies), making definitive comparisons difficult. Given the importance of verbal memory preservation in dominant temporal lobe resections, it has been variably suggested that awake surgery with memory mapping in temporal neocortex [15] or hippocampal ECoG with subtotal hippocampal resection [16] may provide an advantage in preserving memory while assuring a favourable seizure outcome. Additionally, Helmstaedter *et al*. [57] found that a transsylvian approach to the mesial structures resulted in worse material-specific outcomes than a transcortical approach when performed in the dominant temporal lobe.

With the increasing adoption of standardized anatomical resections in contemporary epilepsy surgery, the question of whether awake craniotomy may provide improved seizure control and preservation of language and memory outcomes in selected patients remains to be answered [4]. In the ideal setting, awake surgery with a tailored resection utilizes intraoperative ECoG as well as functional brain mapping to optimize both seizure and functional outcomes in individual patients. This approach is based on two assumptions: (1) that language and memory functions are distributed differentially across the expanse of temporal neocortex in individual patients as documented in numerous studies by Ojemann and others [15,21] and (2) that intraoperatively acquired electroencephalography data provides useful information to guide the volume of resection in selected patients.

A number of retrospective studies suggest that anatomical resective approaches in patients with mesial temporal lobe epilepsy and hippocampal sclerosis provide acceptable outcomes across populations of patients. However, there is still debate as to whether selected patients with a 'non-standard' distribution of epileptogenic tissue or functional (language or memory) cortex might benefit from an approach that incorporates awake surgery, intraoperative ECoG and functional brain mapping approaches.

Intraoperative ECoG addresses the first aim of epilepsy surgery, improvement of seizure control, whereas functional mapping is targeted at avoiding postoperative language, memory and motor deficits. In principle, preresection ECoG findings are useful to guide the extent of resection, whereas the postresection ECoG provides information that can be used to decide whether or not to resect more tissue or even to predict the ultimate seizure outcome of surgery. Some studies in awake patients suggest that the ECoG is predictive of seizure outcome, particularly if spikes are either absent preresection or particularly abundant post resection [58,59]. Other studies, in the context of anatomical, measured resections with maximal mesial resection found no correlation of ECoG with seizure outcomes [60,61]. For example, Schwartz *et al*. [60], in their prospective study of 29 patients undergoing a standardized anatomical resection under general anaesthesia, found no correlation between preresection or postresection ECoG data and seizure outcome. In contrast, in a prospective series of 140 patients at the University of Washington, McKhann *et al*. [16] found a positive correlation between residual postresection ECoG spikes in the hippocampus and a worsened seizure outcome. Of interest, however, the study did not show a correlation between residual postresection spiking in either cortical or parahippocampal regions and worse outcomes. It has been argued, and is important to consider, however, that although preresection data may be predictive of seizure outcome, knowing this information does not improve seizure outcome and, by extension, may not, by itself, justify awake surgery.

Awake functional mapping addresses the second goal of epilepsy surgery: to preserve eloquent (language and memory) brain functions while optimizing resection volume to improve seizure outcome. Ojemann *et al*. [15] suggested that up to 17% of patients undergoing a 'standard' anatomical dominant temporal lobe resection (4.0–4.5 cm) without mapping would experience postoperative deficits; furthermore, a study of patients undergoing a smaller, standard anatomical resection in the dominant hemisphere [62] documented a 7% permanent postoperative language deficit. Such data, combined with Ojemann's demonstration, in large numbers of patients, of significant interpatient variability in language representation across the temporal neocortex, and the '1 cm rule' (which describes enduring deficits in patients with resections within 1 cm of essential language areas) suggest that awake surgery with mapping may be useful in selected patients [15,21].

'Positive' language mapping, in which regions of essential language cortex are localized with electrocortical stimulation, has provided the gold standard technique of language mapping over many decades [15,63]. Recent data acquired in non-epileptic patients with malignant brain tumours [64] suggest that a 'negative' language mapping technique, in which the absence of language representation in a cortical area is determined, may be sufficient to allow a safe resection in these patients. Given the likely differences in the cortical organization of language in patients with intractable epilepsy and with adult-onset brain tumours, particularly in the superior temporal gyrus [63], the use of 'positive' language mapping may be more appropriate in patients with intractable epilepsy, whereas 'negative' mapping may be sufficient in the setting of a brain tumour resection.

In addition to language mapping, functional mapping of material-specific memory may be helpful in minimizing postoperative material-specific memory deficits, which can be more debilitating than the original disease under treatment [65]. Both the lateral temporal neocortex and the hippocampus are felt to contribute to the input and encoding of verbal memory [56,66]. Given that pure lateral or neocortical temporal lobe epilepsies (with no mesiobasal involvement) account for approximately 10.7% of patients with medically refractory TLE [67], and that many patients with medically refractory TLE have some evidence of involvement of both mesiobasal structures and the lateral temporal neocortex, functional mapping of verbal memory function may be useful in these patients.

Finally, there has never been a direct comparison of anatomical resections versus awake tailored resections in a prospective randomized study. Until such a time comes, it will remain impossible to champion one approach strictly over the other. And such a study may very well not be either practical or useful as, in fact, most epilepsy surgeons will continue to utilize both techniques, tailoring their approach to the individual patient, as seems appropriate.

Technical aspects of temporal lobe resection tailored to intraoperative recording and stimulation

Awake surgery with intraoperative functional stimulation mapping is surprisingly well tolerated by most patients. Since 1990 we have performed awake surgery with brain mapping on over 350 patients between the ages of 8 and 67 years. Extensive patient preparation for the procedure, an experienced operative team including a specialized nurse practitioner, a neurophysiology technical staff and improved anaesthetic techniques all have contributed to the success of these procedures.

Preoperative preparation

Before embarking on awake brain surgery, patients are instructed as to the experience of awake surgery and brain mapping, which includes viewing a video of this procedure. In the outpatient setting, preceding surgery, each step of the procedure is explained in detail, all questions are answered and the patient is incorporated as a critical member of the operative team. The patient is presented with a set of 80 object images, projected for 4 s each, and each one requiring the patient to read a short phrase and name an object. The images that the patient has difficulty with are removed from the list. A selection of objects that the patient can reliably and accurately name is identified for use during surgery. A major goal of this encounter is to make the patient

comfortable with the operative procedure and to optimize compliance during the various stages of the operation [26].

Anaesthetic technique

On arrival in the operating theatre, anaesthesia is administered before placement of the Foley catheter, patient positioning and cranial fixation, and is then is continued until the dura is opened. Under most circumstances, the patient will be awake and responsive within 5–10 min of discontinuation of the intravenous infusion. After the 30–60 min required for ECoG and stimulation mapping, the infusion is restarted and the patient re-anaesthetized until the completion of the operation.

Premedication and positioning

Before surgery, patients receive intravenous dexamethasone (10 mg i.v.), prophylactic antibiotics and an adequate dose of anticonvulsant medication (i.v. or p.o.) to assure therapeutic levels during the operation. The head is clipped with an electric shaver and electroencephalography reference electrodes are placed. Benzodiazepines are not used for premedication in order to assure the fidelity of the ECoG. The patient is placed on the operating table with appropriate padding. Pneumatic compression stockings and a Foley catheter are placed, and mannitol (0.75 g/kg), plus or minus furosemide (20–40 mg), is administered. The patient is placed in a modified lateral decubitus position with appropriate padding but no axillary roll. Although the head can be placed on a foam doughnut without fixation, our current preference is to use a Mayfield three-point fixation device with strategic injections of local anaesthetic (lidocaine 0.25% and bupivacaine 0.25%) at the pin sites before placement. The lateral position and slight neck extension usually assure airway patency during the period of deepest sedation. Occasionally, however, a nasal trumpet is required during this period but is usually removed during language mapping so that it does not impede the patient's speech.

Local anaesthesia

For a standard temporal lobe resection, a large question mark scalp incision is used – of sufficient size to allow exposure of the hand motor cortex, Broca's area, Wernicke's area and the entire temporal lobe. Before the skin incision, local anaesthetic (lidocaine plus bupivacaine, 0.25%, final concentration, 30–45 mL^3) is injected as follows: (1) nerve blocks, via targeted injections with a 30-gauge needle in the distribution of the supraorbital, auriculotemporal and greater occipital nerves; (2) a field block, created by connecting these three sites with a series of injections to surround all but the medial aspect of the incision; (3) an incisional block, via subcutaneous injection along the entire incision with a 27-gauge needle; and (4) a deep muscle block via injection directly into the temporalis muscle over the pterion to reduce pain from muscle retraction.

Craniotomy

The question mark scalp incision is fashioned and the unitary scalp/muscle flap is dissected and retracted anteriorly to optimize exposure of the anterior temporal lobe anterior to essential language sites. The first burr hole is placed over the pterion and local anaesthetic is injected with a 30-gauge needle within the leaves of the dura surrounding the middle meningeal artery. Additional burr holes are placed centripetally and a side-cutting saw is used to connect them. A high-speed drill is used to complete the saw cut over the anterior temporal squama and the flap is removed. The inferior temporal squama is rongeured to the middle fossa floor over a distance of 6 cm and all air cells are thoroughly waxed. The skull clamp that will be used to hold the ECoG halo is positioned in the frontal–medial aspect of the craniotomy. The dura may be somewhat tense at this point as a result of hypoventilation and high P_{CO_2}; therefore, prior to dural opening, the patient is usually wakened and instructed to hyperventilate to relax the brain and the overlying dura.

Intraoperative electrocorticography

The goal of intraoperative EcoG recording during surgery is to assist in the delineation of the epileptogenic region. This is described as the volume of tissue that is necessary and sufficient to produce habitual spontaneous seizures [68]. In Penfield's time, the pattern of distribution of interictal spikes on the scalp EEG and during direct cortical recordings at surgery was relied upon to determine the appropriate resection volume [2]. In contemporary practice, the epileptogenic region is identified by a combination of factors, which includes (1) the spatial distribution of interictal spike discharges and the zone of ictal onset, determined through VEEG recordings; (2) the location of epileptogenic lesion(s) revealed by structural imaging [foreign tissue, neuronal migration disorder, mesial temporal sclerosis (MTS), etc.]; and (3) the extent of non-epileptic focal functional deficits determined by the neuropsychological assessment and functional imaging [69]. The role of interictal spikes (IISs) identified on intraoperative ECoG in the determination of the volume of tissue resection is less prominent in current practice, and these data must be considered within the context of the global dataset and the surgically remediable syndrome of each patient.

In a typical patient with mesial temporal lobe epilepsy (MTLE) with a history of early injury, imaging showing hippocampal atrophy and sclerosis, and exclusively unilateral IIS from scalp recordings, characteristic ECoG abnormalities are often identified in anterior and mesial structures via subtemporal strip electrodes. In such patients, a standard, anatomically defined (non-tailored) anterior temporal resection will produce a favourable outcome from the standpoint of seizure control. If this resection avoids the superior temporal gyrus, limits the middle gyrus resection to 2.5 cm and incorporates an anatomical removal of mesial structures then preservation of language functions will usually be satisfactory [62,70].

Our recent institutional experience suggests, however, that a growing minority of patients do not have classic MTLE but may have regional epileptogenic zones (i.e. mesial and lateral) or exclusive lateral neocortical interictal foci and ictal onsets [lateral temporal lobe epilepsy (LTLE)] [67]. Many of these patients with neocortical TLE may have no evident abnormality on MR scans. ECoG recordings will reveal widespread or multifocal discharges or exclusively lateral discharges in patients with neocortical LTLE. In such patients with regional or lateral temporal lobe epileptogenic regions, intraoperative ECoG and functional mapping may permit the resection to be extended beyond standard boundaries in order to incorporate more of the epileptogenic region. In these patients,

the outcome may be improved with the resection of an epileptogenic region that goes beyond standard anatomical boundaries.

Electrode placement and ECoG#1

In our standard ECoG protocol, we sample the activity of the orbitofrontal and subtemporal neocortex with four four-contact subdural strip electrodes. These are positioned with one beneath the frontal lobe and three beneath the temporal lobe, each inserted with a lateral–medial trajectory. In the temporal lobe, the medialmost contacts lie beneath the uncus anteriorly and the hippocampus/parahippocampal gyrus in the more posterior positions. These are inserted gently to avoid inadvertent rupture of subtemporal bridging veins. The halo electrode holder with carbon-tipped electrodes is now placed on the skull clamp and the surface electrodes are lowered to the cortex. Generally, three are placed above the Sylvian fissure over the frontoparietal operculum and three each over the superior and middle temporal gyri. The patient's arousal from sedation should now be complete and the initial recording commenced.

During a 10- to 15-min awake tracing, the distribution of interictal discharges, slowing and voltage suppression is sampled over the lateral and subtemporal cortices. A sleep tracing with a characteristic activation of discharges in selected patients may be simulated via a methohexital bolus, which produces a burst suppression ECoG effect initially, followed by the activation of spike discharges as the methohexital dissipates and the tracing returns to a normal awake pattern. This effect has also been observed with propofol during the transition into and out of the waking state and maybe useful to identify spike foci that may not appear during the exclusively waking state. At the end of the recording, the distribution of spike discharges over the neocortex is noted for subsequent comparison with the localization of eloquent cortical regions.

Stimulation parameters

In our centre, cortical stimulation is performed using bipolar constant-current cortical stimulation, applied across two 1-mm stainless-steel ball electrodes separated by 0.5 cm. Stimulus parameters incorporate 60-Hz trains of biphasic pulses, each phase being 1 ms in duration. In the rolandic region, 'positive' responses are noted (i.e. a movement or a reported perception of a sensation), whereas in language cortex 'negative' responses are typical (i.e. interruption or alteration of reading or object naming).

Motor and sensory responses are usually elicited with currents of 1–4 mA applied for 4-s or until a positive motor or sensory response is obtained. In language cortex, a current that is 1 mA below the lowest determined afterdischarge (AD) threshold is utilized during the 4-s presentation of an object image for the patient to name. The AD threshold is determined by the application of a 4-s stimulus to the cortex adjacent to a carbon-tipped surface electrode. Stimuli of increasing current density are applied until a localized electrical seizure is obtained, usually in the 6–12 mA range. The AD threshold is evaluated across the exposed region of temporal neocortex and parietal operculum, and across the inferior and middle frontal gyri anterior to the face motor cortex. This threshold may vary across the expanse of normal cortex and within, or adjacent to, areas of cortical injury, gliosis, malformation or foreign tissue lesions, where the AD threshold may be unusually low and where prolonged focal electrical seizures may be produced at relatively low currents. Language mapping is then commenced at a current of 1 mA lower than that required to elicit an AD. This current is felt to be large enough to abrogate the function of a discrete volume of cortex through a depolarization blockade, but not so large as to produce a propagating seizure that would affect distant areas. The applied current may have to be altered during language mapping, depending on the cortical responses. If prolonged ADs are elicited then the current may need to be reduced. If no interference with language function is produced, it may need to be increased to the level of the AD threshold.

Motor and sensory mapping

Motor mapping is undertaken first, starting with low currents (i.e. 1.0–1.5 mA) to avoid iatrogenic production of a focal motor seizure or convulsion. Should intraoperative seizures develop, methohexital is administered for abortive seizure therapy. The patient is asked to protrude the tongue and the tongue motor area is identified through observation of tongue deviation. Observation of face and hand movements by an assistant further defines the motor homunculus. Over the sensory cortex, tingling sensations are reported over the appropriate body region. Occasionally, at low currents, the patient may report a sensory experience from the motor area and at higher currents a motor response from the sensory area. Normally, 2- to 4-mA currents are required to elicit robust motor and sensory responses. Numbered (1–10) paper tags are placed over the rolandic cortex for precise identification of functional areas. This region, however, should be avoided during language stimulation that utilizes higher currents, as this could elicit a generalized seizure if such currents are applied to the motor cortex.

Language mapping

The goal of language mapping is to identify essential language sites in the temporal lobe to permit a maximal tailored resection of epileptogenic tissue without adversely affecting language function. A low baseline naming error rate is essential to the mapping procedure and only objects that the patient can reliably name are utilized.

Before language mapping, 20 sterile numbered tickets are placed over the exposed cortex to be mapped. Using a slide projector, images of common objects are presented for 4 s to the patient to name while current is applied to cortex adjacent to each ticket. Over 10–20 min, all ticketed areas of cortex are sampled several times with two objectives: (1) the identification of 'positive naming sites', stimulation of which produces an alteration in naming function ('positive mapping') and (2) the careful sampling of the region of desired cortical resection to ensure that only 'negative sites' (in which no alteration of naming occurs with maximal stimulation) will be incorporated into the resection volume ('negative mapping'). It is our practice to expose a large expanse of temporal–parietal cortex with the craniotomy, as positive language sites may be 8–10 cm posterior to the temporal tip. If these sites are clearly identified then a more aggressive resection of lateral cortex may be undertaken with observation of the '1 cm rule'. Although we thoroughly sample the volume of desired resection to ensure that only 'negative sites' are resected,

as previously noted, we do not rely solely on 'negative mapping' techniques alone to guide a tailored resection of tissue, as has been recently proposed in the context of glioma surgery [64]. If no positive sites can be identified, our approach is to stimulate the region of proposed resection with threshold or suprathreshold currents during language mapping to assure that no positive sites are present and to have the patient actively naming during the resection of lateral neocortex.

Lateral cortical resection: ECoG#2 and hippocampal removal

The lateral cortical resection undertaken is tailored to the results of the ECoG and language mapping. The inferior temporal and fusiform gyri are resected and the ventricle is entered and slit open to expose the entirety of the hippocampus in preparation for ECoG#2. Four four-contact electrodes are placed: (1) under the orbitofrontal cortex; (2) within the temporal horn of the ventricle in an anterior–posterior trajectory with contacts on the surface of the hippocampus; (3) under the parahippocampal gyrus parallel to the hippocampal electrode; and (4) under the posterior temporal cortex running from lateral to medial. Carbon-tipped surface electrodes are placed on the exposed regions of temporal and suprasylvian neocortex. After the ECoG recording, the hippocampal and incremental tailored neocortical resections are completed. Some studies have suggested that tailoring of the hippocampal resection based on ECoG findings may permit a subtotal hippocampal resection with favourable seizure outcome [16]. Our practice is to pursue a total hippocampal removal, assuming that our preoperative multivariate analysis of neuropsychological, imaging and electrographic parameters predicts a favourable outcome with regard to verbal memory [12].

77 Epilepsy Surgery in Children

Jason S. Hauptman and Gary W. Mathern
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Introduction

Although neurosurgical intervention for medically refractory epilepsy has been utilized in adults for over a century, surgical treatment for children began in earnest only 20 years ago. The goal of surgical treatment is to eliminate seizures as quickly and early in brain development as possible while minimizing adverse effects. Seizure control early in cerebral development is important to ensure optimal cognitive and functional outcomes [1]. In this chapter, the concepts of paediatric epilepsy surgery are reviewed with an emphasis on literature published in the last 10 years. The chapter starts with an appraisal of treatment-resistant epilepsy and emphasizes the neurodevelopmental consequences of suboptimal seizure control. This is followed by the presurgical evaluation and surgical management of patients with paediatric epilepsy. Finally, an analysis of surgical outcomes with regards to seizure control, complications, cognitive development and quality of life is described. The objective of this chapter is to assist the paediatrician and neurologist in understanding the rationale behind early diagnosis of therapy resistance and, when appropriate, referral to paediatric epilepsy centres for comprehensive evaluation and possible surgical treatment.

Therapy-resistant epilepsy and the rationale for early seizure control

Which children are surgical candidates?

Epidemiological studies show that the incidence of new-onset seizures in children reaches four cases per 1000 of the population. Other studies point out that once a child has failed to obtain seizure control after trying two to four antiepileptic drugs (AEDs), the probability that additional medications will stop seizures in the long term is under 5% [2]. If the child presents with an identifiable epileptogenic structural lesion on neuroimaging, the possibility that additional medications will help is even lower [3]. These findings allow primary care physicians to identify children with 'therapy-resistant' epilepsy early in the course of their disease, who should be referred to a specialty paediatric epilepsy centre where surgery is one therapeutic option. Exhaustive attempts at trying all available AEDs before referring a child to a specialty epilepsy centre is suboptimal care.

Population studies indicate that approximately 8–10% of children with newly diagnosed epilepsy will have medically refractory seizures when followed over 2 years. Refractory seizures have been defined as seizures persisting after use of more than two AEDs at a frequency of one or more per month [4]. Of those children medically controlled at 1 year, an additional 8% will meet the criteria for intractability when followed to 2 years. Hence, children need to be followed closely, as some who are initially controlled on AEDs will become medically refractory. In addition to response to AEDs, the type of epilepsy syndrome predicts which children are most likely to become therapy resistant. *Symptomatic* epilepsy refers to children in whom seizures are secondary to a structural brain abnormality. The symptomatic group constitutes approximately 20% of children with new-onset epilepsy. Symptomatic epilepsy has lower remission rates with medical therapy. Aetiologies include mesial temporal sclerosis, cortical dysplasia, tuberous sclerosis and tumours. Patients with certain aetiologies such as hippocampal sclerosis, cerebral dysgenesis and dual pathologies have a particularly poor prognosis, with a 11–35% chance of becoming seizure free with medications [5,6]. *Idiopathic* epilepsy refers to children in whom seizures are the only manifestation of this disorder. Idiopathic epilepsies can be localization related (e.g. benign rolandic epilepsy) or generalized, and are presumed to be genetic in origin. These children constitute 30% of new-onset paediatric epilepsy patients and, when the onset is from 5 to 9 years of age, they have high remission rates with medical therapy. *Cryptogenic* epilepsy accounts for approximately 50% of new-onset seizure cases for which no aetiology has been determined with current diagnostic methods. There is a great deal of clinical and scientific interest in the cryptogenic group, as the aetiology may range from polygenic to subtle microstructural lesions as yet unidentifiable by current neuroimaging techniques. It is hoped that in the future the cryptogenic group is reduced in size as a result of better diagnostic approaches.

Of children with medically refractory epilepsy, most have cryptogenic/symptomatic generalized epilepsy, 11% have localization-related cryptogenic/symptomatic epilepsy and 3% have idiopathic epilepsy [4]. Factors such as high initial seizure frequency and focal electroencephalography findings are reported to be associated with a higher risk of becoming medically intractable [7]. Mental retardation, neurological abnormality, positive neuroradiological findings, perinatal anoxia, neonatal convulsion, history of status epilepticus and symptomatic aetiology are other risk factors for the development of refractory epilepsy in children. Age at seizure onset, status epilepticus, mixed type of seizure disorder and history of frequent seizures (more than once per month) are reported as additional independent risk factors for the development of refractory epilepsy in children.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Response to AEDs varies by clinical seizure category. Approximately 55% of children with idiopathic epilepsy will experience remission after 1 year. An additional 40% of children with idiopathic epilepsy will have less than one seizure per month. Thus, 95% of children with idiopathic epilepsy experience near-seizure control with medication. Cryptogenic cases can also expect a good response to medical treatment, with a total of approximately 92% achieving near-seizure control within 2 years. Although symptomatic partial seizures have an approximately 71% rate of remission within 2 years, early-onset symptomatic/cryptogenic generalized epilepsy has a 47% rate of seizure control [8]. Many children considered for epilepsy surgery fall into this latter group of patients with symptomatic epilepsy. A meta-analysis has shown that the development of new AEDs has not significantly impacted the percentage of patients seizure free with medications [9]. This is an important finding, as approximately 16% of children with new-onset epilepsy will be medically intractable and, of those, approximately 50% will have symptomatic epilepsy. Overall, an estimated 10% of children with new-onset epilepsy will likely be both symptomatic and therapy resistant. This is calculated based on the 20% incidence of symptomatic epilepsy with 50% remission rate.

Seizure presentation in children is not the same as in adults. In infants and young children, symptomatic epilepsy from unilateral lesions may manifest as generalized seizures. Children with symptomatic epilepsy often do not present with a clear MRI abnormality (e.g. tumour or vascular malformation) with congruent electroencephalography findings and semiology. Many times children present with severe generalized seizures by semiology and electroencephalography, including infantile spasms, and will have unilateral focal or hemispheric lesions on MRI. It is also common to find focal electroencephalography findings and negative MRI, although there may be an underlying focal cortical abnormality causing the seizures. False-negative MR scans occur because cortical dysplasia is difficult to identify in a young child's brain scan due to brain growth and myelination of white matter tracts in the first 2 years of life. Furthermore, children with multiple brain lesions, as with tuberous sclerosis, can have electroencephalography localization to one of the tubers and be a surgical candidate with the potential for excellent seizure control. Finally, infants with unilateral hemispheric disease, such as Rasmussen's syndrome, hemimegalencephaly and severe cortical dysplasia, may have generalized seizures and bilateral abnormalities detectable by electroencephalography but are extremely amenable to surgical treatment [10]. Because of the variability in clinical presentation, referral to a paediatric epilepsy specialty centre is recommended for children under age 2 years with uncontrolled seizures in order to determine the aetiology and formulate an effective treatment plan [1].

Risks of uncontrolled epilepsy

Why is it critical to control seizures as soon as possible in infants and children even if that means resective surgery?

Inadequately controlled epilepsy in infants and children poses significant neurodevelopmental ramifications. These consequences span cognitive, behavioural, psychosocial and psychiatric realms. One study looking at children with unilateral temporal lobe epilepsy found that preoperative intellectual dysfunction (IQ < 79) was present in 57% of children [11]. The incidence of intellectual impairment was approximately 83% in children with epilepsy onset in the first year of life. The notion of epilepsy-induced intellectual deterioration, termed an *epileptic encephalopathy*, is congruent with other studies that have shown that intractable seizures during the first 24 months of life, especially when occurring daily, are a risk factor for severe mental retardation independent of aetiology [12]. In medically intractable infantile spasms, impaired cognition, language and social/communication abilities (similar to autism) are almost guaranteed to develop if adequate early treatment is not implemented [13]. These findings support the notion that seizure control during the early years of brain growth is critical for intellectual development. Contemporary work suggests that early surgical intervention may result in improved IQ scores and developmental indices [14–17]. Additionally, adolescents with intractable epilepsy can expect to have poorer psychosocial outcomes than those patients whose epilepsy is controlled [18]. Patients with a childhood history of epilepsy have lower rates of high school completion, employment, marriage and overall socioeconomic productivity. Considerable consensus exists among paediatric neurologists and neurosurgeons that the prevention of developmental decline is paramount in the treatment of paediatric patients with refractory epilepsy [1].

Seizure-related morbidity and mortality is also important to consider when discussing the rationale for early surgical intervention. Children with refractory epilepsy are at risk of seizure-related morbidity and mortality compared with children without seizures [19,20]. The mortality risk from uncontrolled epilepsy is 0.5% per year and accumulates over a lifetime, making it particularly relevant in young children. Causes of seizure-related mortality include sudden unexplained death in epilepsy (SUDEP), aspiration pneumonia, trauma and status epilepticus.

Surgical therapy, in appropriate symptomatic cases, should be considered as an option in the management of children with therapy-resistant epilepsy early in the course of their epilepsy disorder. The goal of surgery is to prevent catastrophic developmental arrest or regression by stopping the seizures. Additionally, the functional plasticity of the infant brain allows for neurological recovery and reorganization after surgical treatment. Finally, optimal seizure control may improve or normalize psychosocial function and quality of life. The evaluation and treatment of intractable paediatric epilepsy is complex and requires a multidisciplinary team approach with unique clinical expertise. Thus, referral to a specialty paediatric epilepsy centre for evaluation is an essential early step in the management of infants and children with therapy-resistant epilepsy.

Symptomatic substrates in surgically treated children

The most common histopathological finding in children undergoing epilepsy surgery is cortical dysplasia (Table 77.1) [21]. Cortical dysplasia can be severe or mild, focal or involve most of the cerebral hemisphere (Fig. 77.1). Cortical dysplasia is a congenital structural abnormality consisting at a minimum of cortical dyslamination and columnar disorganization [22]. Severe cortical

dysplasia consists of cortical dyslamination plus the presence of abnormal cells in the cortex and subcortical white matter termed *cytomegalic neurones and balloon cells* [23]. Evaluation of children with cortical dysplasia by structural MRI may present challenges, as the radiographic abnormalities may be subtle or undetectable in 20–30% of cases. Other neuroimaging studies may be necessary to detect cortical dysplasia, including FDG-positron emission tomography (FDG-PET), magnetoencephalography (MEG) and ictal single photon emission computerized tomography (ictal-SPECT). Cortical dysplasia may be localized most commonly in the frontal and temporal lobes, be multilobar or involve an entire hemisphere (Fig. 77.1). Larger dysplastic lesions detected by MRI, with more severe histopathology, are typically present in patients who have early-onset epilepsy.

Low-grade neoplasms, such as gangliogliomas and dysembryoplastic neuroepithelial tumours (DNETs), make up the next most frequent aetiology in paediatric epilepsy surgery patients (Fig. 77.2A and Table 77.1). Tumours are the second most common aetiology behind hippocampal sclerosis in adult epilepsy surgery populations. Complete resection of these tumours typically results in high seizure remission rates [24]. Children who suffer brain damage from perinatal strokes or bacterial/viral infections constitute another group that is treated surgically for refractory epilepsy (Fig. 77.2B and H). Hippocampal sclerosis, which is the most frequently encountered pathology in adult patients undergoing epilepsy neurosurgery, is an infrequent cause of pharmacoresistant seizures in children (Fig. 77.2E).

Table 77.1 Aetiologies in patients undergoing paediatric epilepsy surgery under the age of 18 years

Aetiology	Cases (%)
Cortical dysplasia	38
Focal	25
Multilobar	13
Tumour	19
Atrophy/stroke	10
Hippocampal sclerosis	6
Tuberous sclerosis complex	5
Hemimegalencephaly	4
Hypothalamic hamartoma	4
Sturge–Weber	3
Rasmussen encephalitis	3

Modified from ref. 21.

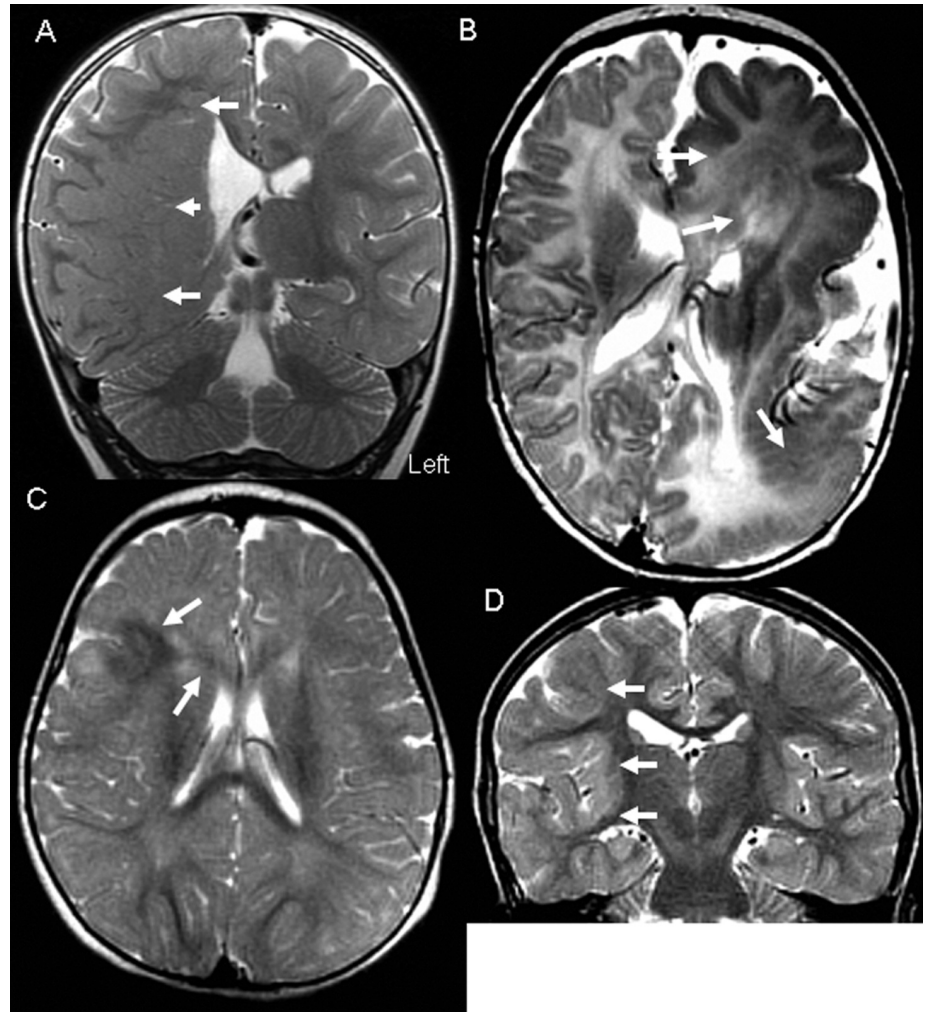

Fig. 77.1 MR scans of cortical dysplasia. (A) Example of severe right hemispheric cortical malformation from a large heterotopia (arrows). Notice the abnormal lateral ventricle, displaced or missing right basal ganglia and thalamus, and obliterated right temporal horn and hippocampal formation. (B) Example of a left hemimegalencephaly (arrows). Notice that the left cerebral hemisphere is larger than the right. (C) Example of a focal right frontal cortical dysplasia that extends to the ventricle (arrows). (D) Subtle cortical dysplasia of the right hemisphere. Note the decreased T2 white matter signal of the right frontal and temporal cortex and thicker insular cortex (arrows). Pathology confirmed Palmini type IIA cortical dysplasia (severe without balloon cells).

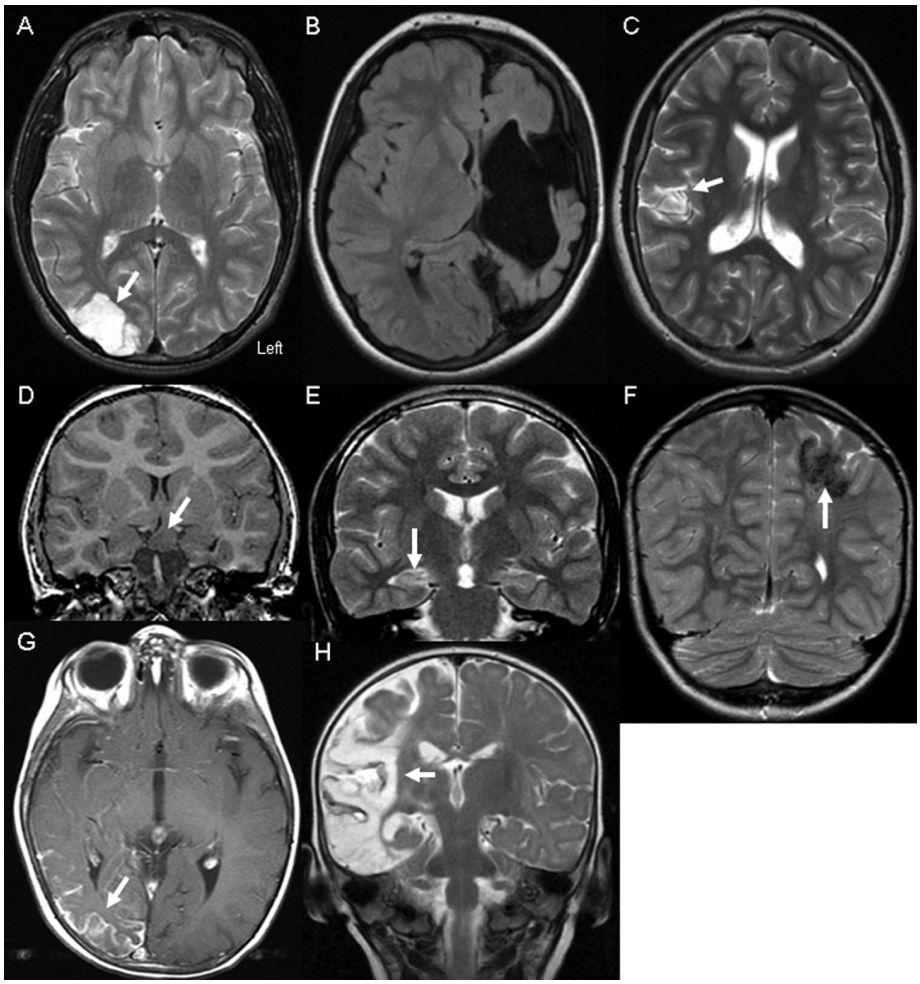

Fig. 77.2 MR scans of other aetiologies found in paediatric epilepsy surgery patients. (A) Example of a right occipital cystic mass that by histopathology was a tumour (DNET). (B) Example of a patient with a large left middle cerebral artery infarct in the perinatal period. Notice the smaller cranial vault over the left hemisphere. (C) This patient had continuous movements of the left face and hand consistent with epilepsia partialis continua (EPC) associated with an area of atrophy in the right perisylvian region (arrow). A previous MR scan 1 year before was normal. Histopathology showed findings consistent with Rasmussen encephalitis. (D) A child with gelastic epilepsy from a hypothalamic hamartoma (arrow). (E) This child had a complex febrile convulsion at the age of 18 months. From the age of 5 years the child experienced episodes of staring and lip smacking associated with an aura of a 'funny feeling in my tummy'. MRI shows increased T2 signal in the right hippocampus (arrow), which, at histopathology, was hippocampal sclerosis. (F) Example of a calcified cortical tuber (arrow) in a child with tuberous sclerosis complex. (G) This child had a port wine stain over the right eyelid. The MRI with contrast shows imaging features of Sturge–Weber syndrome. (H) This child had herpes encephalitis and later developed seizures coming from the damaged right hemisphere (arrow).

Neurocutaneous disorders (phakomatoses), such as Sturge–Weber syndrome (Fig. 77.2G) and tuberous sclerosis complex (Fig. 77–2F), are rarer causes of epilepsy in children but can be treated surgically. In patients with tuberous sclerosis, seizures may appear to be multifocal in origin, are often resistant to antiepileptic drugs and have a negative impact on the neurocognitive development [25]. Many times resection of a single tuber is necessary for optimal seizure control. In other cases, a multistaged approach with resection of multiple epileptogenic tubers may be necessary [26]. In Sturge–Weber syndrome, developmental delay and progressive hemiparesis may occur with suboptimal seizure control, and thus children may require early focal or hemispheric resection [27].

More unusual pathologies encountered in patients undergoing paediatric epilepsy surgery include Rasmussen's syndrome (Fig. 77.2C), hypothalamic hamartoma (Fig. 77.2D), polymicrogyria, Landau–Kleffner syndrome and hemimegalencephaly (Fig. 77.1B). Hemimegalencephaly is a poorly understood phenomenon in which one hemisphere is hypertrophied and contains an abnormal proliferation of unusual glial and neuronal cells, whereas the other hemisphere is smaller than normal [28]. Children with hemimegalencephaly typically have mental retardation and contralateral paresis. Abnormalities detected by electroencephalography may be unilateral or bilateral, often with hypsarrhythmia. Hemispherectomy provides the best chances for seizure control and normalization of psychomotor development velocity in children with hemimegalencephaly.

Pre-evaluation in paediatric epilepsy surgery

Evaluation of children by individuals with expertise in refractory paediatric epilepsy syndromes ensures confirmation of an accurate diagnosis and consideration of appropriate medical and surgical therapies. Not all patients referred to a paediatric epilepsy centre will be offered surgical treatment. In fact, surgery is typically withheld in patients with degenerative and metabolic disorders, benign idiopathic focal epilepsies and medication noncompliance. Many of the symptomatic pathologies are uncommon and it is to the benefit of the child to be evaluated by specialists who are experienced in diagnosing and treating rarer disorders, such as tuberous sclerosis complex, Rasmussen's syndrome and hemimegalencephaly.

Preoperative evaluation involves electroencephalography, structural and functional neuroimaging and, when appropriate, neuropsychological testing and psychiatric assessments. Interictal electroencephalography and video electroencephalography

(VEEG) telemetry are integral to localizing the seizure source and accurately recording the semiology. In certain situations, invasive electroencephalography recordings (grid or depth electrodes) may be necessary when non-invasive alternatives are inconclusive. The use of intracranial electrodes varies widely from centre to centre. Intracranial electrodes are used in approximately 25–30% of paediatric epilepsy surgery cases [21]. Structural imaging refers to MRI with specific epilepsy protocols. Sequences obtained may include T2 fast spin echo (FSE), T2 gradient echo (GE), T1 inversion recovery (IR), fluid attenuation inversion recovery (FLAIR), three-dimensional thinly sliced T1-weighted GE in three planes, magnetization transfer (MT), spoiled gradient recalled (SPGR) and diffusion-weighted imaging (DWI). Fractional anisotropy and diffusion tensor imaging are emerging MRI methods and these are used to identify structural abnormalities that could be generating seizures and to view normal white matter tract anatomy for operative planning. Of importance is the fact that immature myelination in infants of less than 24 months of age may require specialized MR sequences and serial MRI. An initial scan that is normal can become positive, showing an epileptogenic lesion with further maturation of the brain. Functional imaging consists of ictal and interictal SPECT, FDG-PET, MEG/magnetic source imaging (MSI) and blood oxygen level-dependent functional MRI (BOLD-fMRI) for mapping motor, sensory and language areas [29]. In older children, fMRI is particularly useful for identifying eloquent cortex that may affect surgical planning. The use of fMRI helps to spare normally functioning areas, identify abnormal areas that are functionally active and demonstrate areas of eloquent cortex that have reorganized [30]. In about 50% of paediatric epilepsy centres, intracarotid amobarbital infusion is used for language lateralization [21]. At most paediatric centres, multimodal integration of imaging data is performed routinely, with MEG and PET data superimposed on to structural MRI acquisition data in order to assist surgical planning.

Because many paediatric epilepsy disorders are also associated with psychiatric and cognitive co-morbidities, evaluation by an interdisciplinary team of developmental neuropsychologists, psychiatrists and social workers is an important step in the pre- and postsurgical processes. This includes appropriate assessment of family dynamics regarding the expectations for surgery. The process of deciding if surgery is the most appropriate therapeutic intervention depends on an analysis of the intervention's risk–benefit ratio compared with the risks of continued uncontrolled epilepsy. Clinicians and families must decide together whether the risk of continued seizures justifies the risks of epilepsy surgery, including any expected postoperative physical and neurological deficits.

The evaluation and surgical treatment of paediatric epilepsy are customized to the individual child. For example, it is not uncommon for children with symptomatic substrates to present with acute status epilepticus that requires urgent surgery to control life-threatening seizures [31]. Surgery may be directed to invasively record seizures using grid and depth electrodes, resect the epileptogenic lesion, disconnect the abnormal cortex using different techniques or palliate seizure frequency [21]. Approximately 80% of seizure surgery in children involves resection and invasive diagnostic electoencephalography procedures, whereas 20% involves palliation. The most common types of surgery are shown in Table 77.2. About 15% of patients receive hemispherectomy, 13% multilobar resections, 58% localized resections and less than 5% receive only diagnostic electrophysiological recording or multiple subpial transections (MSTs). Multiple techniques of hemispherectomy–hemispherotomy exist, all with relatively similar seizure control rates and efficacy similar to temporal lobectomy for complex partial limbic seizures [9,32,33]. At our institution we use a modified lateral hemispherotomy, which, when compared with other methods of hemispherectomy, results in lower intraoperative blood loss, reduced complication rates and shorter intensive care unit stays [10,17]. In children who receive localized or multilobar resections, seizure control is directly related to the completeness of lesion excision. Multiple subpial transections are useful for children with epileptic lesions in eloquent cortex, in whom transverse synaptic connections can be disrupted while preserving functional vertical columns.

Table 77.2 Frequency of types of paediatric epilepsy surgery in children under the age of 18 years.

Location	Cases (%)
Temporal	30
Frontal	23
Hemispherectomy	20
Multilobar resection	18
Parietal	3
Hypothalamic	3
Occipital	2
Multiple subpial transection/no resection	1

Modified from ref. 21.

Of children who qualify for palliative procedures, most receive vagal nerve stimulators in the USA, whereas only a few receive corpus callosotomy. Corpus callosotomy is a more frequent operation in parts of the world without access to vagal nerve stimulators. These procedures are typically performed in children with catastrophic generalized epilepsy not amenable to resection, such as seen in Lennox–Gastaut syndrome [34]. Radiosurgery has recently emerged as a surgical alternative, particularly in those with hypothalamic hamartoma and mesial temporal lobe epilepsy in older children and adults. The use of radiosurgery in infants and small children has not been adequately studied. Stereoendoscopic techniques have also emerged as new approaches to the treatment of epilepsy in children with hypothalamic hamartoma [35,36].

The appropriate anaesthesia team is necessary in children undergoing epilepsy neurosurgery [37]. Infants have lower cerebrovascular autoregulatory reserves and a relatively high cerebral blood volume, putting them at greater haemodynamic risk during extensive neurosurgical resections. The head constitutes approximately 20% of the body surface area in infants and children, compared with 9% in an adult. Also, infants have a limited capacity to handle changes in fluid and solute loads, affecting fluid management during surgery. Hepatic function can be considerably altered in children on chronic antiepileptic drug (AED)

therapy, and thus drug metabolism and coagulation may be affected. These issues are of importance when considering epilepsy surgery on small children, as high intraoperative blood loss and transfusion requirements (especially in the case of large resections, e.g. anatomical hemispherectomy) may cause considerable haemodynamic and metabolic derangements. A unique example where this is especially poignant is hemimegalencephaly, when the immature, dysplastic hemisphere is particularly vascular and blood transfusion requirements may be considerable. Although haemodynamic risks may at initial glance make one wary of operating on young children when larger resections are usually necessary, the increased operative risks are justified in order to prevent cognitive and developmental delay due to longstanding epilepsy during early brain development.

Preoperative anaesthesia evaluation should include haematological and metabolic analyses, as well as chest radiography and, possibly, echocardiography. In the case of children with tuberous sclerosis complex, appropriate imaging should be performed to rule out lesions in other organ systems that may affect intraoperative physiology, such as the heart and kidneys. An accurate medication history is essential, as many AEDs affect the metabolism of anaesthetic agents. Furthermore, the use of the ketogenic diet may promote metabolic derangements when carbohydrates are administered, and therefore only normal saline should be utilized. Intraoperative monitoring should focus on continuous haemodynamic assessment, and placement of an arterial line and central venous access are necessary. Postoperative care in the paediatric intensive care unit should focus on maintenance of appropriate haematological and coagulation parameters. Surgical drains are utilized many times, especially in the case of larger resections, and intracranial pressure management is important. An experienced multidisciplinary team, consisting of neuroanaesthesiologists, paediatric intensivists, paediatric neurologists and the neurosurgeon, should guide perioperative and postoperative management.

Outcomes in paediatric epilepsy surgery: seizure remission and cognitive/psychosocial results

In a recent study examining 134 children who underwent epilepsy neurosurgery, the overall seizure-free rate was 69% over a mean follow-up time of 62.3 months [38]. This is consistent with other studies that have reported that 65–80% of children become seizure free after epilepsy neurosurgery [9,32]. The seizure-free rate is higher in children who have temporal resections for discrete MRI-identified lesions than extratemporal resections for MRI-negative or ill-defined lesions without clear borders [39]. Early seizure control after epilepsy surgery is the best predictor of long-term control. Patients who do not have a seizure recurrence during the first 6 postoperative months have up to a 95% chance of being completely seizure free over the long term [40]. Successful control of seizures after epilepsy surgery in children is associated with reduced use of AEDs [33,41]. Approximately 30–50% of children discontinue use of AEDs after epilepsy surgery. Seizure freedom after surgery is associated with lower mortality [33].

In studies of focal resection for localized epilepsy, seizure-free rates have been shown to be up to 88% for hippocampal sclerosis, 50% for dual pathology, 81% for tumour, 62% for cortical dysplasia and 80% for cavernous malformations [42]. These focal resections have only rarely been associated with permanent neurological complications. The reduction in seizures is greater in patients with pathologies requiring focal or lobar resections than in patients with a more widespread and diffuse pathology requiring multilobar surgery [43]. That being said, epilepsy surgery may be successful for selected children and adolescents who present with abundant generalized or bilateral epileptiform discharges on electroencephalogram (EEG). Diffuse EEG patterns may indicate an interaction between the lesion and the developing brain [44]. Failure of surgical treatment is related to the absence of radiographic evidence of a structural abnormality, development-associated disease, widespread disease on postoperative EEG, and limited resection due to involvement of functional cortex. Presurgical intellectual disabilities do not predict postoperative seizure outcomes in paediatric epilepsy surgery patients [45].

Risks and complications of epilepsy neurosurgery are reasonably low when compared with the cognitive, developmental and mortality risks of chronic suboptimal seizure control. Surgical mortality is less than 1% for temporal lobectomy and 1–2% for hemispherectomy. Permanent morbidity from surgical resection is generally reported to be less than 5%, with risks varying by type of procedure performed. Temporal resections are most often complicated by visual field deficits, while extratemporal resections are most often complicated by transient hemiparesis [32]. Serious complications include infarct and hemiparesis in temporal lobe resections and motor or language deficits in larger procedures. Operative morbidity and mortality rates are less than those of uncontrolled therapy-resistant epilepsy.

The literature supports the notion that after epilepsy surgery, developmental quotients improve when seizures are controlled. Developmental indices before surgery predict postoperative developmental function [16,40]. Children operated on at younger ages and with epileptic spasms show the greatest increase in developmental quotient after surgery. Studies have also shown a mean increase in IQ following surgery, particularly in patients with a shorter seizure history [46]. Specific cognitive functions, such as behaviour and attention, typically impaired in parietal lobe epilepsy, are improved by epilepsy surgery as well [45]. This translates into better school performance and social adaptation after paediatric epilepsy neurosurgery. Memory and executive function do not seem to be adversely affected by epilepsy surgery in children. Furthermore, epilepsy surgery does not appear to adversely affect motor performance with regards to daily activities and level of caregiver assistance [47]. Although more longitudinal studies are needed to adequately assess cognitive and neurodevelopmental results in epilepsy surgery patients, preliminary data indicate that these faculties are improved.

Studies show that quality of life (QOL) is enhanced after epilepsy neurosurgery in children. Most improvements in QOL occur in the first 6 months after surgery. One study found that all patients who underwent epilepsy surgery experienced improvement in QOL measures, with seizure control being clearly correlated with QOL changes [48]. Children, after epilepsy surgery, experience greater feelings of self-worth and social competence.

Similarly, after surgery, adolescents feel better about their athletic competence and capacity for social interactions. This improvement in QOL is critical for social integration of these children among their peers. In addition, in children who undergo temporal lobectomy QOL indices normalize to that of matched healthy individuals 3 years after surgery [49]. In contrast, intractable temporal lobe epilepsy without surgical therapy has been associated with low QOL scores despite attempts at AED optimization. Studies have also indicated that epilepsy surgery is cost-effective, especially for children, and allows other members of the family to engage in work and school.

Conclusion

Children with therapy-resistant epilepsy are at particular risk for developmental delay, cognitive regression and higher mortality rates. Early identification of intractability and referral to a paediatric epilepsy centre is crucial. Children with structural lesions visible on MRI and who have failed to respond to two to four AEDs have a poor chance of being seizure free on medications and should be quickly referred to a specialty centre for evaluation because of increased seizure-related morbidity and mortality. If the child is a candidate for surgery, preoperative studies include interictal electroencephalography, VEEG telemetry, structural and functional neuroimaging and, when appropriate, psychiatric and cognitive evaluations. Surgical intervention for these children is directed at reducing seizure frequency while minimizing neurological morbidity. Overall seizure control rates are from 65% to 80% after epilepsy neurosurgery in children. Morbidity and mortality rates are reported as less than 5%, which compare favourably with the higher mortality of therapy-resistant epilepsy over 10 years. Furthermore, recent studies have shown that epilepsy surgery improves developmental and cognitive indices and QOL. Thus, surgery for intractable epilepsy in children should not be the treatment of last resort. Instead, it should be considered along with medical treatment to stop seizures as soon as possible to prevent epilepsy-induced disabilities in infants and children.

78 Stereotactic Surgery for Epilepsy

Andrew W. McEvoy and Fiona J.L. Arnold
National Hospital for Neurology and Neurosurgery, London, UK

Introduction

The evolution of surgical treatment for epilepsy in the last century has been critically dependent on technical development [1]. Conventional (i.e. resective) surgery for medically refractory epilepsy has a long tradition and is effective in cessation or amelioration of seizures in 55–80% of patients depending on case selection. Stereotaxy is a navigational technology that allows neurosurgeons to accurately determine their location and direction during surgery. Stereotactic procedures offer the possibility of being highly accurate, more economical and better tolerated than conventional craniotomy and resective surgery; hence these are being used more frequently in the management of medically refractory epilepsy.

During the past decade, technological advances have revolutionized the art of neurosurgical navigation, with frameless stereotaxy perhaps the most elegant. More recently, there has been a trend towards using stereotactic radiosurgery with the gamma knife for placing highly selective discrete lesions in areas of the brain responsible for epilepsy.

The word 'stereotactic', derived from the Greek *stereos* (meaning 'three-dimensional') and *tactus* (meaning 'to touch'), was coined by Horsley and Clark in 1906 [2]. The technique involves the use of neuroradiological imaging modalities, linked to a three-dimensional coordinate system, in order to guide the surgeon to a chosen target with an accuracy of 1–2 mm.

Traditionally, registration of the radiological images to the patient in the operating theatre has involved the use of a stereotactic head frame. This is fixed to the patient's head with screws, is visible on the imaging modality being used and remains on the patient's head during surgery. This rigid head frame has the major advantage of maintaining a fixed three-dimensional coordinate system. Unfortunately, however, the bulky frame is also the system's main limitation, as it puts a constraint on head positioning and physically interferes with performing a craniotomy. Consequently, frame-based systems tend now to be reserved for procedures such as needle biopsy or placement of depth electrodes.

The next step was the development of image-based, intracranial navigation that is independent of an external frame. Several systems have now been developed, each based on a combination of three fundamental concepts: (1) correlating physical space with image space; (2) using a pointing device for interactive localization; and (3) obtaining image-guided feedback through a computer-based interface. Frameless stereotaxy is based on the creation of a mathematical relationship between radiographic images and physical space. This process, known as registration, involves the precise mapping of every location in an image to the corresponding physical anatomy of the patient [3].

The application of stereotactic neurosurgery continues to advance, especially with developments in multimodality neuroradiological imaging. The advent of high-resolution (3-T) MRI, MR sequences demonstrating previously unseen focal lesions and diffusion tensor imaging (DTI), together with functional imaging modalities such as functional MRI (fMRI), magnetoencephalography (MEG), positron emission tomography (PET), singlephoton emission computerized tomography (SPECT) and electroencephalography–fMRI, allied with advances in computer and stereotactic instrument technology, has introduced new possibilities in epilepsy treatment.

The use of preoperative high-resolution volumetric MRI has had an enormous impact on epilepsy surgery planning [4–9]. The responsible pathological substrate is now frequently identifiable using such methodologies [10,11]. In the epilepsy surgery programme at the National Hospital for Neurology and Neurosurgery, London, UK, the number of such abnormalities visualized on preoperative imaging of epilepsy surgery candidates has risen from less that 10% to over 90% with the routine use of volumetric MRI. In this way, epilepsy surgery is becoming increasingly image guided, with less reliance placed on electrophysiological localization. Frameless stereotactic neurosurgery is frequently the method by which this image guidance is best achieved.

In this chapter, we will discuss the principles of stereotaxy and their application to the basics of 'frame-based' and 'frameless' systems. We will show how the increasing use of multimodality imaging and its integration into image-directed neuronavigational systems has led to these techniques becoming an essential part of epilepsy surgical practice.

We will discuss the current status of stereotactic neurosurgery in the surgical management of epilepsy with reference to its role:

- As an aid to conventional (i.e. resective) epilepsy surgery:
  - *Diagnosis*. Stereotactic methods are used to place depth electrodes for invasive electroencephalographical monitoring in the evaluation of epilepsy cases in which there are diagnostic and management difficulties concerning lateralization and localization.
  - *Treatment*. First, selective stereotactic amygdalohippocampectomy has been used as a method of minimizing the

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

resection of the lateral temporal neocortex while continuing the resection to the relevant part of the mesial temporal structures in patients with temporal lobe epilepsy in whom there is concern over the neuropsychological status (particularly with regard to postoperative memory function). Second, stereotactic neurosurgery can be used to guide the surgeon towards small epileptogenic lesions using the techniques of image directed craniotomy.

- For stereotactic lesion making in the central nervous system (i.e. non-resective surgery).

However, it must be appreciated that image-directed surgery is now an inherent part of neurosurgical practice. Its use has become widespread and it is easily applied to almost all neurosurgical procedures.

Frame-based stereotactic neurosurgery

Traditional frame-based stereotaxy offers a high degree of point target localization, but unfortunately the identical stereotactic space is not easily reproducible in the individual patient on different occasions (Plate 78.1). Furthermore, skull fixation using either screws or pins is invasive and uncomfortable for the patient. As a result, with traditional head frames the two phases of stereotaxy (i.e. image acquisition and surgery) need to be closely related to one another in time – in general, one following directly after the other [12,13]. Frameless stereotactic methodologies offer the potential for comprehensive image guidance not seen with frame-based stereotaxy.

Frameless stereotactic neurosurgery

Frameless stereotaxy is uniquely suited to intracranial surgery. The relatively fixed position of the brain within the skull facilitates the referencing of preoperative data with the real-time position of the head.

The main advantages of frameless stereotaxy are that it provides real-time, updated information to the surgeon regarding location and trajectory. It can be helpful in localizing lesions, increasing the chances of complete lesion resection and helping to identify normal structures surrounding a lesion. Typically, the result is faster, more complete and often safer neurosurgical procedures.

Frameless stereotaxy is invaluable at all stages of image-directed epilepsy surgery, including selection of the preoperative approach, sizing of the scalp incision, placement of the craniotomy and selection of the trajectory through or around cerebral structures. Resection of tumours is improved, with corticotomies precisely placed. In tumours with poorly defined margins, the constant feedback on location can be invaluable in maximizing tumour resection while minimizing brain injury. With frameless stereotactic neurosurgery, the surgeon can be accurately and easily guided to the area(s) in the brain responsible for the epilepsy [3].

There are four components to a frameless stereotactic neurosurgical system:

1 pointing device (e.g. a wand);
2 tracking system, which is constantly locating the position of the localizing device in space;
3 hardware system represented by a central processing unit (CPU) and an output device (monitor);
4 software, which is able to reconstruct the data from the tracking system into a three-dimensional image, and is able to register the preoperative image dataset on physical space [14].

Image space is the three-dimensional volume represented by the series of multimodality neuroradiological images that are acquired preoperatively and which make up the imaged anatomy of the patient. Anatomical images obtained from CT and MR scans are frequently defined in the image space and are of high resolution; images from other functional imaging modalities (fMRI, PET and SPECT) can be integrated and also used in image space [15]. As each point in either the CT or MR image dataset is defined in terms of a three-dimensional coordinate (x, y and z), relative to the origin of the Cartesian frame of reference [16], and as each coordinate has an intensity value, these imaging modalities have an already established three-dimensional coordinate system that relates each point in the image to the anatomy. Physical space is the three-dimensional volume represented by the real physical anatomy of the patient and, as such, does not have an obvious coordinate system.

Frameless stereotaxy aims to define a three-dimensional coordinate system for the physical space, and superimpose the images of the anatomy of the patient from the CT or MRI data (i.e. the image space) on to the actual anatomy of the patient in the operating theatre (i.e. the physical space), and thus create a real-time navigational map that the surgeon will use throughout the surgical procedure. This process is called *registration*.

One of the earliest technologies used to localize a point in space consisted of an articulated arm [17–24]. The ISG viewing wand frameless stereotactic guidance system (ISG Technologies, Mississauga, Ontario, Canada) is an excellent example and was used extensively in neurosurgery because of its accuracy to less than 2 mm (Plate 78.1c and d). The wand consists of two segments: a sterile surgical probe and a multijointed, articulated arm with six joints, which gives it a 60-cm reach and six degrees of freedom. Electrical signals from the joints are relayed to and processed by the CPU to give an accurate location of the probe tip in physical space.

The more recent technologies use a system to localize a point in physical space using less bulky and obstructive pointing devices (Fig. 78.1). These systems use a 'free-hand' pointing tool. The data acquisition methods of these free-hand pointing tools are similar. Essentially, the free-hand pointing tool is capable of sending data to a receiver (a microphone or a camera), which will send the received signals to the main CPU without there being a direct physical connection between the tool and the CPU. The CPU will then be able to compute the precise location and three-dimensional coordinates for the pointing tool.

The first examples of these used an ultrasonic triangulating system [25,26]. The more recent systems rely upon the pointing device emitting infrared light from emitting diodes (iLEDs) to cameras located around the operating theatre [27,28]. This information is then processed by the CPU, in the similar way to the ultrasound triangulating system. Although the path between the iLEDs and the camera must be clear, this system does not suffer the disadvantage of interference or of temperature changes. The accuracy of the pointing device is continually assessed during the surgical procedure with known anatomical landmarks. These systems have the advantage that almost any surgical instrument can be converted to the pointing device.

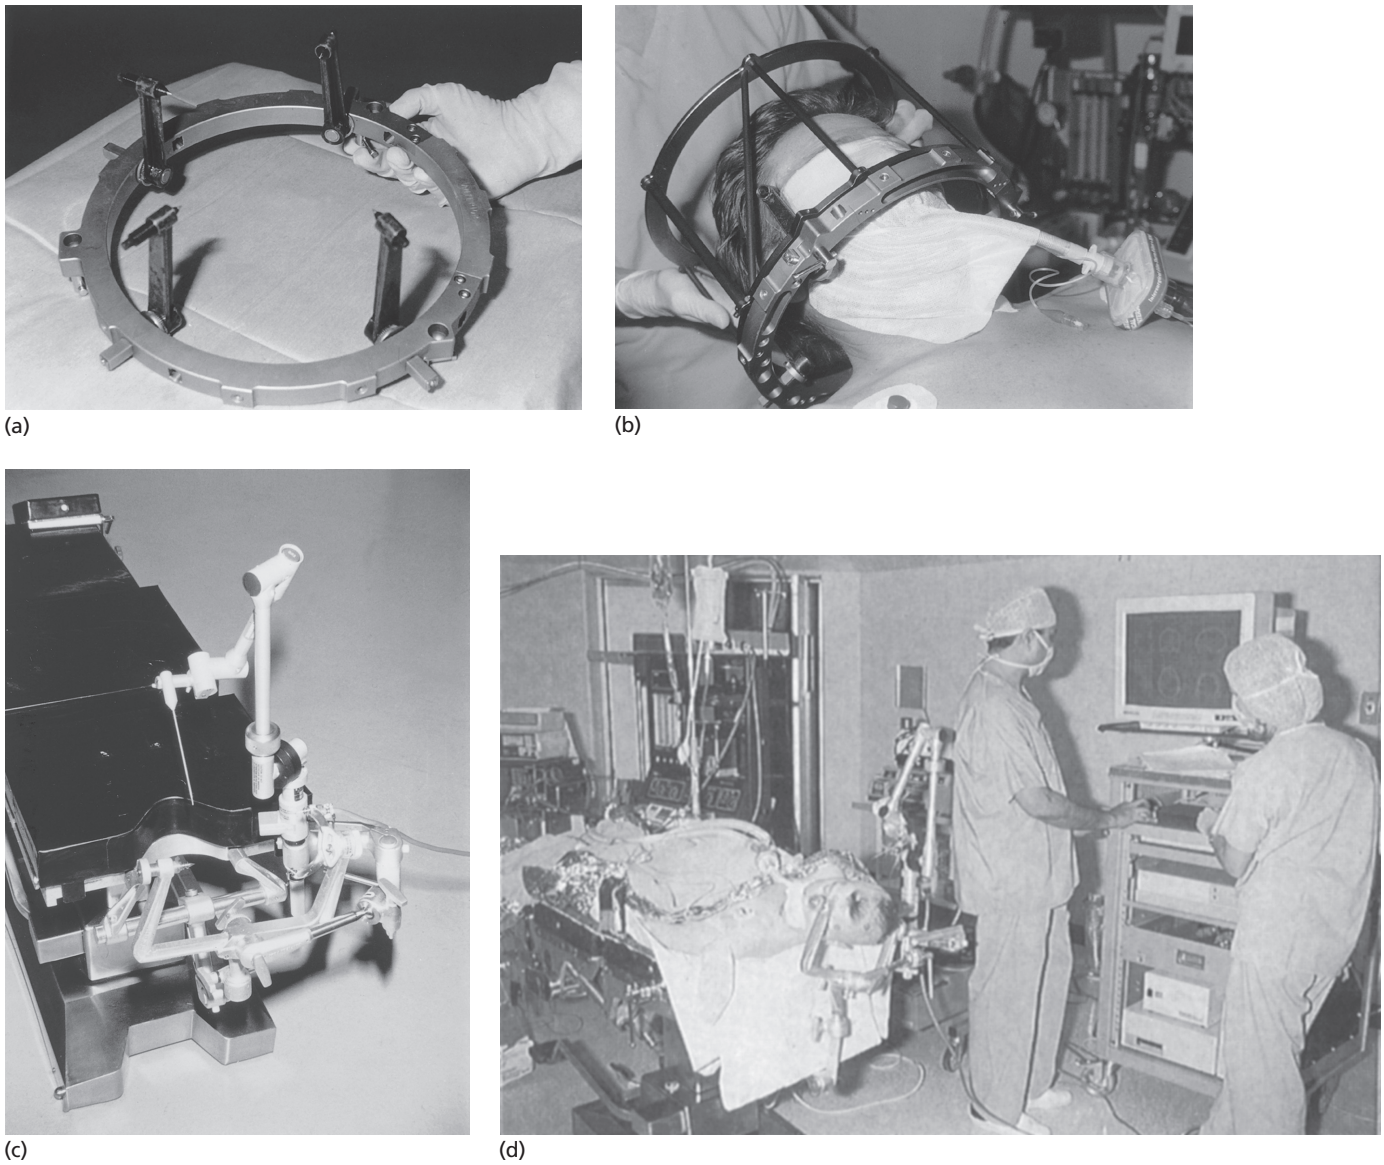

Fig. 78.1 (a) The Cosman–Roberts–Wells base ring. (b) The Cosman–Roberts–Wells base ring and fiducial system being used introperatively. (c,d) The ISG 'Viewing wand' uses a passive mechanical arm for registration and pointing during surgery.

A further development incorporates the localizing function into the operating microscope. Several systems have been developed, one example being the Leica Viewscope (Leica, Deerfield, IL, USA), in which the pointing function is performed by two low-energy lasers that are designed to converge at a single point at the focal length of the microscope. After mapping this point to image space, the corresponding location on the imaging studies can be visualized. These systems have the advantage of continuous update, without the need for a separate pointing device. Although most systems require the surgeon to look away temporarily from the operating field to the computer display, some newer systems incorporate heads-up display of the frameless stereotactic data.

Another recent advancement is the development of frameless stereotaxy without rigid pin fixation. The accuracy and precision of resection with awake brain mapping is greatly augmented when combined with stereotaxy, as described below. Frameless stereotactic-assisted surgery, however, typically involves immobilization in Mayfield pins, which can be uncomfortable for patients undergoing awake craniotomy and can cause complications in paediatric cases. We have recently started to use the Medtronic Stealthstation® Axiem™ system in our institution, which enables similar accuracy of frameless stereotaxy [29] without the requirement for immobilization in Mayfield pins (Plate 78.2). In the future, we also anticipate that the use of intraoperative MRI will be considerably facilitated by frameless stereotaxy without rigid pin fixation.

Registration of the image space on to the physical space is required for the navigational map to be produced. The precise way in which this is achieved is beyond the scope of this chapter; however, there are two basic systems – pairedpoint registration and surface registration.

Paired point registration uses natural landmarks, for example external auditory meatus, nasion or lateral canthus [20,28,30,31],

or artificial landmarks (fiducial markers placed on the head) that are visible on CT and MRI scans [22,25–27,32,33]. Registration error is theoretically minimized at the epicentre of the registered points, so fiducials should be placed on the scalp so they 'surround' the lesion. The most precise landmarks for registration are either bolts or screws in the skull [31].

Surface-based registration systems match numerous points extracted from natural contours. They attempt to align the contour of a physical surface (such as the scalp) with a corresponding image surface.

The corresponding landmarks on the physical space are identified on the image space. With both datasets stored in the CPU, a 'best-fit' transformation matrix is applied by the CPU, transforming and superimposing image space on to physical space as accurately as possible. Hence, the surgeon can readily determine location and trajectory throughout the surgical procedure and the result is navigation.

The disadvantages of image-directed guidance systems are the learning time required to become fully confident with using the device, the preoperative set-up time and the space required for the system in the operating theatre [19]. In addition, changes in the cerebral blood volume, mechanical ventilation, cerebrospinal fluid withdrawal, unopposed gravity and patient positioning can all affect registration. Other problems are brain shift once the skull has been opened or a mass lesion is removed. In this case, the preoperative images will no longer provide an accurate picture of the anatomy of the contents inside the skull. The most definitive solution to this problem is the use of intraoperative MRI and frameless stereotaxy [34–49]. The neurosurgeon can then periodically update the reference images and re-register physical space to updated image space in 'real time'. In other words, the images directing the surgery are not 'historical', but rather are providing information about what is actually occurring during the surgical procedure. The effects of brain shift, which can lead to inaccurate neuronavigation, can therefore be compensated for by an update of the neuronavigation system with intraoperative MR image data. In addition, intraoperative MRI allows resection control images with precise localization of residual tumour tissue and may improve complication avoidance. It also enables online image-guided stereotaxy without preoperative imaging, and 'real-time' tracking of instruments in the operative field. Currently, the main indications for intraoperative MRI are the evaluation of the extent of a resection in glioma, ventricular tumour, pituitary tumour and in epilepsy surgery. Intraoperative MRI offers the possibility of further tumour removal during the same surgical procedure in case of tumour remnants, increasing the rate of complete tumour removal. Claus *et al.* [50] have demonstrated a possible association between surgical resection and survival for neurosurgical patients who underwent surgery for low-grade glioma under intraoperative MRI guidance, and suggested that further study within the context of a large, prospective, population-based project will be needed to confirm these findings. Wirtz *et al.* [51] and Wu *et al.* [52] have demonstrated that the more extensive removal of glioblastoma multiforme enabled by intraoperative MRI leads to significantly prolonged patient survival compared with conventional surgery, but further research is required to determine whether this technique may increase survival in those with low-grade tumors. Another technique of upgrading the accuracy of the navigation system intraoperatively is with ultrasoundd [53–57], which has been shown to be a useful adjunct for the resection of arteriovenous malformations [54] and metastases [55].

Multimodality imaging and image-directed neurosurgery

The last decade has seen neuroimaging take an increasingly important role in the management of epilepsy. New techniques and imaging sequences have appeared that give ever greater sensitivity in the search for abnormalities of brain structure. Neuroimaging has become a powerful functional tool of high spatial resolution that has increased in temporal resolution to the point where it has become an important physiological probe of functions that were previously considered to be entirely the domain of electrophysiology.

A number of imaging modalities are now in common use for the localization of seizure foci as part of the preoperative investigation of patients with intractable epilepsy. In addition, non-invasive methods of mapping brain function, such as functional MRI (fMRI) [58–64], magnetoencephalography (MEG) [65–69], and poistron emission tomography (PET) with the tracer $[^{15}O]H_2O$ are playing an increasing role in the presurgical planning and in intraoperative surgical guidance [15,70–73] (Plate 78.3). However, although these various diagnostic methods can be useful in the diagnosis of epileptic foci, and concordance between presurgical evaluations indicates a better surgical outcome, MRI at present best predicts surgical outcome [74]. MEG can also been used to complement electroencephalography in patients with normal or non-focal MRI findings to determine surgical targets [75]. Also, in patients who are treated surgically for temporal lobe epilepsy the use of these techniques has potential in minimizing morbidity by accurately defining areas of brain function that may be altered, such as language lateralization [76–80].

An exciting new prospect is to combine different types of imaging with complementary information. This has two main uses in epilepsy surgery: first, to minimize surgical morbidity by accurately defining areas of brain function, such as the combination of fMRI and tractography described later; and, second, to enable more precise localization of the epileptic source, such as EEG-correlated functional MRI (EEG-fMRI) [81–85]. Simultaneous acquisition of electroencephalography and fMRI data enables the investigation of the haemodynamic correlates of interictal epileptiform discharges (IEDs) during the resting state in patients with epilepsy. fMRI activation can localize the irritative zone and indicate functional disturbance distant from the spike focus. Salek-Haddadi *et al.* [84] investigated the blood oxygen level-dependent (BOLD) signal correlates of IEDs in 63 consecutively recruited patients with focal epilepsy. Significant haemodynamic correlates were detectable in 68% of patients in whom discharges were captured, and were highly concordant with site(s) of presumed seizure generation where known. Focal activations were more likely when there was good electroclinical localization, frequent stereotyped spikes, less head motion and less background electroencephalography abnormality, but were also seen in patients in whom the electroclinical focus localization was

uncertain. They concluded that EEG-fMRI may provide new targets for invasive electroencephalography monitoring. Lengler *et al*. [82] used EEG-fMRI to study 10 children with typical and atypical benign focal epilepsy of childhood or benign epileptic activity of childhood, and also concluded that it is a useful technique to localize generators of IED. Zijlmans *et al*. [83] have demonstrated the potential added value of EEG-fMRI in the presurgical evaluation of patients with complex source localization. Adult surgical candidates considered ineligible because of an unclear focus and/or presumed multifocality using EEG underwent EEG-fMRI. IEDs in the EEG during fMRI were identified by consensus between two observers. In total, 29 patients with significant, positive BOLD responses that were topographically related to the electroencephalography were re-evaluated for surgery; eight patients were rejected for surgery because of an unclear focus (3), presumed multifocality (2) or both (3). EEG-fMRI improved localization in four out of six unclear foci. In five patients with presumed multifocality, EEG-fMRI revealed one focus in one patient and confirmed multifocality in four patients. In four patients EEG-fMRI opened new prospects for surgery, and in two of these intracranial electroencephalography supported the EEG-fMRI results. In these complex cases, EEG-fMRI either improved source localization or confirmed a negative decision regarding surgical candidacy. Liston *et al*. [81] have further refined this technique by analysis of EEG-fMRI in focal epilepsy based on automated IED classification and *signal space projection*, which reduces the subjectivity of visual IED classification and results in more objective fMRI models of IEDs, as well as increasing experimental fMRI efficiency by significantly increased sensitivity of IED detection. A further recent development is the combination of EEG-fMRI with tractography to delineate the pathways of propagation of epileptic activity [85], which is described below.

Multimodality imaging is now used widely in image-directed surgery. CT, MRI, fMRI, MEG, PET, SPECT and EEG-fMRI contain complementary anatomical and physiological information.

Computerized tomography and MRI scans provide images of the anatomy of the patient. These have good spatial resolution, with MRI giving the best spatial resolution. Functional brain mapping gives information on the location of the main functional areas of the cortex (somatosensory, somatomotor and language) but this imaging has lower spatial resolution. The anatomical location of the functional abnormality can be determined with greater certainty by aligning the functional images with the anatomical images.

Thus, there are two main areas in which multimodality imaging has been used in the investigation and surgical treatment of patients with intractable epilepsy: for functional mapping as an aid to surgical planning and guidance and for localization of the seizure focus.

Functional cortical mapping can have an essential role in resections in eloquent areas of the brain, to assess the surgical risks to normal cortical function and thus to plan the extent of surgical resection. The lesions that cause epilepsy often distort normal cerebral functional anatomy [1]. However, the place of functional imaging as a replacement for intraoperative electroencephalography, somatosensory evoked potentials and awake craniotomy and stimulation [86] has still to be established. In theory, functional imaging has the advantages that it can be used for preoperative planning, the patient does not need to be awake during surgery, operation time is reduced and there is no need for interactive patient cooperation during the procedure.

The integration of functional imaging information can help to accurately localize and delineate the seizure focus [58,87,88]. This offers the surgeon an extensive and more precise stereotactic navigational map that can be used to safely, accurately and optimally guide the neurosurgeon to the focus, with little or no damage to normal brain tissue.

Clinical diffusion MRI (including diffusion tensor MRI and fibre tractography) is a new technique that may have great value in the imaging of epilepsy [89]. The theoretic underpinnings of this technique have recently been reviewed [90]. It allows delineation of white matter tract pathways, which enables it to delineate white matter pathways of functional importance close to an area of surgical [52,91–97] or radiosurgical [98,99] lesioning, demonstrate the alteration of white matter connections that may underlie alterations in brain function in patients with epilepsy, such as disrupted memory and language in temporal lobe epilepsy [100,101], or in the future, in combination with EEG-fMRI [85] or MEG [102], demonstrate white matter connections originating from an epileptogenic focus to delineate pathways of propagation of epileptic activity, which could be a potential target for surgical lesioning. The combination of fMRI and tractography offers a promising tool for studying the reorganization of language functions in epilepsy, and may enable predictions of language deficits following temporal lobe surgery [101,103]. The combination of mapping axonal architecture by diffusion tensor MRI fibre tracking and functional cortical neurones by intraoperative cortical stimulation can be used to delineate the pathways between functional regions. Importantly, the combined techniques also enable improved preservation of eloquent regions during surgery. For example, the combination of intraoperative tractography-integrated functional neuronavigation and cortical or subcortical stimulation in patients with brain lesions adjacent to the corticospinal tract enables accurate identification of the corticospinal tract during surgery, allowing its preservation and avoidance of tract injury while accomplishing optimal tumour resection [52,91–97].

In the future, as techniques evolve and registration improves, the incorporation of EEG-fMRI [81–85], clinical diffusion MRI [52,85,91–97,101,103], SPECT [10,104,105], PET [71], fMRI [58,87,88], MRI spectroscopy [106–109] and magnetoencephalographic data [110] into the evaluation and surgical planning of an epilepsy patient may become routine [111–114].

Stereotactic surgery as an aid to conventional surgery

Diagnosis: depth electrodes and stereotactic electroencephalography

The role of invasive electrophysiological monitoring using depth electrodes (and other methods such as subdural grid electrodes and epidural pegs) is diminishing [4]. These changes are due to the increasing ease with which the structural changes within the brain responsible for the epileptic phenomena can now be identified using multimodality imaging techniques.

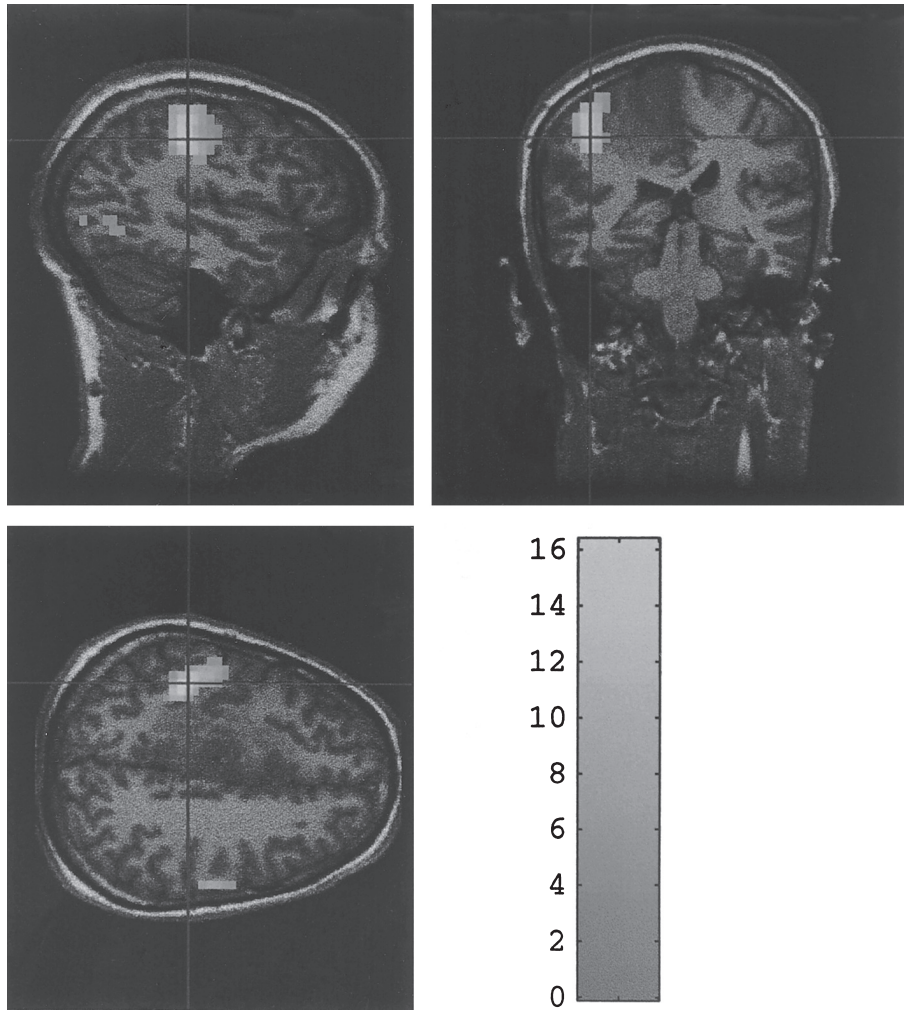
(b)



(d)

Fig. 78.2 CT (a), axial (b) and coronal (c) MRI of an epileptogenic, right-sided, calcified, posterior frontal tumour. Including functional MRI data during left-hand movement (d) in the image-guided operative data demonstrated that it was possible to resect the tumour anterior to the motor strip.

Intraparenchymal electroencephalography monitoring began with the stereoencephalographic method introduced by Talairach *et al.* [115], and has progressed through stereotactic angiography [116] and CT-guided stereotactic techniques [117–119] to multimodal stereotactic imaging using CT, MRI, PET and angiography (Fig. 78.2) [120]. As stereotactic imaging has improved, so has the safety of the procedure [121].

In 1974 Talairach *et al.* described 400 instances of 'stereoencephalographie' in 300 patients over a 14-year period; 20–30% of the patients studied were subsequently operated upon, of whom 80% had a good or worthwhile result. These authors were therefore using 'stereoencephalographie' as the routine by which to accurately localize the epileptic focus in all of their surgical candidates. By 1993 at the National Hospital for Neurology and Neurosurgery, London, UK, less than 10% of patients within the epilepsy surgery programme underwent depth electrode insertion [122]. This group [123,124] and others [122] have also described various computer-assisted methods to register the electroencephalography epileptic focus accurately in stereotactic space, integrated with both MRI and CT.

Other non-invasive imaging modalities can also supply information traditionally obtained from depth studies. In Engel's study from UCLA [125], 153 cases were reviewed in which depth electrodes had been used alongside ictal telemetry and fluorodeoxyglucose (FDG)-PET. The conclusion drawn was that when PET and telemetry information were concordant (and this was the case in over 80% of patients), stereotactic electroencephalography (i.e. electroencephalography recordings from depth electrodes that can be localized highly accurately within the three-dimensional stereotactic space) did not supply further information that would have changed clinical management decisions.

With modern MRI protocols, depth electrode recording should be unnecessary in over 95% of patients with hippocampal sclerosis being evaluated for temporal lobe surgery [1].

Depth EEG records from otherwise functionally inaccessible cortex. At present, depth electrode implantation is used in three main areas. First, depth electrodes can be used to determine from where seizures are arising in patients with MRI evidence of a lesion but otherwise discordant investigations [1]. Second, they can be used to determine where seizures are arising in patients in whom MRI shows dual pathology and the scalp EEG is indeterminate. Lastly, however, the major growth area for intracranial recording is in MRI-negative cases in which other functional imaging modalities and electroencephalography have suggested a possible focal source. In these circumstances the use of intracranial electroencephalography is probably mandatory until the sensitivity and specificity of these alternative investigations is more accurately known. In this way, depth electrode studies continue to play an important defining role in the investigation of potential surgical candidates.

While depth electrode studies continue they provide basic science data concerning epilepsy. However, not only are other modern techniques perhaps more suitable in the investigation of the majority of surgical candidates, but depth electrode insertion also has the inherent disadvantage of being invasive and therefore not without risk.

In 1987, Van Buren [126] described the complications arising from 2674 electrode implantations from 14 centres in the pre-MRI era. There was no mortality but there were 12 intracranial infections and seven intracranial haemorrhages with permanent neurological sequelae. In addition, there were two cases of Creutzfeldt–Jakob disease in patients in whom electrodes had been reused. Other groups have reported complications such as extra-axial haematoma and strip electrode placement within the white matter or within a cerebral sulcus [121]. One further disadvantage is expense, with each study costing at least £10 000 in the UK (including disposable platinum electrodes, 1–2 weeks' hospital stay with continuous telemetry, theatre time and other workforce implications). However, it is likely that invasive monitoring will retain a place in the minority of epilepsy patients whose presentation is not straightforward but in whom it is worth considering surgical treatment.

Stereotactic neurosurgical techniques provide the means of performing such invasive monitoring as safely as possible. Using CT [122] or MRI [121,127] guidance, the desired position and trajectory of each electrode within the brain can be accurately calculated and insertion can then be safely performed. Occasionally, stereotactic angiography or magnetic resonance angiography (MRA) data are integrated within the planning procedure in order to avoid major blood vessels during surgery. This is particularly useful when large numbers of electrodes are to be inserted into the anterior temporal region, Sylvian fissure area or insular cortex, as the risk of haemorrhage is directly related to the number of electrodes inserted.

When investigating a possible temporal lobe onset of epileptiform activity, most centres performing depth electroencephalography studies have tended to use two to four temporal electrodes passed orthogonally from lateral to medial through the temporal neocortex and deep white matter to the hippocampal formation (Plate 78.4). Spencer *et al.* [128], however, generally pass just one electrode longitudinally through the temporal lobe from the posterior temporal region in order to achieve the same end. The electrodes are not totally rigid and, although they can generally be placed to within 5 mm of the intended target, accuracy is inevitably limited by their flexible nature; therefore, postoperatively it is advisable to check the electrode positions that have actually been achieved. Although it is not often critical where the electrodes have been placed for recording purposes, it is essential for the neurophysiologist to know where they are placed in order to interpret the EEG correctly. Therefore, postoperative plain radiographs under stereotactic conditions or MRI may be performed. This makes it possible to determine the exact electrode position and then to translate this corrected position to the planning neuroradiological imaging modalities of MRI and CT. The disposable platinum electrodes in use at present also have the added advantage of being MRI compatible, which allows postoperative MRI studies to be performed with the electrodes *in situ*.

Depth electrodes can be placed with frame-based systems [121]. The added fixation and support that this provides is seen as its major advantage. However, depth electrodes can be placed using a frameless technique, with the use of flexible guide arms to stabilize the drill and the electrode as it is advanced [129]. The technique can thus decrease the operative time and potential risks to the patient [130,131]. The advent of frameless image-directed systems has led to relocatable head frame devices becoming obsolete in this regard [132,133].

Treatment

Stereotactic amygdalohippocampectomy

Although anterior temporal lobectomy remains the standard operation in most neurosurgical centres performing epilepsy surgery for hippocampal sclerosis, there is a trend towards more focal procedures (in part reflecting the neurosurgical trend towards minimally invasive surgery [12]).

Anterior temporal lobectomy is well tolerated but sometimes leads to a bony defect or the possibility of atrophy of the temporalis muscle, and patients also experience discomfort after surgery while chewing. In addition, neurological deficits, including visual field defects, memory impairment and language problems, have also been attributed to this approach [129].

The concept of a selective resection of the mesiobasal temporal structures was introduced by Neimeyer in the mid-1950s [134]. He described a transcortical, transventricular approach through the second temporal gyrus to reach the hippocampus at the amygdala. Several methods have now been described for selective mesiobasal resections, on the basis that lateral neocortical resection is unnecessary for seizure control and can cause postoperative memory problems [128,135–143]. Some authors argue that the lateral aspect of the temporal lobe, which is typically normal on pathological evaluation, does not need to be resected. Furthermore, there is some evidence to suggest that resection of the lateral temporal structures may be responsible for postoperative neurological deficits and only the mesial temporal structures harbour the epileptogenic focus [144]. It is suggested that stereotactic selective amygdalohippocampectomy can be used as an alternative to anterior temporal lobectomy.

Wieser and Yasargil [145] described a pterional transsylvian approach to the mesial temporal structures, which they suggested improved outcomes. Others use a trans-sulcal approach, usually between the middle and inferior temporal gyri [129,135]. When Kelly *et al*. [140] initially described their technique for stereotactic amygdalohippocampectomy using the Compass stereotactic equipment, their approach was first via the occipital lobe and then suboccipitally because of the field defects that occurred through using the former route. Using this type of approach, the hippocampal formation is met along its axis and is entirely suitable for maximal resection. However, most authors have preferred the lateral approach in order to reach the anterior hippocampus and amygdala without damage to the posterior hippocampal structures. Inevitably there is some sacrifice of the neocortical structures using the lateral approach but much less than in a standard temporal lobe resection and potentially without the risk of incurring visual field defects. Yasargil and others [136,146] have also described selective amygdalohippocampectomy, but using solely microsurgical techniques and not stereotaxy.

In 1994, Oliver *et al*. [19] reported using the Viewing Wand (Elekta/ISG, Stockholm, Sweden) to perform selective mesial resections. The Montreal group successfully applied this device to selective mesial resections in a number of patients and found it useful not only in guiding the surgeon, but also in estimating the extent of the hippocampal resection. This paper also documented the successful use of this device in assisting lesionectomy, corpus callosotomy, neocortical resection and the placement of depth electrodes.

Because sulcal anatomy varies among individuals, frameless stereotactic guidance allows a small incision and craniotomy to be placed in the optimal location. This aids complete hippocampal resection though a keyhole approach. The image guidance and trajectory views are critical in gaining access to the temporal horn of the lateral ventricle, allowing visualization of the amygdala and hippocampus [147]. Successful surgery relies on adequate exposure. The most common mistake is inadequate inferior and anterior temporal exposure. The lower extent of the central sulcus must be reliably identified, and this is easily achieved with the aid of image guidance. On the dominant side, the cortical incision must be made in front of the central sulcus and preferably in front of the precentral sulcus. An errant trajectory can lead the surgeon to miss the temporal horn in the dissection through the white matter. A trajectory that is too anterior will pass by the anterior extent of the ventricle; an approach that is too dorsal could lead into the insula or temporal stem [135]. The extent of resection is also demonstrated intraoperatively with the use of neuronavigation.

Neuropsychiatric evaluations performed after selective procedures have suggested no new language impairment [129]. Selective operations are more difficult technically and there is a higher reported risk of vascular disturbance and hemiplegia but a lower risk of dysphasia and visual field defect [1]. Seizure control in these patients is encouraging [135,136,142,145].

Stereotactic craniotomy and lesionectomy

Perhaps the most common way in which stereotactic neurosurgery is utilized at present in the treatment of epilepsy is in the removal of epileptogenic lesions [148–151]. Many of those lesions that cause chronic epilepsy (as opposed to those high-grade brain tumours with a short history and mass effect, which have seizures as part of the clinical syndromes) are cortically based, small and would be difficult to find without some form of stereotactic image guidance.

Just as with tumours, certain vascular lesions [arteriovenous malformations (AVMs), cavernomas] may be difficult to localize if they are situated within deep brain structures. Stereotaxy may allow direct localization as well as localization of associated vascular structures feeding or draining a lesion. With AVMs, stereotaxy helps define both the superficial and deep limits of the nidus and can help ensure its complete removal [14]. Stereotaxy has also been used to assist transcallosal resection of hypothalamic hamartomas in patients with intractable epilepsy, assist in limiting the resection and minimize injury to the third ventricular floor and walls [152].

Stereotactic craniotomy has become a standard operation in epilepsy management, allowing epileptic lesions to be removed in minimally invasive ways (i.e. with ‘mini’ skull flaps and with minimal brain retraction, dissection and, hence, trauma). However, such methods are at odds with the techniques of traditional lesional epilepsy surgery in which electrocorticography and cortical stimulation are used with a view to *en bloc* resection of the surrounding cortex when this is considered to be epileptogenic. A basic principle of surgery for extratemporal neocortical epilepsy is that the wider the excision around an epileptic focus, the more likely it is that complete seizure control will be achieved [1]. Clearly, in this situation, a large craniotomy with a wide cortical

exposure is necessary. Stereotactically guided lesionectomy therefore implies a simple lesionectomy without removal of surrounding brain tissue in an *en bloc* fashion. The relative efficacy of simple lesionectomy and larger *en bloc* brain resections is controversial at present, and the issue must be considered unresolved at the present time [148,149,151,153,154]. Certainly, methods that maximize total lesion excision must be advantageous not only neuro-oncologically, but also in terms of seizure control.

In considering the practical surgical issues when a lesion is being explored under the operating microscope following image guidance, a border between it and surrounding brain has to be determined. Sometimes direct inspection will reveal a clear-cut margin or even a pseudocapsule. However, on other occasions the boundary will be less definite, and in these cases the trend is to remove more rather than to leave suspect or reactive tissue. Image-directed surgery can aid in directing this process. At present, the gold standard for resection of a lesion in the region of eloquent cortex is awake craniotomy with intraoperative cortical or subcortical stimulation [155–161]. Integrating frameless navigation with intracortical mapping can further enhance optimal tumour resection while minimizing morbidity, and this may be further improved in the future by incorporating tractography [52,91–97].

A further diagnostic and also technical issue for the surgeon is the fact that a large proportion of lesions causing chronic epilepsy (cavernous angiomas, dysembryoplastic neuroepithelial tumours, low-grade gliomas) are poorly defined on CT and often visualized solely on MRI. In these instances image-directed surgery using MRI may be invaluable.

Although we have detailed above the specific instances in which stereotaxy may be used, it can be seen that its use may be applied to virtually all branches of epilepsy surgery. These include non-lesional focal resections, multilobar resections (including hemispherectomy) and functional procedures (such as multiple subpial transections and corpus callosotomy [162]).

Stereotactic ablation and stimulation for epilepsy

Lesion-making in the central nervous system (CNS) may be performed using a variety of methods, which, except in one instance, require the opening of the skull and the passage of a needle into the brain substance. The actual method for producing focal brain necrosis can be chemical (absolute alcohol), freezing (using a cryoprobe) or by heating. Radiofrequency thermocoagulation is the most widely used method as it is flexible, yet repeatable, and quick to use. The one closed method of lesion-making in the CNS that is completely non-invasive (in a surgical way at least, as there is a small but definite risk of radiation-induced necrosis of the surrounding normal brain) is stereotactic radiotherapy or radiosurgery.

Both stereotactic ablation and stimulation have been used for many years, in small numbers of patients, in an attempt to control or modify seizures. Targets have included the amygdala, various thalamic nuclei, the fields of Forel, the anterior commissure, the fornix and the posterior limb of the internal capsule [163–172].

Although there are numerous articles in the literature describing stereotactic procedures in the management of epilepsy, analysis of these is complicated by a number of factors:

- Most studies were undertaken in advance of the establishment of a uniform classification of seizures, making it difficult to determine the seizure disorder treated by a particular lesion.
- Often, multiple subcortical targets were used in individual patients, making it difficult to assess the role of a specific target for a specific condition.
- There is sufficient variability in the location of subcortical nuclei with respect to internal reference points that in many cases it is uncertain whether unsuccessful surgery was a result of inaccurate localization, incomplete destruction or inappropriate selection of target.
- There has been a tendency to reserve stereotactic surgery for particularly complex intractable seizure and behavioural problems. This philosophy may have eliminated some of the more straightforward disorders for which the procedures may have been effective [144].

In 1970, Narabayashi and Mizutani [173] described the use of radiofrequency stereotactic amygdalotomy (i.e. a direct but very focal ablation of the epileptic focus) in 25 patients with a 1- to 6-year follow-up. Some had unilateral and some bilateral lesions performed mainly for behavioural problems as the primary indication for surgery. Nine patients (36%) had complete abolition of electroencephalography and clinical seizures, nine had reduction in seizures (36%) and seven had no change (28%). Several other authors have described their experience with stereotactic radiofrequency amygdalotomy [174–181].

Talairach and Szikla [182] used 'stereoencephalographie' to localize the amygdalohippocampal complex and then ablated these structures with yttrium-90. Fifteen cases were described in which an epileptic focus was ablated using stereotactically implanted yttrium-90 pellets to cause a localized necrotizing lesion. Pellets were routinely placed in the anterior commissure, with the rationale of preventing spread to the contralateral temporal lobe. Using this regimen, nine patients were rendered seizure free (with short follow-up of 7–14 months), two were improved and four showed no change.

There are few reports in the recent literature regarding stereotactic lesioning for the treatment of epilepsy. Patil *et al.* [183] described multiple interventions for epilepsy in 24 patients with seizures of multilobar origin. Their technique involved a combination of topectomy, multiple subpial transection and/or amygdalohippocampal radiofrequency ablation (amygdalohippocampotomy). Three of their patients with seizures of medial temporal origin underwent stereotactic amygdalohippocampotomy with good results (seizure free or rare seizures). This procedure involved CT-guided identification of the amygdala and hippocampus for stereotactic targeting. A radiofrequency lesion measuring 11×15 mm was then made in each of these structures [175].

Parrent and Blume [184] performed stereotactic amygdalotomy in 19 patients with temporal lobe epilepsy. All patients were shown to have mesial temporal originating seizures by continuous electroencephalography monitoring with or without subdural electrography, and all recorded seizures originated from the temporal lobe that was ultimately subject to the ablation. Surgical planning involved the identification of the amygdala and

hippocampus on stereotactically acquired MRI scans and postoperative MRI confirmed the accuracy of targeting. In five patients who underwent limited lesioning (mean 6.4 lesions, range 4–9) a favourable seizure outcome (defined as seizure free, auras only or >90% seizure reduction) was obtained in only one patient (20%). However, 15 patients underwent extensive lesioning that was designed to produce a large confluent area of ablation (mean 26 lesions, range 12–54). In this group, nine (60%) achieved a favourable outcome and postoperative MRI demonstrated extensive ablation of the amygdala and hippocampus, sparing the parahippocampal gyrus.

The results of these operations had in general been disappointing and this type of surgery had been largely abandoned until recently. The outcomes were not as good as one would expect following temporal lobectomy or selective amygdalohippocampectomy in a similar group of patients. Therapeutic success was unpredictable and often not without a significant risk of complications. Hence, the overall clinical impression of these procedures was that good outcomes were patchy and difficult to predict, and that the improvements not sustained.

Several strategies can be pursued with stereotactic and functional surgery. The first is to destroy the seizure focus in a minimally invasive manner. Such a targeted approach requires strong physiological evidence of the seizure focus, together with as precise as possible anatomical delineation with modern imaging. A second strategy is to decrease the epileptogenic volume, in this way reducing seizure burden and, at least in theory, putting intrinsic brain mechanisms, as well as anticonvulsants, in a better position to deal with the epileptic tendency. A third use of stereotaxy is for the interruption of the pathways of seizure propagation. Because of the high precision of these techniques, discrete axonal projections can be interrupted, thereby disconnecting the seizure source from adjacent or remote brain structures. Further strategies that are possible with stereotactic neurosurgery are the destruction or modulation of brain structures, which may have an influence on seizure tendency; thalamic lesioning/stimulation may reduce cortical excitability and thus epileptogenesis [185].

A recent resurgence of interest has occurred, encouraged both by the improved anatomical precision of stereotaxy made possible by MRI and better surgical stereotactic instrumentation and also by the success of these procedures in other conditions, such as for Parkinson's disease and pain [186].

Traditionally, functional neurosurgery has relied upon frame-based stereotactic techniques. Recent developments in this field have included the incorporation of brain atlases and microelectrode recording devices into the registration of radiological data of image guidance systems to aid target identification.

The improvements in imaging have worked in concert, with an increased understanding of the pathophysiology of epilepsy disorders such that the identification and selection of targets has a stronger scientific rationale than was previously available. There is also research interest in the possibility of stem cell transplantation and stereotactic drug implantation [1]. The trend towards minimally invasive surgery has led to a re-examination of stereotactic functional procedures. Stereotactic procedures have the possibility of being highly accurate, more economical and better tolerated than conventional craniotomy and resective surgery.

Stereotactic radiosurgery

Radiosurgery is a minimally invasive technique designed to elicit a specific radiobiological response at the target tissue using focused ionizing radiation delivered in a single procedure. The underlying scientific principles, history and current indications for stereotactic radiosurgery are beyond the scope of this chapter and are reviewed elsewhere [187–191]. The technique was pioneered by Lars Leksell at the Karolinska Institute in Stockholm, and devised to treat intracranial lesions by delivering a high dose of radiation precisely at the intracranial target using stereotactic guidance. A variety of different radiosurgery techniques have been developed during the past 40 years. Refinements in stereotactic methodologies, major improvements in dose planning software, and advances in neurodiagnostic imaging have all facilitated the increasingly broad application of radiosurgery. Numerous studies have examined the benefits, risks and long-term results of radiosurgery and support it as a non-invasive alternative for several disorders, including vascular malformations, tumours, trigeminal neuralgia, movement disorders and, perhaps, epilepsy. However, a recent review of the literature on stereotactic radiosurgery by Pollock [192] using evidence-based standards suggests that caution must be used when interpreting many of these studies, as the vast majority of published papers on stereotactic radiosurgery are of level 3 evidence or below. Pollock also concluded that, for various reasons, it is unlikely that randomized clinical trials will be performed to evaluate stereotactic radiosurgery. Nonetheless, the preponderance of level 3 evidence supports the role of radiosurgery as either an adjunct or alternative to surgical resection or fractionated radiation therapy.

The role of stereotactic radiosurgery in epilepsy is reviewed elsewhere in detail [193–195]. However, although stereotactic radiosugery is the only non-invasive surgical form of treatment for epilepsy, it also has some limitations. It relies exclusively on anatomical targeting, as neurophysiological confirmation of the target structure is not possible. Furthermore, lesion sizes may vary and shielding adjacent radiosensitive neural structures may be difficult. Integration of three-dimensional corticospinal tractography (Plate 78.5) into treatment planning for gamma knife surgery may help plan targeting and reduce morbidity as a result [98,99]. Intraoperative MRI in conjunction with stereotactic radiosurgery has also been described [196].

Radiosurgical techniques are used to create image-guided physiological inactivity or focally destructive brain lesions without neurophysiological guidance [197]. It allows, in a single session, the precise and complete destruction of chosen target structures containing healthy and/or pathological cells [198]. It is the only remaining stereotactic technique for the treatment of epilepsy that still involves the use of a stereotactic head frame fixed to the patient's head with screws, rather than the image-based, intracranial navigation independent of an external frame.

Leksell [199–201] originally designed his gamma knife (in which multiple beams of gamma (γ)-rays are focused to a single target using traditional stereotactic methods) for functional neurosurgery. He realized that deep epileptic foci could become targets, especially with future advances in functional imaging.

At present, however, little functional radiosurgery is performed worldwide – probably less that 2% of all radiosurgical proce-

dures, the vast majority of which are carried out for arteriovenous malformations, benign tumours such as acoustic neuromas or treatment of solitary cerebral metastases. The availability of high-quality, three-dimensional imaging with MR (for precise targeting of normal structures) and evidence of some limitations regarding drug efficacy have now prompted a reappraisal of gamma knife surgery for functional disorders [202–207]. In the past decade, the number of studies in which radiosurgery has been described in experimental epilepsy and in clinical situations has increased significantly.

Heikkinen *et al.* [208] illustrated that although 16 out of 29 patients with AVM (55%) had improvement in their seizures following proton beam irradiation, only 17% of these demonstrated angiographic obliteration. Furthermore, three out of five patients with complete obliteration, five out of seven partially obliterated patients and 8 out of 17 non-obliterated patients became seizure free.

Between 1970 and 1984, Steiner *et al.* [209] treated 247 patients with AVM using gamma knife surgery. Out of the 247 patients, 59 had epilepsy; in the majority of these patients (52), seizures improved significantly. The cessation of the seizures appeared to commonly occur several months before the occlusion of the arteriovenous malformation.

The Sheffield radiosurgical group have described the effect of radiosurgery on 160 of their 507 patients with AVM who had been followed for 2 years [210]. In this group, 48 (30%) had epilepsy on presentation. On follow-up, 38% of these patients were seizure free, 22% had improved seizure control and 6% had increased seizures.

The results from most other centres performing radiosurgery for AVMs are similar, i.e. that radiosurgery to prevent rebleeding from AVMs does have some beneficial effect on seizures in a proportion of cases and that the effect may well be independent of any obliteration of the AVM itself [209,211–214].

Cavernous haemangioma is a benign vascular hamartoma of the CNS, which most frequently presents with epilepsy [215]. Some authors have reported a reduced risk of rebleeding after gamma knife surgery [216], whereas others have reported no effect [217,218]. Bartolomei *et al.* [219] conducted a retrospective multicentre study to evaluate the effectiveness of gamma knife radiosurgery in the treatment of drug-resistant epilepsy associated with cavernous haemangiomas. A total of 49 patients were studied (26 male and 23 female), with a mean age of 36 ± 10 years. The mean duration of epilepsy before gamma knife radiosurgery was 7.5 ± 9.3 years. The mean frequency of seizures before gamma knife radiosurgery was 6.9 episodes per month. The cavernous haemangioma was located in the temporal lobe in 23 cases, and in extratemporal cortex in the remaining 26 cases. The mean margin dose to the lesion was 19.2 ± 4.4 Gy (range 11.3–36 Gy). The volume was 2370 ± 2211 mm^3 (range 110–10 296 mm^3). No complications were reported on the day of the radiosurgical procedure. With a mean follow-up of 24 ± 13 months, 26 patients (53%) were seizure free (Engel class I). Of these, 24 patients were in class IA, and two patients with occasional auras were in class IB. A highly significant decrease in the number of seizures was achieved in 10 patients (20%) with class IIB status. The remaining 13 patients (26%) showed little or no improvement in their seizures.

In the seizure-free group, the mean delay between gamma knife treatment and complete remission was 4 months (range 0–9 months, median 6 months). This study demonstrated that the prognosis for seizure control depended on the type of epilepsy and location of the cavernous haemangioma. The outcome was better for patients with simple seizures than for those with complex partial seizures. The location of the lesion was the most significant. In the 14 patients whose lesion was located in the mesial temporal region, 12 showed a poor outcome of treatment. Lesions in the laterotemporal region were associated with a good outcome (six out of seven patients). A location in the central region was associated with an excellent outcome, all four patients in this group remaining seizure free. For other locations, results were unpredictable. A possible explanation for the difference in prognosis is that the epileptic network in the medial temporal region is more complex and diverse, and hence more difficult to ablate completely and accurately than in the extratemporal and indeed in the more central regions. Regis *et al.* [220] and Hsu *et al.* [221] have also reported that gamma knife and linear accelerator radiosurgery, respectively, are an alternative treatment to conventional surgery for epileptogenic cavernomas, particularly when the lesions are located in the central regions or eloquent areas of the brain. The disappearance of seizures following conformal radiotherapy [222] and conventional radiotherapy [223,224] of tumours has also been reported.

In March 1993, in Marseilles, Regis *et al.* [225] used gamma knife surgery to treat the first patient with medically refractory mesial temporal lobe epilepsy with hippocampal sclerosis. The group described that the entorhinoamygdalohippocampectomy was performed with the gamma knife at low marginal dose (25 Gy), a dose that later caused target necrosis. The 7000 mm^3 approximate volume represented the largest functional target irradiated until that time. This patient has remained seizure free with no associated complications. Since then, around 130 patients have undergone epilepsy surgery using the gamma knife in Marseilles [194], all in the context of a successive prospective controlled trial.

This group have also studied the optimal parameters for the treatment of epilepsy without space-occupying lesions using the gamma knife [198,226]. In this study, they recruited seven patients (four men and three women) who had medication-resistant mesial temporal lobe epilepsy. The mean duration of this disease was 27 years (range 16–35 years), and mean age at gamma knife surgery was 33 years (range 25–40 years). They used MRI for target localization. The mean calculated volume of the target was 6500 mm^3 (range 6350–6900 mm^3). According to the volume of the target, they used a dose margin of 25 Gy at the 50% isodose line. The range of patient follow-up was 24–61 months. They noticed a dramatic effect on seizure frequency around 10 months postoperatively (range 8–15 months, mean 10.2). This was coincident with the development of MRI signal changes, followed by atrophy in the related structures. All but one patient became seizure free. The authors suggested that there was a direct relationship between the quality of the results from gamma knife surgery and the dose and volume of the procedure.

In their current protocol, Regis *et al.* [227] describe the target being covered by two 18-mm collimators, with a dose of 20–25 Gy at the 50% marginal isodose line, the target volume being

6500–7000 mm^3. In this study, 25 patients were treated according to this protocol, and the follow-up of the entire group varied between 6 and 72 months. The median latency for seizure cessation was 10.5 (range 6–21) months. With the exception of two patients who immediately became seizure free, the median latency for aura cessation was 15.5 months. There was a gradual decrease in the frequency, intensity and duration of seizures in the other 23 patients. Low-dose steroids reduced reported side-effects, such as headaches, nausea and vomiting.

Regis *et al*. [228] have reported good results after Gamma Knife surgery in temporal lobe epilepsy; however, Srikijvilaikul *et al*. [229] reported failure of gamma knife surgery for mesial temporal lobe epilepsy, and a recent study by Hoggard *et al*. [230] on the clinical course and neuroradiological correlates after stereotactic radiosurgical amygdalohippocampectomy with neuroradiological correlates also demonstrated disappointing results compared with temporal lobectomy or selective amygdalohippocampectomy.

In 1994, Barcia-Salorio *et al*. [231] provided a long-term analysis of a series of 11 patients with temporal lobe epilepsy, who were treated with stereotactic radiosurgery using a dose range of 10–20 Gy. Of these patients, five experienced complete cessation of seizures, and an additional five were improved. Seizures began to decrease gradually 3–12 months after radiosurgery. These authors noted that the main difficulty encountered was the correct localization of the epileptogenic focus. Recent papers from the Marseilles group describing long-term results in 15 patients with mesial temporal lobe epilepsy with over 2 years' follow-up [232] and over 5 years' follow-up [233] have shown results similar to conventional surgery.

Lindquist *et al*. [207] have also described the use of the gamma knife for the radiosurgical treatment of epilepsy. They report six patients with complex partial seizures, all of whom had a reduction in seizure frequency.

Heikkinen *et al*. [234] treated a single patient with temporal seizures by stereotactically irradiating the pes hippocampus. A lower radiation dose of 10 Gy was used and the MR scan at 30 months showed no change to the radiated structures. Seizures ceased 7 months after treatment and had not recurred by 27 months.

In addition, there have been reports of the use of radiosurgery to treat gelastic seizures associated with hypothalamic hamartomas [202,206,227,235–239] and to achieve a functional corpus callosotomy [240,241].

Radiosurgery at doses that produce atrophy presumably work through destruction of the epileptogenic target. However, the mechanism of efficacy of lower dose radiosurgery is not known, but possibly involves changes in the neuronal network involved in seizure generation [144].

The current evidence suggests that stereotactic radiosurgery can be effective in treating focal epilepsy. This form of treatment is closed, tractless and bloodless [242]. More importantly, the current advances in both diagnostic and functional imaging, and improvement of the therapeutic rationale (i.e. directing the radiosurgery towards the epileptogenic lesion itself, rather than interrupting perceived pathways of seizure spread) may improve results further.

The optimal dose selection (necrotizing versus non-necrotizing), methods of non-lesional epilepsy localization, and target volume for irradiation have still to be determined [197,203,205,243]. It is not known what type of tissue effect is required to stop the generation or propagation of seizures. Some studies have shown that low doses (below 20 Gy) are ineffective for the radiosurgical treatment of epilepsy [203,205]. On the other hand, high doses (as much as 100 Gy) can cause target necrosis and regional brain oedema [244].

Potential advantages

- No surgical incision.
- Decreased morbidity and increased patient comfort.
- High accuracy.
- Accessibility of deep sites.
- Potential efficacy in non-resective surgery.
- Single-day stay in hospital.

Limitations

- Delayed response.
- Volume constraints.
- Fewer predictable outcomes than resective surgery.
- Uncertain long-term effects.

Conclusion

Lesion-making in the CNS has a limited role at present, but it is anticipated that the use of stereotactic radiosurgery will become more attractive in the future. Stereotactic lesioning in the medial temporal lobe has produced favourable results in a number of patients. However, the decrease in seizure frequency is not as dramatic as that following temporal lobectomy in properly selected cases. These techniques continue to undergo modification and will require further review in the future. The use of radiosurgery for lesion production is less invasive than radiofrequency ablation and may prove to be safer. Radiosurgical trials in selected epileptic syndromes have shown highly promising, although still preliminary, results. If focal hippocampal (or any other brain tissue) irradiation can eliminate seizures without the need for complete tissue destruction then radiosurgery may become an important therapy for patients with intractable epilepsy.

The future of frameless stereotaxy will include better registration techniques and more accurate positioning of the probe tips in space, along with the integration of further functional imaging modalities. Video and heads-up displays within the surgical microscope will offer increasingly direct and accurate feedback to surgeons. The development of intraoperative imaging techniques will allow real-time anatomical updates to be preformed to compensate for brain shifts associated with the surgical procedure. Intraoperative MRI will facilitate resection of abnormal brain tissue and brain tumours by allowing residual tissue to be identified before closing the case.

The power of computers to generate three-dimensional renderings will also continue to improve. The inclusion of 'picture in a picture' technology in head-mounted displays will allow computer-generated three-dimensional images to be displayed adjacent to the surgeon's field of view, providing simultaneous projection of the surgical field and stereotactic images. The

merging of multimodality imaging into neuronavigation systems will allow neurosurgeons to invstigate and treat increasingly complex epilepsies.

Although stereotaxy and neuronavigation will never be a replacement for surgical skill, it is a powerful weapon in the armamentarium of contemporary neurosurgeons.

79 Complications of Epilepsy Surgery

Charles E. Polkey
Institute of Psychiatry, King's College, London, UK

Introduction

Presurgical assessment involves invasive procedures and the complications arising from these procedures have to be considered. It is known that with certain procedures physical side-effects are inevitable and these will be included as well as those that are unexpected. Procedures such as craniotomy carry general complications, for example haemorrhage and infection, which will be dealt with briefly. More distant possible effects, such as deep vein thrombosis and pulmonary embolus, will not be dealt with except where relevant. Certain groups may be more at risk, for example patients on valproate may have a low platelet level causing a bleeding disorder [1]. In particular, major procedures in young children may carry additional hazards. Modern transparency has made it possible to talk about a learning curve that is experienced in performing invasive procedures and operative techniques when new centres are set up or personnel replaced and this has a bearing on the complication rate [2].

Complications of invasive procedures for presurgical assessment

Carotid amytal test

In the usual and simplest form of the intracarotid sodium amytal test (ISA) the internal carotid arteries are cannulated via the femoral artery, the usual technique for cerebral angiography, which is generally free of complications; the incidence is likely to be lower in patients undergoing presurgical assessment because in general they are young and free of arterial disease. Although large numbers of patients undergo this test, comprehensive data are sparse. In 1993, Rausch *et al*. reported ISA practice having canvassed 71 epilepsy surgery centres and received replies from 68. There was no mortality and in 40 centres there was no morbidity; in 12 centres the morbidity was less than 1% and in the remaining centres the highest morbidity was 5% [3]. Loddenkemper *et al*. [4] describe the incidence of carotid artery dissection (CAD) in these patients. In 435 consecutive intracarotid amobarbital tests (IAT) three patients with a CAD were found (0.7%). The mean age of patients with dissection (51.3 years) was higher than the average age of the 432 patients without dissection (31.7 years) ($P < 0.05$). All patients had clinical symptoms including face or neck pain.

Twelve centres described a selective test in which smaller arteries were cannulated in an effort to avoid some of the theoretical and practical disadvantages of the standard test. Eight of these centres had no morbidity but in four centres there was significant morbidity, the highest being 8% [4]. Jack *et al*. [5,6] first described selective catheterization of posterior cerebral branches but this has given rise to some complications and they abandoned the procedure. There were no problems described with the alternative procedure used by Wieser in Zurich [7]. More recent papers indicate that technical changes in the procedure, including the use of microcatheters and of fluoroscopic tracking systems, have improved the safety of these procedures [8].

In testing for bilateral secondary synchrony, it may be necessary to administer large amounts of intravenous barbiturate anaesthetic, even to the point of producing a silent electroencephalogram (EEG). There should be careful consultation with the anaesthetist about the care and monitoring of these patients – especially their airway – during the test and recovery.

Invasive procedures for placing electrodes

Recording and documenting seizures by videotelemetry, irrespective of the electrodes used, can be troublesome. Constraints of time and finance usually make it necessary to reduce the patient's anticonvulsant medication or even remove it completely. This can result in partial status, secondary generalization of seizures and, occasionally, status epilepticus. These may be accompanied by confusion for which the patient may be amnesic or, occasionally, a postictal psychosis that may require treatment in addition to the restoration of anticonvulsant medication.

It is convenient to discuss two points of general interest here. Most departments will refuse to use MRI to examine patients who have steel or nichrome electrodes in place. Zhang *et al*. [9] has shown that there is no undue heating of these electrodes in a 1.5-T MR scanner, and the Yale group have reported a substantial series in which no complications have been observed [10]. We have successfully used MRI to image platinum-based electrodes without any apparent difficulty. Our neuradiologists examine plain radiographs to assess the proximity of electrodes and the possibility of their crossing before the MRI is performed. The second problem is the possibility of introducing slow virus diseases, such as Creutzfeldt–Jakob disease, as was reported with the reuse of electrodes in 1977 [11]. The only way to avoid this is never to reuse the electrodes.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Minor invasive techniques

There are three techniques, which use the following types of electrodes: sphenoidal, epidural peg and foramen ovale.

Sphenoidal electrodes

These are effectively extracranial electrodes and serious complications are rare. Convulsive syncope has been reported during insertion [12]. Fluoroscopic placement of the electrodes reduces complications [13]. Transient facial palsy after placement of sphenoidal electrodes has been attributed to the effect of the local anaesthesia on peripheral branches of the facial nerve [14].

Epidural peg electrodes

These are not commonly used. Pilcher *et al.* [15] quote a personal report by Wylie in which bacterial colonization was seen in 22% of cases, a haematoma on CT in one patient and two patients were rendered sufficiently anaemic to need a blood transfusion [15]. There is a more recent report of a focal parenchymal haemorrhage under the site of an epidural peg electrode, revealing itself as a transient epileptic focus [16].

Foramen ovale electrodes

These are placed through the foramen ovale, through the fibres of the trigeminal nerve, to lie in the subarachnoid space in the ambient cistern. The method was introduced by Siegfried *et al.* [17] and taken up by a number of other groups. We ourselves have used this method in over 200 patients. Most centres regularly use smooth multicontact electrodes, inserted through an appropriate needle. The possible complications include nerve damage during insertion, haemorrhage within the subdural or subarachnoid space (usually of no significance), misplacement of the electrode within the cerebral substance and infection. In our patients the commonest problems were facial swelling and transient pain or numbness in the trigeminal territory. In our patients a small number (less than 2%) were left with permanent numbness in the trigeminal territory and only one with persistent facial pain. Known penetration of the brain with clinical consequences occurred on four occasions, two with serious consequences. In one case there was a disorder of eye movement, which recovered completely, and in the other there was a capsular haemorrhage that resulted in a permanent hemiparesis. Schuler *et al.* [18] reported serious consequences in patients who have undergone previous temporal surgery. In five of our cases there was frank meningitis, including one case of unsuccessful insertion, all of which responded to appropriate treatment. In a recent account, Wieser [19] notes that in 264 patients there was one serious subarachnoid haemorrhage and two cases of symptomatic subarachnoid haemorrhage. There were two cases of meningitis, both treated successfully. Facial pain was experienced in 19% and other minor and transient effects in less than 10%. A recent report of 331 insertions in 329 patients was given by Pastor and colleagues [20]. Complications were seen in 6.64% of procedures but were severe in only 1.81% of patients (clotting or intracranial haemorrhage); four of these were asymptomatic, one patient developed status epilepticus from which she eventually died, and the other patient, who had a haemorrhage into the fourth ventricle, developed hydrocephalus and required a shunt.

Major invasive techniques

Subdural strips and grids

Most centres now use commercial electrodes; well made, flexible and manufactured from platinum, these are available in many configurations from strips containing only four contacts in line to large arrays of 8×8 with a total of 64 contacts. The complications increase with increasing size and number of contacts and duration of implantation. In all patients with indwelling electrodes we have used antibiotic cover from the time of insertion until at least 24 h after removal.

We prefer subdural strip electrodes to foramen ovale electrodes because the minor complication rate is less and the coverage of the temporal structures is more flexible. In over 100 bilateral subdural strip implantations we have encountered only one problem. An acute subdural haematoma probably arose from rupture of a bridging vein, associated with coughing and vomiting during recovery from anaesthetic. Regrettably the patient was left with a significant neurological deficit. Wyler and colleagues [21] report no such complications in 300 cases.

More complications arise with larger subdural mats. Ninety-three patients have been implanted in our centre with 20, 32 or 64 contact mats and significant complications were seen in 22 patients (23.6%). The commonest complication was infection in 12 patients (12.9%), followed by transient neurological deterioration in seven patients (7.5%) and significant subdural haematomas in only two patients (2.1%). The origin of the changes induced in the underlying brain by subdural grids is complex. Stephan *et al.* [22] report a picture of aseptic meningitis which is severe in 27%. Local cerebral swelling can be a problem, especially in patients who have been previously operated at that site and in whom tedious dissection of adhesions has been necessary. Most of the infection is locally within the wound, invariably in the extradural space, and clear meningitis or encephalitis has not been seen.

In recent literature the authors do not report strip and grid electrodes separately. Reports of implantation in adults and children do not show a significant difference between them. In substantial series the incidence of extradural haematoma is 1–2% and of subdural haematoma around 1% [23–25]. Many of these haematomas are asymptomatic and require only conservative treatment. The incidence of infection in the same reports is around 1–2%; the use of prophylactic antibiotics is universal. The incidence of cerebral oedema and raised intracranial pressure is similar and steroids are not universally used. Araki *et al.* [26] studied 37 patients divided them into treated and control groups and found that the incidence of cerebral swelling on CT was greater in the control group. A surprising finding is mortality from subdural grids. In the Fountas series two patients died: one as a result of raised intracranial pressure and the other following an aspiration pneumonia. In another series there was one death during grid insertion.

Intracranial depth electrodes

Centres using these electrodes report an infection rate of about 2%. In 1993, Pilcher [15] reported 1.4% in 1582 patients pooled from eight centres. The risk of haemorrhage depends upon the technique (which determines the direction of track, and therefore

the structures at risk) and also the number of electrodes used. Insertion techniques use three routes: the orthogonal, axial and posterior approaches. In the orthogonal approach, especially around the insula in the temporal lobe, the major vessels are at risk and some groups insist that angiography is necessary. The axial approach tends to pass through areas that have fewer major vessels. The posterior approach, devised by Spencer [27], has produced visual field defects. Data from Pilcher in 1993 suggested that the orthogonal approach (1–2%) was safer than the axial approach (2–3%), possibly because of the use of angiography [15]. Clinically significant haematoma arose in 3 out of our 57 patients (5.2%). However, with changes of technique and materials we believe that the risk has diminished to those described by other groups. Merriam *et al*. [28] showed that MRI abnormalities could be found along the track of 67% of depth electrodes, although in only one was there evidence of a significant parenchymal haemorrhage [28]. A recent report describing the use of all kinds of intracranial electrodes, including deep brain stimulation (DBS) and radiofrequency (RF) electrodes, records an incidence of symptomatic haemorrhage of 1.2% and of permanent neurological deficit of 0.7% [29]. Guenot *et al*. [30], describing the use of stereo-electroencephalography (SEEG) in 100 consecutive patients, implanted a total of 1118 electrodes. There were five complications: two electrode breakages, two infections and one haematoma that was fatal.

Summary

Presurgical evaluation has both physical and intellectual complications, which are generally dependent upon the invasiveness of the procedure and experience of the centre, and our complication rate has improved with time. Deaths are extremely rare. Significant physical complications occur with more complex interventions in less than 5% of cases and the general level is 1–3%.

Therapeutic procedures

Introduction

In general, candidates for epilepsy surgery, except for some children, are free of chronic or severe medical problems. A high proportion of these procedures are intracranial and are therefore subject to the usual complications of craniotomy. In brief, and except where detailed under the individual procedures, they comprise haematomas (extradural, subdural and intracerebral), infection, possibly hydrocephalus and, rarely, air embolism and pulmonary embolism. These complications usually respond to appropriate treatment and do not influence the outcome of the surgery.

In modern epilepsy surgery operative mortality is commendably low. In the King's/Maudsley series from 1976 to 2001 there were 818 procedures resulting in seven perioperative deaths (0.86%) and 20 late deaths (2.4%) The late deaths were associated with seizures in 15 patients (75%) and, although many patients had poor seizure control, there were six patients in group 1A who died in their first postoperative seizure, in some cases in the course of antiepileptic drug (AED) reduction.

Typical figures from pooled data in 1993, and from an International League Against Epilepsy (ILAE) survey, suggest a perioperative mortality of between 0.5% and 1%, with some centres having no deaths at all [15,31]. In a long series of patients from Vellore there were no deaths since 1960 [32], and in 654 procedures from Sweden between 1990 and 1995 there was only one death from haematoma [33]. A series from Bonn describing patients who were operated on over a period of 6 years reported no deaths [2]. The *Comprehensive Textbook of Epilepsy* suggests that the perioperative mortality rate is currently less than 0.2% [34]. Late mortality does not require further discussion.

McClelland and Hall [35] report the overall infection rate in 2111 neurosurgical patients. In intracranial cases, this was 0.8%, close to the 0.5% reported by Pilcher *et al*. [15]. In a series from Bonn, the commonest complication was infection, which occurred in 21 out of 459 interventions including intracranial recording; there were 15 deep wound infections, requiring removal of the bone flap (3.5%), and six patients (1.8%) had meningitis (which probably caused hydrocephalus in three cases), which was relieved by shunting. There were no intracranial haematomas, except in the intracranial electrode implantations. The lowest complication rate was in temporal lobectomies (7.4%) and the greatest after hemispherectomies and multilobar resections (16.6%) [2]. In 128 temporal lobectomies in children, reported from Toronto, there were no significant surgical complications, including overt infection, although four patients with a fever were treated with antibiotics [36]. A paper by Oertel *et al*. [37] suggests that the use of neuronavigation in temporal lobe surgery for epilepsy reduced complications, including infection. In our series it is commoner when intracranial monitoring has been used. Occasionally, the patient appears to have meningitis or a meningitic reaction, but, more commonly, it appears in the extradural space, often involving the bone flap. No patient in our series has died or come to permanent harm from intracranial infection; it does not appear to affect the seizure outcome of the operation but the misery it can cause to all parties should not be underestimated.

Intracranial resective surgery

Frontal lobe resection

Proper technique should ensure no damage to the medial surface of the remaining hemisphere or its blood supply. Unless the resection encroaches upon the gyrus anterior to the precentral gyrus in a non-dominant hemisphere it is unlikely to produce any hemiparesis. Of course, in the dominant hemisphere, Broca's area must be respected and Comair *et al*. [38] recommend that such resections should be performed under local anaesthesia. Resection in or close to the supplementary motor area, which can now be identified preoperatively using functional MRI (fMRI) [39], has long been known to produce a severe motor deficit that resembles a conventional hemiplegia but is in fact a sort of volitional apraxia. There is a recent description in the paper by Bannur and Rajshekhar [40]. They, and other authors, also note mutism or degrees thereof [40,41]. All authors agree that the deficit invariably recovers within a few weeks or months and that was our experience in our only case. Cognitive effects, even with large resections, can be hard to detect but have been described. Likewise, providing that the remaining frontal lobe is healthy, the gross personality changes seen with frontal lobe disease do not occur. The lack of gross intellectual and psychiatric complications

from frontal lobe resections probably relies upon normal function in the remaining frontal lobe but may also be illusory in that the number of patients undergoing frontal lobe surgery is small and the patients are seldom submitted either preoperatively or postoperatively to intellectual or psychiatric tests of sufficient complexity to reveal deficits. Studies on our patients have revealed that they are impaired on an adaptation task [42] and perform poorly on the use of strategy [43] and on changing from one dimension to another [44].

Olivier [45], summarizing 108 frontal lobe resections in 1995, noted nine complications: three were non-neurological (2.8%), and there were two cases of postoperative oedema, three cases of transient dysphasia and one case of hemiparesis secondary to venous thrombosis (0.9%). In 2002, Schramm and colleagues [46] described 68 patients operated for frontal lobe epilepsy. All underwent lesionectomies, with added multiple subpial transection (MST) in 17 cases: there were 14 complications – three non-neurological complications (4.4%) and 11 cases of neurological deterioration or new deficits, which were temporary in 10 cases and permanent in one (1.5%).

Temporal lobe resection

Postoperative mortality is low; in recent series of mixed patients, children and the elderly, there was no surgical mortality [2,47–49]. In our own series there have been only two postoperative deaths in over 730 operations since 1976 (0.27%), and none since 1988. Other non-neurological complications are acceptably low and perhaps the commonest is postoperative infection, which is given at 0.5% in the Second Palm Desert Symposium [15]. Rare complications include distant haemorrhage in the cerebellum and lumbar spine, which were attributed to excessive CSF drainage [50–53], and a middle fossa cyst causing raised pressure [54]. Seizures are also described in the immediate postoperative period in about 20% of patients. If such seizures are similar to the preoperative ones then they are of poor prognostic significance, otherwise not [55].

Neurological sequelae

Neurological deficits after temporal lobe resections are acceptably low. Lesionectomy and neocortical removal are least likely to produce such problems so long as the superior temporal gyrus is respected. The sequelae of combined neocortical and deep removal and of selective mesial resections are similar.

Penfield *et al.* [56] first described hemiplegia following temporal lobectomy and attributed it to manipulation of branches of the middle cerebral artery [56]. The commonest neurological sequelae of temporal lobe resection are a contralateral hemiparesis or hemiplegia, a contralateral visual field defect and an homolateral third nerve palsy or paresis. Falconer and Wilson [57] showed that the relationship between the length of a temporal lobe resection and the subsequent visual field cut was due to the course of the visual fibres around the temporal horn. Such visual field defects relate to the disruption of the fibres in the roof of the temporal horn [58]. Katz *et al.* [59] showed that the more lateral the resection, the more likely it was to produce a deficit, although there was no close correlation between the size of the resection and the severity of the visual field defect [59]. The size of the defect cannot be predicted with resections of less than 7.5 cm. The extended lobectomy of Spencer *et al.* [60] does not produce more visual field defects than the standard operation. In our series, a complete field defect occurred in 12 operations among 440 (2.3%). A recent paper from Manji *et al.* [61] reports field defects in about 50% of 24 patients and with at least 24% failing the driving test criteria. This occurred in three patients who were seizure free.

The avoidance of hemiplegia or hemiparesis must be related mainly to vascular causes, especially in selective mesial resections, although the vascular injury is seldom apparent intraoperatively. In our series of temporal lobe resections the incidence was 2% in 400 operations, virtually all right sided. In temporal lobe resections the risk varies between 0 and 1–2% (being lower in larger series) and in selective amygdalohippocampectomy (SAH) varies between less than 0.5% in the Zurich series to 4% in our series.

A large series from Bonn notes a third nerve palsy in four patients (1.4%), a hemianopia in two patients and a hemiparesis in two patients (0.7%), with permanent neurological sequelae in five patients (1.8%) [2]. In a series of 89 paediatric cases reported from Bonn there were only two patients with permanent neurological sequelae, both hemipareses (2.2%): one arose from a haematoma after anterior temporal lobectomy, the other from arterial injury in the course of a SAH [47].

Intellectual sequelae

There are three basic questions to be considered. First, what is the influence of the presurgical condition of the patient on cognitive outcome? Second, what risks does the patient face of global amnesia after surgery? Third, is it possible to influence the cognitive outcome by variations in the operative technique?

It is known that patients with unilateral temporal lobe lesions have material-specific deficits and also that those patients with early onset of epilepsy have poorer cognitive performance preoperatively but also suffer less change in their performance as a consequence of the surgery [62,63]. Assessments of postoperative functioning must be seen against this background; most series of temporal lobectomy comprise varying numbers of patients of mixed aetiology.

The risks of global amnesia following temporal lobe resections were first reported in 1957 when it was realized that bilateral resection of the hippocampal structures led to profound and permanent amnesia [64]. It is not appropriate here to enter into a detailed discussion of the methodology for assessing preoperative memory reserve; suffice it to say that this may be a significant reason for refusing surgery. However, the patient undergoing unilateral temporal lobe surgery is still at risk of amnesia from two sources. The first is destruction of the remaining hippocampal complex from seizures, either acute or chronic. In 1992 one of our patients (operated on in 1991 and shown to have intact memory in postoperative assessment) had a prolonged generalized seizure after a weekend of heavy drinking resulting in severe amnesia. Similar cases have been reported from other centres [65–67]. The remaining temporal lobe, due to ageing, may suffer memory problems earlier [68].

There is considerable dispute as to the part played by the hippocampus and neocortex in memory. In addition, mesial temporal sclerosis is seldom purely unilateral and may exist as a primary pathology or in a milder form as a component of dual pathology.

In order to try to limit memory problems following surgery, more restricted operations have been introduced and variously described as 'tailored' or selective operations, of which the most prominent is the transsylvian SAH introduced by Yasargil and Wieser in 1985 [69]. It is generally accepted that the seizure outcome from these variations in temporal lobe resection is equal, provided that the pathology is the same and the removal is complete, and therefore it is the intellectual sequelae that are important. The surgical target may not be achieved as first described from Oxford in a comparison of transsylvian and transcortical amygdalohippocampectomy by the same surgeon. On MRI there was collateral damage, by which is meant unintentional damage to surrounding structures as a consequence of the surgical manoeuvres [70]. Jones-Gotman *et al*. [71] attempted to investigate the contribution of the various structures by examining patients operated in three centres with different techniques but was dogged by the same problem, resulting in the interesting conclusion that the effects on memory of temporal lobe resections were due to disconnection rather than ablation [71].

Wieser [72] notes that two factors influenced improvement: the first was when the non-operated side subserved the function and the second was freedom from seizures. Wieser [73] later suggested that right-sided operations result in an improvement in learning and memory, whereas left-sided operations have the converse effect. Katz *et al*. [59], using a method of quantitative analysis of postresection MR scans, attempted to correlate resection with intellectual changes. Decrease in verbal memory correlated with the extent of resection in the mesial and basal quadrants on the left, and a similar correlation was found with non-verbal memory and right-sided resections. In 1992 we studied 42 patients undergoing either amygdalohippocampectomy or temporal lobectomy, all of whom were left hemisphere dominant [74]. The side and type of operation were approximately equal. If seizures persisted then there was a poor performance in the material-specific tasks performed by the target temporal lobe. SAH had less effect on the functions of the target temporal lobe than anterior temporal lobectomy but the converse was true of the non-target temporal lobe. Jones-Gotman *et al*. [75] found few differences between the two techniques in her investigations. Two matched learning tasks, using abstract words versus abstract designs, were administered to patients with unilateral neocorticectomy, SAH or anterior temporal lobe resection invading the amygdala and hippocampus. Learning and recall for words were impaired in groups with resection from the left temporal lobe, irrespective of whether mediobasal structures were spared or temporal neocortex was spared. All right-resection groups were unimpaired. A recent publication from Bonn reflects our findings. Helmstaeder *et al*. [76] described 97 patients operated by SAH or temporal pole plus amygdalohippocampectomy. Verbal memory outcome was worse after left-sided operation, especially for SAH, whereas figural memory outcome was worse after right-sided operation, preferentially for temporal pole resection with amygdalohippocampectomy (TPR+) [76]. In a very detailed review, Schramm [77] concludes that the evidence (including papers from his own group) is mixed, but, on balance, and particularly in the long view (2–10 years after operation), selective operations have superior cognitive outcome. In conclusion, the cognitive advantages of SAH remain unclear.

Psychiatric consequences and social outcome

Behavioural changes after temporal lobe surgery are well documented but the patient usually benefits from the surgery. It has been long recognized that there is significant premorbid psychiatric morbidity in patients submitted to temporal lobe resections. In general, there is a reduction in psychiatric problems after surgery.

Psychosis supervening upon chronic epilepsy is usually a late event. Temporal lobe surgery, at any rate resective surgery, can produce a schizophreniform psychosis often associated with left-sided resections or a depressive illness more often associated with right-sided operations. In recent material the incidence of schizophreniform illness is low – in our series around 2–3%. The connection with left-handed females with alien tissue lesions described by Taylor and Bruton has not been generally confirmed, although Andermann *et al*. [78] reported similar findings in patients with ganglioglioma. Mace and Trimble [79] note that both left- and right-sided operations may be followed by psychosis. *De novo* postictal psychosis is described in 5.3% of 57 Finnish patients [80]. In a wider survey of patients with intractable epilepsy the most prevalent disorder was anxiety disorder (10.7%), a schizophreniform psychosis in only 4.3% [81]. Mayanagi *et al*. [82] described an incidence of 5% for postoperative psychosis in 100 patients who were subjected to temporal lobectomy. Two patients experienced increase of symptoms to full-blown obsessive–compulsive disorder after surgery [83] and Carran *et al*. [84] report mania in 16 patients out of 415 who underwent temporal lobectomy (3.8%).

A depressive illness presenting after temporal lobe surgery is more common, but does not necessarily occur *immediately* after surgery, and careful questioning may be required to elicit the symptoms. In our material, suicide is relatively rare (one known case in 400 operations) but depression is much more common – an informal survey suggests around 35%, mostly in non-dominant resections. We have found that it is rare after amygdalohippocampectomy and in children, although one 12-year-old child with a large resection developed clinical depression requiring treatment. Paradiso *et al*. [85] put the incidence of depression in their 70 patients at 34% and found that it was under-recognized and undertreated. Pintor *et al*. [86] noticed that a preoperative psychiatric history was commoner in patients who had postoperative psychiatric problems, although overall there was a clear reduction in depressive symptoms from 17.2% to 4.3% 1 year after surgery. Salzberg *et al*. [87] noted hypometabolism on an fluorodeoxyglucose (FDG)-PET scan in patients with depression.

Central and parietal resections

Any resection from the central area (i.e. the primary motor or sensory area) must carry some risk of loss of function, and this risk will be related to the pathology of the underlying disease process which may have already produced a disability or displaced the cortex away. It is now possible to identify the motor and sensory cortex in the context of both normal and abnormal cortices. The sophisticated use of structural MRI has also enabled surgeons to distinguish lesions that are distinct from cortex or displace it from those that involve cortex or may contain functioning tissue. The central cortex can now be identified reliably

on MRI and fMRI has become more accurate. It has been verified in comparison with transcranial magnetic stimulation [88], anatomical criteria [89] and the gold standard of mapping by stimulation during chronic intracranial recording [90] or directly at the surgery. Pinsker *et al*. [91] reported that the use of neuronavigation, cortical stimulation and repetitive neurological and language examinations reduces neurological deterioration from 33% to 12%.

Despite these precautions, unexpected deficits may occur. Although these could be due to wrong identification of the primary areas it may also occur if secondary vascular damage takes place because an artery or vein passing through a resected area is damaged, a mechanism postulated by Olivier and Awad [92]. They also note that the whole central area can be resected when there is no voluntary hand movement, position sense is absent and there is paresis of the lower limb. It is equally important to identify the postcentral gyrus to avoid profound proprioceptive loss in the hand or arm, which can be more disabling than pure motor loss. However, following the resection of discrete lesions there may be a transient deficit or no deficit. In a detailed review of 120 frontocentral resections the Paris group notes that 40% of patients were unchanged immediately after surgery and in 15.8% there was a minor defect, but in the remainder (44.2%) there was either a monoparesis or major hemiplegia. At 1 year or more after operation there was significant improvement with no change in 67.5%, a mild disability in 10% and an additional severe disability in 22.5% [93]. In a group of 57 patients there were eight patients in whom there was a discrete lesion; three of these underwent lesionectomy and the remaining five underwent corticectomy. There were mild deficits in only two of these patients [94]. Cascino *et al*. [95] reported similar findings describing one monoparesis among 14 patients who underwent stereotactic lesionectomy in the perirolandic region. In the dominant hemisphere, resections from the posterior temporal–parietal region run the risk of receptive aphasia, dyslexia, dysgraphia and dyscalculia. For this reason resections from these areas are usually avoided.

Occipital resections

Occipital resections form around 2–5% of most series. Preoperative visual field defects are present in 30–60% of patients [96] and visual field defects increase after surgery. Recently, Curatolo *et al*. [97] have reported the use of intraoperative photic driving to identify central visual cortex and describe two patients in whom they were able to preserve the central visual field. Bidzinksi *et al*. [98] also noted that a complete occipital resection always produced some visual field defect. However, two patients undergoing occipital lesionectomy described by Cascino *et al*. [95] had no defect. Williamson *et al*. [99] noted that most patients adapted to their visual field defect within 1 year of surgery.

Hypothalamic hamartoma

This lesion has come to prominence and there are a number of different approaches to it which partially depend upon the size and situation of the lesion. The pterional approach has now largely been abandoned as being ineffective. Other manoeuvres including stimulation, radiofrequency coagulation, etc. have their place but are little used. The main operations are the transcallosal approach, pioneered by Rosenfeld and Harvey [100], the resection and disconnection approach including endoscopic technique of Delalande and Fohlen [101] and stereotactic radiosurgery [101,102]. The transcallosal approach has been relatively free of complications. In 2004 Rosenfeld *et al*. reported results from 45 patients; morbidity was minimal, including transient hemiparesis in three, ongoing diabetes insipidus in two and early short-term memory impairment in 16 (persistent in six) [103]. A subsequent joint paper with the Barrow Institute describes persisting short-term memory impairment in 8–14% [104]. The Paris group used a combination of pterional microsurgical and endoscopic approach in 49 patients. Neurological complications occurred in two patients, in both cases with the pterional approach [105]. Regis *et al*. [106] has described the effect of gamma knife surgery on 27 patients, with improvements in cognition and behaviour, no permanent neurological complications and three cases of transient poikilothermia.

Major resections

These are defined as resections that involve more than one anatomical lobe. The creation of such a space within the cranial cavity does not in itself create any special problems, although the patients tend to be more constitutionally ill and cerebrally irritable postoperatively than those undergoing lesser resections. The creation or persistence of neurological deficits (especially limb dysfunction, such as hemiparesis or hemisensory loss, visual field defects or deterioration of speech function) is often related to the original pathology, which may have produced such defects in any event.

Hemispherectomy

Although hemispherectomy is a serious operation, it is likely that the mortality rate of 6–8% quoted at the Second Palm Desert Symposium [15] probably includes series of patients operated upon over a long period of time, and more recent series do not have such mortality. In a review of 333 patients by Holthausen *et al*. [107], perioperative mortality was 1.5%. In our own series of 53 operations there has been one immediate postoperative death (1.9%); Villemure and Daniel [108] quote 2.3% for functional hemispherectomy and Delalande *et al*. [109] 3.6% for hemispherotomy. Even series comprising infants now have a low mortality rate; for example there were no deaths among 18 patients aged under 24 months operated at the Cleveland Clinic [110].

It is impossible to discuss this topic without considering the various techniques available that are aimed at reducing serious side-effects and the underlying pathology that determines the extent of the additional damage inflicted by the surgery. In practice, these patients fall into three groups. First are those presenting with a major hemispheric insult (non-progressive) at a very early age. These patients usually have a complete infantile hemiplegia and average to low cognitive function. Their neurological status is usually unchanged by surgery and their cognitive function can be unchanged or improved [111]. The second group comprises those with Rasmussen's disease [112], in whom the hemiplegia may not be complete and there may be no visual field defect. Furthermore, because of the late onset, especially when the dominant hemisphere is involved, there may be irreversible cognitive changes that are worsened by the surgery [113]. Lastly, there is the group of patients with hemimegalencephaly in whom further

deterioration may occur but is less likely than with Rasmussen's disease.

Techniques have been changed to counter the difficulties of a major operation in infants and young children, and the problem of the large space created. In infants and young children blood loss may be sufficient to necessitate transfusion, even if the operation is conducted carefully. The worst problem is venous bleeding, which may be torrential and difficult to control in the short term. The position of the head has to compromise between too much elevation (which would risk air embolism) and too little (which would increase venous pressure, making haemostasis more difficult to secure). At present, most centres have changed from anatomical hemispherectomy or decortication to some form of disconnective hemispherotomy. There are a number of variants of hemispherectomy that were devised to overcome the well-documented consequences of anatomical hemispherectomy as described by Krynauw [114]. These complications of haemosiderosis and associated conditions occur even with modern techniques [115]. A possible solution is the *functional hemispherectomy*, which, in its most recent form, is the peri-insular operation proposed by Villemure and Mascott [116]. A more minimal operation, hemispherotomy, described in two separate forms by Delalande *et al*. [117] and Schramm *et al*. [118], also resolves this problem. These modified operations still have their complications. The exact frequency is difficult to discern because some series extend over a considerable period of time. Of interest is the report from Boston of 10 patients in whom blood loss, of proportions that required intensive care unit care to correct, was the main problem. In addition, haemorrhage into the operation cavity and seizures occurred [119]. A more recent report from Rome describes less severe complications, including anaemia in 12 out of 15 patients; a second surgical procedure was needed in eight patients, including five shunts, all in children operated on at less than 9 months of age [120]. In our own mixed series of 50 adults and children, only four required shunts and there were four cases of severe postoperative infection requiring removal of the bone flap. In two of these there had been exploration with large subdural grids. In terms of operating time and blood loss, at present some form of hemispherotomy or the peri-insular hemispherectomy is to be preferred. In Villemure and Daniel's 43 patients who were undergoing functional hemispherotomy there were two shunts and one haemorrhage [108]. In Delalande *et al*.'s 83 patients who underwent hemispherotomy there were 13 shunts [109]. Finally, Kestle and colleagues [121] made an interesting comparison between hemidecortication in five patients and peri-insular hemispherotomy in 11 patients. Those patients who underwent peri-insular hemispherotomy did better on all measures, such as blood loss, postoperative fever, ventriculoperitoneal shunt insertion and length of stay [121].

In conclusion, hemispherectomy and allied procedures now have acceptable mortality and morbidity rates but they do remain among the most dangerous, although the most effective, resective operations for drug-resistant epilepsy.

Reoperation

All surgeons are familiar with the technical difficulties of second or third operations at the same anatomical site. Awad and colleagues [122] were the first to outline specific difficulties of reoperation, and the matter has also been dealt with in detail by Germano *et al*. [123]. Awad *et al*. [122] noted that anatomical structures will frequently become distorted and MRI and neuronavigation are obvious aids to countering this problem. Vascular adhesions may form between the dura and cortex and these vessels may make a significant contribution to the blood supply of that cortex and therefore should be preserved as far as possible. Only one paper on reoperation, that by Salanova *et al*. [124] describing 39 patients who underwent reoperation in the frontal lobe, reports transient weakness in 28% and permanent neurological defects in 8% [124]. A further report on 41 patients reoperated in the temporal lobe had no morbidity [125]. Recent papers from other sources have similar results with no mortality and morbidity, chiefly increased visual field defects, at 10–15% [126,127].

Functional surgery

These procedures can be divided into three groups: interruption of fibre tracts (as in callosotomy and multiple subpial transection), stereotactic creation of lesions within the brain and stimulation of deep brain and other nervous system structures.

Callosal section

Complications from callosal section depend upon the extent of the section and the nature of the underlying disease process. When performed as an alternative to hemispherectomy in unilateral hemisphere disease it is clearly sensible to approach the midline from the damaged side. If these patients are of mixed cerebral dominance this may affect the side of the approach and the extent of the callosal section posteriorly.

The complications may be divided into acute and chronic and they are related to the extent of the resection, being minimal with a truncal section and greatest with an anterior two-thirds or total section. Venous ischaemia or even thrombosis, when unilateral, would manifest itself as a hemiparesis with the possible addition of focal seizures. There may be transient paresis, usually affecting one leg, due to retraction on the medial surface of the hemisphere. More serious, however, is the risk of akinetic mutism, probably the result of bilateral anterior cerebral artery spasm. Mortality in recent series was between 0 and 1.5% [128–130]. The Montreal Neurological Institute (MNI), reporting 43 operations, had no deaths, but there were some complications in 16 patients, including three patients with transient weakness of the right leg and four with decreased speech output, also transient [131]. Recent series have similar complication rates to earlier ones. Thus, in Nei *et al*.'s series of 87 patients [128] there were complications in 21%, and in Shimuzu's series of 76 patients there were four serious surgical complications (5%) [129]. In our own series of 28 patients who were undergoing anterior callosotomy, there has been one peroperative death from pneumonia and two patients developed acute anterior cerebral ischaemia, both of whom recovered completely. We have had transient limb weakness in a few patients and an extradural haematoma in one. In many series the complications are transient, as described by Maehara and Shimizu *et al*. [132] and Fandino-Franky *et al*. [133]. The former had 14 transient episodes of transient akinetic mutism in 59 cases (23.7%) and the latter had 10 cases of transient weakness and two of mutism in 95 cases (11.6%). Total callosal section has a higher risk of complications, and in a series of 76 patients reported by

Cukiert *et al*. [130] there were complications in 72 patients but all were resolved within 16 days. When callosotomy is carried out using stereotactic radiosurgery there appear to be fewer complications but there is the additional problem of delayed local oedema, common to all such treatments [134]. This invariably responds to steroid treatment. Therefore, in summary, the risk of death at callosotomy seems to be between 0% and 1.5% and the risk of permanent neurological deficit less than 5%, but the risk of transient deficit is up to 20%.

There are two important cognitive complications of callosal section. The first is changes in speech function in patients of mixed cerebral dominance for speech, in whom interhemispheric communication is essential for the proper comprehension and production of speech and related functions. This was first reported by Sass *et al*. [135]. It has been suggested, but is by no means the universal opinion, that a carotid amytal test to establish speech dominance should precede the surgery in every case and the operation, especially total section, should be refused to those of mixed dominance. The second potentially serious complication is the posterior disconnection syndrome. This is a situation in which complex motor or organizational tasks that require the combination of information from both hemispheres become impossible, as first described by Gordon *et al*. [136]. Sauerwein and Lassonde [137] noted that the cognitive effects of callosal section were related to the location and extent of the section as well as the age of the patient at the time of operation. Posterior section resulted in sensory disconnection; total callosotomy introduced problems with bimanual coordination and apraxia of the non-dominant hand to verbal commands. Many of these symptoms subside and those that remain are not disabling [137]. In 25 children, the effects of callosal section were less in younger children, and in older patients tended to resemble the pattern seen in adults [138].

Multiple subpial transection

Morrell *et al*. [139] devised this procedure for use in eloquent areas of cortex, attempting to produce good seizure control with minimal functional disturbance. Their experience is summarized in a review published in 1999. They report transient morbidity in the form of paresis and dysaesthesia lasting 2–3 weeks, although occasionally lasting some months. Permanent deficits were less common, occurring in only 14% of patients. In addition, there were unrelated complications in four other patients, bringing the overall complication rate to 19% [140]. In our own experience in 40 patients there have been severe complications in patients who underwent resection as well as MST; there were six hemipareses (30%) (four transient) and three hemipareses with MST alone (27% – two transient). In 2002, a comprehensive meta-analysis of cases from six centres was published. It was reported that when MST was used alone there were complications in 10 patients (19%), comprising four with memory decline, five hemipareses and one partial visual field defect. There was no persisting aphasia or sensory deficits after MST alone. Thirty-seven patients, however, had a persistent deficit after MST with resection [141].

Stereotactic lesions

The creation of lesions in apparently normal brain to control epilepsy by modification of brain activity has been proposed and performed for many years and by a number of methods. Generally speaking, they were directed to temporal and extratemporal targets. However, these procedures are now not much used.

There are reports on the use of stereotactic radiosurgery in treating drug-resistant epilepsy due to mesial temporal sclerosis and hypothalamic hamartoma. The number of patients reported is small but there do not appear to be any of the particular complications of radiotherapy, such as radiation necrosis. In two recent reports the Marseille group reported only minor complications in 15 patients with mesial temporal sclerosis who were followed up for more than 2 years. Four patients had transient worsening of seizure activity and eight patients had cephalgia [142]. In this paper two patients were described as having a significant field defect and in another paper nine patients had field defects, eight of whom were asymptomatic and the remaining one was hemianopic [143].

Stimulation

Clearly, the use of chronic indwelling stimulating electrodes will run the risk of complications that are commonly associated with such apparatus. These must include implant failure and infection. These are relatively rare and occur with the same frequency as any other implanted device. When the stimulating electrodes are intracranial there is also the possibility of CSF leakage.

At present the only stimulation procedure in common use in epilepsy is stimulation of the left vagus nerve. The complications associated with this procedure fall into three groups.

The surgical complications include haematomas in the generator pouch, which occur rarely and are usually treated conservatively. They are likely to be less common as the devices become smaller. Infection occurs at a steady rate, which is low. Ben Menachem and French [144] quote 3–6%, and this is probably correct, although infection serious enough to need explantation is lower. There are alternatives to explantation, as suggested by Ortler *et al*. [145]. Similar figures have been quoted in recent papers describing series of children [145–47]. Hardware failures are rare, occurring in perhaps less than 1% of cases. Paralysis of the left vocal cord, probably as a result of excessive nerve manipulation, is also seen, in probably less than 5% of cases, and usually resolves with time. In early series there were reports of a Horner's syndrome, which is due to extending the dissection too deeply [148]. There is a substantial literature on the effects of vagus nerve stimulation on laryngeal function. Apart from the more permanent effects, which are rarely observed, as already explained, effects that are normally well tolerated may, in the case of excessive stimulation, result in adductor spasm [149].

There was anxiety about cardiac and respiratory effects of intermittent vagus nerve stimulation, as bradycardia and asystole have been reported during lead testing at implantation. However, this is rare (in Ardesh's recent report 2.7%, and in our series less than 1%) and now is generally not seen as a reason for explantation or not using the device [150,151). Patients undergoing a general anaesthetic for some other reason should have the device turned off. There have been rare deaths from pneumonia but studies have not shown that vagus nerve stimulation causes aspiration [152,153]. In our series of over 120 implantations there has been one death and one serious morbidity from pneumonia in the postoperative period, unrelated to aspiration. Lotvall and colleagues [154] have described deterioration in lung function in

patients with chronic obstructive airways disease. Malow *et al.* [155] have shown adverse changes in respiration during stimulation when the patient is asleep and note that it is more significant in patients with obstructive airways disease.

There are also the problems associated with the intermittent stimulus. These were thoroughly explored in the trials and are described by Ben Menachem and French [144]. They include voice change (usually hoarseness), coughing and, occasionally, shortness of breath. Many of these effects are related to the amplitude of stimulation and tend to become less obtrusive with time and at a constant level of stimulation. Typical figures are those given by Morris and Mueller [156], with hoarseness at 28% and paraesthesiae at 12% at 1 year, hoarseness at 19% and headache at 4.5% at 2 years, and shortness of breath at 3.2% at 3 years. Vagus nerve stimulation and callosotomy have been compared and it is evident that the complications from vagus nerve stimulation are less frequent and much less serious than those from callosotomy [128].

Deep brain stimulation for epilepsy has been directed at two targets: the cerebellum and the thalamic nuclei. Cerebellar stimulation was introduced by Cooper *et al.* [157] but subsequently shown to be ineffectual [158]. Complications were rare; there were anecdotal reports of sudden death but these occur in epilepsy anyway. Deep brain stimulation has also been applied to the thalamic nuclei and to the subthalamic nucleus. Studies are sparse and inconclusive. The same potential complications must exist as with stereotactic lesioning, mainly malposition of the electrodes and haemorrhage.

Risk management

In the surgical management of chronic drug-resistant epilepsy, the use of interventional procedures in presurgical evaluation, and the therapeutic procedures themselves, can never be without risk of significant physical, intellectual and psychiatric complications. The impact of these complications spreads beyond the patient and surgeon to the family, referring physician, referring organization and society itself.

Because most epilepsy surgery or invasive diagnostic procedures are a matter of choice rather than involving decisions made under pressure of clinical circumstances, the concept and application of informed consent is especially important. A person taking such consent must be sufficiently senior and experienced to make them competent for that task and the person giving it must have understood the explanation and implications. It may be impossible to achieve this in one session. It is especially important that any such discussion should include the particular experience or facilities of the group undertaking the procedure, as these will influence the possible frequency and severity of complications. It is not clear what legal validity the present operation consent form used in the UK has. It is commonsense to make sure that it is countersigned by the operating surgeon or equivalent. A written record that a discussion regarding the purpose of the procedure and possible complications has taken place should exist and, if appropriate, the actual complications should be listed. In the Sidaway case it was hoped that an objective frequency of any complication would be suggested, above which the patient must be warned. However, after appeal to the House of Lords it was stated that the surgeon must warn only of those complications that a reasonable body of professional practitioners would warn the patient of, and that, in the UK at any rate, is where the matter stands [159]. This is in keeping with the Bolam test, which uses the proposition that a practitioner cannot be accused of negligence if he/she acts in accordance with practice accepted at the time by a responsible body of medical opinion [160].

Conclusion

- The complications of epilepsy surgery must include the complications from invasive procedures used in presurgical assessment, as well as those arising in relation to therapeutic interventions.
- The intracarotid sodium amytal test has a low complication rate, less than 0.5%, in the classical form.
- Intracranial electrodes have a complication rate that increases with the invasiveness and complexity of the procedure. Mortality is zero, but there is a significant complication rate from haemorrhage and infection of 2–5%.
- Therapeutic procedures are divided into resective and functional operations. Overall perioperative mortality in large series of mixed procedures is 1% and overall mortality, including late deaths, is around 2–3%.
- In resective surgery morbidity depends upon the size and site of the resection. It can be very low in non-eloquent areas such as the non-dominant frontal lobe: around 1% compared with greater than 30% in central and occipital regions.
- In unilateral hemisphere disease the age of the patient, the underlying pathology and the operative technique used will all affect the nature and severity of the potential complications.
- In temporal lobe resections there are additional intellectual and behavioural consequences of the procedure, dependent upon the preoperative status of the patient and the nature of the resection.
- Reoperation and functional procedures such as callosotomy and multiple subpial transection also carry significant risk.
- Risk management is also important.

80 Anaesthesia for Epilepsy Surgery

Barbara Van de Wiele
David Geffen School of Medicine at UCLA, Los Angeles, CA, USA

Preanaesthetic evaluation for epilepsy surgery

Anaesthesia for epilepsy surgery, perhaps more than anaesthesia for any other neurosurgical procedure, requires the anaesthesia team be extremely well informed about the specifics of the condition that necessitates the surgery. Thus, it is the author's practice to have the following questions in mind when conducting the preoperative evaluation of a patient with a chronic seizure disorder scheduled for epilepsy surgery: What is the seizure type and frequency? Does the patient experience a warning symptom or aura? What circumstances, if any, precipitate seizures? What are the ictal manifestations and postictal behaviours? What antiepileptic drugs (AEDs) is the patient taking? Is there a history of any adverse reaction to previously used AEDs? If the seizures are part of a syndrome, how might that syndrome also affect anaesthesia management?

The preoperative assessment should address the potential toxicities of AEDs, such as bone marrow suppression, anaemia, thrombocytopenia, liver toxicity, and electrolyte and acid–base abnormalities. If not identified preoperatively, common side-effects of anticonvulsant therapy might cause perioperative adverse events or, at a minimum, diagnostic dilemmas. For example, patients on topiramate (Topamax) may have markedly low serum bicarbonate levels due to carbonic anhydrase inhibition and increased renal bicarbonate losses [1,2]. The benefit of awareness of a pre-existing acidosis that might be worsened by intraoperative conditions, such as administration of normal saline, hypoventilation and volume depletion, is clear. A similar benefit would be gained from knowledge of hyponatraemia associated with oxcarbazepine and carbamazepine therapy. This side-effect, attributed to altered sensitivity of hypothalamic osmoreceptors, or increased sensitivity of renal tubules to antidiuretic hormone, is usually subclinical but cases of clinically significant hyponatraemia are reported [2–4]. In the absence of clinical symptoms or signs of hepatotoxicity, routine preoperative liver function tests are not indicated. However, mild asymptomatic biochemical abnormalities in liver function are not infrequent during therapy with AEDs that induce liver enzymes (e.g. phenobarbital, carbemazepine, phenytoin) [5]. If discovered, these are not considered a contraindication to anaesthesia and surgery [6]. Finally, blood levels of AEDs should be reviewed to guide decisions about perioperative drug administration.

Prior to anaesthesia for procedures that do not involve intraoperative or perioperative analysis of epileptiform activity, it is appropriate to continue the preoperative antiepileptic drug regimen, whereas before anaesthesia for procedures that involve intraoperative analysis of epileptiform activity, it is best to plan perianaesthetic AED administration in consultation with the neurology and neurosurgical teams. An exception to this general rule is perioperative administration of valproic acid. In some practices valproic acid therapy is continued perioperatively, whereas in others the drug is discontinued before elective neurosurgery. The rationale for stopping valproic acid therapy preoperatively is that it has been shown to affect platelet function and clotting factors, although whether these effects are related to a specific dose range, idiosyncratic or predictable, is not clarified [7]. The rationale for continuing valproic acid is that, although some reports have attributed intraoperative and postoperative hemorrhagic complications to valproic acid, several studies failed to demonstrate any increase in haemorrhagic complications in patients undergoing neurosurgery while taking valproic acid [8,9]. Resolution of this controversy awaits a greater understanding of the effect of valproic acid on haemostasis. Valproic acid is also known to cause dose-dependent thrombocytopenia, which, in any case, would need to be addressed before elective epilepsy surgery [10].

Anaesthesia and antiepileptic therapy

In the past several decades the armamentarium of AEDs has substantially expanded. In addition to the 'classic' and still widely used valproic acid, phenytoin, phenobarbital and carbamazepine, neurologists treating seizure disorders can choose among newer AEDs including felbamate (Felbatol), gabapentin (Neurontin), lamotrigine (Lamictal), topiramate (Topamax), tiagabine (Gabitril), levetiracetam (Keppra), oxcarbazine (Trileptal) and zonisamide (Zonegran). Although some of these drugs are significantly protein bound and several cause mild induction of liver enzymes, clinical experience and limited reports from the literature suggest that interactions of these new AEDs with agents used during anaesthesia are generally of minor clinical significance. In contrast, there is substantial information about the interactions of 'classic' AEDs, for example valproic acid, phenytoin, phenobarbital and carbemazepine. These drugs have significant interactions that alter patient response to agents used during anaesthesia.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Patients receiving chronic anticonvulsant therapy with 'classic' AEDs require increased maintenance doses of fentanyl during balanced anaesthesia for craniotomy [11]. It is not known whether this finding is explained by enhanced fentanyl metabolism or an effect of chronic anticonvulsant medications on opiate receptors. Another clinically relevant interaction with narcotic medication is the induction of hepatic enzymes by chronic administration of phenobarbital causing increased N-demethylation of pethidine to the neurotoxic metabolite norpethidine [12].

After prolonged treatment with 'classic' AEDs, patients may require larger and more frequent doses of neuromuscular blocking drugs to maintain muscle relaxation during surgery because the recovery time of non-depolarizing neuromuscular blockers is markedly reduced. On occasion, the reduction in recovery time is so profound that paralysis due to neuromuscular blocking agents given to facilitate endotracheal intubation has dissipated by the time of head positioning for neurosurgery a short time later. Frequent or continuous monitoring of neuromuscular blockade is advisable to prevent untoward events that are likely to provoke patient movement in these and other circumstances.

Patients who are chronically treated with phenytoin or carbamazepine are resistant to the steroidal muscle relaxants pancuronium, vecuronium and rocuronium [13–16]. These interactions are probably multifactorial, involving altered protein binding, decreased receptor sensitivity and increased numbers of cholinergic receptors, as well as increased metabolism. In contrast, recovery from atracurium, a benzylisoquinolinium class drug, is not affected by chronic administration of phenytoin or carbemazepine [17,18]. However, recovery from cisatracurium, another benzylisoquinoline-derived agent, is faster in patients on chronic phenytoin and carbamazepine, although the magnitude of the effect is smaller than that observed when steroidal non-depolarizing neuromuscular blocking drugs are administered [19].

The anaesthesia team is often asked to administer AEDs intraoperatively, either to augment subtherapeutic blood levels or to provide postoperative seizure prophylaxis for patients on AEDs that cannot be administered intravenously. The most common adverse effect of AEDs that are administered intraoperatively is undoubtedly hypotension during phenytoin administration. Under anaesthesia, and in non-emergent situations, it is wise to administer phenytoin substantially more slowly than the recommended maximum infusion rate of 50 mg/min in adults and 1–3 mg/min in children and neonates. Additive sedation is another potential side-effect of intraoperatively administered anticonvulsants, particularly when phenobarbital is given. Finally, as anticonvulsants are frequently infused towards the end of surgery, it is worthwhile noting that acute phenytoin administration to patients who are not chronically receiving the drug results in augmentation of the existing neuromuscular blockade [20].

Under anaesthesia, gastrointestinal absorption of AEDs is unreliable and might result in inadequate blood levels. Some AEDs have parenteral formulations (phenytoin, valproate, levetiracetam, phenobarbital) that can be substituted for oral medications during the perioperative period. Alternative therapies must be considered if oral administration of medications that do not have a parenteral formulation, for example carbamazepine, will not be resumed in a timely fashion.

The ketogenic diet, prescribed for patients with seizures refractory to medical management, is another therapy that influences anaesthetic management. Postulated mechanisms for the anticonvulsant effect of the diet include improved cerebral energy stores and ketone body-mediated enhancement of chloride conductance at glycinergic and GABAergic synapses [21]. As the diet is more frequently encountered during anaesthetic management of children, the perioperative considerations are included in a later section of this chapter that addresses anaesthesia considerations for epilepsy surgery in children.

Anticonvulsant and proconvulsant properties of anaesthetics

Many drugs used in anaesthesia have proconvulsant or anticonvulsant effects. The literature on this topic is extensive but ambiguous. One source of ambiguity is the doubtful standard of 'movement consistent with convulsive activity during anaesthesia' applied in some reports that lack electroencephalography corroboration to define drugs that are administered during anaesthesia as epileptogenic. Another source of ambiguity is the tendency to extrapolate observations from non-epileptic subjects to patients with chronic intractable epilepsy and vice versa. In fact, different responses to anaesthetic drugs are observed even among populations of patients with different types of epilepsy. To add to this complexity, some drugs used in anaesthesia have proconvulsant and anticonvulsant effects at different doses, some have proconvulsant metabolites and some used to activate seizure foci during epilepsy surgery have also been used to treat status epilepticus. To provide the reader with some general guidelines for the use of anaesthesia drugs during epilepsy surgery, the following discussion summarizes pertinent information from several comprehensive reviews [6,22,23].

Intravenous anaesthetic induction drugs have proconvulsant and anticonvulsant properties. The barbiturate induction drugs thiopental and methohexital have anticonvulsant properties and can be used to treat status epilepticus. On the other hand, methohexital administered in hypnotic doses can precipitate seizures in patient with epilepsy and low-dose methohexital (<0.5 mg/kg) can activate seizure foci in patients with temporal lobe epilepsy, a property that has been used to define seizure foci intraoperatively. Low-dose thiopental can also activate seizure foci in patients with epilepsy but is less effective than methohexital for this purpose [24].

Propofol has anticonvulsant properties in experimental animal models, decreases the duration of seizure activity in patients undergoing electroconvulsive therapy and has been used to treat status epilepticus resistant to other forms of therapy [25]. Infusion of propofol diminishes epileptiform activity in epileptic patients who are undergoing intraoperative electrocorticography. Nevertheless, there are reports of electroencephalography-documented seizure activity in patients after administration of propofol. This phenomenon is observed at lower plasma concentrations and disappears when drug levels are augmented.

Ketamine is proconvulsant in experimental animal models, activates seizure foci in patients with epilepsy and is generally considered to be contraindicated in patients with epilepsy.

Etomidate also activates seizure foci in patients with epilepsy [26]. Both agents have been used to treat status epilepticus. In summary, most of the intravenous induction agents have proconvulsant and anticonvulsant effects or both. Taken together, the information available suggests that methohexital, etomidate and ketamine are unlikely first-choice induction drugs for epileptic patients.

Inhalation agents also have proconvulsant and anticonvulsant properties. The proconvulsant effects of enflurane, an agent not in common use today, especially at high alveolar concentration [1.5–2 minimum alveolar concentration (MAC)] and during hypocarbia, are well known [27]. This consideration, among others, influenced anaesthesiologists to abandon the use of enflurane for neurosurgical anaesthesia when isoflurane was introduced into clinical practice. Isoflurane, despite occasional reports of seizure-like activity occurring during its use, has anticonvulsant properties at commonly used alveolar concentrations and has been used to treat status epilepticus.

Sevoflurane and desflurane are now the inhalation agents most commonly used in the clinical practice of anaesthesiology. Limited information suggests that desflurane is not epileptogenic, even at high alveolar concentration or during hypocapnia. In contrast, studies demonstrate that sevoflurane administration is associated with epileptiform electroencephalographic activity in epileptic and non-epileptic patients [28–32]. This association appears to be dose dependent, with a threshold at 1.5–2 MAC. Proposed risk factors in non-epileptic patients include rapid induction, high alveolar concentration, hyperventilation and female sex [33]. No patient studied to date has suffered any apparent consequence of the epileptiform activity recorded. The information available regarding the epileptogenic potential of sevoflurane has led to the recommendation that the maintenance concentration of sevoflurane be limited to 1.5 MAC [34].

High potency μ-receptor agonists are proconvulsant in animals. High-dose fentanyl and sufentanil induce epileptiform activity in non-epileptic patients who are undergoing cardiac surgery, and in patients with complex partial epilepsy rapid intravenous administration of large doses of fentanyl, alfentanil and remifentanil is epileptogenic [35–37]. The mechanisms postulated to mediate the proconvulsant actions of opioids include interactions with limbic opioid receptors, release of excitatory amino acids and suppression of inhibitory interneurones. A disinhibition mechanism is the hypothesis that is given the most credence, based on available data [36,38].

Anaesthesia and electrocorticography

Electrocorticography is used to define the location of cortical epileptogenic foci, to delineate the limits of therapeutic cortical resection and to confirm complete surgical removal of epileptogenic foci. It involves detection of characteristic interictal electroencephalogram (EEG) abnormalities via grids of electrodes placed over the surface of the brain. Placement of these grids requires a craniotomy. Depending on the circumstance, electrocorticography after grid placement may be performed intraoperatively under general anaesthesia, intraoperatively during so-called 'awake' craniotomy or extraoperatively awake.

Given the anticonvulsant effects of many anaesthetic agents, it goes without saying that if electrocorticography is to be performed in sedated patients or under general anaesthesia the anaesthetic technique must be tailored to provide optimal conditions. Exactly how that should be accomplished is quite a bit more controversial and neither the best anaesthetic for electrocorticography during craniotomy with awake intraoperative brain mapping nor the best anaesthetic for electrocorticography under general anaesthesia, which some consider an oxymoron, has been precisely defined. That said, many agents used during anaesthesia can suppress the interictal spike discharges that are used to identify epileptogenic tissue.

Several drugs used for anxiolysis during anaesthetic management are anticonvulsants at sedative doses and can inhibit interictal epileptiform activity. Avoiding benzodiazepine premedications in advance of procedures involving electrocorticography is widely recommended. Propofol infusion also can suppress interictal spike discharges at sedative doses but the duration of this effect is relatively short and several studies have found adequate conditions for diagnostic electrocorticography when propofol infusion is suspended for 15–30 min in advance of awake intraoperative electocorticography [39,40]. On the other hand, satisfactory conditions for electrocorticography are reported in patients who are administered dexmedetomidine by infusion for sedation [41,42]. Similarly sedative doses of remifentanil (0.1 μg/kg/min) are reported to provide adequate conditions for monitoring epileptiform activity during epilepsy surgery [43].

General inhalation anaesthesia is often administered for epilepsy surgery that does not require awake functional brain mapping. Under certain conditions, all inhalation anaesthetics may decrease interictal epileptiform activity. Isoflurane is reported to decrease interictal spike frequency at 0.5–1.5% [44]. Although at high alveolar concentrations sevoflurane can activate epileptiform activity in patients with intractable epilepsy, even in areas not confined to the ictal zone [28,31,32,45], during fentanyl-based anaesthesia sevoflurane decreases epileptiform activity at 0.5–1.5 MAC [46]. Nitrous oxide also decreases interictal epileptiform activity on electrocorticography in patients with epilepsy [47].

It is the practice at our institution, and many other centres as well, to discontinue potent inhalation agents in advance of electrocorticography and to maintain anaesthesia during recording with a combination of narcotic and nitrous oxide. If this anaesthetic is planned it may be reasonable to inform patients of an increased, although still extremely small, risk of recall during the period of electrocorticography, to explain the rationale for the modification of the anaesthetic technique during mapping of the seizure focus, and to provide reassurance regarding the likelihood of experiencing pain. Other 'light' general anaesthetic techniques and neuroleptanalgesia protocols designed to accommodate electrocorticography during epilepsy surgery are described but these have not been systematically evaluated.

Another widely used approach to delineating seizure foci during general anaesthesia is to administer medications that trigger epileptiform activity. Bolus administration of fentanyl (10 μg/kg), alfentanil (30–50 μg/kg) and remifentanil (1–2.5 μg/kg) induces epileptiform activity in patients with complex partial epilepsy [36–38]. A proposed advantage of remifentanil for this purpose,

compared with other opioid options, is that remifentanil has a short duration, even after a large dose, and, thus, its administration would be unlikely to contribute to postoperative sedation that could hinder early postoperative neurological evaluation. Subhypnotic doses of methohexital (0.3–0.5 mg/kg) and etomidate (0.05–0.1 mg/kg) have also been used to activate seizure foci intraoperatively [24,26]. An enduring debate is whether these triggering agents might mislead by activating epileptiform activity outside the ictal onset zone.

Anaesthesia for presurgical diagnostic tests

Patients undergo a wide variety of tests during the preoperative evaluation for the surgical treatment of epilepsy. These include: brain imaging studies, such as computed tomography, magnetic resonance imaging and positron emission tests; neuropsychological testing to determine hemispheric dominance such as the Wada test; and electroencephalographic evaluation via telemetry, depth electrodes and subdural grids. Some of these procedures are routinely performed under general anaesthesia, some can be performed with general anaesthesia or sedation, and some are performed with anaesthesia only if the patient cannot tolerate the test awake.

Placement of subdural grid electrodes requires a craniotomy and is performed under general anaesthesia. As electrocorticography for seizure focus mapping is performed after the operation there is no limitation on use of anaesthetic agents that suppress epileptiform activity. Venous access should be sufficient to accommodate the rare instances when grid placement breaches an afferent to the sagittal sinus with significant ensuing blood loss.

Placement of depth electrodes is performed under local or general anaesthesia according to institutional preference and patient requirements. Before the patient comes to the operating theatre, a stereotactic frame is placed and an MR scan is obtained with the frame in place. The frame limits neck mobility and, depending on the patient's particular physical characteristics, may also interfere with access to the airway. Thus, careful assessment is needed to plan for intraoperative airway management. Awake fibreoptic endoscopy-assisted endotracheal intubation is one solution but other approaches – the laryngeal mask airway, the intubating laryngeal mask airway and the glide scope – have been used successfully. Of course, whenever any drug with the potential to depress respiration is administered to a patient in a stereotactic frame, the immediate availability of equipment required to remove the frame should be confirmed. Hyperventilation during depth electrode placement can theoretically alter the position of intracranial structures targeted during an MR scan obtained while the patient is breathing spontaneously. Although a very rare event, emergency craniotomy may become necessary in the event of intracranial haemorrhage due to electrode placement. Removal of depth electrodes can usually be performed with intravenous sedation.

Other presurgical evaluations, such as the Wada test, which evaluates language and memory after unilateral hemispheric inactivation by a short-acting hypnotic injected into the carotid artery, functional magnetic resonance imaging, magnetoencephalography and positron emission tomography, are usually performed without anaesthesia except in children and uncooperative adults. Sedation with propofol at doses required to provide immobility may not alter the likelihood of recording interictal epileptiform activity during magnetoencephalography [48] or compromise neuropsychological testing if used for the angiographic portion of the Wada test [49].

General anaesthesia for epilepsy surgery

Focal cortical resection and temporal lobectomy are often performed under general anaesthesia in patients who do not require awake intraoperative mapping for delineation of functional cortex in close proximity to the proposed cortical resection. If intraoperative electrocorticography is planned then premedication with benzodiazepines is inadvisable. Very anxious patients may benefit from premedication with narcotics or propofol, with appropriate monitoring, in the preoperative area. Propofol is also a suitable intravenous hypnotic for induction of anaesthesia. A history of a seizure disorder does not influence the selection of neuromuscular blocker to facilitate intubation although, as noted, the duration of action of aminosteroidal non-depolarizing neuromuscular blockers is greatly reduced by several widely used antiepileptic medications. In common with other intracranial neurosurgical procedures, the goals of general anaesthesia for epilepsy surgery are analgesia, amnesia, stable haemodynamics, optimal operating conditions and early emergence for neurological evaluation. Total intravenous anaesthesia, balanced anaesthesia and inhalation anaesthesia can be used to achieve these goals. Anaesthetic technique may need to be modified to accommodate electrocorticography. Decisions regarding ventilation should take into account the possibility of precipitating seizure activity by hyperventilation. Other effective means to achieve optimal surgical conditions are administration of mannitol and positioning of the patient to optimize cerebral venous drainage. Normovolaemia is maintained by administration of isotonic crystalloid. Significant blood loss is rare. Clinical experience suggests that brief transient decreases in heart rate, which normalize when surgical manipulation is discontinued and rarely require treatment, are common during temporal lobectomy in patients with intractable epilepsy. A report of six cases of severe bradycardia in a series of 42 consecutive patients who were undergoing temporal lobectomy supports this clinical observation. All of the episodes of bradycardia in the reported series occurred during amygdalohippocampectomy. The authors suggest that this phenomenon may be related to stimulation of the limbic system, which, in experimental settings, increases parasympathetic outflow [50].

Anaesthesia for awake intraoperative brain mapping

In some centres, in appropriately selected patients, electrocorticography is routinely performed at the time of craniotomy for lesion resection, with the patient awake for an interval of time during the surgical procedure. In other centres, patients undergo awake intraoperative mapping during epilepsy surgery only if the seizure focus is located adjacent to eloquent brain areas, particularly language areas. And, finally, in some centres cortical mapping is always performed extraoperatively after subdural grids are placed during a craniotomy under general anaesthesia.

Awake intraoperative electrocorticography and functional brain mapping present a unique set of challenges for the patient and the anaesthesiologist. Optimally, the patient is sedated or unconscious, ventilating adequately, haemodynamically stable and immobile during the craniotomy, awake and cooperative for mapping procedures, and then again sedated or unconscious, ventilating adequately, haemodynamically stable and immobile during closure of the craniotomy. Several techniques have been used to accomplish these general goals. Appropriate patient selection, careful patient preparation and excellent teamwork are also important.

Most patients scheduled for epilepsy surgery with awake intraoperative brain mapping are highly motivated. Nevertheless, the anaesthesiologist can do much to allay anxiety about the procedure. Patients should be prepared by frank discussion of what they can expect to experience. The preoperative evaluation should further identify conditions that may increase the risk of the procedure such as morbid obesity, obstructive sleep apnoea, difficult airway and gastroesophageal reflux disease. It is a good idea to have a clear idea of the patient's seizure history and to anticipate any postictal behaviours (such as confusion, abnormal mentation, aggression or vomiting) that might be problematic if they occur with an open craniotomy in a patient with an unsecured airway. Other than inability to cooperate, there are few absolute contraindications to craniotomy with awake intraoperative brain mapping.

All anaesthetic techniques for craniotomy with awake intraoperative brain mapping rely on regional anaesthesia provided by infiltration of long-acting local anaesthetics. Scalp block can be performed by blocking cutaneous nerves at discrete locations, which requires a lower volume of local anaesthetic, or by regional infiltration. Scalp block performed with bupivicaine and epinephrine is effective for 8–12 h. As the scalp is highly vascular, systemic absorption of local anaesthetic is rapid. Plasma levels peak 5–10 min after administration of bupivicaine with epinephrine. Bupivicaine has a long track record in this setting, but the newer long-acting agents levobupivicaine and ropivicaine offer the theoretical benefit of lower potential cardiac toxicity [51,52]. In reviews of complications encountered during awake craniotomy in patients with seizure disorders, local anaesthetic toxicity is an infrequent event.

Craniotomy with awake intraoperative brain mapping has been performed with local anaesthesia alone. However, most patients benefit from some degree of sedation during the stimulating parts of the procedure, which include injection of the local anaesthetic, drilling, bone work and traction on the dura. Anaesthetic techniques vary according to the target level of consciousness, the agents used and airway management. Although anaesthesia techniques that involve sedation and analgesia are widely used, some centres have transitioned to 'asleep–awake–asleep' anaesthesia techniques that provide general anaesthesia for the craniotomy and closure. During the 'asleep' parts of the procedure, three airway management approaches are used: spontaneous ventilation with no intervention (except possibly a nasal trumpet), ventilation maintained via laryngeal mask airway and endotracheal intubation with controlled ventilation.

At the author's institution, for the last decade, we have used an asleep–awake–asleep technique with endotracheal intubation. First reported in 1998, we have now used this technique, or a modification of it, which incorporates routine use of a tube changer, in more than 150 patients [53]. After induction of general anaesthesia, nasotracheal intubation is performed with a commercially manufactured endotracheal tube that allows for intratracheal installation of local anaesthesia. Anaesthesia is maintained with inhalation agents or intravenous anaesthesia during positioning, scalp block, placement of the pin head holder and craniotomy. Hypnotic and analgesic agents are then either discontinued or administered at low dose until the patient is ventilating adequately and responsive, at which point the endotracheal tube is removed over a tube changer. After awake intraoperative mapping is completed, the endotracheal tube is reinserted over the tube changer. This technique provides for maximal patient comfort and a secure airway during the craniotomy, a means of reliable hyperventilation and a means to rapidly secure the airway. Further analysis of our case series is required to fully evaluate and compare this technique with other airway management protocols.

The ideal drug for craniotomy with awake intraoperative brain mapping is sedative, hypnotic, analgesic, amnestic, anxiolytic, easily titratable, rapidly reversible, antiemetic, compatible with electrocorticography, and causes minimal respiratory depression. Although deviating in several respects from these ideal characteristics, propofol and remifentanil do have pharmacological profiles that are particularly suited to rapid adjustment of levels of sedation and analgesia and, both singly and in combination, they are widely used for sedation/analgesia and general anaesthesia for these cases. Although propofol should be discontinued, remifentanil can be continued at sedative doses during electrocorticography without concern for suppression of epileptiform activity. Rapid intraoperative wake-up times prior to brain mapping procedures have been reported with propofol [54] and with remifentanil and propofol in combination [55,56]. Propofol and remifentanil administration, guided by pharmacokinetic simulation and bispectral index monitoring, is also reported to provide for rapid transition from general anaesthesia to a level of consciousness suitable for intraoperative neurological testing [56].

Dexmedetomidine, the latest addition to the armamentarium of sedative drugs used in this setting, has the advantage of producing sedation and anxiolysis without respiratory depression. It has been reported to be useful for craniotomy with awake intraoperative brain mapping as a component of sedation analgesia, as an adjunct during asleep–awake–asleep anaesthesia, and as a rescue drug for patients who, because of anxiety or dysphoria, are no longer able to tolerate being awake before intraoperative testing is completed [41,57–59]. Dramatically suboptimal conditions for neurocognitive testing during arteriovenous malformation embolization with dexmedetomidine sedation have described. In contrast, several reports describe excellent conditions for intraoperative neurocognitive testing with dexmedetomidine sedation during craniotomy [57,60]. The experience to date suggests that the lower range of dexmedetomidine dosing is less likely to result in poor conditions for intraoperative awake brain mapping.

Reliable and rapid emergence for awake intraoperative testing has been accomplished with a wide variety of anaesthetic techniques, including neuroleptanalgesia, combinations of short-acting hypnotics and narcotics, and inhalation anaesthesia. In fact, several studies comparing techniques reveal that practice

modification often diminishes the clinical consequence of drug selection and that the challenges related to drug side-effects decrease as experience is gained [61,62]. Nevertheless, some important differences between techniques have been discerned. For example, in a comparison of neuroleptanalgesia and propofol for sedation during awake craniotomy for epilepsy surgery the incidence of seizures was significantly lower in the propofol group [63].

Although the incidence of major complications is low, in order to provide the safest possible anaesthetic the anaesthesiologist has to be prepared for adverse events that are anticipatable during craniotomy for epilepsy surgery with awake intraoperative brain mapping. These include seizures, nausea and vomiting, hypoventilation, apnoea, hypercarbia, claustrophobia, dysphoria, agitation, pain, inadequate brain conditions and excessive sedation [64,65].

Most seizures are precipitated by cortical stimulation procedures, are short lived, of minimal consequence, and do not require therapy. Occasionally, intravenous hypnotics or benzodiazepines are required to terminate longer seizures. From time to time postictal depression will confound functional testing. Rarely, seizure-associated brain swelling and/or motor manifestations will require emergent conversion to general anaesthesia with controlled ventilation.

Nausea and vomiting may be a side-effect of anaesthetic agents or related to manipulation of the dura and meningeal vessels. With the anaesthetic regimens used at present, intraoperative nausea and vomiting occurs infrequently (<1%). Most reports describe administration of antiemetics as part of the local protocol for these procedures. Interestingly, the incidence of early postoperative nausea and vomiting is less after awake craniotomy than after craniotomy under general anaesthesia [66].

Problems with airway obstruction and respiratory depression during sedation can be minimized, but not eliminated, by careful titration of sedative and analgesics, patient positioning and close monitoring. Transiently decreased oxygen saturation, mild airway obstruction and decreased respiratory rate were noted in 18% of subjects during conscious sedation for craniotomy with awake brain mapping in a recent report [65] and at least one 30-s epoch of apnoea was recorded in 72% of patients undergoing asleep–awake–asleep craniotomy without airway instrumentation in another series [55]. Obesity has been described as a consistent risk factor for problems with inadequate oxygen saturation during intravenous general anaesthesia without airway intervention during asleep–awake–asleep craniotomy [64]. Although the jury is still out on the issue of airway management during asleep–awake–asleep craniotomy, there are now many reports describing placement of a laryngeal mask airway during the 'asleep' phase. The potential benefits of a laryngeal mask airway in this setting are that it provides a secure airway allowing for controlled ventilation if necessary and it permits titration of drugs during painful or stimulating parts of the procedure with less concern for respiratory depression. One group documented a lower incidence of airway complications with an asleep–awake–asleep technique with laryngeal mask airway placement compared with sedation without airway adjunct [67].

The potential for intraoperative hypoventilation or apnoea is one reason to have a back-up emergency airway management plan. Another is that emergent conversion to general anaesthesia is required in 1–8% of patients. Problems necessitating conversion to general anaesthesia include incomplete regional block that cannot be remedied, marked anxiety or agitation, postictal confusion and dysphoria. If conversion to general anaesthesia with controlled ventilation is suddenly necessary in a patient with an open craniotomy, under the surgical drapes, and in some cases with the head fixed in the pin head holder, ventilation and airway management may be challenging. Optimizing conditions for emergency airway management include positioning the patient initially in a manner that facilitates airway management (limiting neck rotation and flexion) and tenting the drapes in a manner that provides for easy access for airway management as well as neurophysiological testing. Laryngeal mask airway placement, even in the lateral position, has a high rate of success and is probably the rescue airway technique of choice in this circumstance [68]. Securing the airway with a laryngeal mask airway with the head in a pin head holder device is reported, although the success rate is not quantified [69].

Several series that have prospectively evaluated patient satisfaction suggest that most patients tolerate these procedures well, with 80–90% of patients reporting that they are either entirely satisfied or recall only minor difficulties [65,70,71]. Of note, when patients are asked what aspect of the procedure might be improved a repeated theme is postural discomfort. Padding, particularly under the flank and hip area and allowing limited supervised movement, reduces postural discomfort. Another comfort issue is the bladder catheter, particularly for male patients. If bladder catheterization will be performed (practice varies among centres) introducing lidocaine gel into the urethra at insertion decreases catheter-related discomfort in men and women [72].

Anaesthesia for epilepsy surgery in infants and children

When planning anaesthesia for epilepsy surgery in infants and children the anaesthesiologist has to keep in mind that some of the anaesthesia considerations for infants and children with intractable epilepsy who present for surgical therapy have been documented to be similar to adults, some are merely assumed to be similar and others are dissimilar or unique.

An illustration of how differences between children and adults might alter clinical anaesthesia management for epilepsy surgery is the higher incidence of topiramate-related metabolic acidosis in children than in adults [1]. This finding supports obtaining baseline blood chemistries in all children treated with topiramate who are about to undergo major neurosurgical procedures, a practice that will assist the differentiation of medication-related acidosis from acidosis due to more ominous diagnoses such as poor circulatory function or even malignant hyperthermia intraoperatively. An example of an anaesthesia management consideration documented to be similar in adults and children undergoing epilepsy surgery is that children, like adults treated with phenytoin and carbamazepine, are resistant to the non-depolarizing muscle relaxants rocuronium and vecuronium [73,74]. Nevertheless, in many circumstances the anaesthesiologist must be guided by inference from data obtained in adults. For example, oral

midazolam premedication is administered primarily to children. In adults taking phenytoin and carbamazepine both the plasma concentration and effect of oral midazolam are greatly reduced by induction of cytochrome enzymes [75] but data to confirm a similar effect in children are not available. Additional differences between children and adults that affect anaesthetic management for intracranial procedures for treatment of epilepsy are differences in the range of cerebral autoregulation, a greater likelihood of haemodynamically significant blood loss during craniotomy in children, a greater risk of intraoperative hypothermia in children, and differences in cognitive and emotional maturity.

Anaesthesiologists providing care for infants and children are more likely than those caring for adults to encounter patients on the ketogenic diet because the efficacy of this therapy is more clearly established in the paediatric population. Furthermore, the just-published results of a clinical trial that confirmed effective seizure reduction make it likely that anaesthesiologists will encounter more children on the diet in the future [76]. Although limited, some information is available to guide perioperative anaesthesia care [77–79]. A retrospective review of nine children (aged 1–6 years) on the diet, who received general anaesthesia (duration 20 min to 11.5 h) with carbohydrate restriction, found that although serum glucose levels remained stable there was a tendency to metabolic acidosis, particularly in longer procedures [78]. If the ketogenic diet is to be maintained perioperatively it is important to recognize that carbohydrates in liquid medications and chewable tablets and some blood products may be sufficient to reverse the ketogenic state. Also, as it is postulated that inadequate carbohydrate intake may be a predisposing factor for propofol infusion syndrome, the decision to maintain the diet may influence choice of anaesthetic for maintenance, and anaesthetic maintenance requirements might influence the decision to maintain the diet [80]. With attention to these metabolic and pharmacological nuances it appears that children on the ketogenic diet can safely undergo anaesthesia, even for prolonged procedures. Perioperative management should include measurement of electrolytes, serum albumin and calcium, which may be reduced, as well as repeated assessment of acid–base status and measurement of ketones and blood glucose levels. The ketone bodies beta-hydroxybutyric acid and acetone produce anaesthesia in animals [21]. Whether the ketosis in patients on the ketogenic diet affects requirements for anaesthesia has not been determined.

A number of syndromes are associated with intractable seizures in children. Syndrome-associated co-morbidities that may influence anaesthetic management include developmental delay and behaviour disturbance in children with Lennox–Gastaut syndrome, and developmental delay and angiomas of the central nervous system, mouth and airway in children with Sturge–Weber syndrome [81,82]. Children with tuberous sclerosis may have tuberous lesions in the heart (rhabdomyomas), kidneys and airway as well as the brain, with potential for a gamut of problems including renal dysfunction, lesion-related obstruction of blood flow, conduction disturbance, dysrhythmia and problems with airway management [83].

Awake intraoperative functional brain mapping and electrocorticography are not feasible in infants and many children. Thus, delineation of seizure foci by electrocorticography before cortical resection in infants and children is most often performed extraoperatively after craniotomy and placement of subdural grids or intraoperatively under general anaesthesia. Although the procedure is widely performed in this manner, the optimal anaesthetic for electrocorticography in children is not established. However, in a series of children with neocortical epilepsy the interictal spike frequency, although decreased by general anaesthesia with isoflurane (0.5–1%), reflected the awake interictal spiking pattern when intraoperative spike frequency was greater than one spike per minute [44]. At the author's institution, the protocol for general anaesthesia for electrocorticography during seizure surgery in infants and children is a combination of nitrous oxide, narcotic and inhalation anaesthesia. Pin sites and scalp around the planned incision are injected with local anaesthesia to minimize painful stimuli during light anaesthesia. Inhalation anaesthetics are discontinued and minimal end-tidal concentration is confirmed before commencing electrocorticography.

In older children and adolescents, awake intraoperative electrocorticography and awake intraoperative functional mapping are possible in carefully selected patients. Awake craniotomy has been reported in children as young as 9 years old [83]. Extensive preoperative counselling has been recommended. Adequate conditions for craniotomy with awake intraoperative brain mapping in children and adolescents undergoing epilepsy surgery with deep sedation and asleep–awake–asleep techniques with various anaesthetic agents including propofol and dexmedetomidine are reported [40,59,74,84].

The most common surgical procedures performed for the treatment of intractable seizures in the paediatric population are lobar and focal resections of the frontal and temporal lobes, followed by cerebral hemispherectomy and vagus nerve stimulator placement [85]. Cerebral hemispherectomy and placement of vagal nerve stimulator have some specific implications for anaesthesia management that warrant further elaboration.

Blood loss is the major issue for the anaesthetic management of cerebral hemispherectomy. The procedure is performed in infants and small children, who are at greater risk of haemodynamically significant blood loss during craniotomy than older children and adults. Frequent instances of marked precipitous blood loss, severe hypotension, coagulopathy, hypokalaemia and hypothermia have been described [86], as well as intraoperative demise due to uncontrollable bleeding. Although evolution of surgical technique has reduced the overall risk of these procedures, blood loss remains a major issue, with reported intraoperative blood loss greater than one blood volume in 25–50% of patients depending on hemispherectomy technique [87]. Safe conduct of anaesthesia requires excellent venous access and arterial pressure monitoring. At the author's institution central venous pressure monitoring, often via femoral venous catheters, is also frequently used, but practices vary. Blood products should be available in the operating theatre at the time of incision. In this and other intracranial procedures in children blood loss is difficult to gauge. The combined assessment of the several available haemodynamic parameters and serial blood sampling is required to guide fluid and blood product administration. Dilutional coagulopathy is predictable with blood loss in excess of one blood volume, and serial platelet counts, fibrinogen, partial thromboplastin time and prothrombin time are followed during the procedure to assess the need for component blood products, including

fresh-frozen plasma, cryoprecipitate and platelets. Even with blood loss that is less substantial, coagulation parameters should be checked intraoperatively to rule out a developing coagulopathy related to brain injury. Acid–base balance as well as P_aCO_2, P_aO_2, electrolytes and glucose should also be monitored at intervals during volume resuscitation. Loading doses of AEDs intended for postoperative seizure prophylaxis are given at the end of the surgical procedure so that drug levels are not reduced by ongoing haemorrhage. In our current practice the endotracheal tube is removed in the operating theatre in the majority of cases.

Vagal nerve stimulation is a new treatment modality for children and adults with seizures that are refractory to medical therapy. The vagal nerve stimulator device is placed during a surgical procedure that, in children, is performed under general anaesthesia. The device, about the size of a hockey puck, is positioned subcutaneously on the left chest in a manner similar to a cardiac pacemaker. The patient is positioned with the head turned to the right, a neck dissection is performed, and electrodes from the stimulator are wrapped around the mid-cervical left vagus nerve distal to branches to the atrioventicular node. Considerations, as outline above, for general anaesthesia in patients with chronic seizure disorders apply. If tested in the operating theatre under general anaesthesia, the absence of neuromuscular blockade allows for phrenic nerve stimulation to be detected on the capnograph waveform. Severe bradycardia leading to reversible asystole has been reported in 0.1% of device tests performed immediately after implementation [88]. Postoperative complications, which are uncommon, include unilateral vocal cord paralysis, which usually resolves over a period of weeks reported in 1% of cases, lower facial muscle paralysis, neck haematoma and airway compromise [89]. Chronic vagal nerve stimulation may cause a decline in respiratory function in patients with pulmonary disease and worsen symptoms of obstructive sleep apnoea [88].

Conclusion

Anaesthesia for epilepsy surgery describes a broad range of clinical situations and procedures. Each patient presents with a unique combination of neuropathology, medical conditions, concurrent pharmacological therapy and psychology. The best possible approach to anaesthetic management for many aspects of epilepsy surgery has not been defined. Clearly, a single recipe for success is not available. However, an understanding of the information available regarding the potential for anaesthetic agents to modulate seizure activity, the potential interactions between anaesthetic agents and drugs used in the treatment of epilepsy, and the particular requirements of the surgical procedure to be performed puts the anaesthesia team in the best position to contribute effectively to the multidisciplinary group working together to provide our patients with the maximum potential benefit of epilepsy surgery.

81 Vagal Nerve Stimulation

Steven C. Schachter
Harvard Medical School, Boston, MA, USA

Introduction

Despite the availability of numerous antiepileptic drugs (AEDs), seizures in many patients with epilepsy remain refractory to medical therapy at maximum tolerated dosages. Vagal nerve stimulation (VNS) (VNS Therapy™ System; Cyberonics, Houston, TX, USA) is a non-pharmacological antiepileptic therapy that was approved in 1997 by the US Food and Drug Administration for use as adjunctive therapy in reducing the frequency of seizures in adults and adolescents over 12 years of age with partial-onset seizures that are refractory to antiepileptic medications. VNS is also approved in numerous European Union countries for use in reducing the frequency of seizures in patients of any age whose epileptic disorder is dominated by partial seizures (with and without secondary generalization) or generalized seizures. As of June 2008, over 45 000 patients with epilepsy have been treated with VNS therapy (http://www.vnstherapy.com/Epilepsy/hcp/forsurgeons/implantedcomponents.aspx – accessed 6 June 2008).

Practical aspects

The VNS Therapy pulse generator, which is usually implanted in the patient's upper left chest, is powered by a lithium carbon monofluoride battery that produces charge-balanced waveforms at constant current. The latest single-pin version of the hermetically sealed titanium generator weighs 16 g and is 45 mm × 32 mm × 6.9 mm in dimension.

Before the operation is completed, diagnostic tests are performed to check the system for proper operation. At most centres, the generator's output current is then set to 0 mA for the first 2 postoperative weeks, after which ramping up of the output current is initiated. Other centres begin stimulation within the first postoperative day.

Clinicians set the parameters for automatic stimulation via computer software, which are then transmitted by the programming wand using radiofrequency signals to the generator (Table 81.1). Parameter settings for magnet-activated on-demand stimulation are also programmable. The wand is further used to perform diagnostic checks of wand–generator communications, lead impedance, programmed current and an estimation of the remaining generator battery life.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

The ramp-up procedure and settings for chronic, intermittent stimulation are individualized according to patient tolerance and clinical response. Besides intermittent stimulation, on-demand stimulation is achieved by the patient or a companion placing the supplied magnet on the patient's chest over the generator for several seconds. The stimulator settings used for on-demand stimulation usually utilize a higher current and pulse width than those used for intermittent stimulation. Some patients have reported that on-demand stimulation interrupts a seizure or reduces its severity and/or duration, particularly if applied during the early phase of the seizure [1]. Stimulation can be stopped temporarily by securing the supplied magnet over the device with tape or by inserting the magnet in an athletic bra over the generator. This may be necessary, for example, if the patient wants to avoid hoarseness while speaking, during eating if pre-existing dysphagia is present, during intense exercise if the patient experiences dyspnoea while exercising or at night if either stimulation-related discomfort or an exacerbation of sleep apnoea occurs.

The latest generator is estimated to provide 6 or more years of operation, assuming typical stimulation parameters, after which it can be replaced with a minor procedure performed under local anaesthesia.

Actions of vagal nerve stimulation and efficacy in animal models of epilepsy

Anatomy

The vagal nerve is a mixed nerve with regard to fibre size and direction of nerve transmission. Most vagal fibres are small-diameter unmyelinated C fibres; the rest are intermediate-diameter myelinated B fibres and large-diameter myelinated A fibres. Just as for other peripheral nerves, there are direct relationships between vagal fibre diameter and conduction velocity, and between fibre diameter and stimulation threshold. The threshold for C fibre activation is 10–100 times higher than for A fibre activation.

Special visceral vagal efferents innervate the pharynx and the larynx, the latter via the recurrent laryngeal branches of the vagal nerve. The general visceral efferents supply parasympathetic innervation to the heart (resulting in slowing of the heart rate), lungs (bronchial constriction and pulmonary secretions) and gastrointestinal tract (increased peristalsis and secretions).

Sensory vagal afferents constitute 80% of vagal fibres and transmit visceral sensation from the head, neck, thorax and abdomen. The cell bodies of the vagal nerve in the nodose ganglion project to the nucleus of the solitary tract (NTS). The NTS,

Table 81.1 Available stimulation parameter settings (Model 103 VNS Therapy).

Stimulation parameter	Available settings
Output current	0–3.5 mA in 0.25-mA steps ≤1 mA, ±10% > 1 mA
Signal frequency	1, 2, 5, 10, 15, 20, 25, 30 Hz ± 6%
Pulse width	130, 250, 500, 750, 1000 μs ± 10%
Signal on time	7, 14, 21, 30, 60 s ± 15% or ± 7 s
Signal off time	0.2, 0.3, 0.5, 0.8, 1.1, 1.8, 3 min, and 5–180 min (5–60 min in 5-min steps; 60–180 min in 30-min steps) +4.4/–8.4 s or ±1%, whichever is greater

in turn, projects to autonomic preganglionic and related somatic motor neurones in the medulla and spinal cord, and to the medullary reticular formation and the forebrain [2].

Most NTS output is relayed via the parabrachial nucleus (PBN), located in the dorsal pons lateral to the locus coeruleus, which sends efferents to the hypothalamus as well as the amygdala and orbitofrontal cortex [2]. The PBN has direct input to several thalamic nuclei, including the ventroposterior parvocellular nucleus, which relays visceral sensation to the insular cortex and the intralaminar nuclei of the thalamus, which have widespread effects on cortical activity. Both the PBN and the NTS project to the hypothalamus, amygdala and basal forebrain. The lateral hypothalamus and basal forebrain, in turn, project diffusely to the cerebral cortex and influence overall cortical activity [2].

Mechanism of action

The possible mechanism(s) of action of VNS are discussed elsewhere [2] and are clearly different from those known to be associated with pharmacotherapy, such as effects on neuronal membrane ionic conductance or neurotransmitters and their receptors. It is not clear, however, which of the observed effects are related to the anticonvulsant mechanism of action of VNS. Nevertheless, there are emerging clues. Krahl *et al*. [3] showed that chemical lesions of the locus coeruleus eliminated VNS-induced seizure suppression in rats, suggesting that the locus coeruleus is critically involved in the mechanism of action of VNS, possibly through the release of noradrenaline [3]. Furthermore, because increased γ-aminobutyric acid (GABA) transmission or decreased glutamate transmission in the rat mediocaudal NTS reduces susceptibility to limbic motor seizures [4], it is reasonable to hypothesize that VNS inhibits the rat NTS. The functional interrelationships between VNS, the locus coeruleus and NTS inhibition remain to be elucidated.

A study of transcranial magnetic stimulation in five patients treated with VNS for epilepsy showed significantly increased cortical inhibition associated with stimulation without any evidence of an effect on cortical excitability [5]. Further, in a limited series of patients whose seizures responded to VNS, Marrosu *et al*. [6] found normalization of impaired neuronal inhibition.

Animal studies

Vagal nerve stimulation has been investigated in a number of animal models of epilepsy. In most of these studies, stimulation was applied just before or immediately after the onset of a seizure [7–9]. Other studies evaluated the relationship between cumulative duration of vagal stimulation and seizure prophylaxis [10,11].

In male rats, VNS prevented or reduced clonic seizures that were induced by intraperitoneal pentylenetetrazole (PTZ) and 3-mercaptopropionic acid (an inhibitor of GABA synthesis and release), as well as tonic–clonic seizures caused by maximal electroshock [8], especially with stimulus frequencies and pulse widths of 10–20 Hz and 0.5–1 ms, respectively. In this model, the effectiveness of VNS directly correlated with the fraction of C fibres stimulated, consistent with another study in male rats that showed that penicillin-induced focal interictal spikes in male rats were reduced by 33% by direct C fibre stimulation [7]. Effectiveness also correlated inversely with the delay of stimulus from seizure onset – the greater the delay before vagal stimulation, the greater the seizure duration; therefore, stimulation worked best when applied as soon as possible after a seizure began.

In a dog model of strychnine-induced generalized seizures and PTZ-induced muscle tremors, VNS stopped seizures and tremors within 0.5–5 s when acutely applied [9]. Furthermore, VNS protected against seizures for a period that was four times longer than the duration of stimulation. Stimulation frequencies of over 60 Hz were less effective than slower frequencies, consistent with other studies [8].

In a study of both the acute and prophylactic effects of on-demand and intermittent vagal stimulation, VNS was administered at the onset of each spontaneous seizure or at least every 3 h for 40 s in an alumina-gel monkey model of spontaneous partial and secondarily generalized seizures [11]. Seizures were completely controlled in two out of four monkeys and decreased in frequency in the other two. Furthermore, the prophylactic anticonvulsant effect persisted into a stimulation-free period. No diminishment of interictal spike frequency was observed.

Takaya *et al*. [10] demonstrated that VNS protected against experimentally induced seizures even when discontinued before seizure onset. The anticonvulsant effect was nearly half-maximal 5 min after VNS was discontinued. In addition, they showed that 60 min of continuous VNS protected awake and freely moving rats from PTZ-induced seizures more effectively than 60 min of intermittent VNS with the same stimulation settings, and that intermittent stimulation was more effective than a single 1-min stimulus. Although it is impractical to apply continuous electrical stimulation to the vagal nerve due to safety considerations and limitations in battery life, these results suggest that the stimulation parameters used to treat seizures in humans are reasonable.

In cats, VNS applied during amygdaloid kindling significantly delayed the onset of seizures compared with control subjects and prevented the attainment of stage VI (generalized tonic–clonic convulsive seizures) [12]. The relevance of these results to patients with epilepsy is uncertain. Finally, a recent report in Genetic Absence Epilepsy Rats from Strasbourg showed no effect of VNS [13].

Epilepsy efficacy studies

The first pivotal trial of VNS was the E03 study, a multicentre, double-blind, randomized, parallel, active control trial of VNS in 114 patients with predominantly partial seizures [14–16]. The

second pivotal clinical study was the E05 study, a multicentre, double-blind, randomized, parallel, active control trial of VNS in 199 patients with complex partial seizures [17]. In 1991, a compassionate-use trial enrolled 124 patients with all types of intractable seizures (the E04 study) [18].

The E03 and E05 studies

Study designs

The E03 and E05 studies compared two different VNS stimulation protocols: high stimulation (30 Hz, 30 s on, 5 min off, 500-ms pulse width) and low stimulation (1 Hz, 30 s on, 90–180 min off, 130-ms pulse width). Low-stimulation treatment was expected to be less effective than high-stimulation treatment.

Study candidates were monitored over a 12- to 16-week prospective baseline period, during which seizures were counted and changes in AED dosages were allowed only to maintain appropriate concentrations or in response to drug toxicity. Patients who satisfied all inclusion and exclusion criteria were then implanted with the VNS system. Two weeks later, patients were randomized to receive either high or low stimulation. Over the following 2 weeks, patients randomized to the high-stimulation group had their generator output current increased as high as tolerated, whereas those randomized to the low group had the current increased until stimulation could be perceived. Efficacy was then assessed during the remaining 12 weeks of the treatment phase. At the conclusion of the study, patients were eligible to enter long-term open studies.

Enrolment information

Participants in the E03 and E05 studies were at least 12 years old, had at least six seizures per month during the baseline period, and were taking one to three AEDs. In the E05 study, patients had to have partial seizures with alteration of consciousness.

In the E03 study, 125 patients participated; 114 completed the prospective baseline and were implanted. The average duration of epilepsy was 23 years for patients in the high group ($n = 54$) and 20 years for the low group ($n = 60$). Patients in both groups were taking a mean of 2.1 AEDs at study entry.

There were 254 participants in the E05 study; 55 discontinued from baseline for failing protocol eligibility and 199 were implanted. One patient was not randomized due to device infection, and two randomized patients (one in each treatment group) were excluded from the analysis for administrative reasons. The baseline characteristics for patients in both groups were similar and consistent with the E03 study.

Results

In both studies, the primary efficacy analysis was percentage change in total seizure frequency during treatment relative to baseline, comparing the high- and low-stimulation groups. In the E03 study, the high-stimulation group had a mean reduction in seizure frequency of 24.5% versus 6.1% for the low-stimulation group ($P = 0.01$). In the E05 study, the mean percentage decreases in seizure frequency during treatment compared with baseline were 28% and 15% for the high- and low-stimulation groups, respectively. The between-group comparison was statistically significant in favour of high stimulation ($P = 0.039$).

Secondary efficacy measures in both studies showed statistically significant effects in favour of high stimulation. In the E03 study, 31% of patients in the high-stimulation group had at least 50% reduction in seizures compared with 13% of patients in the low-stimulation group ($P = 0.02$). In the E05 study, 11% of patients in the high-stimulation group had a reduction in seizure frequency greater than 75% versus 2% for patients in the low-stimulation group ($P = 0.01$). In addition, both the high- and the low-stimulation groups showed a statistically and clinically significant difference in within-group mean percentage change in seizure frequency during treatment compared with baseline ($P < 0.0001$).

Long-term efficacy

DeGiorgio *et al*. [19] prospectively evaluated seizure frequencies during a 12-month period in patients who had completed the E05 study, including patients who had been randomized to low stimulation during the E05 study but were then transitioned to high-stimulation settings as tolerated. The primary efficacy variable was the percentage change in total seizure frequency at 3 and 12 months compared with the 3-month preimplantation baseline. The median seizure reductions at 3 and 12 months were 34% and 45%, respectively ($P = 0.0001$, 12 months versus 3 months). In addition, one out of five patients had at least 75% or greater reduction in seizure frequency at 12 months. Retrospective analysis of changes in stimulation parameters showed that device changes were not the predominant predictor of increased efficacy after 12 months [20].

In a prospective study of 21 patients treated with VNS for a mean duration of 13.2 months, Tatum *et al*. [21] showed that reductions in numbers or dosages of AEDs without loss of seizure control and with improved patient satisfaction were possible in 15 (71%) [21]. In addition, seven patients were able to discontinue psychotropic drugs.

Other efficacy studies in epilepsy

Labar *et al*. [18] reported on 24 patients with medication-resistant generalized seizures and only generalized epileptiform activity or generalized EEG slowing. Epilepsy was idiopathic in seven patients and symptomatic in the remaining 17. Median seizure frequency was reduced by 46% after 3 months of stimulation compared with a 1-month baseline. Eleven patients had at least a 50% reduction in seizure frequency. The best responses to VNS occurred in patients with high baseline seizure rates and later ages of seizure onset.

Hosain *et al*. [22] studied 13 patients with Lennox–Gastaut syndrome (age range 4–44 years, mean 16.7 years) and found a median seizure rate reduction of 52% during the first 6 months of treatment (range 0–93%, $P = 0.04$) [22]. After 6 months of treatment, three patients had >90% reduction in seizures, two had >75% reduction and one had >50% reduction. No patient had a worsening of seizure frequency. Other anecdotal reports in patients with Lennox–Gastaut syndrome are similarly encouraging [23,24].

Among 12 children aged 4–16 years with medically and surgically refractory seizures who were treated with VNS, five patients had a greater than 90% reduction in seizure frequency and four patients were able to reduce the number of AEDs used

[25]. In another series of 16 children aged 4–19 years, six children experienced at least a 50% reduction in seizure frequency during the tenth to twelfth months of VNS [26].

Sixteen children with epileptic encephalopathy were treated with VNS and prospectively studied for changes in seizure frequency, EEG, adaptive behaviour, quality of life (QOL) and language performance [27]. One device was explanted due to infection. Of the remaining 15 children, four had at least 50% seizure reduction at 1 year after implant; conversely, two had at least a 50% increase in seizure frequency. Perceived treatment side-effects and general behaviour improved and in six children there was significant improvement in verbal performance that did not correlate with changes in seizure frequency.

Vagal nerve stimulation was studied in 60 children aged 3–18 years with pharmacoresistant epilepsy; 27% of these children had generalized tonic–clonic seizures [28]. After 6 months of VNS treatment ($n = 55$), the median reduction in seizure frequency was 31%. The corresponding figures at 12 and 18 months were 34% ($n = 51$) and 42% ($n = 46$), respectively. None of the adverse events required discontinuation of stimulation. Patwardhan *et al*. [29] reported reductions in atonic (80%), absence (65%), complex partial (48%) and generalized tonic–clonic (45%) seizures in an uncontrolled study of 38 children with a median follow-up period of 12 months (range 10–18 months) [29].

Six children under the age of 3 years with catastrophic epilepsy were treated with VNS and had a mean follow-up period of 42 months [30]. Four had a persistent improvement in seizure control, ranging from 60% to 90%.

Sirven *et al*. [31] studied the efficacy, safety and tolerability of VNS for refractory epilepsy in 45 adults who were 50 years of age and older [31]. After 3 months of treatment, 12 patients had a >50% decrease in seizure frequency; at 1 year, 21 out of 31 patients had >50% reduction. Side-effects were mild and transient, and QOL scores improved significantly during the first year of treatment.

Safety and tolerability of vagal nerve stimulation

The E03 and E05 studies

In the E03 study, safety and tolerability were evaluated with interviews, physical and neurological examinations, vital signs, electrocardiogram rhythm strips, Holter monitoring in a subset of 28 patients, gastric acid monitoring in 14 patients and AED concentrations. Similarly, safety and tolerability were evaluated in the E05 study with interviews, physical and neurological examinations, vital signs, Holter monitoring, pulmonary function tests, standard laboratory tests and urinalysis.

In the E03 study, the adverse events (side-effects) that occurred in at least 5% of patients in the high-stimulation group during treatment were hoarseness (37%), throat pain (11%), coughing (7%), dyspnoea (6%), paraesthesia (6%) and muscle pain (6%). Hoarseness was the only adverse event that was reported significantly more often with high stimulation than with low stimulation.

Table 81.2 Treatment-phase adverse events among patients treated with low or high stimulation in the E05 study [17].

Adverse event (*n*, %)	Low stimulation ($n = 103$)	High stimulation ($n = 95$)
Voice alteration	31 (30.1)	63 (66.3)
Cough	44 (42.7)	43 (45.3)
Pharyngitis	26 (25.2)	33 (34.7)
Pain	31 (30.1)	27 (28.4)
Dyspnoea	11 (10.7)	24 (25.3)
Headache	24 (23.3)	23 (24.2)
Dyspepsia	13 (12.6)	17 (17.9)
Vomiting	14 (13.6)	17 (17.9)
Paraesthesia	26 (25.2)	17 (17.9)
Nausea	21 (20.4)	14 (14.7)
Accidental injury	13 (12.6)	12 (12.6)
Fever	19 (18.4)	11 (11.6)
Infection	12 (11.7)	11 (11.6)

Only adverse events that occurred in more than 10% of high-stimulation patients are listed.

In the E05 study, none of the serious adverse events that occurred during the treatment phase was judged to be probably or definitely due to VNS. Implantation-related adverse events all resolved and included left vocal cord paralysis (two patients), lower facial muscle paresis (two patients), and pain and fluid accumulation over the generator requiring aspiration (one patient). The perioperative adverse events that were reported by 10% or more patients included pain (29%), coughing (14%), voice alteration (13%), chest pain (12%) and nausea (10%). Following randomization, the adverse events that were reported by patients in the high-stimulation group at some time during treatment and which were significantly increased compared with baseline were voice alteration/hoarseness, cough, throat pain, non-specific pain, dyspnoea, paraesthesia, dyspepsia, vomiting and infection (Table 81.2). The only two adverse events that occurred significantly more often in the high-stimulation group than the low-stimulation group were dyspnoea and voice alteration. Adverse events in both treatment groups were rated as mild or moderate 99% of the time. There were no sedative, visual, affective or coordination side-effects, or any cognitive changes. No significant changes in Holter monitoring or pulmonary function tests were noted.

Two E05 patients had VNS discontinued during the treatment. One patient in the high-stimulation group had two episodes of Cheyne–Stokes respirations postictally; after the device was deactivated, two more episodes were reported and the patient's mother requested that the device be reactivated. One patient in the low-stimulation group had the device deactivated due to a group of symptoms that the patient had experienced preimplantation as well as subsequent to device deactivation. No deaths occurred during either study.

As would be predicted from a non-pharmacological therapy, there were no changes in haematology values or common chemistry values in either study. Similarly, no changes in AED concentrations were seen.

Long-term safety and tolerability

Among a cohort of 444 patients who entered a long-term trial following participation in a short-term clinical study of VNS,

97% continued for at least 1 year, and 85% and 72% continued for at least 2 and 3 years, respectively [32]. The most commonly reported side-effects at the end of the first year of VNS were hoarseness (29%) and paraesthesia (12%); at the end of 2 years the most often reported side-effects were hoarseness (19%) and cough (6%), and at 3 years shortness of breath (3%) was the most frequently reported side-effect.

Hoppe *et al*. [33] studied cognition in 36 adult patients before and at least 6 months after implantation using tests of attention, motor functioning, short-term memory, learning and memory, and executive functions. No evidence of cognitive worsening was found.

The mortality rates and standardized mortality ratios of 1819 patients treated for 3176 person-years with VNS were contrasted with other epilepsy cohorts [34]. These rates and ratios were similar to those of other young adults with refractory seizures who were not treated with VNS. Additionally, the incidence of definite and probable sudden unexpected death in epilepsy (SUDEP) was 4.1 per 1000 person-years, which was consistent with other non-VNS epilepsy cohorts. Interestingly, the rate of SUDEP was 5.5 per 1000 over the first 2 years of VNS treatment, and 1.7 per 1000 thereafter.

Cardiac arrhythmias attributable to VNS in patients undergoing chronic stimulation have not been described, although Frei and Osorio [35] reported changes in heart rate and heart rate variability in a study of five subjects. In another study, high-strength stimulation produced no observable acute cardiorespiratory effects [36].

The possible relationship of VNS to swallowing difficulties was studied by barium swallow in a series of eight children [37]. Laryngeal penetration of barium was present in three patients without stimulation, and was caused by VNS in one other patient. Results from another small series of children treated with chronic VNS suggest that some children with severe neurological deficits who are dependent on assisted feeding may be at increased risk for aspiration if VNS occurs during feeding [38].

Anecdotal reports in the literature of complications of VNS have appeared as the number of patients treated with VNS has grown [2,39]. These reports include transient asystole lasting up to 20 s (approximately 0.1% of all implantations) during the intraoperative lead test [40–42]. The intraoperative lead test assesses stimulation function and system integrity by turning on the generator briefly at 1.0 mA, 500 μs and 20 Hz. Four patients had the device acutely explanted, whereas the others were chronically stimulated without difficulty. There were no sequelae in any of the patients.

As the VNS generator battery becomes expended, seizure frequency may increase in some patients [43] and others may note decreased or irregular perception of stimulation [44]. The end of battery service can be predicted with the current VNS model, allowing for elective generator replacement before the battery is fully depleted in those patients for whom VNS has been beneficial.

In a 2001 safety alert, the manufacturer cautioned against the use of short-wave diathermy, microwave diathermy or therapeutic ultrasound diathermy in patients implanted with the VNS Therapy system due to the possibility that the generator or lead could become hot and cause tissue damage or discomfort. At the time of the alert, there had been no reports of injuries related to these modalities in patients treated with VNS. Diagnostic ultrasound was not mentioned.

Clinical use of vagal nerve stimulation for epilepsy

Successful clinical implementation of VNS requires a team approach to implant the device, teach the patient and his/her family about its use, titrate the stimulation parameters to optimum clinical response, and monitor the patient's side-effects and the device's remaining battery life. Before implantation, patients should be counselled about the likely necessity of ongoing AED treatment, the possible delay in onset of efficacy and use of the supplied magnet to activate and turn off the generator.

Usual target stimulation parameters are shown in Table 81.3. Ramping up of the device typically occurs at outpatient follow-up visits every 1–2 weeks over the several months after implantation. At these visits, the current is usually increased by 0.25-mA increments to the maximum tolerated settings or until reduction in seizure frequency exceeds 50% compared with the pre-implantation baseline. If side-effects become intolerable or do not resolve following a change of stimulation parameters then the current is reduced by 0.25-mA increments as necessary. Reducing the pulse width may also improve tolerability [45].

If a patient's seizures have not satisfactorily improved with regard to frequency or severity after 6–9 months of stimulation, most clinicians would shorten the off time from 5 to 3 min. Subsequent staged reductions of the off time to 1.8 min and 0.2 min (with an associated decrease of on time to 7 s – 'rapid cycle') have been tried with success in some patients [46].

A minority of patients have the device explanted because of lack of sufficient efficacy. Based on the long-term efficacy studies it appears prudent to wait at least 12–18 months before deciding to remove the generator. Once the decision is made, the generator should first be turned off for several weeks or longer depending on the patient's preimplantation seizure frequency. If seizures then worsen for no other apparent reason it may be surmised that the device may have actually been efficacious for that particular patient and device removal should be reconsidered.

Explantation can be performed as an outpatient procedure under local anaesthesia. Because dissecting the helical coils off the vagal nerve is laborious and there are no reported complications of leaving them in place, most surgeons do not explore and

Table 81.3 Usual initial target stimulation parameters for VNS stimulation in patients with epilepsy.

Stimulation parameter	Setting
Output current	1.5 mA
Signal frequency	20–30 Hz
Pulse width	250–500 μs
Signal on time	30 s
Signal off time	5 min

remove the stimulating electrodes during the explantation procedure.

The application of VNS therapy will be enhanced once a measurable physiological response to VNS is identified that can be used to 'titrate' stimulation. In this regard, Koo *et al*. [47] used EEG findings at 6 months post implantation, including clustering and synchronization of epileptiform activity, to guide, with impressive results, further VNS programming in 20 patients [47].

Epileptologists generally consider VNS therapy as an option for patients (a) whose partial-onset seizures adversely affect QOL despite trials with three or more AEDs that are appropriate for partial seizures and that have been titrated to maximally tolerated doses and (b) who do not have surgically remediable partial seizures or who may, but are unwilling to undergo an intracranial procedure. The use of VNS in patients with generalized epilepsies at the present time is supported only by open, uncontrolled studies, although results are promising.

Conclusion

Vagal nerve stimulation is effective, safe and well tolerated in patients with long-standing, refractory partial-onset seizures [48], and may be beneficial to patients with other forms of epilepsy. There has been no indication of tolerance to therapeutic effect in long-term, open studies. Efficacy results for other seizure types and in children and the elderly are encouraging but are based on open studies or anecdotal experience.

Relatively few patients with medically resistant epilepsy become seizure free with VNS. There are suggestions that efficacy and QOL further improve over time [19,21,49–51], although published outcomes in long-term, open, unblinded studies should be interpreted cautiously. Given the possibility that efficacy may be delayed following implantation, it is prudent to wait at least 1 year, if not longer, before tentatively concluding that VNS has had no effect on seizure frequency or severity.

The most frequently encountered side-effects occur during the period of stimulation are usually mild to moderate in severity and resolve with reduction in current intensity or pulse width or spontaneously over time. Conspicuously absent with VNS stimulation therapy are the typical central nervous system side-effects of AEDs. Pending further studies, caution may be warranted when recommending VNS for patients with dysphagia, sleep apnoea and cardiac conduction disorders.

Further controlled studies should be performed to explore the use of VNS for generalized seizures and epilepsy syndromes. Additional controlled studies are also needed to determine (a) how VNS therapy can be individualized to maximize its effectiveness, either with intermittent stimulation or acutely with on-demand stimulation, perhaps triggered by automated seizure detection [52]; (b) whether VNS complements AEDs or non-AEDs with particular mechanisms of action; (c) how to prospectively identify patients who are most likely to benefit from VNS; and (d) the efficacy and tolerability of adjunctive VNS compared with adjunctive AED therapy, particularly early in the course of epilepsy.

82 Brain Stimulation

Gregory K. Bergey
Johns Hopkins University School of Medicine, Baltimore, MD, USA

Introduction

Neurostimulation in the treatment of epilepsy involves stimulation of the brain or associated structures (e.g. vagus nerve). The goal of neurostimulation is to prevent seizures or reduce seizure frequency. Vagus nerve stimulation (VNS), currently the only Food and Drug Administration (FDA)-approved method of neurostimulation for the treatment of epilepsy, is the topic of the preceding chapter. VNS will not be discussed in detail here; the failure of VNS therapy to produce high rates of seizure freedom or responder rates much different than new antiepileptic drugs (AEDs) has stimulated the search for other methods and targets of neurostimulation for epilepsy treatment. VNS therapy has demonstrated that neurostimulation therapy avoids medication side-effects (e.g. cognitive) and is generally well tolerated. Although the actual mechanism of action of VNS and other neurostimulation therapy remains to be defined, it is generally thought that neurostimulation acts by different mechanisms from AED therapy.

Vagus nerve stimulation therapy provides extracranial stimulation of the tenth cranial nerve and its influences on epileptic seizures are via polysynaptic brainstem pathways with broad cerebral influences [1]. Although this offers the potential of cerebral neuromodulation, more recent efforts with neurostimulation have targeted intracranial structures in the hope that direct stimulation of intracranial regions, either with chronic or with intermittent stimulation paradigms, would be more effective than VNS. These intracranial targets for neurostimulation are discussed below.

There are several potential concerns about directly stimulating the human brain. As epileptic seizures represent increased excitatory activity, there are potential concerns that externally delivered excitatory stimuli may either be ineffective or possibly even cause seizures. Stimulation of subdural grid contacts in patients who are undergoing presurgical evaluations can, on occasion, trigger afterdischarges that may produce clinical manifestations [2]. The question as to whether direct stimulation of some human brain regions (e.g. hippocampus) could kindle the brain has been raised but not demonstrated. Unless the stimulating electrode is contacting a pain-sensitive structure (e.g. dura), chronic or responsive neurostimulation of intracranial structures produces no discomfort and indeed is typically not noticed by the patient. VNS therapy may produce some discomfort, although this typically is minimized with slow introduction of therapy over time [3].

Concept and requirements for programmed or chronic stimulation

The concept of neurostimulation in the treatment of epileptic seizures is based on two separate hypotheses that reflect the two basic types of stimulation. 'Chronic' or 'programmed' stimulation, somewhat like that used with the VNS but directed to other targets (e.g. hippocampus, thalamus), is hoped to provide modulation that will reduce the frequency of epileptic seizures. The mechanisms for the potential benefits of neurostimulation-induced neuromodulation are not established but one concept is that such stimulation may directly or indirectly reduce background synchrony. The normal brain has synchronous activity; indeed, all waveforms seen on the normal electroencephalogram (EEG) reflect synchronous cerebral activity – synchronous brain activity is not intrinsically undesirable. What is undesirable is the transition to abnormal synchronous activity that produces altered awareness and responsiveness (e.g. a complex partial or generalized seizure). Whether the transition to abnormal synchronous activity seen in a seizure is a gradual one or an abrupt state change is still unresolved, but desirable antiepileptic therapy, whether medical or neurostimulation, would reduce or prevent these transitions.

Reduced background synchrony could conceivably reduce or prevent the onset of partial seizures or affect the subsequent network recruitment and reduce or prevent secondarily generalized seizures. Although clinical trials of neurostimulation have been directed to treatment of partial seizures, conceivably thalamic or other deep brain stimulation (DBS) could benefit primary generalized seizures. Primary generalized seizures, however, are often readily controlled with medication, whereas only <50% of patients with remote symptomatic partial seizures have their seizures controlled with available therapies [4].

Chronic or programmed stimulation typically utilizes an open-loop system and as such the hardware requirements are much less sophisticated than with closed-loop systems (Table 82.1). The stimulating electrodes are placed in the target site (e.g. anterior thalamus) using stereotactic guidance and the electrodes are connected to the battery-operated stimulating device, which can be placed remote from the site of stimulation. Much of the experience with chronic stimulation devices is derived from the use of high-frequency DBS in movement disorders, both the treatment of tremor (essential and parkinsonian) and the motor fluctuations

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel

Table 82.1 Characteristics of neurostimulation for epilepsy treatment

Chronic stimulation	Responsive stimulation
External stimulator placement	External stimulator placement
Stimulating electrode may be at site remote from seizure focus	Stimulating electrode is targeted to be near seizure focus
Open-loop system	Closed-loop system
No event detection required	Designed to detect events with high sensitivity
Programmed periodic stimulation; chronic repetitive stimulation	Programmed to respond to detected events, intermittent stimulation
No option to review seizures	Can download and review detected events

and dyskinesias seen in drug-treated Parkinson's disease. Common targets for DBS in movement disorders include the thalamus, globus pallidus and subthalamic nucleus [5]. Risks of intracerebral haemorrhage with stereotactic placement of stimulating electrodes are in the range of 1–2%, and often these haemorrhages are small and resolve without deficits. The stimulation devices being used for chronic programmed trials of epilepsy treatment are similar to those approved for use in these movement disorders.

Concept of responsive neurostimulation

Epileptic seizures are brief, transient periods of focal, regional or generalized increased network synchrony and excitation. Partial seizures are rapidly evolving dynamic events, characterized by increased signal complexity, which include periods of seizure onset, organized rhythmic activity and intermittent bursting activity [6]. The onset characteristics of partial seizures from a given focus in a given patient are remarkably stereotyped as determined by both time–frequency decompositions and measures of signal complexity [6,7]. The typical partial seizure lasts less than 120 s [8] and spontaneously terminates with or without intervention. Patients in epilepsy monitoring units who have their medications reduced or withdrawn have more frequent seizures and more frequent secondarily generalized seizures but the seizures are still typically self-limited and not necessary longer [9]. Even patients with status epilepticus usually have recurrent seizures rather than continuous seizure activity, although the latter certainly occurs.

This concept of partial seizures as rapidly evolving, dynamic, but transient self-limited events has led to interest in interventions that could produce early termination of these events. The concept of responsive neurostimulation (RNS) is not to prevent the occurrence of seizures but to rapidly detect the seizure and deliver a stimulus that will alter the seizure dynamics and result in a brief seizure that is not disabling. RNS utilizes a closed-loop system that incorporates seizure detection hardware and software; detection then triggers therapy (Table 82.1). These closed-loop systems are considerably more sophisticated than simple open-loop systems.

As epileptic seizures are characterized by periods of increased synchronous excitatory network activity, the idea that external excitation may be beneficial is at first counterintuitive, but in fact there is experimental evidence supporting the potential therapeutic benefit. Studies in neural network models incorporating both excitatory and inhibitory neurones have shown that excitatory stimulation can terminate abnormal bursting activity [10–14]. Indeed, in these same model networks, termination can be produced when there is no functioning inhibition. This is not to say that inhibitory networks are not important in modulating human brain activity, just that inhibition may not be necessary for seizure termination, either spontaneous or triggered. The human brain and hippocampus comprise predominantly (80–90%) excitatory connections [15]. This has important implications for the application of responsive neurostimulation.

For responsive neurostimulation to be clinically beneficial, intervention has to be early, to prevent seizure evolution from an electrical or simple partial event (i.e. with no altered awareness) to a disabling seizure (complex partial or secondarily generalized). As partial seizures are being treated, it seems desirable to have the recording and stimulating electrode near the seizure focus to facilitate early detection and intervention before regional propagation, although more remote stimulation could still have potentially beneficial effects.

The fact that seizure onset patterns recorded from intercranial electrodes are very stereotyped facilitates early detection using computationally efficient detection algorithms that can be adjusted or tuned to the specific patient and their seizures so that seizure detection can be very sensitive. If a seizure could be predicted minutes before seizure onset then there is the potential for intervention even earlier with responsive stimulation [16]. At present, however, seizure prediction is at best very computationally demanding and cannot be carried out with small hardware devices, online, or with sufficient sensitivity to be reliably applied. This could change in the future, however, as the result of ongoing efforts to improve seizure prediction methods and applications.

Previous studies of chronic or programmed central neurostimulation

A number of cerebral structures have been targets for chronic or programmed brain stimulation. Cerebellar stimulation, the earliest target of therapy in humans, is discussed in the paragraph below in the historical context as this is no longer being investigated. More recently, the thalamus, hippocampus and subthalamic nuclei have been targets for modulation by high-frequency chronic neurostimulation. Although preliminary unblinded studies have been promising in a number of these areas, true measures of efficacy require evidence-based blinded trials. Because the brain is pain insensitive, the blind can be easily preserved (all patients are implanted and the placebo group is later stimulated) with central neurostimulation as the patient is not aware of whether stimulation is activated or not. As such, the blinding of central neurostimulation therapy is more easily undertaken than with VNS or medications. Typically in the neurostimulation trials, one investigator is unblinded to allow for adjustment of stimulation parameters. This investigator needs to be careful to 'preserve the blind' (e.g. to spend as much time with patients receiving therapy as those who are not).

Stimulation of the cerebellum

Stimulation of the cerebellum was one of the earliest attempts at treating epilepsy. One stimulation paradigm utilized two eight-contact strip electrodes, placed on the upper surface of the anterior lobe of the cerebellum through a burr hole or craniotomy and stimulus intensities of 1–9 mA, at 10 cycles per second, were used. In addition to implanting patients with epilepsy, cerebellar stimulation was used in attempts to reduce spasticity in patients with cerebral palsy [17].

The rationale for cerebellar stimulation as a treatment for epilepsy was not unreasonable. The cerebellum is known to modulate other brain activity and the cerebellar outflow tracts project to cerebral regions that modulate motor activity. The output from cerebellar Purkinje cells is inhibitory. Cerebellar stimulation had been shown to shorten trains of hippocampal discharges induced in humans [18] and to provide inhibition of cortical excitability [19].

Unblinded studies of heterogeneous patient populations [20–22] suggested that there were significant benefits in a majority of patients and hundreds of patients had cerebellar stimulators implanted – many for treatment of spasticity but not epilepsy. When a double-blind trial of chronic cerebellar stimulation in the treatment of epilepsy was performed, however, although 11 out of 12 patients subjectively reported improvement, there was no significant quantifiable reduction in seizures shown for any patient [23]. The safety of chronic implantation of intracranial strips was demonstrated with these studies. One might speculate that one potential reason for failure is that the resting firing rate of Purkinje cells is already quite high (e.g. 60–70 Hz) and that further stimulation might have relatively little impact on inhibitory cerebellar output. Whether larger blinded studies would have provided different results is not known, but cerebellar stimulation in humans for the treatment of epilepsy has been abandoned.

Chronic stimulation of the thalamus

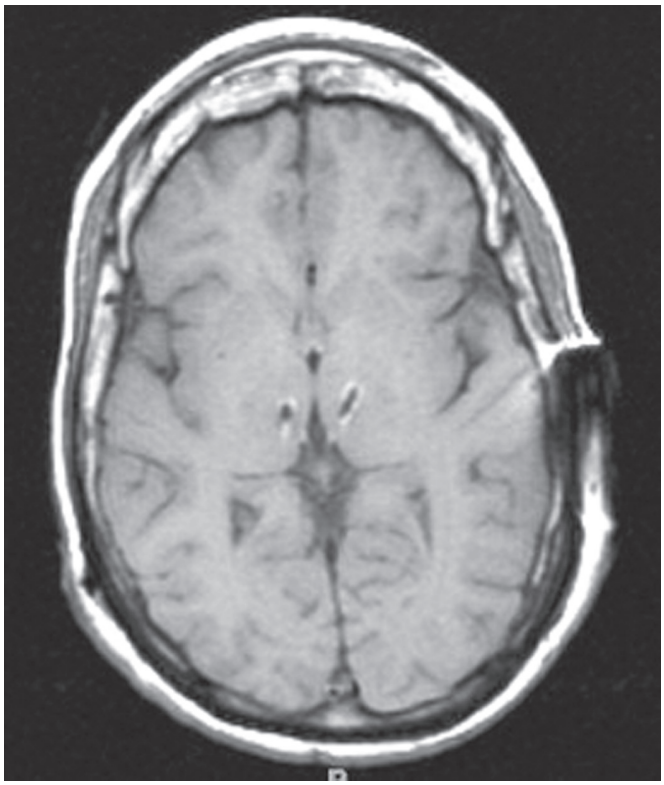
The extensive application of thalamic stimulation for the treatment of tremor and Parkinson's disease has provided considerable experience with long-term implantable devices for chronic, programmed stimulation. In the treatment of epilepsy, stimulation of both the central median nucleus of the thalamus and of the anterior thalamus has been tried. The thalamus is an important relay for afferents to the cortex and midline thalamic nuclei have strong connections with limbic regions [24,25]. Animal models have provided some evidence for medial thalamic involvement early in seizures [26]. A recent study [27] in kindled rats demonstrated that seizures were prolonged when drugs that either enhanced excitation (e.g. glutamate) or reduced inhibition (e.g. GABA antagonist bicuculline) were infused into the medial dorsal nucleus. These studies illustrated that pharmacological manipulation of midline thalamic regions could influence hippocampal seizure discharges, although typically the changes in duration were less than 50%.

Stimulation of both the centromedian (CM) and anterior (AN) thalamic nucleus is postulated to affect cortical synchrony [28]. Stimulation of the thalamus can influence the cortical EEG, and the EEG of the anterior thalamus is highly coherent with cortical EEG [29,30]. Electrical stimulation of the reticular nucleus in the rat suppresses kindled limbic seizures [31]. High-frequency stimulation of the anterior nucleus of the thalamus raises the clonic seizure threshold; however, low-frequency stimulation may be proconvulsant [32]. Anterior nuclear stimulation increased the threshold for motor cortex excitability in three patients [19]. A recent report of pilocarpine-induced seizures in rats suggests that stimulus intensity (500 μA better than 1000 μA) may be more important than stimulus frequency [33].

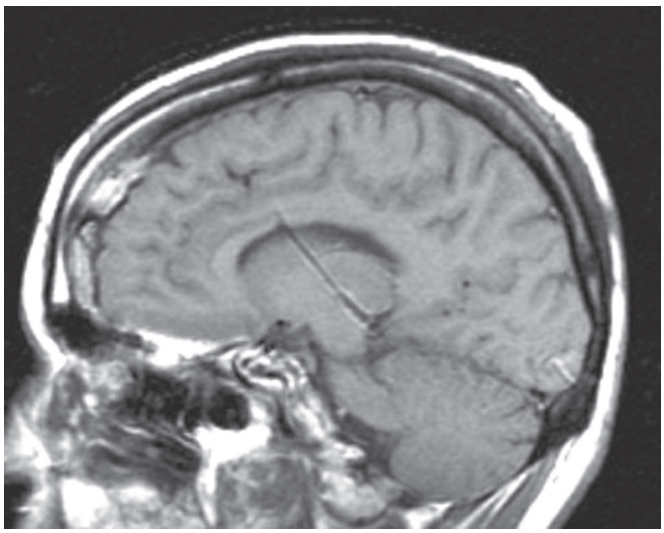
The first studies of thalamic stimulation targeted the centromedian thalamic nucleus (Fig. 82.1). Early unblinded studies of CM stimulation in patients with convulsive seizures suggested dramatic benefits [34]. However, a small ($n = 7$) randomized, double-blind, cross-over trial of CM stimulation in patients with medically intractable epilepsy documented a 30% reduction in generalized tonic–clonic seizures (GTCSs) with the stimulator on compared with an 8% reduction with the stimulator off (P = n.s.) [35]. In an open-label extension, no patient had a >50% reduction in seizures. Other uncontrolled small series have suggested benefit [36]. Additional later unblinded reports [37,38] suggest that GTCSs and atypical absence seizures have the best responses. In these studies of stimulation of the thalamic parvocellular centromedian subnucleus, best results are reported to be with bipolar stimulation at 60–130 Hz, 1 min on, 4 min off, with stimulation of alternating sides.

A recent review of chronic AN stimulation in the treatment of epilepsy has been published by Wennberg [28]. This review discusses many of the unanswered questions regarding AN stimulation and has a useful table summarizing the results of pilot studies to date. Early unblinded studies of chronic AN stimulation for the control of epilepsy have suggested benefit [39–43]. One pilot study [41] showed a significant reduction of seizure severity (e.g. secondarily GTCSs) with AN stimulation. Interestingly, as mentioned by Wennberg [28], the reported benefit for AN stimulation is not clearly associated with stimulation, as some patients who had been implanted and were not receiving stimulation also appeared to benefit [40,44]. Median stimulation frequencies have been typically 100–150 Hz (range 90–185 Hz). In the long-term follow-up of six patients with AN stimulation [44], five patients had ≥50% seizure reduction, although in two of these patients, as acknowledged by the authors, this level of benefit only occurred in years 5 and 6 when AEDs had also been changed. In the report of Lim *et al.* [42], AN implantation and stimulation produced a reduction in seizures of 49% in four patients, with one patient having ≥50% reduction in seizures; however, some patients in this study also experienced benefit during the sham period without stimulation. The best results from pilot studies were in the series of Osorio *et al.* [43], in which all four patients had ≥50% reduction in seizure frequency. This study, as noted by the authors, had a higher mean stimulus frequency (157 Hz) than other studies (~100 Hz). The maximum benefit was achieved at 10–12 months in these patients.

A multicentre controlled trial of AN stimulation, the SANTE trial (stimulation of the anterior nucleus of the thalamus for epilepsy), finished recruitment in 2007 [45]. This SANTE study enrolled patients with intractable partial seizures (with or without secondary generalization) and included an initial 3-month period when patients were randomized to stimulation or no stimulation, something that was not included in some of the pilot trials [41,43]. In contrast to chronic stimulation with VNS, DBS does not need to be ramped up slowly due to issues of patient comfort, as DBS



(a)



(b)

Fig. 82.1 Patient with bilateral stimulators in centromedian thalamic nuclei. T1 axial (a) and sagittal (b) MRI images are shown. The patient did not benefit significantly from the stimulation and the stimulator was turned off.

is painless. Still, studies of the efficacy of chronic stimulation need to be long term (i.e. >12 months) owing to potential neuromodulatory effects or if stimulus parameters are allowed to be adjusted to optimize effect. The most important measure of efficacy is obviously seizure frequency, particularly disabling seizures (complex partial and generalized tonic–clonic). Whether other measures of effect of chronic thalamic stimulation, such as measures of cortical synchrony, can be developed remains to be determined. Preliminary results just presented from the SANTE trial of anterior thalamic stimulation in humans have indicated efficacy with a median reduction in seizure frequency of 38% at 3 months and even greater efficacy in long-term studies (unpublished data presented at 2008 American Epilepsy Society meeting).

Chronic stimulation of the subthalamic region

Subthalamic nucleus (STN) stimulation has been demonstrated to benefit the motor symptoms of Parkinson's disease; many patients have received implantations for DBS [5]. Many of these patients are those who had become less responsive to dopaminergic agents or who had developed disabling dyskinesias and STN–DBS has provided considerable benefit. There is, therefore, as with anterior thalamic stimulation, considerable technical experience with targeting and implanting these structures.

Subthalamonigral inputs can influence amygdala-kindled seizures in rats [46] and suppression of nigral activity can be antiepileptic [47]. It is thought that the substantia nigra plays an important role in modulating seizures via forebrain mechanisms [48]. The STN provides excitatory input to the substantia nigra reticulata (SNr), and inhibition or suppression of this input could be antiepileptic by reducing the inhibitory influence of the SNr on midbrain regions that can be anticonvulsant [49]. The STN is a more discrete target for DBS than the SNr, is more easily approached, and there is considerable previous experience in the population with Parkinson's disease. Bilateral high-frequency stimulation of the STN (~130 Hz) suppresses seizures in a genetic rat model of absence [50]; other animal studies suggest that absence and clonic seizures benefit most. Not all seizure types may be suppressed with STN manipulation, with tonic seizures appearing resistant [51,52].

These experimental studies have prompted several small uncontrolled trials of STN–DBS in humans with refractory partial epilepsy. An early report of benefit (80% seizure reduction) in a single patient appeared in 2002 [53]. One preliminary report of three patients with refractory partial seizures found a mean reduction in seizures of 49% with all three patients benefiting [54]. Another report of STN high-frequency stimulation showed a 67–80% reduction in seizure frequency in three patients with medically refractory partial seizures, and one additional patient with severe myoclonic seizures (Dravet's syndrome) also responded, whereas a single patient with autosomal dominant frontal lobe epilepsy had no benefit [55]. Bilateral STN–DBS reduced partial seizures by about one-half and one-third, respectively, in two patients in another case report [56]. These preliminary studies most often utilize bilateral implantation and stimulation with frequencies of 130–185 Hz because animal studies have demonstrated that 130-Hz stimulation of the STN elevated seizure threshold, whereas stimulation at 260 Hz had no effect and 800 Hz stimulation actually lowered seizure threshold [57].

Additional blinded trials of STN stimulation in humans with intractable epilepsy are needed for evidence-based data supporting efficacy. Enthusiasm for pursuing these trials is muted somewhat by recently reported adverse effects of bilateral STN stimulation on working memory, and a growing number of reports of occasional undesirable behavioural effects [58,59].

Chronic stimulation of the hippocampus

In contrast with the anterior thalamus and STN, no anatomical or physiological justification is needed for the role of the hippocampus in complex partial seizures. The hippocampus is a common focus for complex partial epilepsy, and many patients with mesial temporal onset seizures have seizures that remain refractory to medical therapy. Patients with mesial temporal onset seizures, especially with associated mesial temporal sclerosis, are often excellent candidates for resective surgery. Resective surgery is a less desirable option in other patients with bilateral temporal lobe foci or seizure foci in functional regions of dominant temporal lobes. Although responsive stimulation can be directed to hippocampal regions (see below), other studies have used chronic stimulation paradigms.

Rat models (kainic acid) using limited programmed stimulation have demonstrated reduced interictal spiking during the period of high-frequency stimulation (200 Hz) [60]. In other studies by the same group, low-frequency stimulation (5 Hz) reduced the number of spontaneous seizures in the kainic acid model [61]. Low-frequency stimulation (1 Hz) of the amygdala can prevent kindling in the rat or suppress already kindled rats [62]. Studies in the low-calcium hippocampal slice model have shown that continuous intermittent stimulation (140 Hz) or continuous sinusoidal stimulation suppresses epileptiform activity [63]. Sinusoidal stimulation also suppressed bursting produced in hippocampal slices by high K^+ or picrotoxin. Interestingly, the suppression of epileptiform activity was greatest near the stimulation electrode. The group that has been most active in human studies has also reported that high-frequency stimulation (130 Hz) increases the threshold of afterdischarges in hippocampal kindled rats [64].

Two groups have reported small unblinded studies of the effects of hippocampal stimulation in patients with refractory mesial temporal lobe epilepsy. One group reported benefit from limited (2–3 weeks) stimulation at 130 Hz in patients who subsequently proceeded to temporal lobectomy. Stimulation reduced both seizures and interictal spike activity and did not appear to produce any pathological changes in this limited time [65]. Chronic stimulation of hippocampal structures has been reported [37]. The group in Ghent has the largest published experience with now 12 patients with refractory mesial temporal-onset partial seizures [66–69]. Although unblinded, the 12 patients were consecutive. Acute stimulation (7 days to 5 weeks) was performed (130 Hz, 450 μs) for 7 days with unilateral stimulation in the patient with unilateral seizures, including regional onsets ($n = 11$), or bilateral stimulation in one patient with bilateral independent foci. Two patients proceeded to selective amygdalohippocampectomy, one early in the study. Overall, 10 out of the 11 remaining patients had a >50% reduction in interictal spikes of sampled epochs. The one patient who did not have a reduction in interictal spikes proceeded to resective surgery and has done well. The other 10 patients entered a long-term stimulation period with a implanted pulse generator. Stimulation was typically 130 Hz but with one patient stimulated at 200 Hz. Mean follow-up was 31 (range 12–52) months and mean monthly seizure frequency during the last 6 months was compared with baseline. Two patients [with baseline complex partial seizures (CPS) frequencies of 4 and 6 months, respectively] were seizure free. Including these two patients, 8 out of 11 had ≥50% reduction in disabling (i.e. CPS or GTCS) seizures. Although AEDs could be altered after 12 months, this did not affect outcome. The only stimulus parameter altered was stimulus intensity; although this may affect a larger tissue volume, it is not clear that this provided added benefit. No increases in seizure frequency or afterdischarges were observed; stimulation was well tolerated. The investigators speculate that stimulation produces reversible increased local inhibition. They appropriately conclude that larger, randomized controlled trials are needed to determine efficacy.

A small blinded study of hippocampal stimulation by a group with considerable experience with anterior thalamic studies was reported recently [70]. The four patients selected were not ideal resective candidates because of potential risk to memory. Unilateral left-sided simulation was carried out through electrodes placed along the hippocampal axis, similar to the placement used by the Ghent group. One-month on periods were compared with 1-month off periods. Low-intensity stimulation was carried out at 190 Hz, 90 μs. During on periods, seizure frequency was reduced a median of 26% compared with baseline, and 15% compared with off periods. One patient who had highly refractory seizures and had failed contralateral surgery became seizure free after 4 months, regardless of whether the stimulator was activated. The stimulator was subsequently turned on to continuous chronic mode and she has been seizure free for 4 years. This group also appeals for larger randomized blinded trials of chronic hippocampal stimulation.

Clinical studies of responsive neurostimulation

The idea that electrical stimulation could terminate epileptic seizures (rather than cause them) was one that initially was questioned by some. As mentioned above, neural network models supported the concept that stimulation could result in early termination of bursting behaviour. Proof of principle trials in humans demonstrated that the afterdischarges produced on occasion during subdural grid mapping in humans undergoing presurgical evaluations for intractable epilepsy could be terminated by stimulation at low currents (<12 mA) [2,71].

With these preliminary results, human studies were first done using a NeuroPace external closed-loop responsive neurostimulation system (eRNS) [72]. These studies were carried out in patients who were undergoing invasive monitoring with subdural electrodes as part of their presurgical evaluations. The eRNS was connected in parallel, and detection parameters were adjusted to determine whether seizures could be reliably detected; this was demonstrated. If time permitted, without delaying surgery, the loop was closed and responsive stimulation was undertaken for a day or so. This study was not designed to demonstrate efficacy. Seizure detection could be carried out with high sensitivity. Responsive stimulations were well tolerated.

A safety and feasibility trial of the implantable NeuroPace responsive neurostimulator was next performed. This device is the only implantable responsive device undergoing controlled trials in humans at present [73]. The device (Fig. 82.2) is implanted in the skull (in a holder ferrule) and connected to intracranial leads (either depth arrays or subdural strips) that are placed near the presumed seizure focus. The implanted device contains a battery, programmable stimulator, digital processor and memory chip. The device, which is under the skin and muscle, can be

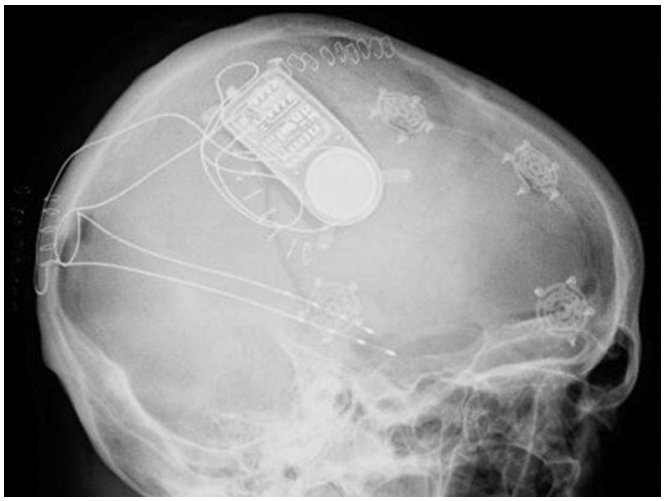


Fig. 82.2 Skull film of a patient with a NeuroPace responsive neurostimulator. The patient has intractable complex partial seizures with bilateral independent mesial temporal lobe foci (documented by previous invasive video-EEG monitoring). The two depth electrode arrays targeting the left and right hippocampal regions are seen connected to the NeuroPace responsive neurostimulator, which is inset into a ferrule recessed into the skull.

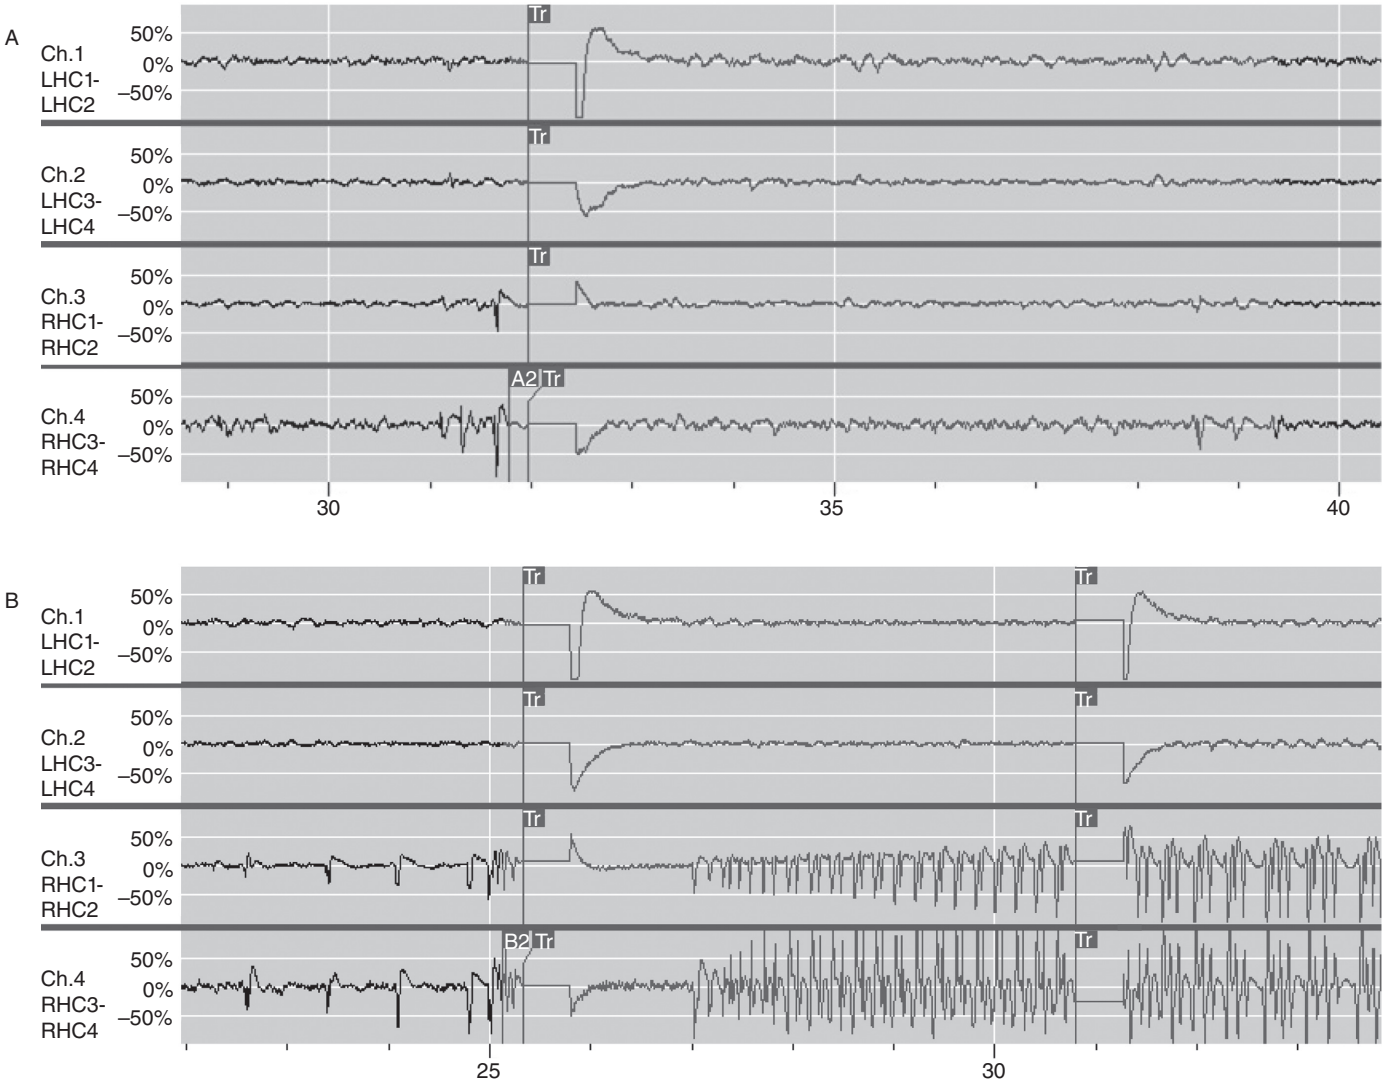

Fig. 82.3 Two epochs recorded from the patient illustrated in Fig. 82.2. These epochs were detected by the responsive neurostimulator and stored in the NeuroPace device and later downloaded by the patient. Channels 1 and 2 are bipolar recordings from the four contacts in the left hippocampus. Channels 3 and 4 are bipolar recordings from the four contacts in the right hippocampus. (a) A delivered therapy in response to detection of right-sided seizure activity. The detection algorithms were tuned to detect this activity within 2 s. No further evolution of seizure activity is seen after delivery of therapy; no clinical symptoms occurred. This may represent positive effects of therapy, although other interpretations are possible (see text). (b) Delivered therapy in response to another right hippocampal event. In this instance stimulation (two out of five are therapies are shown) did not prevent further evolution of seizure activity and a subsequent complex partial seizure.

painlessly programmed transcutaneously with a wand. In addition, the patient can download stored seizures and real-time EEG that can then be reviewed remotely. Storage capacity is limited by the size of the device, but all detections and stimulations are documented.

Seizure detection is tuned for the individual patient. Detection algorithms can incorporate one or more of half-wave, line length or area under the curve. When responsive therapy is activated, therapy is delivered after seizure detection (typically 2 s after seizure onset). Pulse frequency can range from 1 to 333 Hz, although typically frequencies of 100–200 Hz have been utilized. Single or multiple contacts can be stimulated. Each therapy can have two bursts and up to five therapies can be delivered for each seizure detection (Fig. 82.3). Total current is modest (up to 12 mA total for all stimulated contacts) with typical charge densities of <6 coulombs.

A safety and feasibility trial was conducted with this implanted device. This study was unblinded and was not designed to demonstrate efficacy. A total of 65 patients at 12 centres were enrolled and this study was completed in 2005. Some preliminary reports [73,74] have appeared. The device and repeated stimulation was well tolerated. Complex partial, generalized tonic–clonic and totally disabling seizures were significantly reduced by 40%, 55% and 41%, respectively [75,76]. As mentioned, this was not a trial of efficacy; in retrospect some non-responders had suboptimal placement of electrodes (e.g. remote from seizure focus) or multifocal epilepsy.

A pivotal, blinded trial of responsive neurostimulation is ongoing; recruitment was completed in late 2008. Thirty centres are participating with over 180 patients randomized. AED therapy is kept constant throughout the blinded portion of the trial (16 weeks), but detection and stimulation parameters can be adjusted.

The most important outcome parameter is number of disabling seizures (complex partial and secondarily generalized seizures). The original concept of responsive neurostimulation was not to prevent seizures *per se*, but to prevent seizure evolution after early detection. Assessment of the effects of RNS on a given event involves a number of factors. Figure 82.3 illustrates two right mesial temporal-onset seizures occurring at different times in the same patient. In the first instance (Fig. 82.3a), no further evolution of seizure activity after stimulation is seen. Although this may represent an effect of the delivered therapy, one cannot be certain that further evolution to a disabling seizure would have occurred without therapy. The second illustration (Fig. 82.3b) shows failure of the responsive therapy to prevent evolution of the seizure into a complex partial seizure. Failure or suboptimal responses to RNS therapy can result from a variety of potential factors, including the site of the stimulating electrode (i.e. proximity to seizure focus), the contacts being stimulated and the frequency of stimulation applied.

When the closed-loop responsive therapy system is tuned to be sensitive to epileptiform activity, it is triggered (with corresponding therapy) many more times than would be expected based on the seizure history of the patient. These stimulations are not triggered by false-positive detections *per se*, as they are triggered by epileptiform activity. Although it is possible to tune detection to be highly sensitive and specific for fully evolved seizures if, for instance, 20 s of activity was used, such specificity is difficult if one wants detection after 1–2 s. The net result is that patients with responsive therapy can receive a large number of delivered therapies. This appears to be well tolerated. If patients achieve benefit, however, it may be difficult to determine whether this is a result of the therapy directed at what would have been clinical events, or due to therapy directed to subclinical or interictal activity.

Conclusion

Neurostimulation for the treatment of epilepsy continues to hold considerable promise. Within the next year the detailed results of two randomized controlled trials will be available: the SANTE trial of chronic programmed stimulation of the anterior nucleus of the thalamus and the NeuroPace responsive neurostimulator trial. The pattern of previous unblinded trials of neurostimulation has been to overestimate efficacy. These blinded trials provide the best available data regarding responses to these two stimulation paradigms. The technology for neurostimulation is fairly well developed, although advances in battery life and storage capacity (for RNS) would be desirable. The potential benefits over AED therapy are appreciated, with no drug-related side-effects. It is hoped that the blinded trials will better provide evidence for responder rates than AED trials of new agents. Patients with certain seizure profiles (e.g. neocortical, mesial temporal) might achieve greater benefit.

Whether chronic programmed stimulation or responsive paradigms are more or equally effective remains to be determined. If responsive therapy is indeed better, then the future may see detection moved from early seizure onset to the preictal zone. One very real challenge is determining the optimal stimulation parameters for neurostimulation. These stimulation parameters may be different for chronic and responsive therapy, for different brain regions or even for different patients. Although this offers the opportunity for an infinite number of therapy options, in contrast to AED trials, it also presents one of the greater challenges to determining the most effective therapy.

83 Stereotactic Radiosurgery for Medically Intractable Epilepsy

Isaac Yang, Edward F. Chang and Nicholas M. Barbaro

University of California at San Francisco, San Francisco, CA, USA

Introduction

Radiosurgery is the precise application of focused radiation with stereotactic guidance to a targeted volume within the brain identified on magnetic resonance imaging (MRI) [1]. Conceptualized by Leksell for use in functional neurosurgery, radiosurgical treatment for neurological disorders has progressively widened its utility and is now also a treatment option for several neoplastic and cerebrovascular indications. In contrast to standard fractionated radiotherapy, radiosurgery delivers effective, precise and accurate radiation to a small volume without affecting large portions of normal brain parenchyma [2–4].

Approximately 20% of patients with epilepsy have seizures that fail to respond to medications. Despite modern advances in new antiepileptic medications, the percentage of patients with medically intractable epilepsy has not significantly improved. Patients with medically intractable seizures may be referred for surgical evaluation, and approximately one-half are found to be suitable candidates for resection of their seizure focus [5–8].

The most common type of open surgery performed for medically intractable epilepsy is an anterior temporal lobectomy, which is a resection of a portion of the temporal lobe [6,8–11]. With modern advances in surgical and anaesthetic techniques, microsurgical resection of mesial temporal lobe structures can be performed with relatively low morbidity. The inherent risks and possible complications of open surgery can be serious, however, and include hemiparesis, language and memory disturbances, and hemianopsia [12–15]. Several clinical studies evaluating the morbidity of open microsurgery for temporal lobectomy report that approximately 1–20% of medically intractable epilepsy patients who underwent open microsurgery had a symptomatic neurological postoperative deficit [9,12,13,16,17]. Furthermore, open procedures require several days of inpatient hospitalization including typically a course in intensive care. A significant proportion of patients with pharmacoresistant epilepsy, though, are deemed unsuitable for conventional microsurgery, as they may have an epileptic focus in difficult-to-access regions or in eloquent regions of the brain in which surgical resection could result in unacceptable and irreversible language, motor or visual impairment.

Radiosurgery is now being evaluated as an alternative treatment modality to open resective microsurgery for medically intractable epilepsy. High-dose radiation is toxic to all living cells, but the highly focused nature of radiosurgery allows stereotactic guidance and spares adjacent tissues from the damaging effects of radiation. At present, radiosurgery is under investigation as an alternative treatment modality for epilepsy associated with vascular malformations, gelastic epilepsy associated with hypothalamic hamartomas, and mesial temporal lobe epilepsy associated with mesial temporal sclerosis.

The two main types of radiosurgery are gamma knife and linear accelerator (LINAC). The original gamma knife was first developed in 1968 using a radioactive source of cobalt-60, which was placed in a helmet with central channels for irradiation using gamma rays. In the latest version of this device, hundreds of sources of radioactive cobalt direct gamma radiation to the centre of a helmet, in which the patient's head is inserted. The gamma knife uses multiple beams of radiation converging in three dimensions to focus precisely on a small volume, permitting intense doses of radiation to be delivered to that volume safely. A similar principle applies to LINAC, except that LINAC utilizes a different source of radiation produced by X-rays from the impact of accelerated electrons. Furthermore, for LINAC, the gantry must move in space to change the delivery angle of radiation.

Preclinical evidence

Preclinical studies investigating radiosurgery in animal models have demonstrated their potential utility when applied to models of epilepsy. Early animal experiments indicated the efficacy of focused radiation in a cat model of epilepsy to reduce seizure activity [7,18,19]. Using doses of between 10 and 20 Gy [one gray (Gy) is equivalent to one joule of energy per kilogram of tissue], cats with epileptic foci treated with a cobalt radiation source had reduced seizure activity. Histological tissue analysis of these treated animal specimens revealed 'neuronal reafferentation' as a proposed potential mechanism for seizure amelioration by focused radiation.

Sun and colleagues [20] report that focused LINAC radiosurgery successfully reduces seizure activity and raises seizure thresholds in a rat hippocampal kindling epilepsy model [20]. Seizure thresholds to external electrical stimulation were significantly increased and the length of afterdischarges was significantly decreased in the group treated with 40 Gy of radiosurgery. These antiepileptic effects were observed 1 week after radiosurgery treatment and persisted at the 3-month follow-up period.

In another model of chronic spontaneous limbic epilepsy in rodents [21], rats that received the lowest dose (10 Gy) of gamma knife radiosurgery showed no improvement in seizure activity, whereas the 20-Gy group exhibited a gradual and

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

progressive reduction in seizure frequency between 2 and 6 months after radiosurgery treatment. Lastly, the 40-Gy treatment group displayed a dramatic reduction in seizures by the second month after radiosurgery. Histological tissue analysis of targets treated with radiosurgery in this animal study noted no necrosis in the tissue specimens. Instead, remnants of synaptically driven neuronal firing was found to be intact in these treated rodent brain slices, suggesting that neuronal death was not responsible for the identified seizure reduction.

A dose–response study for gamma knife radiosurgery was carried out in a kainic acid-induced epilepsy rat model [22]. Ten days after kainic acid injection, the epileptic focus was treated with a range of 20–100 Gy. The animals treated with the lowest dose of 20 Gy demonstrated a reduction in the number of daily seizures during each week of observation after radiosurgery. Furthermore, 3 weeks after radiosurgery, all treated animals at each radiosurgery dose – 20, 40, 60 and 100 Gy – showed a statistically significant reduction in seizure activity, confirmed by electroencephalography. Tissue histology revealed radiation-induced necrosis only at the 100-Gy radiosurgery dose. Another study using the same rat kainic acid–epilepsy model was undertaken to further evaluate the behavioural effects of these 'subnecrotic' radiosurgery doses [23]. Radiosurgery did not worsen deficits in a new memory attainment task with water maze testing compared with non-treated control animals injected with kainic acid alone (but both groups showed behavioural impairments when compared with control animals without kainic acid injection). Histopathological tissue evaluation of study animals confirmed that seizure activity reduction was not associated with tissue necrosis or a concomitant loss of neurons.

The long-term effects of radiosurgery were evaluated in rats that underwent a low radiation dose (35 Gy) of radiosurgery at 16 months after radiosurgery treatment [24]. At 6 months post irradiation, T2-weighted signal abnormalities suggestive of oedema were observed on MRI, and were most pronounced at 9 months. After 16 months, two out of six treated animals demonstrated radiation-induced necrotic cavities after treatment with a 35-Gy dose of radiosurgery. The four remaining treated animals without frankly necrotic cavities had other notable findings, such as severe atrophy of the corpus callosum, loss of thickness of the somatosensory cortex and damage to the striatum oriens hippocampi. These animal studies suggest that the full radiobiological and histological effect of radiosurgery may manifest only many months after radiosurgery treatment.

These preclinical studies report the amelioration of seizures as well as histological neuronal changes associated with radiosurgical treatment in different animal epilepsy models. Most of these studies suggest a dose-dependent effect of radiosurgery, with a minimum dose of about 20 Gy to see any therapeutic antiepileptic effect. Furthermore, the full histological effects may require several months to fully develop.

Clinical evidence

The first clinical application of radiosurgery for epilepsy was utilized by Talairach in the 1950s with the implantation of radioactive yttrium in patients with mesial temporal lobe epilepsy (MTLE) [25]. Further clinical experiences with gamma knife radiosurgery and linear accelerator (LINAC)-based radiosurgery for the treatment of arteriovenous malformations [4,26–32] and low-grade tumours have also reported incidental antiepileptic effects of radiosurgery treatment. Although it was not clear whether the effects on the epileptic lesion itself or the surrounding tissue accounted for the incidental seizure reduction, these clinical reports provided the original impetus for investigating radiosurgery as an alternative treatment for medically intractable epilepsy.

Mesial temporal lobe epilepsy

Mesial temporal lobe epilepsy associated with mesial temporal sclerosis (MTS) is perhaps the most well-defined epilepsy syndrome responsive to a structural intervention such as surgery. When temporal lobe epilepsy is due to underlying MTS, seizure improvements with open microsurgical structural resections has been reported to be between 65% and 90% of patients [6,8,33–37]. This form of medically intractable epilepsy is particularly amenable to radiosurgery because 80–90% of these cases show identifiable changes on magnetic resonance imaging (MRI), which is used to plan targeting and dose volume [2].

Recently, radiosurgery has been explored as an alternative treatment to open resective microsurgery for MTLE. In a small cohort of patients with MTLE, treated with gamma knife radiosurgery, Regis *et al*. [38] reported amelioration of seizures with minimal morbidity. A subsequent prospective, multicentre European study evaluating gamma knife radiosurgery for MTS-associated epilepsy showed similar efficacy rates (65%) for seizure reduction by conventional microsurgery or radiosurgery after 2 years of follow-up [39]. Using a marginal dose of 24 Gy, Regis *et al*. demonstrated that radiosurgery can be used as an alternative treatment to conventional resective microsurgery to effectively treat MTLE associated with MTS and improve quality of life with similar rates of morbidity and mortality. In the USA, a multicentre pilot trial is being conducted at present, with preliminary results showing that 85% of patients treated with 24 Gy (to the 50% isodose line) to the medial temporal lobe (including the amygdala, anterior hippocampus and nearby cortex) with 2 years of follow-up are seizure free with minimal morbidity (Barbaro *et al*., unpublished). This study group is also planning a larger, phase 3 multicentre trial comparing open microsurgery with radiosurgery for patients with clinically and radiographically defined MTS-associated MTLE.

Long-term results of gamma knife radiosurgery for MTLE were recently reported in two studies from France. In one paper, with a mean follow-up of 8 years, 60% of patients were found to be seizure free at last follow-up [40]. In the other French paper, with mean follow-up of 5 years, 47% of patients were reported to be seizure free [41]. In the five of 15 patients who had stereoencephalography findings showing that the epileptogenic zone extended beyond the mesiotemporal structures, the seizure control was less successful after radiosurgery. These studies show that radiosurgery provides improved long-term seizure-free outcomes in well-selected patients with mesial temporal lobe epilepsy. The actual efficacy and safety of this radiosurgery treatment procedure still awaits a larger prospective study. In all clinical studies con-

ducted to date the beneficial effects of radiosurgery have not been demonstrated immediately after radiosurgery. Typically, patients with MTLE treated with radiosurgery can achieve seizure reduction at 9–12 months and possible complete cessation of seizures between 18 and 24 months after radiosurgery treatment. A transient increase in partial seizures (auras) can be noted at approximately the same time when complex seizures decrease [39]. More than one-half of all treated patients may require corticosteroids to treat the radiation-induced delayed oedema associated with the initial radiosurgical effect, commonly 10–15 months post treatment [39]. The delayed effect of radiosurgery is an important consideration for radiosurgery compared with open surgery, as it may expose patients to the continued morbidity of ongoing seizures, including sudden unexpected death and traumatic injury. Two deaths occurred during the latency period in a case series of five patients treated with 'low-dose' radiation (20 Gy) [42].

In patients who failed radiosurgery, subsequent open resective surgery has provided an opportunity to evaluate the histopathological effects in human subjects. After a reduced radiation dose, Cmelak *et al.* [43] report no radiation-induced histopathological changes in tissues treated with 15 Gy of radiosurgery. In another series with two patients treated with 18 Gy, one patient was noted to have a necrotic focus with some prominent vascular changes consisting of vessel wall thickening, and fibrinoid and hyaline degeneration, whereas the other patient treated with this subtherapeutic dose showed no necrosis or vascular histopathological changes [44]. When treated with a higher, yet subtherapeutic, dose of 20 Gy, all five patients from a series reported from the Cleveland Clinic demonstrated histopathological necrosis, perivascular sclerosis, and macrophage infiltration upon resection and evaluation [42]. These reports suggest that significant reduction in seizures may only be observed with radiation doses of greater than 20 Gy. These radiobiological and histological alterations, such as necrosis and vascular changes, may be required for an effective anti-seizure effect to manifest. Thus, a dose that produces some tissue necrosis and histopathological effects without producing an excessive biological response such as oedema, for example 24 Gy, may be the optimal effective dose in the radiosurgical treatment of MTLE [4,38,45].

At present, the radiobiology of radiosurgery in the setting of MTS-associated MTLE is not yet completely understood. Although some preclinical studies have suggested an antiepileptic effect of radiation with subnecrotic doses [23], human clinical studies have suggested that a certain amount of tissue necrosis and histopathological changes may be required to see a significant amelioration of MTS-associated MTLE seizures. The importance of this issue on biological effect is that radiosurgical treatment of eloquent brain regions would be possible if an effective subnecrotic dose could be found.

In parallel with preclinical animal studies, clinical trials have suggested that a lower marginal dose of 20 Gy may be less effective in reducing seizures. Cmelak *et al.* [43] report unsuccessful seizure reduction with radiosurgery using a 15-Gy marginal dose. Kawai *et al.* [44] also report two cases of radiosurgery with unsuccessful antiepileptic effect with a marginal radiosurgery dose of 18 Gy. Finally, Srikijvilaikul *et al.* [42] from the Cleveland Clinic also report their series of ineffective radiosurgical treatment for seizure control with a 20-Gy marginal dose.

In summary, radiosurgery for MTS-associated MTLE is an attractive option because it is relatively non-invasive, with lower morbidity than major surgery. Conventional open temporal lobectomy surgery can also be pursued if the initial radiosurgical treatment is ineffective and after sufficient time has been permitted for the delayed radiosurgical antiepileptic effect after 3 years [39]. Its main disadvantage at present is the delayed response on seizure control during which time patients continue to suffer from the sequelae of seizures. The long-term effects of radiosurgery on cognitive and neuropsychological functioning are yet to be determined.

Hypothalamic hamartoma-associated gelastic epilepsy

Hypothalamic hamartomas are uncommon lesions with a prevalence of 1–2 in 100 000 and are commonly associated with precocious puberty, developmental cognitive delay and gelastic epilepsy. Typically, seizures associated with hypothalamic hamartomas are gelastic and medically refractory. These hypothalamic hamartomas are ectopic tissue consisting of glia, neurones and other neuronal fibre bundles.

Microsurgical resection of hypothalamic hamartomas has been reported to improve control of gelastic seizure activity but, owing to the technical and surgical difficulties of reaching these lesions in a deep and critical area, open microsurgical resection is often complicated, incomplete and associated with a high risk of neurological sequelae, such as motor, visual and hypothalamic deficits [46–49]. Recent small case series have reported varying rates of seizure remission (from 37% to 40%); however, all have noted significant improvements in behaviour, sleep quality and even learning [50–54].

A European prospective multicentre trial of radiosurgery treatment has enrolled 60 patients, 27 of whom have exceeded 3 years of follow-up [55]. Among these, 59.2% have an excellent result, with a dramatic behavioural and cognitive improvement, and are completely seizure free (37%) or have only rare non-disabling seizures (22.2%). No permanent neurological complications were observed, although three patients presented with a transient poikilothermia. This alternative treatment of radiosurgery for hypothalamic hamartoma-associated gelastic epilepsy holds great promise given the significant surgical morbidity associated with microsurgical dissection of hypothalamic hamartomas. In further investigations with larger series, longer follow-up must be conducted to establish the true safety and impact of this treatment option compared with open surgery.

Arteriovenous malformations

The potential efficacy of gamma knife radiosurgery in the treatment of symptomatic localization-related epilepsies is most evident in the treatment of arteriovenous malformations (AVMs). In a representative case series of 59 patients, Steiner *et al.* [56,57] reported seizure remission in 69% of patients with AVM and epilepsy. A recent large case series emphasized that the incidence of seizure remission is better with smaller AVMs [58]. However, Steiner *et al.* noted that seizures remitted independent

of radiological remission of the AVM, a finding that suggests that the effects of irradiation near the lesion, rather than the improvement of the AVM itself, may be important in control of seizures after radiosurgery.

Cavernous malformations

The most common presentation of patients with cavernous malformations is seizure. These congenital vascular malformations can cause haemorrhage and neurological insult but, more frequently, manifest as intractable seizures. Radiosurgical treatment for cavernous malformations is controversial because clear evidence for protection from haemorrhage and the risk of rehaemorrhage has yet to be established [59–61]. For example, the early Swedish experience determined that gamma knife surgery did not appreciably alter the natural course of cavernous malformation while exposing patients to radiation-induced complications that exceeded by seven times those expected for AVMs [62]. A recent retrospective comparison concluded that traditional open resection resulted in better seizure control and rebleeding avoidance than radiosurgery [63].

Although resective, open microsurgical treatment of cavernous malformations remains the standard treatment modality, a recent series by Regis *et al*. [59] suggests a role for radiosurgery in the treatment of seizures associated with challenging cavernous malformations near 'highly functional cortex' that may preclude open microsurgical resection [59]. Using a mean dose of 19 Gy in a series of 49 patients with refractory seizures, 59% of patients became seizure free at 2 years' follow-up after radiosurgery treatment [59].

Long-term radiosurgical complications

Although the long-term complications of radiosurgery are not yet fully characterized, it appears that these delayed risks are minimal. There are several reported cases of radiosurgery-associated 'radiation-induced' malignancies, but these reported cases are rare [64–67]. Much longer periods of follow-up must be investigated to fully characterize the possible long-term complications and risk of radiation-induced neoplasms, as the development of new radiosurgery-associated neoplasms may require decades to develop. A conservative estimate of this chronic delayed risk of neoplasm after radiosurgery suggests this rate to be 1% at 20 years post treatment. which may be a negligible risk of increased malignancy with radiosurgery. Nonetheless, this may be an important consideration in younger treated patients who have a longer opportunity for oncogenesis.

Antiepileptic mechanisms of radiosurgery

Although radiosurgery has been shown to reduce seizures in various forms of medically intractable epilepsies, the mechanism by which this abatement occurs is not well understood. It has been suggested that radiation itself has a direct antiepileptic effect that may operate through several mechanisms. As glial cells are more radiosensitive than neurones, Barcia-Salorio [68] proposed that low-dose radiosurgery may reduce glial scar formation, allowing increased dendritic sprouting and improved cortical reorganization, resulting in fewer seizures. Elomaa *et al*. have theorized that the antiepileptic effect of radiation is further mediated through effects of somatostatin [69]. Although the clinical results of the most recent human studies suggest that the therapeutic efficacy of radiosurgery is linked to histopathological changes and identifiable necrosis of mesial temporal structures, proof for this theory would need to come from direct observation and histological evaluation of tissue samples in patients in whom radiosurgery has effectively controlled seizures. This is unlikely to occur, as only patients with persistent seizures after radiosurgery are likely to undergo further open resective microsurgery.

Surrogate markers of radiation effect and radiobiology, such as imaging changes on MRI, have thus far shown variable results. Radiation-induced oedema typically becomes evident in most patients 9–15 months following radiosurgery (Fig. 83.1). However, these imaging findings are usually time limited and are often followed by focal atrophic changes. Thus, MRI changes may not be diagnostic or indicative of true radiation necrosis. Furthermore, our pilot clinical trials have shown that MRI changes and peak MRI effects were poorly correlated with post-treatment symptoms. The actual biomechanism by which high-dose radiation and radiosurgery reduces neuronal hyperexcitability to ameliorate seizures will probably not be found or elucidated from human studies.

Although preclinical evidence and the results from early clinical human trials suggest that control of seizures might be possible with doses of radiosurgery that were lower than those typically applied to tumours [70,71], recent case reports also demonstrate the failure of low-dose radiosurgery to control seizures [42–44]. Although failure of seizure control is easy to identify, it is a much more difficult task to determine that lack of seizure control is caused by an insufficient radiation dose. The time dependence of radiosurgical effects is also a confounding factor that has not been fully elucidated, and a consensus among different treating radiosurgical centres for when radiosurgical treatment has 'failed' has not yet been agreed upon. Furthermore, radiosurgery patients reported with inadequate seizure reduction commonly had radiation doses of 20 Gy or less, and these patients showed little evidence of radiation-induced necrosis or histopathological changes in their tissue specimens [42–44]. Thus, the best evidence to date from human and animal preclinical experiments suggests that there is a steep dose–response curve for seizure reduction and that some neuronal necrosis is required to produce seizure abatement. This suggests that the radiosurgery radiation dose required to reduce seizures is very close to the absolute tolerability threshold of human brain tissue.

Conclusion

Recent studies suggest that radiosurgery may be an effective and safe treatment modality for medically refractory epilepsy. Prospective trials with larger numbers of patients in multicentre studies will be required to establish radiosurgery as a standard alternative therapy to open surgery. Currently investigated indications are epilepsy associated with mesial temporal sclerosis, AVM,

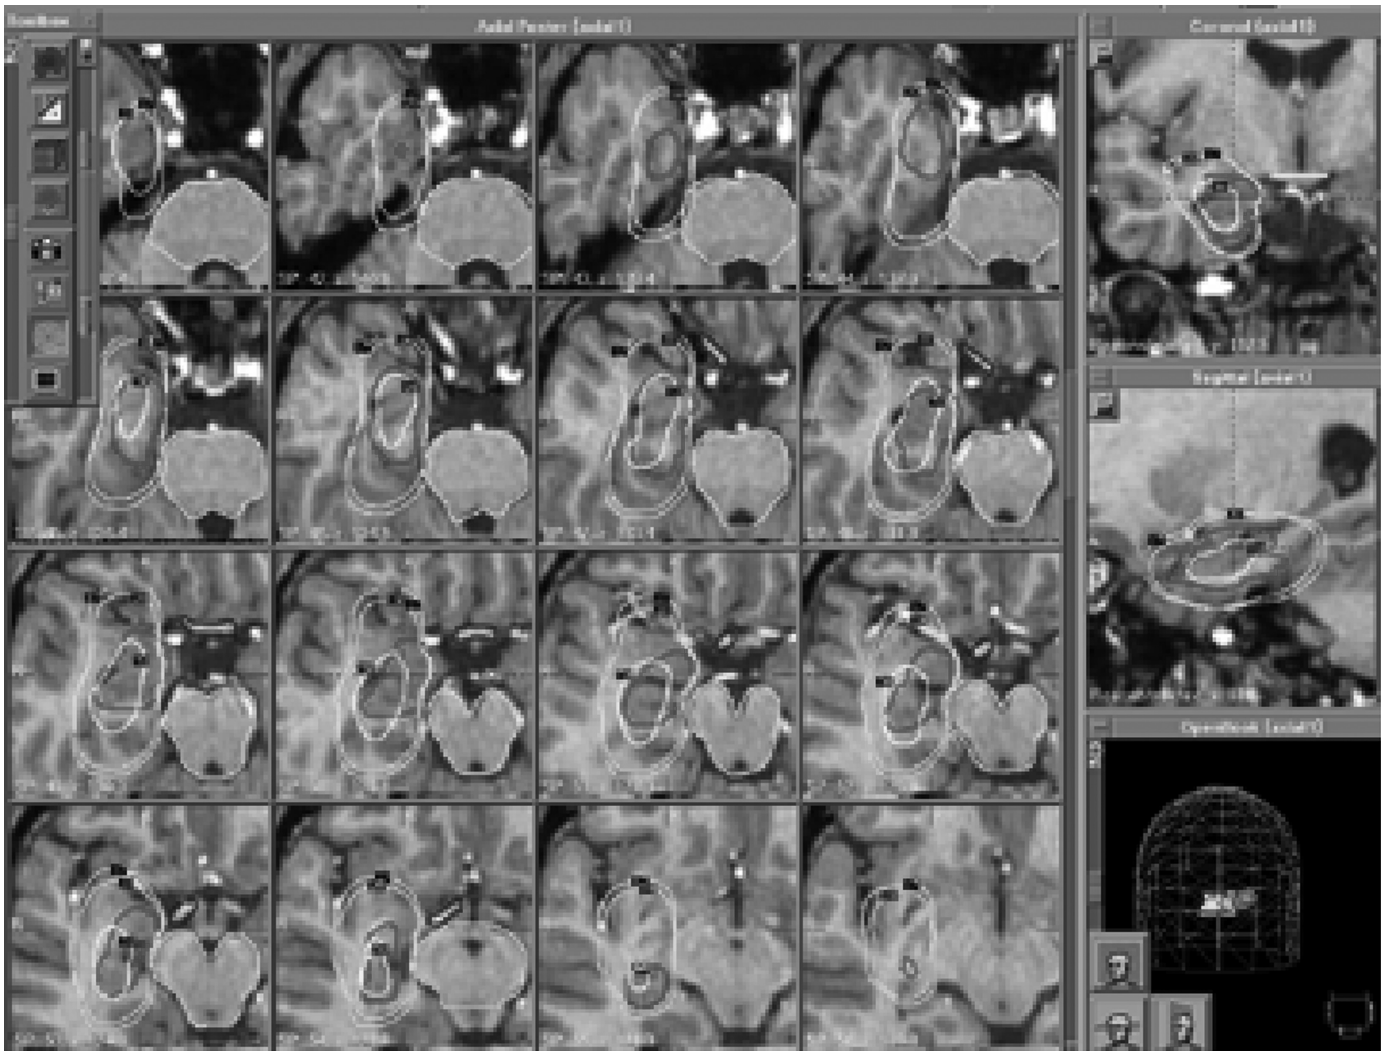

Fig. 83.1 Gamma knife treatment plan of the medial temporal lobe for MTLE with dosing curves.

cavernous malformation and hypothalamic hamartoma. Radiosurgery may prove to be especially appealing in treating lesions near functional cortex or deep-seated lesions when open microsurgical resection may not be feasible without significant morbidity.

84 Future Focal Treatment Approaches to Epilepsy

Hannah R. Cock and Karen E. Nilsen

St Georges University of London, London, UK

Introduction

As has been addressed in previous chapters, there have been considerable advances in antiepileptic drug therapy in recent years. In addition, both traditional surgical approaches and newer ablative/stereotactic methods, supported by neuroimaging developments, have also proved successful for many patients. However, despite these impressive achievements, up to one-third of patients continue to experience seizures on maximal tolerated therapy (see Chapter 2), for whom alternative strategies are urgently needed. Focal drug delivery and genetic and cell grafting techniques are newer strategies that are under development at present in this context. Focal cooling is also being explored (for a review see ref. 1) but will not be further discussed in this chapter. To date, almost all of the work is in preclinical experimental models, which cannot exactly model human epilepsy and which have limitations, but, nonetheless, provide a good basis from which future clinical studies might be developed. This chapter will consider the principles behind these focal treatment strategies, critically review the work to date and discuss if and when this might translate into new treatment options for currently intractable patients.

Focal treatment principles

Epilepsy represents the clinical endpoint of a wide range of aetiological processes but the common pathophysiological themes underlying seizures are well established, including hyperexcitability, altered inhibition and dysfunction of membrane channels. Many effective existing therapies target these known features by, for instance, increasing inhibitory transmission, interfering with excitatory transmission or modifying channel function. Almost inevitably when given systemically, such drugs have dose-limiting side-effects due to actions both outside the central nervous system and on non-epileptic brain regions. To this end, clearly a system that allowed delivery of drugs just to regions involved in seizure generation or propagation, rather than the whole brain, might be advantageous. Similarly, neuronal/stem cell grafts, or modification of genes in specific brain regions, might also prove beneficial with the potential to effect long-term local changes in the neurochemical environment, and to alter the structure and function of local neuronal networks. For any focal approach, there are a variety of sites in the brain that might be targeted (Fig. 84.1). The most obvious, as for surgical resections, would be the epileptogenic region, where this can be identified by imaging or electrophysiological means. Such focal treatment approaches, being less destructive and affording potentially more subtle manipulation than simple resection, might, for example, be applicable for many patients in whom resection or lesioning is not considered appropriate due to proximity to eloquent cortex. Second, when considering reflex epilepsies, for which the most common clinical scenario is photosensitive seizures, targeting the trigger site (e.g. occipital cortex) might be effective. Finally, for the many patients with multiple foci, or without a clear focal onset, manipulation of key propagation pathways might at least limit the clinical severity of seizures, if not completely prevent them. This is almost certainly the mechanism underlying vagal nerve stimulation (see Chapter 81) and other focal stimulation techniques (see Chapter 82) that are in clinical use and will not be further discussed here.

Focal drug delivery

The epileptic focus

The majority of studies have investigated the effects of GABAergic (γ-aminobutyric acid-secreting) drugs at the epileptic focus [area of maximal spiking on electroencephalogram (EEG)], as it is well established that GABAergic enhancement has an anticonvulsant effect. Thus, for example, in rats with seizures evoked by hippocampal bicuculline, a $GABA_A$ receptor antagonist [2], subsequent hippocampal infusions of diazepam (a $GABA_A$ receptor agonist) significantly reduced both clinical seizures and interictal EEG spiking. Several other compounds injected into the epileptic focus in a variety of models have also demonstrated antiepileptic effects, at least in the short term (Table 84.1). Although in some studies partial beneficial effects were also observed with control injections of vehicle substances, suggesting a non-specific effect perhaps related to the effect of cannula placement per se (e.g. unintended ablation or lesioning of the focus), the majority demonstrate convincing antiepileptic effects from a wide range of pharmacological modulations directed to the epileptic focus. However, these studies have largely been performed in acute seizure provocation models rather than more clinically appropriate models with spontaneous seizures, and mostly involve experimental paradigms which inevitably have a limited therapeutic

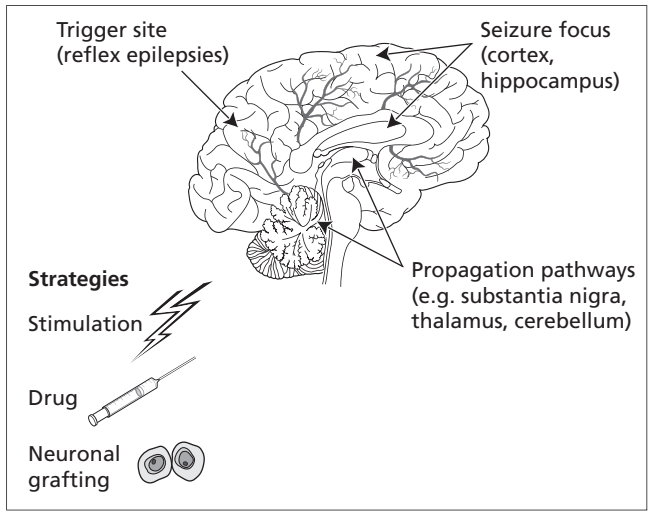

Fig. 84.1 Overview of focal treatment strategies.

Table 84.1 Positive focal injection studies into the seizure focus in rat experimental epilepsy models

Antiepileptic agent	Seizure model	Reference
Taurine	Amygdala electrical kindling	a
Lidocaine hydrochloride	Pyriform cortex bicuculline	a
Serotonin agonists	Hippocampal electrical kindling (cats)	a
Diazepam	Hippocampal bicuculline, cortical cobalt, systemic pilocarpine	a
mGluR II agonists	Amygdala electrical kindling	a
Glutamate antagonists	Prepyriform cortex electrical kindling	a
TRH	Amygdala electrical kindling	a
Adenosine	Hippocampal electrical kindling, cortical penicillin, hippocampal bicuculline	48, 49
Phenytoin	Cortical cobalt, cortical tetanus toxin	4
Gap junction blockers	Cortical tetanus toxin	50

All studies are in rat unless otherwise stated.
mGluR II, metabotropic glutamate receptor, group II; TRH, thyrotropin-releasing hormone.
[a] Reviewed in ref. 9.

time-course, lasting at most hours, so, at best, provide proof in principle. That said, when models with spontaneous seizures have been used, the results are still promising: in a well-characterized model of cortical epilepsy [3], refractory to several systemic agents, direct injection of phenytoin into the epileptic focus was effective without obvious behavioural effects, whereas high sedative doses of systemic phenytoin had no impact on the seizures, although the same did not apply to other tested AEDs [4]. This methodology also permits use of agents with widespread effects that preclude systemic use, such as gap junction blockers, which again show convincing effects at least in the short term [5].

Few studies have addressed the problem on a more long-term basis in spontaneous seizure models, although it is hoped that as technological developments that could facilitate such studies are rapidly advancing (e.g. osmotic mini-pumps, synthetic polymers and nanostructured materials), this will soon change. Remler and Marcussen [6] administered intravenous GABA to cats with a cobalt-induced focus and found little effect on the subsequent spontaneous seizures. However, if GABA was given, after local radiation to permeabilize the blood–brain barrier directly over the epileptic focus, then there was a significant suppression of spike activity, which was maximal 7–9 days after irradiation. Radiation itself had no effect on the seizures and the procedure was well tolerated with no obvious loss of function. The authors interpret the clinical effects seen as representing local delivery of GABA to the epileptic focus, although this was not directly confirmed. More recently, using the same model in rats, Tamargo *et al*. [7] used a surgically implantable synthetic polymer implanted over the epileptic focus. *In vitro* studies demonstrated continuous release of phenytoin (0.2–0.7% loaded dose per week) for up to 1 year, with loading doses that would theoretically deliver for up to 3 years in total. The *in vivo* efficacy studies included behavioural and electrocorticographic monitoring before and after implantation of phenytoin-loaded or sham polymers. In the treatment groups, both the incidence of clinical seizures (2 out of 9 animals versus 7 out of 10) and the mean electrocorticographic spike frequency (22/10 min versus 70/10 min) were significantly reduced compared with the shams, with no observed behavioural side-effects. Sadly, the seizures in this model spontaneously remit after 21 days or so, so *in vivo* data were only available for up to 2 weeks. Nonetheless, the results are promising and should be investigated in models with a more chronic epileptogenic region. Proof in principle of a focal drug delivery approach in man has also recently been published [8]: in patients undergoing resective surgery for refractory focal epilepsy, maximal spiking cortex was identified using intraoperative electrocorticography (EcoG). Subsequent direct application of lidocaine-soaked gel foam squares resulted in a clear reduction in spike count in all of the three patients studied.

The trigger site

Another potential treatment site for some patients with reflex epilepsies might be the brain area in which seizures are triggered. There are a number of established animal models of reflex epilepsies. The most widely used are genetically epilepsy-prone rats (GEPRs), in whom intense sound stimulation induces hyperlocomotion followed by clonic then tonic motor activity. These audiogenic seizures seem to be triggered from the inferior colliculus and can be suppressed for as long as 3 days with a group II glutamate metabotropic receptor agonist, and for shorter time periods with GABAergic agents or glutamate antagonists (reviewed in ref. 9). Longer-term drug delivery to a trigger site has also been achieved using an implanted mini-pump in the photosensitive baboon, *Papio papio* [10]. In this model, intermittent light stimulation induces bilateral myoclonus preceded by paroxysmal discharges, the neural generation of which has been localized in the motor cortex and has human parallels in some primary generalized epilepsy syndromes. These photoconvulsive responses were blocked during chronic 7-day infusion of GABA into the motor cortex (seizure focus), but also to the occipital cortex (trigger site), which was believed to carry the motor cortex afferents necessary for the induction of paroxysmal discharges. Perhaps surprisingly, there

were no observed behavioural effects in terms of either visual or motor function. In clinical practice, however, a trigger site is rarely identifiable other perhaps than in the context of photosensitivity, and even then it is hard to imagine an agent that might suppress photosensitivity without also affecting vision. Thus, although interesting experimentally, this approach is probably of less clinical relevance than targeting the epileptic focus/seizure onset zone.

Propagation pathways

In patients without an identifiable seizure onset or trigger focus, focal therapies may still offer the chance of at least disrupting the spread of seizure activity around the brain by targeting known key propagation pathways. The substantia nigra has been shown to play a critical role in the spread of seizure activity. In addition to electrical stimulation studies (see Chapters 81 and 82), various focally directed pharmacological manipulations in this region have proved to have at least partial effects in a range of acute seizure provocation and kindling models (reviewed in ref. 9). However, there are neither studies in spontaneous seizure models nor longer-term studies, and, as lesioning of the substantia nigra can produce similar effects and not all of the studies have adequate histological or pharmacodynamic data, whether observed effects represent specific pharmacological drug effects is not always clear. One big potential limitation in terms of clinical applicability is that GABAergic manipulations of the substantia nigra in rats seem to result in consistent side-effects, with unilateral applications producing turning and circling behaviour and bilateral applications inducing increased gnawing and sniffing. How this might translate to man is not yet clear but it is obviously of concern. In addition, as at best this approach seems to reduce seizure severity rather than reducing seizure frequency, it is dubious whether the benefits in all but a few individuals with severe frequent falls and convulsion would outweigh the risks involved.

Seizure-stimulated drug release

In most patients all but very localized minor seizures are associated with a detectable EEG change at onset, and in some this may precede the clinical event by a matter of seconds. Therefore, a further step on from chronic focal drug delivery might be to link seizure onset with acute focal drug delivery, which is an area under investigation. Using a computerized electroencephalography detection system in rats, Stein *et al.* [11] set up a linked, automated drug release system delivering diazepam into the seizure onset zone, which rapidly terminated seizure activity induced by hippocampal bicuculline in rats. In terms of automated electroencephalography detection this is a very preliminary study, and any such system in man would have to be very sophisticated to guarantee accuracy and protect against potential confounding factors, such as movement artefacts and triggering unnecessary release of drugs. However, patient-activated drug delivery systems might be devised for some patients who have a reliable clinical aura of sufficient duration.

Other focal drug delivery approaches

Other ways of targeting drug delivery to the central nervous system (CNS) are also under active investigation in a range of animal models, including epidural/transmeningeal delivery [12,13], which might carry less risk of damage to underlying brain, liposomal formulations of agents [14] and intranasal delivery [15] as a mechanism of at least partially overcoming difficulties related to blood–brain barrier penetration and CNS bioavailability.

As discussed, many of these studies have limitations but, nonetheless, they demonstrate a proof in principle that may open new therapeutic avenues for patients with identified but non-resectable epileptic foci, and potentially also for others with poorly localized onset by targeting known propagation or trigger pathways. However, even with the best of slow-release mechanisms or drug delivery systems, in the lifetime of an epilepsy patient, repeated implantation or refill procedures would be needed, with the attendant increasing risks of complications. In this context grafting of neuronal stem cells, particularly given the potential to manipulate their later differentiation, and for genetic modification in advance of implantation, might provide a more long-term solution. In addition, many epilepsies involve focal brain damage, which at least in principle might be repaired by neuronal grafts in the same way as has been applied in other conditions [16].

Genetic approaches to treatment

Molecular biology advances mean that now we can not only change the genetic make-up of cells *in vitro* before grafting into the brain (as will be reviewed in the next section), but also achieve modifications *in vivo* using recombinant viral vectors to insert genes into host cells in living brain. This is proving to be a very important research tool, enabling term expression of the inserted gene/relevant protein in a way that is not limited by either poor survival of grafted donor cells or the inevitable need to replenish drug delivery devices during the life of the individual. At present, adenoassociated virus (AAV) and lentiviral vectors look the most promising in the context of the brain, as they can transduce non-dividing cells, have an inherent preference for neurones and seem to result in long-lasting gene expression with minimal induction of host immune/inflammatory responses. AAV vectors, as recently reviewed [17,18], have been most widely used in epilepsy, as they can efficiently express therapeutic genes with a wide range of regulator elements, for example cell-specific/condition-dependent promoters, improving the efficiency with which alterations can be targeted to the key cell population that is believed to be relevant in the seizure model in question. This area is really still in its infancy, with most studies being focused on the induction of antiepileptic neuropeptides, such as galanin and neuropeptide Y (NPY), which look promising. Unfortunately, most studies to date involve transfection before the epilepsy/seizure-inducing insult in kindling or acute seizure provocation models, so are of largely mechanistic rather than clinical interest, although anticonvulsant effects are demonstrable. Two studies perhaps deserve specific mention, having shown what appears to be disease-modifying/antiepileptogenic effects in models with spontaneous recurrent seizures. The first of these [19] used AAV vectors to increase expression of $GABA_A$ receptor α1-subunit mRNA and protein in the dentate gyrus at 1–2 weeks after status epilepticus (SE), and

showed this to correlate with a threefold increase in mean seizure-free time after SE and a convincing 60% decrease in the number of rats developing epilepsy in the first 4 weeks after SE. The study is noteworthy in that it made novel use of a condition-dependent promoter, up-regulated after SE, to effect this change, although its clinical promise is hampered by the fact that AAV transfection was performed 2 weeks before the SE-inducing insult, and 30% of the transfected animals had excessive sedation, anorexia and weight loss persisting for the duration of the study. The more recent study used a more clinically relevant paradigm in which AAV transfection of the NPY gene was undertaken 3 months after electrically induced SE, in a well-characterized rat model with established spontaneous seizures [20]. In this model, the spontaneous seizures typically progress in severity and frequency over time, as was evident over a 2-week period of continuous video-EEG recording in sham-transfected and control animals. In a series of very carefully controlled experiments this progression was prevented by hippocampal NPY overexpression, despite the fact that immunohistochemical studies showed the biochemical effect to be limited to only 3 mm around the injection site. In addition to this antiepileptogenic effect, 40% of transfected animals had significant reductions in seizure frequency compared with their pretransfection baseline, thus supporting antiepileptic actions also athough all animals continued to have seizures. The Food and Drug Administration is said to be evaluating a clinical study based on this work [18]; whether this will prove practical at this stage remains to be seen, given that only a minority of patients with SE go on to develop epilepsy and that very anatomically accurate gene delivery appeared necessary.

Neuronal grafting

Repletion of depleted neurotransmitters

A number of studies have been conducted in experimental epilepsy and seizure models to address the potential for neuronal grafting as a treatment for epilepsy, and have been authoritatively reviewed elsewhere [17,21]. The majority of initial studies used similar experimental paradigms in which specific neurotransmitter inputs to the hippocampus (noradrenergic, cholinergic or serotonergic) are specifically targeted using physical or chemical means, increasing susceptibility to subsequent seizure provocations. This is followed by grafting, usually using cells of same-species fetal origin, with the aim of replenishing the previously depleted neurotransmitter and restoring seizure susceptibility to control (predepletion) levels. This type of study has been undertaken either in previously normal animals with subsequent electrical kindling or in models with established seizure tendencies such as the GEPR. The results of such studies (reviewed in ref. 9) are sometimes conflicting and are not always easy to interpret, given the variation in models, experimental detail and variable graft–host integration. Broadly speaking, however, particularly with respect to noradrenergic grafts, the results support that after specific neurotransmitter lesioning, appropriate fetal grafting can restore the targeted neurotransmitter levels to near normal, with some host integration and synaptic connectivity. In addition, as long as grafts are undertaken before any seizures have been provoked, then the seizure threshold is similarly returned to control (unlesioned) levels. These studies thus support the potential of neuronal grafts in terms of neurochemical restoration in epilepsy, but the real question is whether this approach can be utilized in models with spontaneous seizures in the absence of specific prior neurochemical lesioning.

Grafting fetal cells in other models

Sadly, when grafts similar to those described above have been undertaken in animals not subjected to prior specific neurotransmitter lesioning, or when grafting has been undertaken only after seizures have already occurred, results are mostly disappointing. Thus, even in noradrenergic depleted rats, the grafting of locus coeruleus noradrenergic cells after kindling seizures had been established produced no significant benefits [22]. Similarly, although GEPRs have been documented to naturally have both widespread deficits in noradrenergic function, and some serotonergic deficit before seizures occur [23], grafting of fetal locus coeruleus tissue into the lateral ventricles or inferior colliculus of GEPRs without additional prior noradrenergic depletion results in, at best, minor improvements that are unlikely to be of clinical significance [24]. Similarly, in the same model, others have reported no significant reduction in seizure severity with fetal locus coeruleus [25] or raphe [26] grafts to the hippocampus, although the power of such studies is often limited by small numbers and considerable variation in graft survival and integration.

Noradrenergic grafting has also been assessed in models without specific known deficits and in whom spontaneous seizures occur, which might be considered to be more appropriate to human epilepsy. The pilocarpine rat model has initial SE, following which the animals develop chronic spontaneous temporal lobe seizures with pathology similar to that of hippocampal sclerosis and additional widespread limbic forebrain damage. Bilaterally grafting cell suspensions of fetal locus coeruleus tissue into the hippocampus after SE in this model significantly reduced the number of spontaneous seizures in comparison with non-grafted animals and animals with grafts into the cerebellum or olfactory bulbs [27]. The decrease in seizure frequency, which occurred 6 weeks after grafting, when host integration would be expected to be maximal, was maintained for up to 15 weeks. However, it was not seen in all animals and, crucially, the study did not provide any histological evaluation of graft placement, survival, phenotype or integration. Thus, it is unclear whether the apparent treatment effect was in any way related to neuronal grafts as opposed to other non-specific focal effects (including hippocampal lesioning/destruction, which is of known efficacy) and further studies have not been reported. In contrast, implanting locus coeruleus cells bilaterally in to the hippocampus after pretreating with kainic acid, which produces a similar clinical phenotype, had no effect on subsequent kindling parameters [28]. However, the animals grafted with locus coeruleus cells did have fewer spontaneous seizures after kainic acid administration than control subjects, suggesting a mild treatment effect and illustrating that the outcome in provoked seizure models cannot necessarily be extrapolated to those with spontaneous seizures.

With the established efficacy of several licensed GABAergic drugs in epilepsy, and the promising results from initial focal drug

delivery studies, grafting of GABAergic neurones, which are most commonly derived from the fetal striatum, might be a more useful treatment strategy. Numerous studies have demonstrated that such grafts can survive, make axonal connections and restore GABA release in lesioned animals (reviewed in ref. 9), and there have now been a number of studies specifically addressing this in epilepsy. Fine *et al*. [29] increased seizure susceptibility by lesioning the caudate putamen with a glutamate receptor agonist, ibotenic acid, before grafting fetal striatal cells or a control graft of sciatic tissue into the substantia nigra pars reticulum. Unfortunately, both GABAergic and the sham/control sciatic nerve grafts reduced the severity of pilocarpine-induced seizures to almost that of the intact animal, and the survival of grafted neurones was not evaluated. Thus, this may represent a non-specific effect from lesioning the substantia nigra, although the treatment effects were slightly greater in the GABAergic grafted animals. Studies of fetal GABAergic grafts to the substantia nigra in fully kindled animals have been disappointing [30], producing only a transient initial increase in the threshold for eliciting focal epileptiform EEG activity, without any significant difference in clinical or electrographic seizure duration.

Hippocampal repair

Given the frequency of hippocampal sclerosis with its characteristic pattern of specific neuronal loss as a pathological substrate for human epilepsy, many investigators have concentrated on the therapeutic potential for neuronal grafts to effect hippocampal repair. Several animal models exist that mimic this pathology, usually with initial acutely provoked (electrical stimulation or chemical – e.g. kainic acid, pilocarpine) SE followed by chronic spontaneous seizures.

A series of eloquent studies in rats given unilateral intraventricular kainic acid are reviewed in ref. 21. This typically results in significant loss of CA3 pyramidal cells and glutamic acid decarboxylase (GAD)-positive interneurones, with relative preservation of CA1 and dentate granule cells. In this model, fetal hippocampal cells (either mixed hippocampal cell populations or those derived from the CA3 subfield) grafted into the lesioned hippocampus are associated with a restoration of total neuronal number, and, moreover, with limited damage to the host hippocampus by the graft itself. The grafts also appear to reverse or prevent other secondary pathological consequences. This includes aberrant sprouting of host mossy fibres into the dentate supragranular layer, thereby restoring the damaged cytoarchitecture, possibly by providing appropriate target neurones. The grafts themselves survive well, differentiate into mature neurones and form connections with host tissue; GAD-positive interneurone numbers are also restored, although it seems not directly from the grafted population. For good connectivity both the precise location of the graft within the hippocampus and the donor cell type appear to be important. All grafts (mixed hippocampus, CA1 or CA3 cells) showed good cell survival and sent projections to the ipsilateral septum, but only grafted tissue located in the degenerated CA3 cell layer and containing CA3 donor cells contained neurones that established robust projections to the contralateral hippocampus, resembling the projection pattern seen in intact animals. Similarly, grafts from the CA1 subfield had no effect on GAD-positive interneurone numbers, which the authors interpret as reflecting that the loss of CA3 afferents contributes to a secondary loss of the GAD protein expression, thus reversed only by repleting CA3 cells. The specificity and success of neuronal grafting to the hippocampus clinically could therefore depend upon matching specific cells to specific lesion types and, as the authors point out, in contrast to the kainic acid model, human hippocampal sclerosis involves damage to the CA1 region as well as the CA3 region and would therefore potentially require multiple grafts of appropriate cells.

A further problem is that grafting is most commonly undertaken only days after kainic acid lesioning in many of these studies, as it had been previously found that grafts implanted after this time resulted in steadily decreasing cell survival [31]. When cells were grafted 45 days post lesion, and examined 1 month later, cell survival had fallen to 31% [32] in comparison with 69% at 4 days post lesion [33]. It is not known when hippocampal cell loss in epileptic patients occurs but it is likely that any grafting would only be considered relatively late in the disease process and, inevitably, after seizure onset. However, survival 1 month after grafting appeared to be a good predictor of long-term (1-year) cell survival [34], and even the lower survival levels appeared to be sufficient to result in structural repair of the local damage.

The biggest limitation of these studies, however, is that the model did not exhibit spontaneous behavioural seizures (personal communication, A.K. Shetty, 2002), so no information on the potential therapeutic benefits of these grafts in terms of seizure outcome is available. It is also recognized that hippocampal cell death is neither necessary nor sufficient for epileptogenesis [35], so any repair that can be achieved may have little influence on the epilepsy although it may affect other clinically important parameters such as memory function. Other groups have found that grafts to both the intact hippocampus [36] or to lesioned hippocampi [37] may in some instances themselves be epileptogenic, with both electrographic spiking and occasional behavioural seizures occurring in previously non-epileptic animals. Thus, there are a number of concerns about the potential of attempted hippocampal repair as a strategy for neuronal grafting in epilepsy, particularly when balanced against the established efficacy of surgical resection of hippocampal foci in man.

Some studies have reported slightly more promising results. A study in a small number of amygdala-kindled rats showed that fetal hippocampal cells grafted near the CA2 region of the hippocampus reduced the severity of subsequent kindling-induced seizures to some extent in 80% of animals [38]. However, for most animals the seizure severity levels fluctuated with increasing number of stimulations, sometimes reaching pregraft levels. A very mild beneficial effect was also seen after transplanting hippocampal cells into the kainic acid-degenerated hippocampus. Although grafting had no effect on subsequent kindling-induced seizures, there was a slight reduction in the number of spontaneous seizures following the kainic acid administration [28]. More recently, Rao *et al*. [39] grafted hippocampal cells, with and without pretreatments (growth factors and caspase inhibitors) to improve graft survival, on to rats with spontaneous temporal lobe seizures following kainic acid-induced SE. The grafting was undertaken 4 months after the SE, when the animals had well-established seizures (a clinically relevant paradigm), and although there are no electroencephalographic data and small numbers

(five animals per treatment group), the results look convincing. In animals receiving untreated fetal hippocampal grafts, in which approximately 30% of grafted cells survived, no benefits were seen. However, in those receiving pretreated grafts, with 57–98% graft survival, seizure frequencies were up to 75% lower than those in ungrafted control subjects and also less severe. Interestingly, this seemed to correlate not with extent of hippocampal injury/restoration or hippocampal damage but simply with the presence of the graft per se, so the mechanism of this effect is unclear.

Overall with respect to hippocampal grafting/repair, work in this area is again still in its infancy. There is no conclusive evidence as yet that this approach will work; even if grafting in the first few weeks after an epileptogenic insult such as SE does prove consistently effective in animal models, clinical application will be difficult as the majority of patients with temporal lobe epilepsy do not have a clear initial insult and, conversely, many with the commonest insults (febrile seizures) do not ever develop epilepsy. Furthermore, many methodological questions (for example relating to cell type, strategies for enhancing graft survival, timing of grafting, etc.) need to be answered before we will know the real potential of fetal stem cell grafting as a treatment for epilepsy, and in our view it is unlikely this will translate into clinical practice within the next decade.

Transplantation of genetically engineered cells

Arguably, a more promising approach is to effectively combine what we know from focal drug studies and epilepsy therapeutics generally with advances in genetic and stem cell biology, by engineering cells for grafting that can effectively serve as a potentially permanent drug delivery reservoir. Several groups are now exploiting this potential, which, in our view, is the one most likely to directly benefit patients out of all of those that are discussed in this chapter.

GABAergic cell grafting

Initial studies using conditionally immortalized neuronal cell lines, genetically engineered to increase production and release of GABA by driving GAD_{65} expression [40], grafted to the substantia nigra in a limbic kindling model gave conflicting results depending on whether the graft was in the anterior substantia nigra (anticonvulsant) or posterior (pro-convulsant) substantia nigra, illustrating the complexity of seizure propagation pathways. The results of grafting this cell line in to the piriform cortex in the same model [41] were also disappointing, with only a very transient effect on seizure threshold before kindling, and no significant difference on any parameters after kindling. Grafting to the dentate gyrus [42] at face value looked a little more promising, with clear effects on subsequent afterdischarge threshold/duration and on kindled seizures. In the only published study by this group in a model with established spontaneous seizures [43], grafting to the substantia nigra in epileptic rats 2–3 months after pilocarpine-induced SE did reduce spontaneous seizures and epileptiform electroencephalographic activity more convincingly. However, a consistent problem faced by the investigators has been poor graft survival, <30% in the most recent studies even after a few days, which might in part explain the disappointing results, together with the possibility of down-regulation of GABA synthesis/receptors, and is certainly a barrier to moving forwards. Others have managed to achieve longer-lasting effects with immortalized GABAergic grafts to the substantia nigra, most recently including in a model of recurrent spontaneous seizures following kainic acid-induced SE in rats [44], although the benefits (30–50% reduction in the incidence of more severe, convulsive seizures) were perhaps modest, similar to those of new AEDs in the refractory epilepsy population.

Conversely, galactosidase (GAL)-labelled (encoded) human neural stem cells injected intravenously the day after pilocarpine-induced SE in rats [45] led to an impressive reduction in spontaneous seizures assessed 28–25 days later, with 87% of non-grafted animals developing spontaneous convulsive seizures compared with only 13% of the grafted group. Furthermore, subsequent *ex vivo* electrophysiological slice studies similarly demonstrated less excitability in the hippocampus of grafted animals. Histological studies showed GAL-positive cells throughout the brain, although few had mature neuronal phenotypes. In the hippocampus and piriform cortex, however, areas of maximal damage following pilocarpine SE, GAL-positive cells with GABA interneurone phenotypes were identified. The authors conclude that the neural stem cells have resulted in GABA-synthesizing cells in the injured hippocampus, thus suppressing spontaneous seizures; this is certainly plausible, although longer-term and more detailed experiments are required to take this work further and problems remain relating to identifying at-risk patients and the timing of grafting after any insult.

Adenosine

Adenosine is an endogenous neuromodulator with established antiepileptic and neuroprotective actions and, as such, is an attractive target in epilepsy. However, therapeutic use of adenosine or its agonists is largely precluded by significant peripheral and central side-effects, making it in many ways an ideal compound to explore using focal techniques. Initial work in this area used polymer-based drug delivery systems but has since moved on, as reviewed in ref. 46, to bring together technology from drug delivery systems, genetic engineering and stem cell grafting. Thus, studies involving paracrine release of adenosine from genetically engineered myoblasts and fibroblasts have each demonstrated clear antiepileptogenic potential, mostly studied in a kindling model. Long-term potential, as with GABAergic grafts, has been limited by poor cell survival. This group thus are now moving on to explore the use of technologies, such as encapsulation of grafts within synthetic polymers, or the use of biopolymer substrates to promote long-term adenosine release from encapsulated cells [47], which might provide some solutions and is certainly an area to watch. In addition, further studies in different models are needed, particularly when seizures are already established.

Conclusion

Epilepsy is a heterogeneous neurological condition and, despite recent advances, it seems likely that there will remain a significant cohort of intractable patients for whom other treatment approaches need to be developed.

At present many of the focal treatment studies have been carried out in experimental models with provoked seizures and there are still relatively few in good models with spontaneous chronic seizures, in part reflecting the practical difficulties and resource implications of long-term seizure monitoring in animals. If we are to develop strategies that might be translatable into clinical practice, which surely must be the primary aim, it is these long term studies that are now needed.

Focal drug delivery systems certainly show promise, although more detailed long-term studies in a range of experimental models, including behavioural outcomes, are needed. Neuronal grafting on face value holds the promise of effecting potentially permanent local change and initial studies demonstrate the feasibility of restoring neuronal loss, altering circuitry or increasing local neurochemical concentrations, all of which might prove beneficial in epilepsy. However, in addition to the limitations posed by the models used, the most promising results have arisen when the time between the initial insult and transplantation was short: (1) when specific known lesions and depletions were made before grafting and the appropriate type of grafted cells was used to match the lesion and (2) when therapeutic intervention occurred in advance of a chronic epileptic tendency being established. None of these scenarios can be applied to most clinical situations and it is recognized that grafts take less well to brain that is not acutely damaged, and that achieving long-term graft survival in cortical brain regions is especially difficult. Furthermore, although there is also increasing interest in antiepileptogenic treatments, which are often it seems perceived as a 'holy grail', it is a huge challenge to identify in practice which patients would benefit from such an intervention and at what stage in the development of their epilepsy.

Finally, whether considering focal drug delivery, genetic manipulation or grafting studies we do not yet know whether the benefits might only be transient, even with a permanent therapeutic local manipulation, given the known highly adaptable capacity of the brain in terms of receptor function and reorganization. The long-term ethical and safety aspects of using stem cell and genetic engineering approaches also require further careful scrutiny, particularly for epilepsy patients who have a normal life expectancy. Nonetheless, focal treatment techniques in epilepsy offer a novel approach to an important clinical problem and the promise that more patients may lead seizure-free lives with ongoing work in this field in the years to come.

85 Epilepsy Surgery in Countries with Limited Resources

Andre Palmini

Porto Alegre Epilepsy Surgery Program, Hospital São Lucas – Catholic University (PUCRS), Porto Alegre, Brazil

Introduction

Ten years ago, the International League Against Epilepsy (ILAE) included in one of the main sessions of the International Epilepsy Congress in Prague a talk on epilepsy surgery in developing countries [1]. The preparation of that talk led to a reflection on the issue and to a review of the pertinent literature available at the time. Furthermore, it prompted a debate on the issue with experienced epileptologists from some of the main epilepsy centres in develop*ed* countries and also stimulated consultations on the issue with a number of specialists from develop*ing* countries who were involved in selecting patients with refractory seizures for surgical treatment, with the constraints imposed by limited resources. A couple of publications resulted from that initiative [2,3].

Here, it is interesting to note that some predictions made 10 years ago have become reality, particularly that technological and conceptual advances promoted by epilepsy centres in developed countries have indeed helped to streamline presurgical evaluation and surgical decisions in epilepsy programmes of countries with more limited resources. Below, it will be demonstrated that research conducted by technologically sophisticated centres has translated into simpler and effective strategies to evaluate patients for surgery in poorer regions of the globe. Such efforts in the industrialized world to support and disseminate advances that make epilepsy surgery more cost-effective are already aiding thousands of people in developing countries who need not suffer the consequences of medically refractory seizures [4,5]. In countries of limited resources, where the implementation of epilepsy surgery centres has proved successful, epileptologists and neurosurgeons have found financial and academic support to train in well-established epilepsy centres from richer countries. Such training has been crucial to promote the effective 'blending' of the knowledge resulted from high-class clinical research with the development of realistic protocols to be in applied in emergent epilepsy centres in developing countries.

This chapter reviews the evolution of epilepsy surgery in countries with limited resources. It starts by emphasizing the need for epilepsy surgery in these countries and then explores how clinical research conducted in technologically developed countries is impacting on the approach to refractory epilepsy in countries with limited resources. A discussion follows on how epilepsy centres in these latter countries are organized in order to offer surgery as a treatment option in epilepsy.

Before starting, attention to some important issues must be drawn. Firstly, it should be understood that there are two levels of heterogeneity in this discussion. At one level is the fact that expertise and technology in some countries of limited resources are similar to those in the developed world, whereas in others the gap is profound [6,7]. At another level, inequalities of access to good-quality of care *within a given country* are also a source of heterogeneity. Because the latter is a crucial issue, the views expressed here will be biased to what is offered by public health systems in countries with limited resources. A second point is that it is important to avoid a naive view of epilepsy surgery and accept that different centres approach a given 'epilepsy scenario' in different ways. Thus, some of the statements to be made here will not meet with unanimous acceptance – to say the very least. Nevertheless, in a field lacking randomized, controlled trials comparing the efficacy and/or the effectiveness of different evaluative or resective procedures, this is an unavoidable debate. Finally, it is commonplace in epilepsy surgery texts to stress diagnostic and localizing aspects of refractory epilepsies, putting less emphasis on the role of the surgeon's knowledge about epilepsy and his/her technical abilities to resect epileptogenic tissue. Clearly, there is no point in launching an epilepsy surgery programme without a good epilepsy surgeon. Developing countries are home to some extremely capable neurosurgeons, and the importance of getting them interested in joining an epilepsy team cannot be overemphasized.

The need for epilepsy surgery in countries with limited resources

The establishment of specialized epilepsy centres in developing countries makes sense epidemiologically, and has been instrumental in providing good-quality training programmes. Epileptologists who are trained in these centres can then provide much better care for patients with epilepsy in the community and also become regional leaders in the field. In addition, the establishment of such centres has allowed access to surgical treatment for a significant number of patients with surgically remediable epilepsy syndromes.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Approximately 90% of persons with epilepsy live in developing countries [6–10]. Thus, 90% of epileptic patients who could potentially benefit from surgical treatment live in these regions, providing an important ethical argument for the establishment of epilepsy surgery programmes in developing countries. A treatment modality exists which can significantly alleviate disability for large numbers of people with refractory epileptic seizures; therefore, there is an ethical obligation for those involved in the care of these patients to pursue all possible avenues in order to make this treatment modality available where it is most needed.

Moreover, developing countries appear to have a greater prevalence of epilepsy, with figures ranging from 15 to 20 per 1000 persons [8,9,11], as compared with develop*ed* countries, where the prevalence is closer to 4 to 10 per 1000 persons [12,13]. Suboptimal obstetric care, poor regulation of driving and working conditions, and the general health (including poor nutrition) are partially responsible for this difference.

An ongoing challenge is to reconcile the need for expertise with the need to make epilepsy surgery widely available. The most important resource to implement successful surgical programmes is well-trained personnel. As will be further discussed below, advances in epileptological research have streamlined the processes of presurgical work-up for a large proportion of surgically remediable epilepsy syndromes. However, the only reliable way to translate these advances into practical and effective protocols for countries with limited resources is through solid training of the specialists who will lead the process. As alluded to in the introduction, the best models involved the interaction between specialists who have been trained abroad and their local colleagues, boosting development of regional epilepsy surgery programmes. More recently, there has been a move towards new specialists being trained locally, at least in some centres in countries with limited resources, such as Brazil.

In countries with limited resources, it is counterproductive to confuse the minimum with the ideal requirements for an epilepsy surgery programme and, thereby, postpone the benefit for those who can be helped immediately [1–3]. Epilepsy centres in developing countries should not be prevented from performing surgical treatment because they are not as well equipped as centres in developed countries, *provided that adequate expertise exists*; well-trained personnel can do a qualified job without the latest, most expensive technological advances.

The economic feasibility of surgical treatment in countries with limited resources is readily apparent. Data from countries such as Brazil and India show that epilepsy surgery can be performed at one-tenth or less of the cost in developed countries [5,10].

Also, it is important to understand that antiepileptic drugs (AEDs) are often unavailable, unaffordable or irregularly distributed in countries with limited resources [14]. It is clear that Third World governments are not purchasing and/or distributing adequate amounts of AEDs, and that most patients with epilepsy cannot afford to buy them. For those with medically refractory seizures – the ones taking more AEDs, and in greatest need of regular supplies – the situation is even worse. To operate successfully on some of those with medically refractory epilepsy would have an enormous, far-reaching impact on this aspect of medical care. The realistic goal to reduce or eliminate the need of AEDs in many patients should be critically considered in both the ethical and economic arguments for epilepsy surgery in developing countries [15].

Because opportunities for education and work are considerably more limited in developing countries, the handicap imposed by uncontrolled epilepsy is almost certainly greater than in areas where schooling and employment are easier to obtain. Recent data have shown that about one-half of the people who are unemployed before epilepsy surgery can find a job after operation, providing the patient does not have learning difficulties and his/her seizures are satisfactorily controlled by the procedure [16]. Psychological and social rehabilitation, however, is dependent on the preoperative educational and vocational status of the patients, indicating the need for an earlier and more aggressive approach to surgical intervention [16–19]. For non-welfare states, losing a job, or not obtaining one in the first place, can be catastrophic for the lifetime of the individual. If the cost incurred by the whole 'entourage' of the person with epilepsy is considered – money spent to travel to the doctor's office, time of caregivers off their workplaces, impossibility of caregivers holding jobs [8,20–22] – there would be an exponential beneficial effect of controlling seizures surgically. Reintegration into society, not only of the patients, but also of their caregivers [8,20–22], would justify the costs of supporting the implementation of epilepsy surgery programmes in countries with limited resources.

Surgically remediable epilepsies: conceptual advances and the impact on epilepsy surgery in countries with limited resources

The concept of surgically remediable epilepsies refers to those epileptic syndromes that are usually refractory to AEDs but respond well to surgical treatment [4]. Major advances in epileptology have had a significant impact on the feasibility of epilepsy surgery for many surgically remediable epilepsies in countries of limited resources. Technology-based research with sophisticated imaging and neurophysiological tools [18,23] resulted in a simplification of presurgical protocols in such a way that presurgical evaluation and surgical management of patients with many of these conditions can now be performed without excessive technological sophistication, provided that skilful personnel are available to identify, evaluate and operate on them.

In at least three common surgically remediable 'scenarios', technological and conceptual advances generated by developed centres translated into more practical and feasible approaches to the evaluation and surgical treatment of patients with refractory seizures: (1) temporal lobe epilepsy associated with hippocampal sclerosis (TLE/HS); (2) epilepsies due to neocortical and limbic tumours; and (3) the understanding of the relevance and simplification of surgical decisions associated with large unilateral (hemispheric) lesions in children with severe epilepsies. These advances will be briefly reviewed and their role in helping out countries of limited resources to offer surgical treatment of epilepsies will be highlighted. Situations within these broader scenarios in which a higher level of experience and

technological sophistication are still needed will also be pointed out.

Patients who have temporal lobe epilepsy associated with hippocampal sclerosis can be evaluated non-invasively, often without the need for ictal recordings

Gone are the days when major uncertainties revolved around decision-making in TLE. In the pre-MRI era, any ratio of bilateral independent interictal discharges or any deviation from classical semiology dictated the need for invasive evaluation with intracranial electrodes [24,25]. The advent of MRI made clear that bilateral independent discharges are a common finding in patients with TLE associated with unilateral hippocampal atrophy, and outcome analysis in these patients demonstrated that favourable surgical results could be obtained with unilateral resection of the atrophic mesial temporal structures despite bitemporal spikes [15,26]. This obviated the need for invasive recordings, except for very selected cases (briefly reviewed below). In addition, two more recent developments have had even more impact for streamlining the evaluation of these patients. One is the possibility to move on to surgery based upon the combination of a typical semiological description, MRI identification of unilateral hippocampal sclerosis, and interictal epileptic discharges and neuropsychology concordant with the MRI [18]. The other is the reduced need for the Wada test for determining memory reserve, which derived from extensive experience with non-invasive neuropsychological evaluation and the correlation of these non-invasive findings with MRI, results of the Wada test and postoperative memory outcomes [15].

An obvious note of caution is that extensive experience with presurgical evaluation is crucial to take advantage of these simplifications in the work-up. However, such experience can be built (and is being built) in epilepsy centres in developing countries in such a way that advances derived from extensive research in developed centres are indeed being translated into better chances for patients with epilepsy who require surgery but who live in countries of limited resources. The readier availability of pertinent literature, the fact that training in the epilepsy surgery field mimics the long-held tutoring tradition in medicine (in the sense that some or most leaders of epilepsy centres in developing countries were trained – practically tutored – by experienced epileptologists in developed centres) and the energetic enthusiasm demonstrated by emerging multidisciplinary teams in countries with limited resources all contribute to a rational and straightforward development of the field.

However, there are situations in which patients with clinically and MRI-determined TLE/HS will need a more sophisticated presurgical evaluation, either including scalp ictal recordings, the Wada test or possibly invasive electrodes. These include at least those patients with bilateral hippocampal atrophy, those in whom despite unilateral atrophy the interictal discharges predominate in the opposite side, those with discordant findings between ictal electroencephalography and MRI, and also those in whom results from non-invasive memory testing are not straightforward or are discordant with the electroencephalogram (EEG) or imaging. In addition, patients with a strong suspicion of psychogenic non-epileptic seizures may also need a more detailed presurgical work-up. The goal of this chapter is not to analyse all these situations in detail (most are indeed the subject of active current research with the benefit of technologically advanced methodologies such as functional imaging), but to highlight the fact that these are the minority of cases of TLE/HS in epilepsy centres in developing countries. Today, most patients with TLE/HS can be worked up in a simplified fashion, and this is a clear demonstration of the benefit of advances in the field that are generated by developed centres helping the treatment of patients from countries with poorer resources.

Lesionectomy plus electrocorticography-guided corticectomy can successfully treat most medically refractory epilepsies due to neocortical and limbic tumours

A never-ending debate contrasts the views of epileptologists when approaching patients with refractory seizures due to low-grade gliomas and developmental tumours. These are patients in whom seizure semiology either reflects the cortical area harbouring the lesion or well-known symptomatogenic zones activated by ictal propagation through predictable pathways. Not unexpectedly, there are indeed instances when seizure semiology is uncharacteristic or poorly indicative of a specific cortical localization. The 'focus' of debate is whether one can assume that the 'focus' (i.e. the epileptogenic zone) is contained in the surroundings of the lesion or if it should be actively probed through invasive strategies. A number of (descriptive) studies have shown that resection of the lesion combined with electrocorticography (EcoG)-guided corticectomy can lead to very good results (reviewed in ref. 27). My understanding is that opposing views (i.e. those in favour of invasive evaluations in these patients) are fuelled much more by conceptual differences than by the objectivity of better results.

As in the situation concerning TLE/HS, there are instances when one needs a more sophisticated evaluation of patients with seizures due to low-grade tumours, particularly when the lesions are located in the vicinity of eloquent motor or language cortical regions. Again, these are the minority of cases, and the clinical research entertained by different centres in rich countries suggests that in most instances presurgical evaluation can be conducted non-invasively leading to high grades of seizure control with surgery.

In children with severe epilepsies, surgical decisions associated with large unilateral lesions are usually straightforward

The work of centres of excellence in paediatric epilepsy surgery has demonstrated that epilepsy surgery in children aims both at seizure control and at unleashing motor/cognitive development [28,29]. Taking advantage of (and promoting) brain plasticity in the first years of life is crucial to an adequate management of children with severe epilepsies due to unilateral large lesions. Most of these children have one of a limited number of aetiological entities that are amenable to a simplified, objective presurgical evaluation and early surgical referral. Thus, children with hemimegalencephaly and other hemispheral malformations, Sturge–Weber disease, Rasmussen's encephalitis and large unilateral porencephalies often present with congenital hemiparesis, severe epilepsy, psychomotor retardation and a pseudoencephalopathic

EEG [30]. Understanding that these children with unilateral epileptogenic lesions must be referred to surgery despite diffuse electroencephalographic abnormalities is a crucial epileptological construct, and such knowledge should see no boundaries between countries with extensive or limited resources.

For the present discussion, it should be made clear that a very good surgeon and adequate postoperative management in paediatric intensive care units are the key elements in these cases. It really does not matter very much whether interictal spikes are unilateral, bilateral independent or generalized. When facing a child with refractory epilepsy and psychomotor slowing due to a large unilateral lesion, the lesion must be removed either through a multilobar resection or a functional hemispherectomy. There is usually no need for invasive recordings or sophisticated functional imaging studies, although in some selected cases long-term prognosis may be related to the extent, for instance, of metabolic abnormalities in the 'good' hemisphere [31]. Important issues in this scenario sometimes must be dealt with by more experienced teams. For example, some large cortical malformations may apparently spare the primary motor cortex but microscopic extension to this region is often seen. Thus, to determine the best strategy may be difficult, and reoperations are not uncommon when a more conservative approach is preferred. There are also issues related to language dominance and transfer. When dealing with children with large destructive lesions also involving language cortex, language is almost certainly transferred to the other hemisphere; however, this is not always the case with malformative lesions, for instance, and the age at operation is then most relevant in terms of anticipated language plasticity [32]. Despite intricacies involved in decision-making in some cases, the point here is that surgery is indicated in many or most cases of large hemispheric lesions in children with refractory epilepsy and psychomotor retardation, and may be planned on the basis of simplified presurgical protocols that are accessible to epilepsy centres in areas of limited resources.

How epilepsy centres in countries with limited resources are organized to offer surgery as a treatment option in epilepsy: the stepwise approach, the minimal requirements and the Brazilian experience

In general, the level of organization and expertise of epilepsy centres in countries of limited resources has not really changed in the last 10 years. What has happened, however, is that some centres have clearly upgraded their capabilities and many others have started out, naturally focusing on the simpler cases.

Stepwise approach

Before discussing the approaches for refractory epilepsies in epilepsy centres in countries with limited resources, let us briefly review the performance and the type of cases evaluated and operated upon by centres in developed countries. Of 11680 operations for epilepsy reported by developed countries throughout 1990, 7766 (66%) were anterior temporal lobectomies or amygdalohippocampectomies performed for refractory temporal lobe epilepsies. In 2000, the group at the Mayo Clinic reported their results for the 5-year period 1989–1993. At the latest count, only 210 out of 493 operated patients (42%) had achieved 1 year or more of seizure freedom at any time during the follow-up. Interestingly, almost 90% of these 210 patients (188 to reproduce the exact figure) were temporal lobe cases [33]. These results from a highly regarded institution in the USA demonstrate that there is still much room for improvement in the performance of centres from developed countries when tackling extra-temporal epilepsy patients presenting with refractory seizures.

Minimum requirements

The minimum requirements to run an epilepsy surgery programme in countries of limited resources depend upon the types of surgically remediable epilepsy syndromes that a given centre would want to approach [2]. A rational framework would be to get organized to evaluate and operate on patients presenting with the three surgically remediable epilepsy scenarios discussed above: mesial temporal lobe epilepsy, low-grade gliomas and developmental tumours, and large unilateral lesions in children. These entities are common and their presurgical evaluation is not too demanding in terms of 'requirements'. Most patients who harbour these surgically remediable epilepsies can be successfully operated on the basis of epileptological and neurosurgical expertise, scalp electroencephalography, clinical semiology, MRI and neuropsychological testing [34–43]. Thus, these are the basic requirements for an epilepsy surgery programme in countries of limited resources [1–3]. However, well-trained specialists, providing the necessary expertise, are the key. A stepwise approach to more complex epileptic disorders would then be matched by an increase in the technological capabilities at selected regional and national centres [2].

In addition, there is the obvious need to optimize the allocation of limited technological resources. In practice, this means that potential candidates for epilepsy surgery must have access to MRI and video-EEG monitoring in countries where inequalities of medical care may tend to restrict availability of costly procedures to certain strata of the population. National campaigns, with the support of the ILAE, can, and should, be promoted to rationalize the use of the necessary resources in favour of those patients who will most likely benefit from a surgical procedure (see section on the Brazilian experience, below).

The Brazilian experience

In Brazil, 1994 saw the establishment of a national epilepsy surgery programme within the public health system, sponsored and coordinated by the Health Department. This programme was created by the joint efforts of the Brazilian League of Epilepsy, the Brazilian Society of Clinical Neurophysiology and the Brazilian Society of Neurosurgery, all of which were active participants of a Committee named directly by the Minister of Health. The main objectives of this Committee were threefold: (1) to establish a nationwide epilepsy surgery programme; (2) to implement internationally accepted medical standards; and (3) to maximally optimize resources at low costs. In order to achieve these goals a two-step strategy was implemented, which included strict criteria for accreditation of epilepsy surgery centres based on minimal requirements and clearly defined guidelines for indication of epi-

lepsy surgery (temporal and extratemporal resective surgery, hemispherectomy and callosotomy).

The first 10 years (1994–2004) of the programme have proved to be highly successful in several aspects. It started out in 1994 with three accredited centres and expanded to eight centres, distributed in different geographical regions – seven connected to academic institutions that were dedicated not only to medical assistance, but also to education and research. Other emerging centres are applying at present for accreditation as epilepsy surgery centres, in an organized process led by the Health Department.

The implementation of this programme led to universal access to epilepsy surgery in Brazil, increased 13 times the annual number of epilepsy surgeries, and boosted the scientific development in the field of epileptology. Moreover, the programme encouraged a network of centres with full capacity to train young Brazilian professionals in epileptology, with tremendous gains in patient care at all levels, including in the surgical treatment of epilepsy.

Are minimum requirements for performing epilepsy surgery changing?

The answer to this question is 'probably not'. What is changing is the profile of patients being operated on at epilepsy surgery centres in develop*ed* countries as a result of technological advances, particularly in neuroimaging [44]. A stepwise inclusion of more and more complex epileptic conditions (i.e. broadening of the indications for epilepsy surgery) can occur both in develop*ed* and in developing countries at the same rate as refinements in the preoperative diagnostic technology. It is clear that more patients benefit with technological advances, but it is important not to hamper development of epilepsy surgery in countries with limited resources just because the latest advancements are not at hand.

Despite all the difficulties that need to be faced by those who wish to perform epilepsy surgery in developing countries, there is already a transformation in progress. Successful epilepsy surgery is a reality in many developing countries, and the number of these has increased steadily in the last 10 years [6].

A final word on education, early identification of refractory seizures and the value of epilepsy surgery

Specialized epilepsy centres in developing countries could break the cycle of intellectual and technological dependency on the industrialized world. This is a first step to generate knowledge and begin a process of good-quality training locally. Highly trained personnel are crucial to the process; this has to be taken seriously and an investment in such training – abroad or in already established centres in some developing countries – is a necessary first step. Once these epilepsy centres in countries with limited resources begin to produce good epileptologists, a 'positive cascade' may ensue, with better diagnosis of epilepsy syndromes, clearer understanding of rational ways of pharmacological treatment and increased awareness in society of the need for governmental measures to ensure epilepsy care at all levels, including the purchase and distribution of adequate supplies of the more useful antiepileptic medications. Thus, raising the set point of epilepsy care as a whole is a background goal of epilepsy surgery in countries with limited resources. Furthermore, when it becomes apparent that developing countries can generate credible original research in epilepsy, epileptologists from these regions will gain the confidence to create reliable protocols to investigate and treat patients in a manner relevant to their environment. Cost-effective, high-quality care within the (realistically) available means of each society is likely to be achieved more easily by locally generated knowledge and experience.

Recently, two seminal studies have confirmed long-held beliefs that patients with refractory seizures can be identified early in the course of the epilepsy [45] and that surgical treatment is more effective than AED treatment for patients with temporal lobe epilepsy whose seizures have been refractory to medications for some years [46]. These robust findings leave few doubts about the unfavourable evolution of patients with a number of well-defined epilepsy syndromes and the possibilities of reversing this unfavourable picture with surgery for epilepsy. There is no justification for people with epilepsy living in countries with limited resources to be excluded from the benefits of epilepsy surgery.

Acknowledgements

I would like to thank my colleagues, epileptologists and neurosurgeons who are involved in the establishment and development of epilepsy surgery programmes in the various accredited academic centres in Brazil for a fruitful and friendly partnership that has endured through the years. I would single out my friend Americo Sakamoto, from Ribeirão Preto, who contributed to this chapter with a detailed description of the successes generated by the public initiative to foster the development of epilepsy surgery, described herein as 'the Brazilian experience'. However, in particular, I would like to acknowledge the guidance and friendship of my colleagues from the Porto Alegre Epilepsy Surgery Program: Drs Eliseu Paglioli, Jaderson Costa da Costa, Mirna Portuguez, Eduardo Paglioli, José Victor Martinez, Ney Azambuja and Carolina Torres. We have been together for 16 years and are all very proud of each and every fellow and resident whom we have trained and who has moved on to improve the care of patients with epilepsy in all regions of Brazil.
