Foreword

This year the International League Against Epilepsy (ILAE) is celebrating its 100th anniversary. The celebrations will begin with the 2009 International Congress in Budapest, the place where the League held its first organizational meeting. However, epilepsy is a disease that has been with us for eons. It has been recognized by ancient cultures with detailed writings about its symptoms, causes, consequences and treatments. Out of all brain disorders, epilepsy is the one that offers a unique opportunity to understand normal brain functions as derived from excessive dysfunction of neuronal circuits because the symptoms of epileptic seizures are not the result of the usual loss of function that accompanies many diseases that affect the brain. The powerful insights that epilepsy may provide have also been depicted in literature with specific fictional characters, such as Prince Myshkin in Dostoevsky's *The Idiot* or Simon, 'the batty boy who faints', in Golding's *Lord of the Flies*; both characters had a unique understanding of the human psyche, perhaps from the enhanced understanding that can occasionally be reached during an epileptic aura. It should be noted that epilepsy is often perceived with fear, and even in these novels it is not named. Thus, in *Lord of the Flies*, Golding tells us that Simon had 'one of his times' rather than using the word 'seizure'. Prince Myshkin was extremely frightened whenever the aura would begin because he was dreading the actual convulsive seizure. Indeed, epilepsy can be a debilitating disorder with long-lasting consequences for the person's life in terms of development, education, employment and family life. This is the reason that all of us involved in the care of patients with epilepsy are working to elucidate its secrets, eliminate the stigma with which it is wrongly associated and, most importantly, develop new effective treatments to cure epilepsy without any side-effects.

Over the past two centuries, there have been many discoveries with the advent of astute clinical observations, the development of the EEG and imaging techniques and the explosion of genetics and epigenetics. In addition, much has been accomplished with the detailed analysis of the epileptic substrate in basic studies. These studies have created the foundation on how to develop novel treatments that may deal with specific seizure disorders and syndromes. The explosion of knowledge in synaptic physiology as well as in the outputs of brain circuits (systems) has allowed the discoveries of novel treatments that may be age- or sex-specific for a particular aspect of epilepsy, that is seizurogenesis, epileptogenesis or the appearance of the epileptic state. There are insights on the role of specific neurotransmitters, inflammation, breakdown of blood–brain barrier as well as the presence or absence of a variety of malformations or lesions. New research has also advanced the understanding of the mechanisms involved not only in the initiation of the epileptic discharge, but also in how the epileptic discharge actually stop. These advances have undoubtedly led to the targeting of therapies and even to the prevention of epileptogenesis in certain animal models, although this may still be an elusive goal for our patients. Through the geometric increase of scientific data acquisition, we can also begin to understand that different factors may be involved for each type of the process that can be modulated or even reversed by specific treatments.

The third edition of this volume edited by Shorvon and colleagues is an attestation of the progress we have made as a medical community regarding epilepsy. The huge expansion of knowledge is encapsulated with state-of-the-art reviews that cover most of the currently available treatments and modalities. The editors have chosen the topics and authors well. The 85 chapters of the textbook encompass the principles of medical management, old and new antiepileptic drugs as well surgical approaches.

I am therefore extremely honoured to present the third edition. Undoubtedly, it will be an extremely important addition to our efforts to educate people on how to best utilize current and perhaps future modalities to treat epilepsy. It is also fitting that this outstanding volume will be published during the centennial year of the ILAE. It has been customary that the presidents of the League write a foreword for each edition, and I am very pleased to do so during the centennial presidency that will begin in 2009. With chapters from nearly 100 countries, the ILAE is the recognized society of medical and allied health professionals sharing the goal of improving the lives of people with epilepsy throughout the world. To accomplish this goal, we have mobilized international teams that promote education, training and research as well as the promulgation of the new treatments. Many of the contributors in this textbook have been active members of the League, who have made significant contributions in the past and will continue to in the future. ILAE guidelines and consensus statements, such as the classification of seizures and epilepsy syndromes and standards for optimal diagnosis and care for persons with epilepsy, are respected and applied around the world. The ILAE has also helped to bring epilepsy 'out of the shadows' through the Global Campaign Against Epilepsy. This important partnership between the ILAE, World Health Organization and the International Bureau for Epilepsy (IBE) has helped to identify medical and financial resources available for epilepsy care by geographic region, determine areas of treatment gaps, and raise awareness and reduce social barriers for individuals with epilepsy so that everyone will have access to effective, almost tailored treatments derived from the wealth of scientific data that our community has developed. Together we can hope that we will identify ways to improve the treatment of patients with epilepsy, determine areas of treatment gaps, and improve the livelihood of all individuals with epilepsy.

Solomon L. Moshé
2009

Preface to the Third Edition

It is 5 years now since the second edition of this book (2004) was published and 13 since the first (1996). A new edition is necessary and timely. The choices available for the treatment of epilepsy have continued to broaden, the knowledge base has grown strikingly in many areas, and updates are needed on existing treatment as well as new therapies, both medical and surgical. Increasing choice brings with it increasing complexity, and the information required to provide best practice has also probably never been greater. It is in response to this complexity that this edition is conceived.

The book has changed in many ways. First, the editorial team has been altered. Professor Ed Dodson has stood down as third editor because of the onerous nature of his administrative duties in his role as Associate Vice Chancellor and Associate Dean for Admissions at Washington University School of Medicine, and both readers and editors will miss his valuable insights and contributions so evident in the previous edition. In his place, it is a pleasure to welcome Jerome (Pete) Engel Jr, who is, of course, one of the outstanding epileptologists of our times, an enormously experienced editor and a worthy successor. Pete brings a great deal of wisdom and expertise to this edition, for which the other editors are enormously grateful. The number of chapters has also increased, from 63 in the first edition, to 74 in the second and to 85 in this edition. There are 26 completely new chapters, as well as extensive updating of the others. Also welcomed to the team are 90 new authors, joining the 53 who contributed to both this and the previous edition. The new chapters reflect the significant changes which have been made to the principles of, and approaches to, epilepsy therapy, the introduction of new drugs and the development of new surgical techniques. These changes give the book a new freshness of approach, which it is hoped will find favour with our readers.

In other ways, though, the book has not changed. The underpinning structure and principles which guided previous editions have not been tampered with. The division into four sections is retained, but the first is more focused on therapy and the practical aspects of therapy. As before, the editing has been heavy, and this has been particularly so in the pharmacological chapters to provide more uniformity, and in doing so has minimised overlap and repetition as far as this is possible. The use of summary tables is also retained, especially in the pharmacological section, in order to present data for easy reference.

Both the writing and editing have been massive tasks, and an enormous debt of gratitude is owed to all our authors for their timeliness and great forbearance in the face of numerous examples of idiosyncrasy and nit-picking by the editors in their editing work; the email traffic between all has been at times overwhelming, and one wonders how such multi-authored books were possible to fashion in the pre-electronic age. Indeed, it is pleasing to reflect on the fact that the book was completed ahead of schedule – a rare feat in publishing – for which all concerned have reason for our gratitude. The overall purpose of the book is also unchanged, and here I thought it worthwhile reproducing what was included in the preface of the second edition:

> The primary objective is unaltered [from the first edition] – namely to provide a systematic review of the whole field of contemporary therapy in epilepsy. The emphasis is, as before, on a text that provides practical information, useful for the clinician but which is comprehensive, accurate and concisely given. We [the editors] have asked the contributors to examine the evidential basis of both conventional and experimental therapies and have attempted to cover all therapeutic options . . . It remains the basic purpose of the book to guide clinical practice and rational therapy, and to be a source of reference for clinicians at every level.

Our reviewers of the last edition were kind enough to consider that these objectives were largely met, and there is confidence that this current edition is an improvement over both its predecessors. As before, the book aims to assist any doctor treating patients with epilepsy, acting both as a practical handbook as well as a work of reference. Although large, it is intended to be organised with sufficient clarity to allow the rapid access to information required by any hands-on text. It is designed for those treating children and adults, and for both trainees and specialists in the fields of neurology, neurosurgery, neuropsychiatric and general psychiatric, paediatrics and developmental medicine, neurogenetics and neuro-rehabilitation.

One remarkable feature of modern epilepsy is the global consensus that exists on the principles of therapy. This is partly due to the fact that information and opinion spreads now more rapidly than ever throughout the world via the worldwide web (the public launch of which was only in 1991) and the electronic bibliographic indices, but much credit also should go to the International League Against Epilepsy (ILAE). This organisation celebrates it centenary this year (2009) and it is now, and has been for many years, a vital link in the dissemination of knowledge in epilepsy globally, and the upward levelling of therapy in all countries. It does this largely through its congresses and its scientific journal (*Epilepsia*), and this book is heavily dependent on both. To reach the age of 100 years is a remarkable achievement and the ILAE is indeed the oldest international subspecialist society in the field of neurology; and it is in celebration of this achievement that this edition is dedicated to the ILAE. At the time of

publication of the first edition, there were only 48 chapters in the ILAE, and now there are over 100 (a growth which exceeds even that of this book!) and a membership which exceeds 15 000. All three editors are, or have been, long-standing members of the ILAE executive and almost all of the lead authors of the chapters of our book are involved deeply in the league. Indeed, contributors to the book are from 17 countries in all five continents, reflecting the global reach. In the historical introduction to this edition, the historical survey of drug therapy in epilepsy is continued, bringing this up to the year 1989. In the previous two editions, the survey covered the years 1857–1938 and then 1938–1955. Here, the story is advanced by 35 important years to 1989, and is written from the particular perspective of the ILAE.

I must offer my sincere thanks to my two fellow editors. Both have been lead editors of previous books which have dominated epilepsy publishing, and both have utilized this previous experience and have unsurpassed skill in editing as well as epileptology. Their work has been outstanding, as will be evident to all who peruse this book. Thanks, too, are owed to the chapter authors, who have largely managed to complete the task on time and to an exceedingly high standard. Writing book chapters is important but often thankless and time-consuming, not counting towards university rankings, and yet performing a valuable function for clinicians needing rapid access to knowledge in their clinical practice. The contributors to this book have excelled in their work. The production of such a book involves not only editors and authors but also a team at the publishing end, and we have reason to be greatly thankful for the efforts of the various persons at Blackwell, now subsumed into Wiley-Blackwell. The team was led by Martin Sugden, his colleague Rebecca Huxley from Wiley-Blackwell; and Catriona Vernal, the production editor, from Prepress Projects Ltd. It has been a pleasure to work with each and their expertise has been exceptional. Rebecca Huxley was also involved in the second edition, and it is a tribute to her patience that she allowed herself to be dragged again into the world of epilepsy, and yet to provide a life-raft for editors and contributors drowning in and buffeted by the heavy undercurrents of their task. The final thanks go to my patients, and those of the other contributors. Clinical practice is very much a partnership between the clinician and patient, and an understanding of epilepsy and of its treatment can be gained best by listening to those to whom we offer treatment. It is to be hoped that this book will reflect back the experience and knowledge gained in this process and result in better practice and improved therapy.

Simon Shorvon, for the editors
London, 2009

Preface to the First Edition

Epilepsy is one of the oldest recorded diseases. Throughout its history strange and varied methods of therapy have been employed. Medicaments, potions, ointments, amulets, enemas, exorcism, magic, spiritualism, magnetism, galvanism, dietary regimens, surgical and physical and moral and behavioural therapies have all been popular; reputations have been made (less often broken) and are still being made by therapeutic manoeuvres, yet none has provided the cure. Within this compass have been some effective therapies but others which are ill-directed, useless, misleading, and at times frankly fraudulent. Epilepsy is, of course, a difficult taskmaster for the inquisitive. Its fluctuating nature, its ready influence by environmental factors, its easy confusion with hysterical disorders, its multifactorial causation and its tendency to spontaneous remission, all render judgements of treatment difficult. Such confounding factors allowed ineffective and fashionable therapies to flourish in the past, and today marketing and commercial pressures add to the difficulties of evaluation.

This book is an attempt to catalogue the contemporary treatment of epilepsy in the late 1990s, both medical and surgical, in a comprehensive, concise, balanced and practical manner. Each chapter has been commissioned from an acknowledged authority, known personally to the editors as knowledgeable, intellectually honest and capable of clear communication. We have covered all matters of importance to those treating patients with epilepsy, and provide clear clinical advice on these issues. We have avoided unsupported speculation and highly biased opinion, but have asked our contributors to be as up-to-date as is compatible with our evidence-based exigencies. These are difficult and challenging requirements, which, I hope, have been largely realized.

What are the boundaries of the volume? When bromide was introduced in 1857, a new era can be said to have been entered, with a treatment that was indubitably effective. Ironically, one can note that similar claims had been made many times before in earlier and less competitive times, and the single most important lesson of history is surely scepticism. In our historical chapter, we have surveyed treatment from the time of the introduction of bromides to the outbreak of World War II, a fascinating period which provides the context for today's therapeutic approaches. From about 1940 onwards, more scientific methods were adopted to devise and assess therapy, and more rigid standards were set for proof of effectiveness. Various new therapies were introduced, but most have not stood the test of time. Even as recently as 1970, the orthodox practitioner in most countries could still offer only phenytoin and phenobarbitone as effective options for most epileptic patients.

There has been, however, in the past decade or so, a sea change, almost a revolution in the field, and a wide range of highly effective new therapeutic possibilities has become available. Not only has a series of new medicaments been introduced, but new approaches to drug therapy have become possible, and also with improvements in the investigation of epilepsy, much more effective and ambitious surgical treatment. This expansion in the options for effective treatment, both medical and surgical, is enormously welcome, but brings its own problems. The physician now has to make much more difficult decisions about treatment because of the greater range of therapeutic choices and also because the evidence on which to base rational therapy is more complex, at times contradictory, and not all readily accessible. In this book we have addressed these issues.

Our principal objective is to provide a systematic review of the whole field of contemporary therapy. We have included individual chapters on all licensed medications, on drugs in an advanced stage of clinical trial, on all specific surgical therapies of value in epilepsy, and also chapters on treatment in specific clinical situations. The contributors were asked to examine the evidential basis of both conventional and experimental therapies, and to provide a clear assessment of this. We have attempted, therefore, to encompass all therapeutic options, and their relative values in the varied clinical circumstances of the person with epilepsy. In this sense, the book should be a useful platform for all doctors treating epilepsy. Although the book is primarily about the treatment of epilepsy, we have also included an initial section of six chapters, the purpose of which is to place therapy in context. In these chapters we have also highlighted those areas in which rapid advances are being made, for herein will the context of treatment also change (the chapters on pathophysiology, the developmental basis of epilepsy, diagnosis and prognosis, and on economic cost, for example).

The information contained within the pages of this book is sufficiently comprehensive to act as a reference for specialists, and concise enough for more general clinical usage. It is very much a hands-on text, and, we hope, a constant companion. The aim of the book is to guide clinical practice and rational therapy and to be a source of reference. It has been designed for doctors in adult and paediatric medicine, both generalists and also specialists in the fields of neurology, neurosurgery, psychiatry, paediatrics, alienist medicine and in learning difficulty. It will also appeal to practitioners of the paramedical specialties who are involved in the management of epilepsy.

One remarkable fact about modern epileptology is its internationalism. In countries all around the world, the same issues about the treatment of epilepsy arise, the same therapeutic questions are debated, and there is a large and surprising measure of agreement on specific points. The international nature of epilepsy

is in no small part due to the endeavours of the International League Against Epilepsy (ILAE) which has chapters now in 48 countries and nearly 10 000 members, and whose meetings are a forum for the dissemination of information about epilepsy and its treatment. The influence of the league has left no area of epilepsy untouched. We are therefore greatly honoured, in this book, to Dr E.H. Reynolds, the current president of the ILAE, for contributing a foreword. A distinguished and accomplished physician, Dr Reynolds is also a mentor and a friend, and a person whose influence on modern British and international epileptology has been benevolent and all-embracing. Our contributors are from four continents and provide a truly international perspective. Almost all are active in the ILAE, and the text reflects to a great extent the current interest and research of ILAE members. Matching this internationalism, nearly half of the chapters are by contributors (from various countries and continents) whose training was partly at the National Hospital for Neurology and Neurosurgery at Queen Square in London. Our preliminary historical chapter looks at the history of epilepsy therapy (from 1857 to 1939) using the National Hospital as an historical mirror, and as epilepsy is still an important area of contemporary neurology at Queen Square, subsequent chapters also reflect current practice at the National Hospital. This is another thread which runs through the book and gives to the volume, at least in part, a specific flavour which I hope provides the text with an interesting perspective.

A book of 63 chapters will always pose a challenge for its editors and its publisher. In this volume, we have heavily edited some individual contributions, and worked assiduously in conjunction with the authors to avoid repetition or overlap. Where overlap has been permitted between chapters, this is because individual authors have taken differing (and occasionally conflicting) approaches which are, in the editors' view, sufficiently instructive to allow inclusion. We have also added editorial tables in places to ease comprehension and in particular to make the information contained in the text easy to follow and readily accessible to the reader, often a busy clinician. Also, we have tried to provide a uniform style, and a high quality of writing. To assemble chapters on such a disparate subject from authorities around the world, to edit and to produce a pleasing and useful book has been a major task. In this, the editors have been expertly helped by Dr Stuart Taylor from Blackwell Science, the publishers, whose skill and expertise were the essential ingredients of the successful completion of our work. We are enormously grateful to Dr Taylor, not least for his humour and forbearance in executing (a seemingly, at times, well-chosen word) the task, also to Lorna Dickson, our production editor who has worked absolutely tirelessly on this project, and other members of the design and production team at Blackwells; they have all been pre-eminent in their work. Finally, we would like to thank the chapter authors for their outstanding contributions, their patients for providing the experience on which our current therapeutics is based, and epileptologists around the world, ILAE members and others, who have stimulated our thoughts and actions in the field of epilepsy treatment.

Every effort has been made in the preparation and editing of this book to ensure that the details given (for instance of drug dosages and pharmacokinetic values) are correct, but it is possible that errors have been overlooked. The reader is advised to refer to published information from the pharmaceutical companies and other reference works to check accuracy.

S.D. Shorvon, for the editors
London, 1996

History of the Drug Treatment of Epilepsy Between 1955 and 1989 with Special Reference to the Role of the International League Against Epilepsy (ILAE)

Simon Shorvon

In the previous two editions of this book, introductory chapters were included on the history of drug treatment of epilepsy between 1857 and 1939 and then between 1938 and 1955. The first considered the topic from the perspective of therapy at the National Hospital in London and the second was written with special reference to *Epilepsia*, the journal of the International League Against Epilepsy (ILAE). This chapter considers the next 35 years, to the beginning of 1989, a period marked by a number of major developments: carbamazepine, benzodiazepines and valproate were discovered and introduced; extraordinary advances occurred in the basic sciences of pharmacology and neurophysiology; therapeutic drug monitoring (TDM) was introduced; a series of highly influential physicians became important players in the field of epilepsy therapeutics and in the ILAE; the pharmaceutical industry rapidly expanded with concomitant rapid commercialization of the therapeutic arena; and regulation and restriction arose in parallel.

The ILAE, too, grew in this period in terms of size and importance, and began – as an organisation – to influence epilepsy practice, not least through the establishment of 'commissions', of which the most important was the Commission on Antiepileptic Drugs, and the active involvement of its leaders with drug therapy. ILAE conferences were the showplace for information about these new drugs and *Epilepsia* was increasingly the journal of first choice for publishing in this area [1]. These were also the post-war period years of plenty, characterized for most of the time by sustained economic growth and optimism; in these years, very major advances were made in epilepsy therapy, and the basic approach to therapy which evolved then remains virtually unchanged today.

All history has a perspective – and all narrative can be viewed from differing points of view. Here, I have decided to adopt broadly the perspective of the international neurological community, and in particular that of the ILAE, an organization celebrating its centenary in 2009, and which has been at the policy centre of professional affairs in epilepsy during most of the period under consideration.

Epilepsy therapy in the 1950s

A good place to start this historical consideration of these years is the two-volume textbook [2] entitled *Epilepsy and Related Disorders* written by William Lennox. Lennox was the first president of the ILAE after its re-awakening in 1937 and was also largely responsible for nursing the ILAE and its journal through the Second World War [1]. This book (Fig. 1), published in 1960 in the year of Lennox's death, and written in his typical decorative style, was the definitive American text. Like most others before him, Lennox discussed treatment under a series of headings, of which drug therapy is only one: hygienic and metabolic; drug therapy; surgical therapy; and psychotherapy. Perhaps surprisingly at this late date, hygiene had first place in Lennox's book. This category included various lifestyle issues and diet, and the recommendations were similar to those of earlier authors (e.g. Kinnear Wilson, Muskens and Turner). The metaphorical language, which Lennox so favoured, though, was more curious than most:

> The close relationship of measures that make for good health is exemplified by the fact that Hygeia, the goddess of health, was no other than the daughter of Aesculapius, the god of medicine.

In regard to diet, Lennox had no particular recommendation except for an endorsement of the ketogenic diet, but he commented:

> In spite of the proven value of the ketogenic diet, it is little used today except in certain long-established centers, such as the Mayo and Johns Hopkins Clinics and the colonies of Denmark and Holland. The reasons are obvious: effective medicines are now available, the diet is limited and distasteful to the patient, and time-consuming and expensive for the parent.

Lennox considered dehydration to be ineffective, starvation to be temporarily helpful, activity to be encouraged and convulsive therapy to have some place: 'To hold a drowning man under the water seems no more illogical than to give an epileptic a convulsant drug. Yet fire can be fought with fire, and cowpox prevents smallpox.'

The focus of this chapter is on drug therapy, and to this Lennox devoted 100 pages of his book. He offered 'fifteen suggestions that as possible guide lines lead towards successful drug therapy', all of them homespun of the type 'Treat the patient', not just his symptoms, 'Prescribe adequate dosage' and '[Watch] the waves' (the EEG). His philosophy no doubt partly reflected the complacency

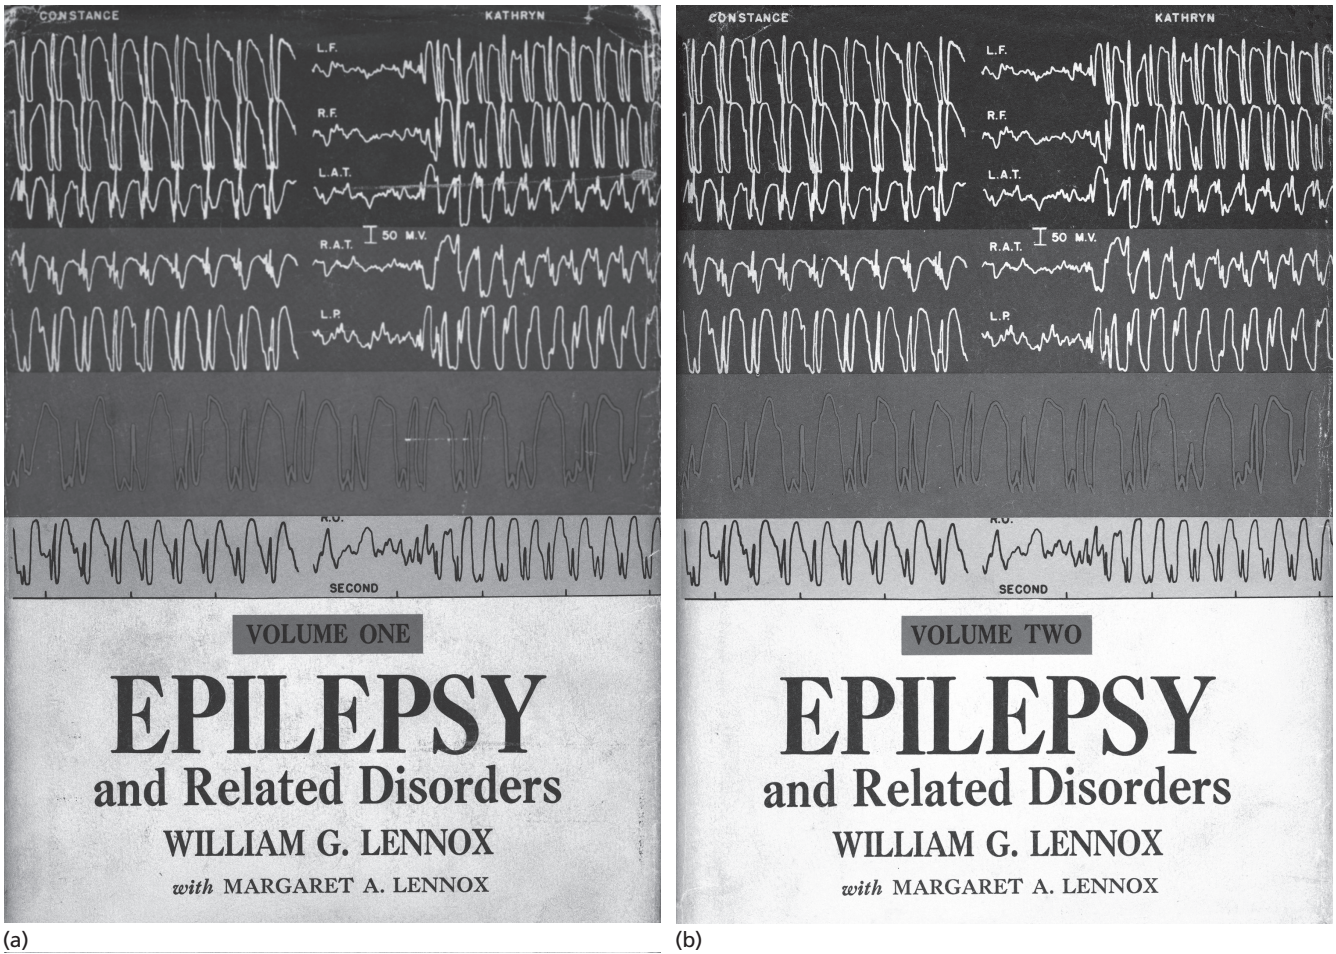

Fig. 1 The two volumes of the celebrated book by Lennox (ref. 2).

and smugness of his class, but the principles of therapy he outlined have been very influential and indeed are essentially similar to those that determine treatment today – and this despite 50 years of subsequent clinical research and a massive literature.

Lennox detailed his 'therapeutic arsenal', 16 drugs 'in use in the United States' (Table 1). The list was prefaced by a section on the question of drug-induced fatalities. Lennox wrote (strangely) that 'agranulocytosis may be an "act of God" coming or going without any explanation that man can offer'. It seems clear that drug risks concerned physicians less then than now, but this was, nevertheless, the first major epilepsy book in which drug-induced fatalities were a prominent consideration. Severe skin and blood reactions were discussed, principally in connection with mesantoin, phenurone, the diones and diamox.

At the top of Lennox's arsenal of drugs were bromides, which, owing to their side-effects and relative ineffectiveness, were 'little used today'. Barbiturates were greeted more enthusiastically. Lennox mentioned that 2500 compounds had been synthesized and of these 50 compounds marketed, of which phenobarbital was the most frequently used for epilepsy. Mephobarbital (mebaral) he pronounced 'the only barbiturate besides phenobarbital effective against epilepsy' and a drug which seemed to have more effect on 'petits' (Lennox's familiar name for petit mal). He was enthusiastic about phenytoin, especially for patients 'with long-standing convulsions previously unrelieved by phenobarbital', although Mesantoin outranked it on several points, and indeed he favoured their combined use:

> Mesantoin and Dilantin are Damon and Pythias in respect to their suitability for joint action. Similarity of action gives a doubled therapeutic effect; the dissimilarity of their side reactions keeps these within bounds.

Ethotoin was said to be one of the 1500 compounds screened by Abbott Laboratories in the previous 8 years (presumably using the maximal electroshock method formalized by Merritt and Putnam) and although effective, was associated with a high rate of blood dyscrasia. Primidone was 'especially welcomed as a contribution from abroad' (manufactured by ICI in England). Phenacemide was

> what in athletics might be called a triple threat because, more than any other drug, it acts against each of the three main types of seizures, and especially against the most feared psychomotor seizures. However, it is also a triple threat to the patient himself because of possible effect on the marrow, the liver or the psyche.

Given a 1 in 250 chance of not surviving this treatment, he asked with no apparent sense of irony, 'Is the risk too great?'. Meth-

Table 1 Lennox's 'therapeutic arsenal'.

Non-commercial official name	Patented trade name	Possible danger to
Grand mal and psychomotor seizures		
Bromides	Bromides	
Phenobarbital[a]	Luminal	
Methobarbital	Mebaral	
Diphenylhydantoin[a]	Dilantin	
Mesantoin	Mesantoin	Blood
Ethotoin	Peganone	
Primidone[a]	Mysoline	
Phenacemide	Phenurone	Blood, liver
Methsuximide[a]	Celontin	
Acetazolamide[b]	Diamox	?Blood
Petit mal		
Trimethadione[b]	Tridione	Blood, kidney
Paramethadione[a]	Paradione	?Blood, ?kidney
Phensuximide[a]	Milontin	
Ethylmethylsuccinimide	Zarontin	
Quinacrine hydrochloride	Atabrine	
Metharbital	Gemonil	

Reproduced from ref. 2, with permission.
Phenurone and Diamox were noted to be often effective against petit mal as well, and phensuximide to be often effective against grand mal.
[a]Drugs of initial choice.
[b]Drugs of second choice.

Table 2 Annual cost of anticonvulsant drugs available in the USA in 1960 (at 2007 values).

Drug	Daily dose (mg/day)	Cost of a year's supply (US$)	Manufacturer
Bromide	4000	140	–
Celontin (methsuximide)	900	476	Parke, Davis
Dexedrine (dextro-amphetamine sulphate)	10	308	Smith, Kline and French
Diamox (acetozolamide)	1000	1225	Lederle
Dilantin (phenytoin)	400	203	Parke, Davis
Gemonil (metharbital)	400	203	Abbott
Mebaral (methobarbital)	500	343	Winthrop-Stearns
Mesantoin (mesantoin)	600	147	Sandoz
Milontin (phensuximide)	2000	644	Parke, Davis
Mysoline (primidone)	1500	992	Ayerst, McKenna and Harrison
Paradione (paramethadione)	900	462	Abbott
Peganone (ethotoin)	1500	441	Abbott
Phenobarbital	200	77	–
Phenurone (phenacemide)	1500	399	Abbott
Tridione (trimethadione)	900	399	Abbott

Data derived from ref. 2.
2007 values calculated on the basis of the change in consumer price index (CPI) between 1960 and 2007 (an approximately 70-fold rise in CPI over this period).

suximide (Celontin), useful in the treatment of petit mal, was like a 'pusher' locomotive. Acetazolamide (Diamox) was noted to 'lack . . . staying power' – in other words, tolerance. Trimethadione (Tridione)

> heads the list of drugs that are peculiarly beneficial to persons subject to petits, and less distinctly for the other members of the petit mal triad . . . World-wide acceptance of Tridione was attained more quickly than acceptance of Dilantin, [but] Tridione had no competitor.

Paramethadione (Paradione) he thought to be somewhat better than trimethadione for the treatment of petit mal but worse for grand mal. Phensuximide (Milontin), ethylmethylsuccinimide (Zarontin), quinacrine hydrochloride (Atabrine), and metharbital (Gemonil) were also mentioned briefly, as well as two combination compounds and three 'accessory preparations' and some tranquilizing drugs. Cost was an important issue for Lennox. Table 2 shows his list of the costs of drugs (to the patient in the USA) converted to current values. It is interesting to note how relatively cheap most drugs were at this time.

Therapeutic drug monitoring and the rise of pharmacokinetic study of antiepileptic drugs

The application of pharmacokinetic principles to epilepsy therapy was a most important clinical advance in the 1960s and 1970s. This was an area in which, epilepsy initially at least, was in the vanguard of other medicine specialisms, and in which ILAE officers took an active lead. The involvement of the league was indeed undoubtedly a factor in recognizing the importance of these principles in clinical epilepsy practice.

The measurement of antiepileptic drug serum levels began to be studied systematically only in the late 1950s, although the technologies had been available for some years before. This early development was methodology driven (as is almost always the case when new technologies are introduced, and as shown for instance also in EEG and neuroimaging). It was also stimulated by the regulatory requirement for pharmacological information by the pharmaceutical industry. Extensive studies of bromide, ethosuximide, phenytoin and phenobarbital were conducted initially, and within a decade or so the clinical pharmacokinetic properties of all the antiepileptic drugs – their absorption, distribution, metabolism and excretion – were quite fully documented. In the 1960s, too, the measurement of serum levels of drugs entered clinical practice, and soon, in advanced units in several countries, laboratories were routinely measuring levels (Fig. 2). Initial studies were conducted in the late 1950s and early 1960s by Fritz Buchthal (the husband of Margaret Lennox-Buchthal, the future editor of *Epilepsia*) and colleagues, who found a relationship between the blood levels of phenytoin and phenobarbital to antiepileptic effects and to central nervous system (CNS) toxicity [3–8]. The classic paper by Kutt and Penry [9] was particularly influential. These were landmark studies and spawned an enormous explosion of interest in TDM, and in pharmacokinetic studies of antiepileptic drugs. Phenytoin was of course a lucky choice, as the strong level–effect relationships and the saturation kinetics render clinical serum level measurements extremely useful. This does not apply to many other drugs, and had phenytoin not been a dominant therapy, it is possible that the whole field of TDM in epilepsy might not have flourished.

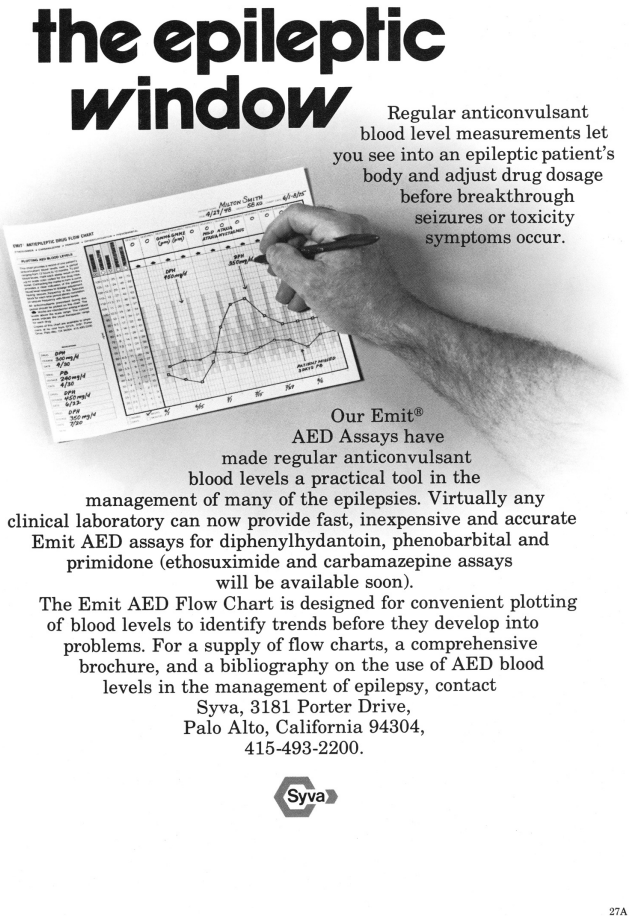

Fig. 2 An early attempt to encourage the use of serum blood level estimations.

In the late 1960s, a fairly comprehensive definition of the pharmacokinetic parameters of all the available antiepilepsy drugs had been achieved. These data were now required for registering drugs, and studies were stimulated in part by the pharmaceutical industry. During the 1970s, it also became clear that studies were needed in special populations such as children, the elderly, those with renal and hepatic disease, and in pregnancy. By the early 1980s, the characterization of the hepatic enzyme systems was largely complete, and the relevant factors, both environmental and genetic, were intensively studied.

A veritable industry has arisen related to drug interactions. This started with the study of phenytoin in the mid-1960s, and by 1972 large-scale interactions with warfarin, disulfiram, sulthiame, phenobarbital, digoxin, chloramphenicol, isoniazid, methylphenidate and chlordiazepoxide had been defined. The finding of the massive interaction between sulthiame and phenytoin also largely terminated the use of the former drug. Interaction studies have continued ever since, and although the database is progressively enlarged as new drugs are introduced, the basic principles have not changed. In the 1980s, the subgroups of the cytochrome P450 hepatic enzyme system (and to a lesser extent the UDP-glucuronosyltransferase and other systems) were characterized, and their genetic and epidemiological features explored. The regulatory agencies in the 1980s responded by requiring the pharmaceutical industry to provide more and more interaction data prior to licensing and to register data about dosage adjustments (sometimes very complex, as was the case, for instance, with lamotrigine). This not only increased the time and cost of drug development but also stimulated interest in producing drugs which avoided metabolic processes at the hepatic enzyme level. Interactions were also a major factor in the move to monotherapy in epilepsy.

In the last decade, *in vivo* testing models for determining the relevance of individual enzymes has provided a mechanism for the preclinical prediction of drug interactions. Another area of interest is that of pharmacogenomics. This has focused on drug targets, cerebral drug transporters, hepatic enzyme activity and susceptibility to idiosyncratic reactions. The work on hepatic enzymes and idiosyncrasy has been useful, but to date pharmacogenetic work on drug targets and transporters has not made discoveries of any clinical utility.

Therapy developments in the USA: the epilepsy section and epilepsy branch at the National Institutes of Health

By 1970, there was considerable disquiet in the American epilepsy community about the lack of new drugs. No drug had been licensed in the USA for 10 years, and yet there was a sizeable population of intractable patients and all the 13 contemporary drugs had side-effects which were of increasing concern. European colleagues were able to use various compounds which were not available in America, including carbamazepine, valproate, sulthiame and clonazepam. This was partly attributed to the restrictions imposed by the Kefauver–Harris amendments but also the prevalent view within the pharmaceutical industry that epilepsy 'did not need new drugs'.

In 1959, Richard Masland was appointed director of the National Institute of Neurological Diseases and Blindness (a post he held until 1968). Masland had previously been professor of neurology and psychiatry at the Bowman Gray School of Medicine at Wake Forest College in Winston-Salem and had a prior interest in epilepsy. Soon after his appointment, he decided to set up an epilepsy section, and in 1966 he recruited the young J. Kiffin Penry (Fig. 3), who had studied under Masland in Bowman Gray, to head up the section. This was a momentous decision, for over the next two decades whilst at the National Institutes of Health (NIH), Penry (later also ILAE president) led an enormous revival of epilepsy research in the USA. The epilepsy 'section' was later transmuted into a 'branch', and Penry was appointed its head and also director of the Neurological Disorders Program. In these positions, Penry spearheaded a range of activities which was without parallel. He obtained funds from the NIH administration for a multifaceted epilepsy programme. This effort was due largely to Penry's very focused vision, his energy and his extraordinary enthusiasm. He first set about reviewing current research. He realized that no company was developing antiepileptic drugs and no large-scale facility for assessing drugs existed, apart from work carried out by Goodman and Swinyard in Utah. A report was commissioned from James Coatsworth [10], which showed that current therapy was old-fashioned and inadequate. On the basis of this assessment, Penry set up the Antiepileptic Drug Development Program in 1969, which had a number of arms. Six

Fig. 3 J. Kiffin Penry, one of the most important figures in 20th-century epileptology.

'comprehensive centres' for epilepsy across the country were established to act as a focus for research and training. An ad hoc committee was created to design clinical trial protocols which would be acceptable to the Food and Drug Administration (FDA). Six drugs licensed in Europe were then evaluated in a series of controlled clinical trials, via NIH contracts, conducted at medical universities and a state hospital. On the basis of these trials, three drugs received FDA approval and were marketed (carbamazepine, 1974; clonazepam, 1975; and valproic acid, 1978. Sulthiame, albutoin and mexiletine failed to provide sufficient evidence of clinical efficacy). When Roger Porter (future ILAE secretary-general) was appointed to the epilepsy branch, he, with Penry, formed two new sections: a section on preclinical pharmacology (headed by Harvey Kupferberg) and a section on technical information (headed by Billy White). Both were to prove highly influential. In a third important development, to fill the void in preclinical anticonvulsant research and to stimulate new drug development, Penry then launched, with Kupferberg and Ewart Swinyard, a preclinical anticonvulsant screening project (ASP) in 1975 and a toxicity testing project in 1979.

The ASP was based at the University of Utah, where it remains, an enduring legacy of the Penry period at NIH [11,12]. The programme provides facilities for screening new compounds for antiepileptic drug action, at no cost, for academic medicinal chemists and the pharmaceutical industry. Within 2 years of its establishment, 1780 compounds had been tested, which originated from academic sources and the pharmaceutical industry. In these initial 2 years, 27% of compounds were shown to have antiepileptic efficacy, of which 21% were potent and 13 were thought to have potential in the treatment of human epilepsy and entered clinical trial. This programme was also set up partly in response to the belief then that the commercial value of new antiepileptics was not high enough for the pharmaceutical industry to take on the full cost. Criticisms have been levelled at the preclinical screening programme, of which the most fundamental is that the screening methods – initially only the maximal electroshock (MES) and pentylenetetrazol (PTZ) tests – will identify me-too compounds and miss compounds with novel action. (Levetiracetam, for instance, an extremely important antiepileptic drug with a novel mechanism of action, would have been discarded in the ASP screening protocol.) However, the programme continues, and 800 new compounds are tested each year, currently with an initial screening programme of MES, subcutaneous pentylenetetrazol (scPTZ) and 6 Hz psychomotor seizure tests. A total of over 22 000 compounds have been investigated since its inception. Three compounds which were initially identified in the programme have been licensed (felbamate, topiramate and lacosamide). The programme has also been involved in pharmacological work and model profiling of other compounds initially screened by the pharmaceutical company (e.g. drugs such as gabapentin, lamotrigine, levetiracetam and retigabine). Random screening is still one preferred method of drug discovery, and the relatively small number of drugs licensed from the huge number of screened compounds is an illustration of the mountain that has to be climbed.

Another very important project orchestrated by Penry and the Epilepsy Branch was the production of the book *Antiepileptic Drugs* [13], which immediately became, and has remained, the standard work on the topic, and which is now in its fifth edition. Penry had a remarkably prodigious written output, and amongst the large bibliographical projects he launched was a compilation of all published epilepsy articles extracted from the Index Medicus, another indispensible stimulus to epilepsy research [14]. On 29 July 1975, the US government established a Commission for the Control of Epilepsy and its Consequences, which in 1978 published an enormous four-volume report [15]. Penry, being an employee of NIH, was not a member of this commission, but he influenced it from outside. Numerous recommendations were made for developing epilepsy services, and this report stimulated funding and activities in the field of epilepsy for a generation. Prior to these NIH activities, epilepsy in the USA, as elsewhere, had been a rather backward subject, of little general interest. By the time Penry left NIH in 1988, there were excellent academic centres in epilepsy throughout the country.

The ILAE antiepileptic drug commission and workshops on the determination of antiepileptic drugs in body fluids

As the age of consumerism dawned in Western societies, and as the ILAE grew in stature in the late 1960s, the organization became,

Table 3 ILAE Antiepileptic Drug Commission.

1st	1971–1974	David Daly (chairman), J. Kiffin Penry, Dieter Janz, Harry Meinardi, Carlo Alberto Tassinari. Fritz Buchthal was a consultant to the Commision. This was initially known as the *Pharmacological Advisory Committee*
2nd	1974–1977	Morris Parsonage (chairman), Anthony Glazko, Mogens Lund, Ted Reynolds (secretary). Daly and Penry were active ex-officio members
3rd	1978–1981	Paolo Morselli (chairman), Mogens Dam (secretary), Rene Levy, Pierre Loiseau, F. Rubio Donnadieu (secretary-general ILAE), J. Kiffin Penry (ex-officio, president ILAE)
4th	1981–1985	Rene Levy (chairman), Lennart Gram (secretary), Paolo Morselli, Mogens Dam, Svein Johannessen, Dieter Schmidt
5th	1985–1989	Rene Levy (chairman), Mogens Dam, Lennart Gram, Hakki Hakkareinen, Paulo Morselli, Jolyon Oxley, Dieter Schmidt
6th	1989–1993	Lennart Gram (chairman), A. Baruzzi, Olivier Dulac, H.H. Frey, A.A. Gonzalez-Astiazaran, Ilo Leppik, Pierre Louseau, A. Perret (Sanofi) (with consultants for the guidelines on trials in children: C. Dravet, J. Farrell, J. Mumford, W.O. Renier, J. Roger)
7th	1993–1997	David Chadwick (chairman), Ettore Beghi, Paulo de Bittencourt, Noel Callaghan, Olivier Dulac, Lennart Gram, Tony Johnson, Dick Mattson, Franco Pisani, Roger Porter, Alan Richens, Dieter Schmidt, Cees van Donselaar

for the first time, a body which government and industry listened to in relation to epilepsy therapy. This was partly indicative of the changing social environment, but also of the outstanding quality of ILAE leadership, particularly of Penry and Fritz Dreifuss. The influence led to the recognition by industry that interaction with the ILAE could improve market share, and this changing attitude was demonstrable in concrete terms through the increasing involvement of industry in ILAE international congresses. Two ILAE activities were of particular note. The ILAE Commission on Antiepileptic Drugs (Table 3) was the one of the earliest two ILAE commissions (the other being the commission on classification and terminology, which had itself produced in 1969/70 the ILAE Classification of Seizure Type, which was to become the standard classification scheme used around the world). The commission was first set up in June 1970, under the chairmanship of David Daly, who was then the ILAE treasurer and had, at its inception, two published goals: to promote increased knowledge of currently available antiepileptic drugs and to improve the application of this knowledge in the treatment of epilepsy; and to promote development of new antiepileptic drugs with greater efficacy or equal efficacy but less toxicity than those currently available [16]. The commission was soon to be a force to be reckoned with. Its first meeting in September 1971 resulted in publication of the first edition of *Antiepileptic Drugs* [13], and a set of guidelines for the clinical testing of antiepileptic drugs followed in 1973. By 1974, it had reviewed surveys of antiepileptic drug regimens used by clinicians in France and the USA, and had held the first Symposium on Antiepileptic Drugs during the ILAE's 12th International Congress of Epilepsy in Barcelona in September 1973. Most of the Commission's work in the early years was closely aligned with that of the NIH epilepsy branch. One focus of the second term of the commission was chronic toxicity, and the chairman, Ted Reynolds, published a landmark paper on the topic [17]. The third commission modified its objectives to include information on AED use in various countries, promoting the application of ILAE guidelines to clinical trials, defining high-quality clinical centres and promoting collaborative studies. Some progress was made on all fronts, but the commission's activities did not compare with those of the Penry years. The third and fourth commissions did publish an interesting list of drug availability in developing countries – finding 'the present situation alarming' [18]. A major task of the fourth commission was to compile a glossary of antiepileptic drugs, which eventually appeared in 1991. Other guidelines were also produced [19–21]. In 1989, the fourth commission also undertook the task of updating the *Guidelines for the Clinical Evaluation of Antiepileptic Drugs*, which proved an important influence on the parameters for drug trialling by the FDA [22]. The later commissions also produced reports, but by then many bodies existed which focused on therapeutic issues, and the ILAE commission had rather lost its energy and its way.

A second ILAE initiative worth noting is the Workshops on the Determination of Antiepileptic Drugs in Body Fluids (under the rather clumsy, but memorable, acronym WODADIBOF). Between 1972 and 1979, four such workshops took place, and these helped drive the clinical chemistry agenda, at least insofar as it evolved in hospitals and universities. The topics treated included methods for quantitatively determining antiepileptic drugs; the clinical pharmacology of antiepileptic drugs; TDM; and clinical applications of antiepileptic drug monitoring. In 1972, Alan Richens started the first quality control scheme for antiepileptic drug measurements in London. The importance of this was quickly recognized, and soon Richens was providing an international service. Another workshop was set up – the Workshop on Laboratories for the Determination of Antiepileptic Drugs in Serum – which first met in New York in November 1972, but as far as I can tell was a one-off affair. A few years later, the NIH epilepsy branch, with the American Epilepsy Society, set up an Antiepileptic Drug Quality Control programme throughout the USA and Canada. This followed the model of Alan Richens and defined reliable methods and standardized procedures. The ILAE Commission on Antiepileptic Drugs was also intimately concerned with TDM and published its own guidelines in 1993, though bizarrely, the commission devoted little space to drug interactions [21].

Antiepileptic drug monotherapy

One of the most influential changes in treatment strategy – the emphasis on single-drug therapy (monotherapy) – dates from the late 1970s. This became possible with the introduction of a wider range of new effective drugs (carbamazepine and valproate) and the widespread adoption of TDM. Prior to this, combination therapy was, in effect, the norm, even for newly diagnosed patients. A survey in 1975 of 11 720 patients from 15 centres in four European countries showed that the mean number of drugs taken per patient was 3.2, of which 84% were antiepileptic drugs [23]. Furthermore, many pharmaceuticals were available in combination preparations. Reynolds, future ILAE president, and his colleagues pioneered a series of studies demonstrating that, with

appropriate use of serum level monitoring, both new patients and chronic patients were often better off with single-drug therapy [24–28]. Another factor in the previous trend to polytherapy was the poor quality of antiepileptic drug trials. Of 155 studies of carbamazepine and phenytoin reviewed in 1980, for instance, only 17% studied the drug in monotherapy, and of these none were controlled, all were of fewer than 100 patients, all were of less than 6 months' duration and none were of new patients [29].

All this was to change over the next two decades. Monotherapy became a theme in many national and international ILAE conferences and workshops, and a byword in advanced therapy. Most combination preparations of antiepileptic drugs were removed from the market. There was a marked swing to monotherapy protocols in patients with epilepsy, and the nearly universal recommendation that antiepileptic monotherapy be initiated in new patients with the disorder. By the late 1980s, the regulatory authorities had began to request monotherapy trials. Without them, a licence for a drug would be granted only for use in combination therapy. The latter requirement can be viewed rather cynically as a mechanism for restricting spending on novel drugs, for no drug that I am aware of is effective in polytherapy but not monotherapy. The requirement certainly had the effect of greatly delaying licensing of new drugs for use in monotherapy in new patients.

Monotherapy as a concept had become central to drug prescribing, and remains so (by mid-2007, the PubMed database contained over 2300 references to anticonvulsant monotherapy). Recently, and perhaps as a counter-reaction, the concept of rational polytherapy – i.e. combinations of drugs with different modes of action which might have a synergistic as opposed simply to an additive effect – has been mooted, but there is little robust clinical evidence that it is advantageous.

The treatment of epilepsy in developing countries and the concept of the epilepsy treatment gap

From its beginnings, the ILAE has shown an interest in global aspects of epilepsy therapy, but a focus on the specific problems of epilepsy in developing countries really dates only from the mid-1980s, when thereafter successive ILAE presidents showed a particular commitment to developing countries. In 1985, a landmark was the setting up of an ILAE Commission for Developing Countries. This interest reflected the more general engagement of the public in Western countries in the plight of Asia and Africa, which dates from the early 1970s and is now at the centre of political debate. Epidemiological studies of epilepsy were first carried out in the 1970s and showed that epilepsy was, as everyone always knew anyway, a universal phenomenon which respected no national or racial boundaries. Incidence and prevalence rates showed then, and have continued to show, approximately similar findings in most parts of the world albeit with a tendency to generally higher rates in developing countries and some clusters of very high rates. The higher proportion of children in populations of developing compared with developed countries meant also that the total number of people with epilepsy is highest in developing countries. Furthermore, before 1980, most of what is accepted dogma about the clinical aspects of epilepsy derived from studies done in the developed world and simply extrapolated to the situation in the developing world. This, of course, is highly inappropriate and particularly in relation to sociocultural aspects.

Table 4 The first reported treatment gap figures.

Country	Estimated numbers of people with active epilepsy[a]	Estimated number of people receiving treatment[b]	Treatment gap[c] (%)
Pakistan	450 000	22 000	94
Philippines	270 000	14 000	94
Ecuador	55 000	11 000	80

Reproduced with permission from ref. 30.
[a] Based on a prevalence of active epilepsy of 0.5%.
[b] Based on drug supply figures, minimum standard doses, monotherapy.
[c] The percentage of people not receiving therapy at any one time.

Various large-scale research projects were launched to investigate therapeutic endeavours, and some were affiliated to the ILAE. Amongst these were the studies of the International Community Based Epilepsy Research Group (ICBERG), which carried out a series of studies that were the topic of an entire session at the league's international congress in New Dehli in 1989.

The 'epilepsy treatment gap' was a term coined by Shorvon and Farmer in the ICBERG programme [30,31]. It refers to the percentage of patients in a defined population on any one day, with active epilepsy, not receiving anticonvulsant medication. The treatment gap was first calculated theoretically by dividing the figures for antiepileptic drug supply to a country by the estimated number of patients in the country with epilepsy (using an assumed prevalence of non-febrile seizures of 0.5%, monotherapy, standard anticonvulsant drug dosages and drug consumption figures based on commercial data). The method produced shocking results – such as an estimated treatment gap of 94% in Pakistan and the Philippines and 80% in Ecuador (Table 4) [30]. The one common factor in developing countries is a general lack of medical treatment available for people with epilepsy and the lack of programmes to help sufferers. This is partly because epilepsy is not a fashionable disease. But other important factors include the challenge of treating a chronic condition, lack of reliable drug supplies, cultural views of patients and the often very inadequate levels of medical manpower.

In 1997, in partnership with the International Bureau for Epilepsy (IBE) and the World Health Organization (WHO), the ILAE launched the Global Campaign Against Epilepsy (GCAE). This campaign was conceived by then ILAE president Ted Reynolds and is the culmination of ILAE interest in global epilepsy issues. A primary goal of the GCAE is to reduce the epilepsy treatment gap through community-based interventions, and to address the other problems listed above. How successful this will be is as yet not known, but a recent review of treatment gap figures suggests indeed that it may be lessening [32]. Another important output of the GCAE was an atlas of epilepsy care which was published in 2005 [33] and which provides information about resources for epilepsy care from 160 countries. The data show that there are high levels of inadequate care and large inequalities of care – with low-income countries generally faring very poorly.

As a reaction to the hegemony of modern Western pharmaceuticals, one intriguing aspect of epilepsy treatment which has been explored in the last 40 years is the value of traditional therapies still employed in all cultures. A detailed description of these is outside the scope of this paper, and some are outlandish and even ridiculous to Western eyes. But they are widely practised and adhered to. Nor is the use of alternative medicine confined to developing countries [34,35]. A recent survey of all members of the Epilepsy Federation of Arizona found that 44% had used a non-conventional treatment for their seizures at some time [27].

Antiepileptic drugs introduced into clinical practice between 1957 and 1988

During this period, a series of highly effective new drug therapies became available, some of which have endured and remain at the centre of therapeutics today (Table 5).

Ethosuximide (Zarontin®)

One of the first groups of compounds to emerge in the euphoria that followed phenytoin was the oxazolidine-diones. Trimethadione (Tridione) was one of the first, but its use was limited by unpleasant side-effects, especially hemeralopia, and occasionally exfoliative dermatitis and agranulocytosis. Miller and co-workers within the Parke-Davis Company, the manufacturers of phenytoin and indubitably then the 'epilepsy' company, systematically explored other succinimides [36,37]. Based on this work, three derivatives were identified, licensed and marketed: phensuximide (Milontin, 1953), methsuximide (Celontin, 1957) and then the ethyl derivative, ethosuximide (1958). The latter drug, α-ethyl-α-methylsuccinimide, initially studied as its laboratory name PM 671, was then given the approved name ethosuximide (or ethosuccimide) and the trade name Zarontin in 1958. The structural chemistry of all three succinimides is very similar. Ethosuximide differs from Milontin by the substitution of an ethyl in place of the phenyl group at position 3 of the basic ring structure, and from Celontin by addition of a methyl group with the phenyl group.

In the 1950s it was recognized that these minor chemical changes result in markedly different anticonvulsant spectrum and efficacy. And so it was. Celontin shows clear effectiveness in both petit mal and psychomotor seizures, but Milontin and Zarontin only in petit mal, with Zarontin far more powerful at clinically acceptable doses.

Table 5 Drugs licensed in European countries between 1957 and 1988.

1957	Ethotoin
1957	Methsuximide
1958	Ethosuximide
1960	Chlordiazepoxide
1962	Sulthiame
1963	Chlormethiazole
1963	Diazepam
1965	Carbamazepine
1967	Valproate
1968	Clonazepam
1975	Clobazam
1985	Progabide

Licensing varied from country to country and so given here is the date of first licensing or the first mention of its clinical use, in a country in Europe.

Ethosuximide acts by blocking the low-voltage T-type calcium channel, a mechanism which was identified only in 1984, some 16 years after licensing. It was investigated in animal studies first, by protecting rats against the effects of metrazol-induced seizures at a dose of 125 mg/kg. Toxicology was reported in monkeys, showing normal biochemical and haematological findings and a reasonable side-effect profile. Zimmerman and Burgemeister [38] were the first to report its effect in 109 cases of petit mal epilepsy, mixed petit mal (what we would probably now call atypical absence epilepsy in Lennox–Gastaut syndrome) and petit mal combined with other seizures. The drug was trialled at the high dose of 1750 mg/day. An 85% reduction against baseline seizure rates during a follow-up of 10–96 weeks was reported. Forty-two per cent obtained complete control, and 24% obtained 80–99% control. The drug proved much more effective in 'pure petit mal' than in mixed petit mal or in petit mal combined with other seizures (grand mal and psychomotor), an effect independent of baseline seizure frequency, and no tolerance was observed. Toxic side-effects comprised drowsiness, dizziness, nausea and gastric distress, and were reported in only nine patients. Other reports followed, which were essentially confirmatory [39–44]. Heathfield and Jewesbury [41] used doses which would be accepted as conventional today (most patients on 500–750 mg/day) and reported a more conventionally recognizable side-effect profile (34% of patients reporting apathy, depression, drowsiness, nausea, vomiting and leucopenia). All of these early authors recognized that Zarontin was superior in effect, and caused less toxicity, than the other succinimides.

Psychosis as a side-effect was first reported amongst the 60 patients studied by Lorentz de Haas and Stoel [40]. A case of Stevens–Johnson reaction was first reported in 1963 [45] and of drug-induced systemic lupus erythematosis in 1968 [46]. The first case of fatal pancytopenia was reported in 1962 [47], and it has since become clear that the drug has a propensity to cause acute and severe allergic reactions of many types.

A significant advance in the use of ethosuximide was the introduction of serum level monitoring. A rather non-specific assay was published in 1963 [48]. A gas-liquid chromatography method was published in 1965, and by 1969, a modification of this method was in routine clinical use. The relation of efficacy to serum levels was first reported in 1970 [49] in 21 patients and then by Penry and colleagues [9], who found maximum clinical control at levels of 40–80 μg/ml. Sherwin and colleagues [50] carried out a similar study and found that 93% of those controlled on ethosuximide had plasma levels above 40 μg/ml and confirmed the excellent correlation between effectiveness and plasma level. The conclusion from these studies has been repeatedly confirmed, and even today ethosuximide plasma levels remain an indispensable guide.

From about 1960, there was little disagreement amongst physicians that ethosuximide was the drug of choice for typical absence seizures, but it had limited effect on tonic–clonic seizures or atypical absence. Valproate was licensed in France in 1967 and was soon shown to be as effective as ethosuximide in controlling absence (but no more effective) and also to have a broader spectrum and to be safer. Rather surprisingly, it was not for many years that ethosuximide was replaced by valproate as drug of first choice in absence epilepsy. Perhaps this was because valproate

licensing was so delayed in the USA, or perhaps because of Parke-Davis's reputation in epilepsy. Even into the late 1980s, ethosuximide was still widely prescribed as first-choice therapy, and it has only been in the past 5 years or so that the drug was finally relegated to the far margins of conventional therapy.

Methsuximide (Celontin®)

Methsuximide, with phensuximide and ethosuximide, was discovered in the systematic exploration of the oxazolidine-diones [36,37]. The first human studies were reported in 1951 [38,51–53], and it was licensed in 1957. It was soon recognized to have effects in psychomotor as well as petit mal seizures. The drug is highly metabolized, and the active metabolite is largely *N*-desmethyl-methsuximide. The first studies of correlation between serum levels and seizure control and toxicity were published in 1972. Although the drug shows the same general toxicity profile as other succinimides, it has a much smaller risk of serious haematological or dermatological allergy, and it has continued to have a minor place in therapy, right up to the present day.

Ethotoin (Peganone®)

Ethotoin is a hydantoin drug, similar to phenytoin, and found as the result of the large screening of hydantoin drugs. Ethotoin has fewer side-effects than phenytoin, particularly in relation to the cosmetic effects of gingival hyperplasia and hirsuitism, but it is less effective, and because of its short half-life requires frequent dosing. It also, in some patients, requires high doses (up to 3000 mg/day). Although it was moderately popular when launched, it never achieved the position of phenytoin and is now only occasionally prescribed. It was manufactured by Abbott and is now available from Ovation Pharmaceuticals.

Sulthiame (Ospolot®)

This drug was produced in the laboratories of Bayer by Helferich and Kleb [54] and launched in Europe in 1962. It is a sulphanilamide drug, somewhat related to acetazolamide, and is a carbonic anhydrase inhibitor and this is probably its main mode of action. It became widely used for the treatment of partial seizures. However, a randomized clinical trial in the USA, carried out as part of the NIH initiative, was negative, and for this reason it was never licensed in America [55]. Soon after its launch, a major interaction with phenytoin was recognized, with sometimes very large rises in phenytoin levels when used in co-medication [56]. Because of this, doubts arose as to whether it had intrinsic antiepileptic action. It remained fairly commonly prescribed until the fashion for monotherapy prevailed, and the view that its efficacy was mediated largely via the interaction with phenytoin. In 1986, sulthiame was withdrawn from the market in the UK and other countries. Although licensed originally for use in partial seizures, a specific action in benign rolandic epilepsy has been suggested, and the drug was also used in West syndrome, for myoclonic seizures and for behavioural disorders. The ownership of sulthiame was transferred to Desitin in 1993 and nowadays it is sold in only a few European countries.

Carbamazepine (Tegretol®)

By the end of the Second World War, research into antiepileptic drug therapy (indeed, all drugs) was largely conducted, not as before by the universities and clinical schools, but by pharmaceutical companies (valproate is the only major exception). The rise of the pharmaceutical industry and its power and domination of the epilepsy agenda is a story as yet untold. Carbamazepine was developed in this way by the Swiss pharmaceutical firm Geigy, and was perhaps the first drug to produce large profits in the field.

Carbamazepine, initially known as G32883, was a compound first produced by Walter Schindler at Geigy in 1953 [57]. It has a tricyclic structure, similar to Tofranil, and was first investigated as a drug for depression and psychosis. Its effects on neuralgic pain were discovered by animal screening, and clinical trials confirmed its usefulness [58]. It was in fact licensed and marketed, in 1962, first for trigeminal neuralgia (although even then the blurb described it as a 'new anticonvulsant drug') (Fig. 4). Its antiepileptic effects had been investigated clinically in 1959, and first reported in 1963 by Bonduelle *et al*. [59] and Lorgé [60]. In 1964, Jongmans [61] published in *Epilepsia* a series of 70 patients treated with carbamazepine who were refractory to conventional drugs. Seventeen of 43 patients with grand mal seizures were rendered seizure free, and seven improved by more than 75%. Seven out of 24 patients with psychomotor seizures were rendered seizure free, and three improved by more than 75%. Doses of 600–2400 mg were used, and no patient was withdrawn because of side-effects. Its positive psychotropic effect was also noted. The drug rapidly gained a reputation in Europe as a very promising new antiepileptic. The first controlled trial was was undertaken at a hospital for the mentally subnormal in 1966 [62], and this was a landmark in epilepsy trial design. Tegretol was substituted for existing therapy with phenobarbital in 50% of the subjects and compared with the continuation of phenobarbital in the other 50%. Identical white tablets were produced containing phenobarbital, phenytoin, primidone and carbamazepine, and the staff and patients were blinded to which drug was being taken. The study was conducted over 18 months in 45 patients, and carbamazepine was found to have an equivalent antiepileptic action to phenobarbital, phenytoin and primidone given either separately or in combination. It was hoped that there would also be a psychotropic effect, but no difference between groups was noted. Four patients on carbamazepine died during the study, but this was felt by the investigators (one of whom worked for Geigy) to be no more than would be expected. Seven more controlled (or semi-controlled) trials were reported over the next 10 years [63–69]. In 1965, the drug was approved for use as an anticonvulsant in the UK, but approval in the USA was delayed until 1974. Its principal mechanism of action – the blockade of sodium channels – was not recognized until 1983, although earlier studies in peripheral nerves [70] had demonstrated that carbamazepine reduced sodium current in Myxicola giant axons but only at supra-maximal concentrations. The effects on repetitive firing were first demonstrated in peripheral nerves and then in cell culture of spinal cord neurons [71].

There are several important subsequent landmarks in the history of carbamazepine. With the advent of serum level monitoring around 1972, a tentative therapeutic range was set with an upper limit of 10 mg/100 ml [72]. A series of clinical trials in the 1980s established its value in monotherapy [25], but it was not until the mid-1990s that formal randomized trials in newly diagnosed patients were carried out [73,74]. Within 10 years of

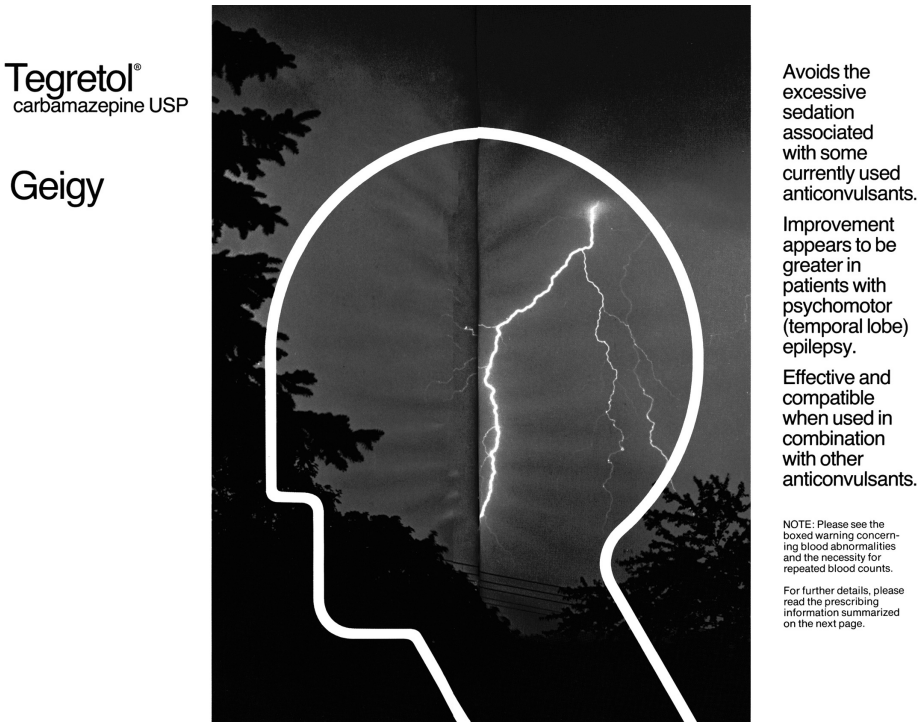

Fig. 4 One of the first advertisements for carbamazepine.

its first licensing, carbamazepine became very widely used and had, with phenytoin, become the drug of first choice in psychomotor and grand mal epilepsy. By 1965, the first reports of idiosyncratic rash, haematological toxicity and hepatic dysfunction were made, and the drug began to acquire a reputation for hypersensitivity. The rate of reactions seemed to fall after these years, and some early cases may have been due to the incipient rather than the active molecule. The rate of agranulocytosis is now known to be about 0.5 cases per 100 000 treated persons, and the rate of hepatic failure 16 per 100 000. It was not until 2004 that the strong association of Stevens–Johnson syndrome with HLA-B*1502 was noted in the Han Chinese, resulting in 2007 in an NIH advisory letter recommending human leucocyte antigen testing in all Chinese prior to starting carbamazepine [75]. The teratogenic potential of carbamazepine was recognized first in the early 1970s. In 1984, the first of several slow-release formulations was produced, but it took another decade or so for the slow-release formulations to become the preferred routine method of administration.

Most of the major characteristics of carbamazepine were identified early on, and by the late 1960s, data were available on the pharmacokinetics, carbamazepine's potential for complex drug interactions, and its common neurological and gastrointestinal side-effects (dose related). Its major routes of biotransformation were also known, but it was not until 1972 that the epoxide was recognized as a metabolite. Its central role in toxicity and the effects of drug interactions were not established until the late 1970s. Its excellent efficacy in partial and secondarily generalized epilepsy was recognized from the very first trials, as was the risk of exacerbation of absence and myoclonic seizures, and its relatively limited value in the generalized epilepsies and syndromes. Another important landmark was the introduction of slow-release formulations (which curiously differ completely in the USA and in Europe) and the recognition that many of the transient peak-dose side-effects of carbamazepine are alleviated by this formulation in a twice-daily regimen.

By the mid-1980s, carbamazepine was the most prescribed antiepileptic drug in Europe, and still is. Some 40 years after its introduction, it remains the gold standard for comparative studies of antiepileptics and the drug to beat for any new compound. By 1989, 2700 citations for carbamazepine had already appeared in the medical literature (and by 2008, 11 052) and the drug is probably the most cited and most studied compound in the history of epilepsy.

Sodium valproate and its derivatives (Epilim®, Depakine®, Depakene®)

Dipropylacetic acid (as valproate was then better known) was synthesized in 1881 and had been in use for about 80 years as an organic solvent, when in Grenoble in 1962, a small pharmaceutical company, La Laboratoire Berthier, directed by two brothers, decided to test a series of compounds in the rat for tranquillizing action. This was carried out in collaboration with George Carraz from the University of Grenoble. Dipropylacetic acid was chosen as the solvent, and when all compounds were found to be apparently antiepileptic in this model, the Meunier brothers decided to test the solvent alone. Immediately, it was obvious that the organic solvent had marked antiepileptic action. The laboratory then started to develop valproate in-house and carried out the first experimental study of the compound in 1963 in 16 rabbits given the convulsant cardiazol and protected by intraperitoneal, rectal and intravenous routes [76]. In those days, clinical testing could

Fig. 5 An early advertisement for valproate.

be started early (the thalidomide tragedy was soon going to put pay to this) and so it was with valproate. In 1964, Carraz and colleagues published the first clinical report of the effect of the sodium salt of dipropylacetic acid (sodium valproate) [77]. The drug had been initiated in November 1963 in 16 patients with largely previously intractable petit mal and grand mal epilepsy. Thirteen of the 16 cases showed marked improvement in the study, which was carried on for up to 7 months. Some patients were rendered seizure free, and the authors noted that petit mal as well as grand mal and psychomotor seizures were improved. It was soon apparent that more resources than were possible in this small laboratory were needed and the drug was sold on and licensed in the mid-1960s by Sanofi-Labaz (Fig. 5). The new company rapidly promoted the drug, and in 1967 it was approved in France and then in other European countries (Spain 1970; Belgium and Holland 1971; and Britain, Switzerland and Italy since 1972). By 1970, valproate was being widely used in Europe. The drug was not launched in the USA largely because of the lack of enthusiasm from Abbott, which held the US licence. J. Kiffin Penry, then ILAE president, then led a campaign to the US Senate seeking access to the drug. The FDA then took the unprecedented step of requiring Abbott Laboratories to supply information on valproate so it could be considered for expedited approval [78]. The battle for the approval of valproate was dramatized in a 1987 ABC television movie, *Fight for Life*, starring Jerry Lewis, in which Penry was portrayed as Dr Monroe Keith. Partly as a result of Penry's campaign, the drug was eventually licensed in 1976 in the USA, albeit initially only for the treatment of absence seizures.

The effects of valproate against absence epilepsy, myoclonic epilepsy and tonic–clonic seizures (especially when part of the syndrome of idiopathic generalized epilepsy) were well recognized by the early 1970s. In 1975, Simon and Penry published a major review of the drug that formed the basis of the subsequent FDA approval [79]. They found reports of 13 clinical trials, including two double-blind cross-over studies [80,81] and carried out what was essentially an early meta-analysis of the 10 trials which had sufficient data, in 1020 patients, and found over 50% had a reduction in tonic–clonic, myoclonic and absence seizures and about one-third of patients had a reduction in partial seizures. By the early 1970s, the effect of valproate on EEG – the abolition of photosensitivity and of spike–wave paroxysms – and the effects in atypical absence were also recognized and the pharmacokinetics fully established. The drug was rapidly gaining prominence, and increasingly being recommended as first-line therapy.

The problems which dogged the prescription of valproate thoughout this period were anxieties over its safety, and the slowness in acknowledging all aspects of valproate toxicity is rather shocking. The rather common cognitive side-effects and effects on hair were also early recognized, as was the encephalopathy (two patients in the initial trials were rendered comatose). The common effects on weight were surprisingly not recognized for many years, and even as late as 1983, Dreifuss wrote that increased appetite resulting in obesity was an 'occasional' problem. The first report of teratogenicity was by Dalens *et al*. in 1980 [82], of a dysmorphic child, and by Gomez in 1981 [83], of a neural tube defect. In 1982, the increased incidence of myelomeinigocoeles in children exposed *in utero* to valproate was described, which (15 years after licensing) established the risks of the drug in pregnancy [84]. The possibility that valproate also results in increased incidence of childhood learning disability was not reported until 2001 [85]. Hyperammonaemia was first reported in 1981 [86] and the risks of the drug in ornathine transcabamalase deficiency also in 1981. The first hepatic deaths were reported in 1978, and in 1987 these were definitively reviewed by Dreifuss, who found a risk of fatal hepatic dysfunction ranging from 1:500 in children 0–2 years old receiving valproate as polytherapy to 1:37000 in patients receiving valproate as monotherapy, with no hepatic

fatalities reported in patients above the age of 10 years receiving valproate as monotherapy [87]. The reports of pancreatitis were first published in 1979 and resulted in another review by Dreifuss and colleagues in 1993 [88]. The possibility that the drug caused polycystic ovarian syndrome and other hormonal problems was first reported in the 1990s in findings promulgated largely by a single research group and often unconfirmed by others. These risks have still not been clearly defined.

These various problems have limited the use of the drug, which is a pity given its clear efficacy. But even today, valproate remains one of the two most prescribed antiepileptic drugs (sharing the honour with carbamazepine) and a clear favourite in the idiopathic generalized epilepsies. The value of valproate was emphasized in the recent SANAD study [89]. In the generalized epilepsy arm, valproate proved superior in efficacy to both lamotrigine and topiramate, confirming its place as the drug of choice in generalized epilepsy. The old lady, it seems, can still hold her own.

1,4-Benzodiazepine drugs (chlordiazepoxide, diazepam, clonazepam)

A most significant pharmacological development of the post-war period in general psychiatry was the development of a new class of drugs, the benzodiazepines. These compounds have had a major impact on popular Western society and culture and have entered the folklore of the age (e.g. the 'little yellow pills' and 'mother's little helpers' of the famous song). They helped fuel a revolution in biological psychiatry and its social reaction, the antipsychiatry movement of the 1960s. Of course, the main impact of this class was its anti-anxiolytic and hypnotic action, but the benzodiazepines were also early recognized to have antiepileptic effects. The 'benzodiazepine story' as related by the protagonists at the time is an intriguing insight into contemporary pharmaceutical development. In 1952, the first reports of the clinical effects of chlorpromazine were published, and its obvious commercial importance and rapid success led the pharmaceutical industry into a race to discover other psychoactive drugs which might have improved properties. The Swiss pharmaceutical giant Roche was a leader in the field, and had developed a range of animal-testing models for assessing sedative properties. Leo Sternbach was a medicinal chemist in their research laboratories [90]. In the mid-1950s, he decided to investigate the pharmaceutical actions of a group of compounds he had created which came to be known as the benzodiazepines. They were attractive candidates as they were readily produced, capable of chemical manipulation to produce a whole family of compounds, largely unstudied in pharmacology and had the 'look', as he later put it, of being biologically active. He chose first to study benzheptoxdiazines and synthesized a range of these with different side-chain products. Initially, no biological action was found, and his laboratory was then asked to focus on other research areas. In cleaning up, his technician found a few hundred milligrams of some crystallized compounds which were thought to be quinazoline 3-oxides prepared in 1955. They decided to submit these for animal screening. The results were unexpectedly exciting – the drugs had powerful sedative and antiepileptic effects. Sternbach pressed on. He found first that the compounds were not in fact quinazoline oxides but had a seven-membered diazepine ring. In May 1958, a broad patent was filed for the 2-amino-1,4-benzodiazepine 4-oxides and various substituents in the benzo- and phenyl rings. It was granted in July 1959. An intensive pharmacological programme of work ensued, and one of the original compounds, given the generic name chlordiazepoxide, proved superior to its derivatives and was submitted for licensing to the FDA. In short order, in 1960, the compound was approved and licensed under the name of Librium. Sternbach then carried out further chemical exploration and discovered that the *N*-oxide function was not necessary for the pharmacological action (contrary to the then hypothesis on mechanisms of action) but that biological activity depended on the presence of a chlorine in the 7-position. With additional manipulation, another compound, given the name diazepam, was discovered and found to have a broader spectrum of activity than Librium, stronger antiepileptic and muscle relaxant properties, and very low toxicity. Following clinical studies, the drug was licensed in 1963 under the name Valium. In the next 15 years, over 4000 related compounds were synthesized and screened, and by 1978, 23 compounds had been licensed worldwide (including eight in the USA). It is instructive to note that the compounds were not produced rationally in the sense that they were designed with a specific epilepsy or anticonvulsant mechanism in mind, but initially rather randomly discovered following screening in an animal model – much as was phenytoin. However, the chemical family was then explored using systematic chemistry – with thousands of products each analysed and again screened in the same models. In this way, the basic chemical structures necessary for clinical action were elucidated. Such a programme was only possible in the research factories of the major pharmaceutical companies. The story of the benzodiazepines opened a new chapter in the history of drug development [90].

The value of these drugs in human epilepsy was rapidly recognized. The anticonvulsant effect of Librium was first reported in 1960 [91]. In 1962, a series of cases of epilepsy treated with Librium (Ro 5-0690) and Valium (Ro 5-2807) were presented by Hernandez at the second Latin American Congress on Psychiatry in Mexico and by Madalena in Brazil in 1963. Madalena also mentioned the use of clonazepam in epilepsy, which he considered superior to diazepam due to its lower dosage, almost complete absence of side-effects (an extraordinary assessment from today's perspective), better effects on the behavioural disorders associated with epilepsy, safety and more favourable efficacy in petit mal than either Valium or Librium (Fig. 6). These drugs were beginning to be widely used in epilepsy. In 1965, Henri Gastaut weighed in with a laudatory report of the use of Valium in status epilepticus [92], and 6 years later was even more enthusiastic about the new agent clonazepam (Ro 05-4023) [93,94].

In 1973, Browne and Penry [95] published a major review of the use of the benzodiazepines in the treatment of epilepsy. (Penry's colleague Ewart Swinyard had published reviews of the experimental effects in 1966 and 1969.) This review was a definitive statement on the position of these drugs after a decade of use, and its main purpose was surely to persuade the regulatory agency of the need to license these drugs, which were now widely available in Europe and elsewhere but not in the USA (Penry and colleagues had written similar reviews of carbamazepine and valproate for similar reasons – see above). The review covered clinical pharmacology and toxicology, effects on EEG and clinical

Fig. 6 An early advertisement for clonazepam – one of the first advertisements to advise the use of the drug based clearly on the modern classification of seizures.

effects, and summarized the status of the benzodiazepines 10 years after the first licensing of Valium. By then there were 28 open studies of benzodiazepines in patients with refractory petit mal and one open study of new cases – dating from 1961; Browne and Penry were scathing about the methodology, but noted that the results were uniformly encouraging. They concluded that controlled studies were needed 'to establish definitively the role of benzodiazepines in the treatment of absence attacks'. In 1977 they reported one such study, a double-blind comparison of clonazepam and ethsuximide. The drugs were reported also to be useful in photosensitive epilepsy, myoclonic epilepsy, West syndrome, akinetic seizures, alcohol withdrawal seizures and eclamptic seizures. However, the results of treatment in grand mal and focal epilepsies were generally less good, and indeed, grand mal seizures could be exacerbated. On the question of status epilepticus, Penry was more lukewarm than Gastaut had been. He reviewed 35 articles on the effectiveness of diazepam in various types of status epilepticus, but failed to mention Gastaut's article, and noted lasting control of the status in between 20% and 89% of cases, depending on the seizure type. The principle objection to diazepam was its respiratory depressant and hypotensive side-effects. Also, because of the propensity for tolerance to develop on continuous oral medication, the drugs were most useful in their parenteral formulations. It is difficult to disagree with any of the conclusions in Penry's review, which still largely apply today.

The mechanism of action of the benzodiazepines was the subject of intensive study in the 1960s and 1970s. The importance of γ-aminobutyric acid (GABA) as the main cerebral inhibitory transmitter was established by 1975, and shortly after this the main site of action of the benzodiazepines was shown to be at the GABA receptor. The benzodiazepines still used in long-term oral therapy for epilepsy now are clobazam and clonazepam, and occasionally nitrazepam and diazepam. None are currently considered first-line therapy. Only clobazam is widely used worldwide (although not licensed in the USA), and clonazepam is used extensively in France. Enthusiasm for their antiepileptic effect has been tempered by the occurrence of tolerance and the problems of dependency and sedation. Rectal diazepam, buccal and intranasal midazolam, and intravenous diazepam and lorazepam, however, are still the drugs of choice in the first-line therapy of convulsive status epilepticus and in generalized absence status epilepticus.

Clobazam (Frisium®)

Clobazam is an outsider in the benzodiazepine family. It is the only benzodiazepine which has been extensively studied clinically in which the diazepine ring is substituted by a nitrogen atom in the positions 1 and 5 of the B ring and no imine group at positions 4 and 5. It has distinctive properties which set it apart from the other benzodiazepines, and which are probably explicable by its different differential action on subtypes of the $GABA_A$ receptor. This structural change results in an 80% reduction in its anxiolytic activity and a 10-fold reduction in its sedative effects when compared with diazepam in animal studies. It has been licensed in Europe since 1975 and Canada since 1988, but is unavailable in the USA. It is widely used in specialist epilepsy clinics, where this underdog of a drug has many champions.

The antiepileptic effects were reported in mice in 1973 and then in baboons [96]. The first human trials were reported in 1979 by Gastaut and Low [97]. It has since then been the subject of at least two international conferences and is the most widely used of the benzodiazepine drugs in chronic epilepsy, at least outside the USA. It was discovered in 1984 that its main effects are due to its active metabolite, *N*-desmethylclobazam, which has a longer half-life and greater serum levels than the parent drug. Clobazam was first trialled as an anxiolytic and was licensed for this purpose, although it was withdrawn in recent years for this indication as it has few advantages over the 1,4-benzodiazepine drugs. Its antiepileptic properties were discovered a few years later when clobazam was made available, in October 1977, to the Marseilles group of Gastaut. It was tested first for a few days in 140 patients with frequent seizures, and then continued in patients who showed a response at a dose of 0.5 mg/kg/day. Its effects were dramatic initially, as has been confirmed many times since. Seventy-six per cent of the patients with severe epilepsy showed a marked and potent response, although this was maintained in only 52% after

a matter of months. Side-effects were slight, and good results were obtained in patients with all types of seizure, in reflex epilepsy and in Lennox–Gastaut syndrome. Since then, its strong antiepileptic effects have been confirmed in numerous open and also eight double-blind placebo-controlled studies carried out between 1982 and 1991, four from the UK, and one each from France, Germany and Canada and one multicentre European study (reviewed in Shorvon [98]). The study from Canada found clobazam to have equivalent efficacy to carbamazepine and phenytoin as monotherapy for childhood epilepsy [99].

The major problem with clobazam, as noted immediately by Gastaut, is the propensity for tolerance to develop in 50–80% of patients, sometimes within days or weeks of its initiation. Manoeuvres such as drug holidays, initiation at very low doses, the use of partial benzodiazepine agonists and of very high doses have all failed to circumvent this problem. Other side-effects, such as drowiness, dizziness, weakness, restlessness and aggression, are either less common or less marked than with any of the 1,4-benzodiazepine drugs. It is, in routine practice, very well tolerated. Its mild anxiolytic effect is also useful in some patients with epilepsy.

It retains a special place in the therapy of chronic epilepsy and is widely used. It also has a useful role as one-off prophylactic therapy on special occasions when it is particularly important to prevent a seizure (e.g. on days of travel, interview, examinations and so on) or in catemenial epilepsy [98,100]. Its availability in Canada, but not the USA, is said to have resulted in a lucrative cross-border trade.

Progabide (Gabrene®)

As might be surmised from its name, this drug was designed as a prodrug of GABA, and was manufactured and developed by the French company Synthelo Laboratory. It was a direct product of the GABA wave (described below) of neurochemical research, and in animal studies progabide was shown to have a wide spectrum of anticonvulsant actions [101]. This was, furthermore, also one of the first drugs to be identified in the NIH Antiepileptic Drug Development (ADD) programme. Although it is a GABA prodrug, its exact mode of action is still not entirely clear. It may act at the $GABA_B$ receptor (subunit 1) and regulate the availability of functional $GABA_B$-R1A/$GABA_B$-R2 heterodimers by competing for $GABA_B$-R2 dimerization. It certainly is not a direct GABA agonist in the same way as vigabatrin. Its effectiveness is complicated by the fact that it elevates phenytoin concentrations and enhances the metabolism of carbamazepine to the epoxide. Some clinical studies showed positive effects and others were negative in both partial and absence seizures. It was also trialled in a head-to-head comparison against valproate which was terminated prematurely, as it caused elevated levels of liver enzymes and was less efficacious than valproate. There have remained persisting anxieties about its hepatic toxicity. It has been extensively studied as a drug which improves tardive dyskinesia in Parkinson's disease, although has never been licensed for this use, and has been found to have mild psychotropic effects. Progabide (a French drug) was licensed in France first in 1985, and by 1992 was reported to have been used in over 2500 persons. It is now licensed in France for use in monotherapy and also as adjunctive therapy for generalized tonic–clonic, myoclonic and partial seizures, and for Lennox–Gastaut syndrome, in both children and adults. It is not licensed in any other European country nor in the USA.

Other drugs

Corticosteroids and particularly adrenocorticotropic hormone (ACTH) were also introduced into clinical epilepsy practice in 1950. Prior to this, steroids were thought to be proconvulsant, although ACTH and cortisone were both known to normalize the EEG [102]. The first report of efficacy in childhood epilepsy was in 1950 [103] and then in 1958, when Sorel and Dusaucy-Bauloye [104] demonstrated the dramatic effect in infantile spasms. Thereafter, ACTH rapidly became, and remains, first-line therapy for this indication. ACTH and cortisone were also shown in the 1950s to have value in occasional cases of other types of childhood epilepsy and in status epilepticus. Paraldehyde became another drug widely used in status epilepticus. The first report of its anticonvulsant action was by Wechsler in 1940 [105]. Apart from its use in status epilepticus, it was also frequently helpful in alcohol withdrawal seizures. Its intravenous use in status epilepticus required a complex series of glass tubing (as it degrades plastic), had the appearance of a chemistry lesson, and is still seared in the memory. It continues to be used as a rectal instillation, particularly as out-of-hospital use in patients with severe epilepsy (e.g. in epilepsy institutions). Its undoubted safety and efficacy make it a popular choice, although few who have observed the effects of paraldehyde will forget its lingering odour, a madelaine of institutional practice. The first report of the use of chlormethiazole in status epilepticus was in 1963 [106] and a number of uncontrolled studies were reported in the next 10 years, all showing that the drug rapidly controls seizures in most patients, including those unresponsive to diazepam infusion [107]. It became a standard second-line therapy in the 1970s, especially in Britain, and I remember many cases of status treated by chlormethiazole infusions well into the 1980s. It has a tendency to accumulate dangerously though, and by 1990 was only occasionally used, as other safer alternatives entered clinical practice and protocols for the therapy of status become more standardized.

Epilepsy therapy in 1989 – the textbook *Antiepileptic Drugs*

An appreciation of contemporary advanced therapy for epilepsy in 1989 can be gained by a reading of the third edition of the textbook *Antiepileptic Drugs*, which was published in that year and which became a standard text [108]. It is clear, by comparing this and Lennox's book published some 30 years earlier, just how the introduction of carbamazepine and valproate, and to a lesser extent the benzodiazepine drugs, had made a rapid and enormous impact on epilepsy practice. By the mid-1970s, carbamazepine and valproate dominated therapy in Europe and, 10 years later, were doing the same in the USA. Their advent pretty well marked the end of all prescription of bromide, the virtual end of the routine use of phenobarbital, at least in Europe (e.g. in my own practice in 1978 this had now largely disappeared), and a marked reduction in the use of phenytoin in Europe and less so in the

USA. The rise of clinical pharmacokinetics was the second major development in this period – with most of the advances in this area made between 1960 and 1972, and by 1989 most of the major parameters relating to the absorption, distribution, metabolism, excretion and drug interactions of all drugs were fully established, as was the characterization of the P450 system (emphasizing particularly the various genetic phenotypes) and the importance (and mechanisms) of drug interactions. The first mention of teratogenicity appeared in 1968 [109]. The selection of antiepileptic drug therapy was also by this time firmly linked to seizure type, using the new ILAE classification, and indeed the therapeutic framework and approach of that time is essentially unchanged today, 20 years later.

One less obvious consequence of these changes was the much greater interest in 'epilepsy' as a subject. In most advanced neurological units, by 1910 epilepsy had fallen from its position as 'queen' of neurology to a rather peripheral subject. It remained in the doldrums at least until 1940, with a reputation as a tiresome condition (with the inference of having tiresome patients) which neither challenged the intellect nor stimulated the interest of the neurological establishment. Neurology had the reputation of being an essentially diagnostic subject which required high intelligence and a rigorous approach based on interpretation of the clinical examination. Epilepsy was not generally a diagnostic challenge, nor did the patients need a sophisticated neurological examination. The attractions of the topic, though, progressively grew in the second half of the 20th century, with the introduction of diagnostic aids, notably EEG, TDM and neuroimaging, and particularly with the introduction of novel therapy. Few neurological specialties had such a range of effective therapies. Furthermore, the establishment of specialized epilepsy units, of which the most celebrated was Lennox's Seizure Unit in Boston, was an important step in raising the profile of the disorder. Similar units opened in the 1970s and 1980s in Europe. The example of the National Hospital at Queen Square in London illustrates this point well. In 1975, for instance, there was no particular epilepsy interest, no research and no specialized clinic. Epilepsy was considered a subject of little interest, in spite of the illustrious role the institution had played in the history of epilepsy. In 1983, an epilepsy group was formed and epilepsy became progressively, again, one of the hospital's leading specialties in both clinical and research fields. This new dynamism in the field of epilepsy was partly stimulated by financial support from the pharmaceutical industry. This was a period in which Ciba-Geigy, which manufactured carbamazepine, and Sanofi-Labaz, which manufactured valproate in Europe (Epilim, Depakine), provided sponsorship in increasing quantities to many educational activities. Consequently, the ILAE conferences grew in size and ambition, and in this period the modern conference, with satellites and a commercial exhibition, was born.

The antiepileptic drug market, the rise of the pharmaceutical industry and the rise in regulation

The post-war period was marked by an enormous rise in the power and profits of the pharmaceutical industry and the intense commercialization of this therapeutic area (as of many others in medicine). Initially, this was a period of great optimism. The drugs developed in the 1950s and marketed in the 1960s included the first oral contraceptives, cortisone, antihypertensives, monoamine oxidase inhibitors, chlorpromazine, haloperidol and Valium (the latter drug becoming at one point the most prescribed drug in history). The profits of the drugs companies soared in the 1960s, and for many years; for instance, the US pharmaceutical sector was judged the most profitable of all industrial sectors in terms of rate of return (2006: 17% on revenue).

Between 1955 and 1989, a number of important antiepileptic drugs were introduced and the drug industry had come to occupy centre stage in the epilepsy world, as never before. The leadership of drug development has moved away from the university academic environment to the in-house laboratories of the companies. The research is now much more focused and more applied, and this move is probably the fundamental reason for the rapid increase in the number of compounds being brought forward for clinical testing. The move has had negative effects also, not least the fact that transparency has diminished and drug development has become more secretive. In the next 20 years, the pharmaceutical industry was to become a more ruthless commercial enterprise kept under conditions of tight secrecy to protect commercial interests. Epilepsy therapeutics has also experienced a transfer of influence away from the academic neurological community to the marketing departments of pharmaceutical companies. This latter change was first noticeable in the 1960s, and has been especially prominent in the last 10 years. The relationship between the two continues to be at the still centre of the topic.

The increasing influence and power of the pharmaceutical industry has been paralleled by, and has no doubt contributed to, an increase in governmental regulation and restriction. This reflected the growing public interest in, and concern about, drug therapy in many areas of medicine. In fact, it was a series of well-publicized debacles which led to incremental changes in governmental regulation.

The example of the legislation in the USA is instructive, although similar legislation tended to follow the American example in other countries. Prior to 1906, there was almost no regulation of drugs or medicines in the USA, which lagged behind Europe in this regard. The first major legislation was the Federal Pure Food and Drugs Act, passed by the US Congress in 1906, in response to public concern about excessive misbranding and adulteration of food. This act required, for the first time, simply 'accurate' labelling, but there was no obligation to provide any real evidence of either toxicity or efficacy. By the 1930s, the nascent consumer movement raised the awareness of the US public (if not their doctors), who became increasingly concerned about the quality of medicines. Efforts were made to tighten regulatory control, for instance through the ill-fated Tugwell bill of 1933, but such efforts never made it to the legislature, partly because of the powerful industrial lobby. However, in the 1930s, the deaths of more than 100 people caused by 'elixir of sulphanilamide', a liquid form of sulphanilamide, dissolved in diethyleneglycol, ignited public anger. In response to this, in 1938, a new act – the Food, Drug and Cosmetic Act – was passed into legislation. This required, amongst other things, evidence of safety to be submitted to the FDA prior to marketing. Between 1938 and 1962, no other major changes were made to the laws concerning drugs and medicines (although there were changes to

laws concerning foodstuffs), but that was all changed by the thalidomide tragedy. Thalidomide was a drug very widely sold during the late 1950s and early 1960s to pregnant women to alleviate morning sickness and to assist sleep. It was inadequately tested, and between 1956 and 1962, approximately 10 000 children were born with severe malformities in Europe and elsewhere (not, however, in the USA, where the drug had not been licensed). In response to the massive public outcry, new laws were drafted, and in 1962, the Drugs Amendment Act (the Kefauver–Harris amendment) was signed into law by John F. Kennedy. These amendments were a milestone in medical history, and for the first time required evidence of efficacy as well as safety of medicines, and also the continuing evaluation of drugs already on the market and the retrospective evaluation of efficacy of all drugs introduced between 1938 and 1962. The Kefauver–Harris amendment also required drug advertising to disclose accurate information about side-effects and efficacy of treatment and placed on the FDA an obligation to establish guidelines for testing all classes of drugs, including antiepileptics. A new system of licensing was devised by which the FDA required each company to obtain an IND (a notice of claimed investigational exemption for a new drug) before it was permitted to use the drug in human subjects. Complete chemical and manufacturing information, preclinical screening and animal investigation, including toxicology, teratogenicity and safety, had to be submitted to the FDA before the IND was granted. Once an IND was granted, clinical testing could begin and was divided into phase I (healthy volunteers), phase II (initial controlled studies in seizure patients) and phase III (broad and varied clinical studies). After completion of these studies, a 'New Drug Application' (NDA) could be filed. If approved, the drug could then be licensed.

These new regulations no doubt protected the public from dangerous compounds, but there were also immediate negative consequences. The cost of developing antiepileptic drugs increased greatly due to the huge increase in the number of animals and procedures needed in preclinical testing, and in the complexity and scope of this testing. Large controlled clinical trials were also required, and gone were the days when a few short open studies were sufficient (as applied, for instance, for phenytoin or ethosuximide). This led to a rapid fall-off in the number of drugs being developed, and the US companies in particular largely withdrew from the field of epilepsy, engendering considerable concern in epilepsy and ILAE circles. Responding to these concerns, in 1972 the US National Institute of Neurological Disorders and Stroke (NINDS) set up an ad hoc committee on anticonvulsant drugs to translate the new rules into practice. This body, in conjunction with the ILAE Commission on Antiepileptic Drugs and the FDA, produced a detailed document outlining the approved design, patient selection and protocols for new drug trials [110]. This new schema became the framework for drug development right up until the present day.

In the middle of the 1980s, the FDA again began to tighten its regulations in relation to antiepileptic and other drugs. This was not driven by legislation, but rather the agency itself raising the bar and initiating more scientifically valid methods of assessment. By now, epilepsy had entered the era of the randomized controlled trial (RCT), which had for some time already been introduced in other areas of medicine. In epilepsy, the FDA decided that RCTs were a necessary prerequisite of licensing. They also made the momentous decision that the new drugs had to demonstrate superiority over a comparator compound rather than equivalence, and so almost all the studies compared the new drug with placebo rather than a conventional therapy. This decision was based on the perceived difficulties of interpreting the finding of non-inferiority, but resulted in a lamentable lack of head-to-head RCTs. This decision was to have a major influence on the conduct and design of clinical trials.

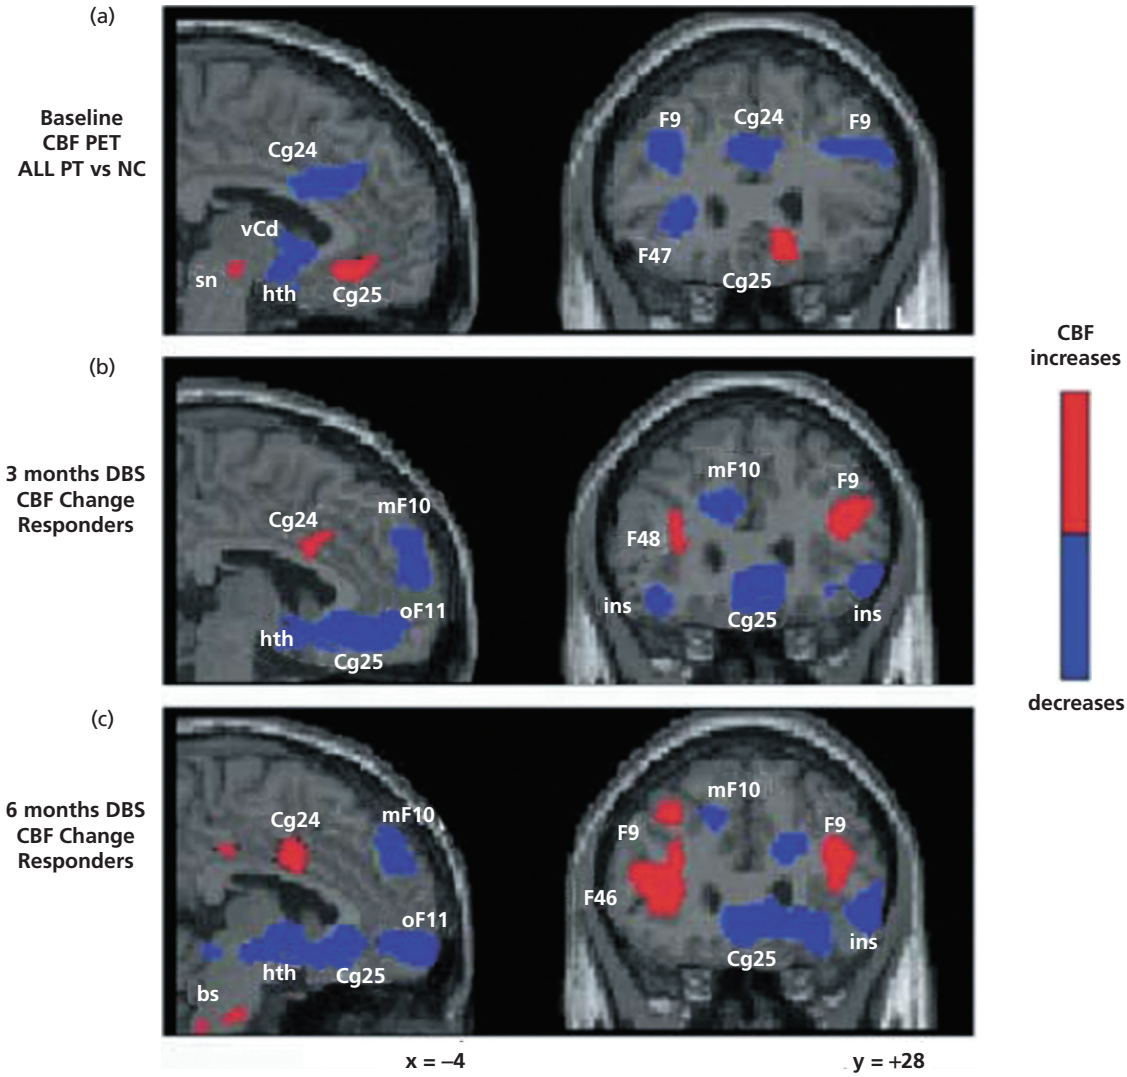

Plate 21.1 The regional cerebral blood flow (CBF) changes [positron emission tomography (PET)] in depressed patients treated with deep brain stimulation (DBS) [65]. (a) Baseline: increase in subgenual cingulate (Cg25) and decrease in dorsolateral prefrontal (F9), ventrolateral prefrontal (F47) and anterior cingulate (Cg24) cortices. (b) Three months: decrease in Cg25, hypothalamus (Hth), anterior insula (ins), medial frontal (mF10) and orbital frontal (oF11); increases in prefrontal (F9/46) and dorsal cingulate (cg24). (c) Six months: this same pattern is maintained, although additional increases are seen in the brainstem (bs). Significant CBF increases in red; decreases in blue ($P < 0.001$).

Plate 29.1 Informal taxis overloaded with people are a common form of public transportation in low-income countries. Traumatic head injuries in road traffic accidents are common (photo courtesy of Michael J. Potchen).

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

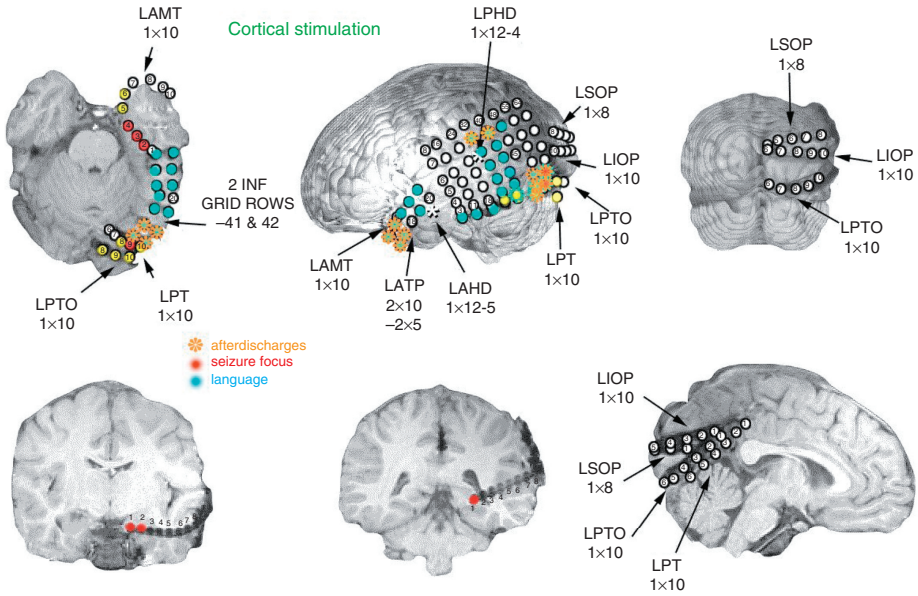

Plate 62.1 Cortical stimulation was undertaken after recording of seizures, including language mapping. The patient was brought to the operating room for resection of the left inferior occipital temporal region of epileptogenesis and multiple subpial transections of the left parieto-temporo-occipital area as it neared or overlaid language areas. A second-stage amygdalohippocampectomy was performed subsequently.

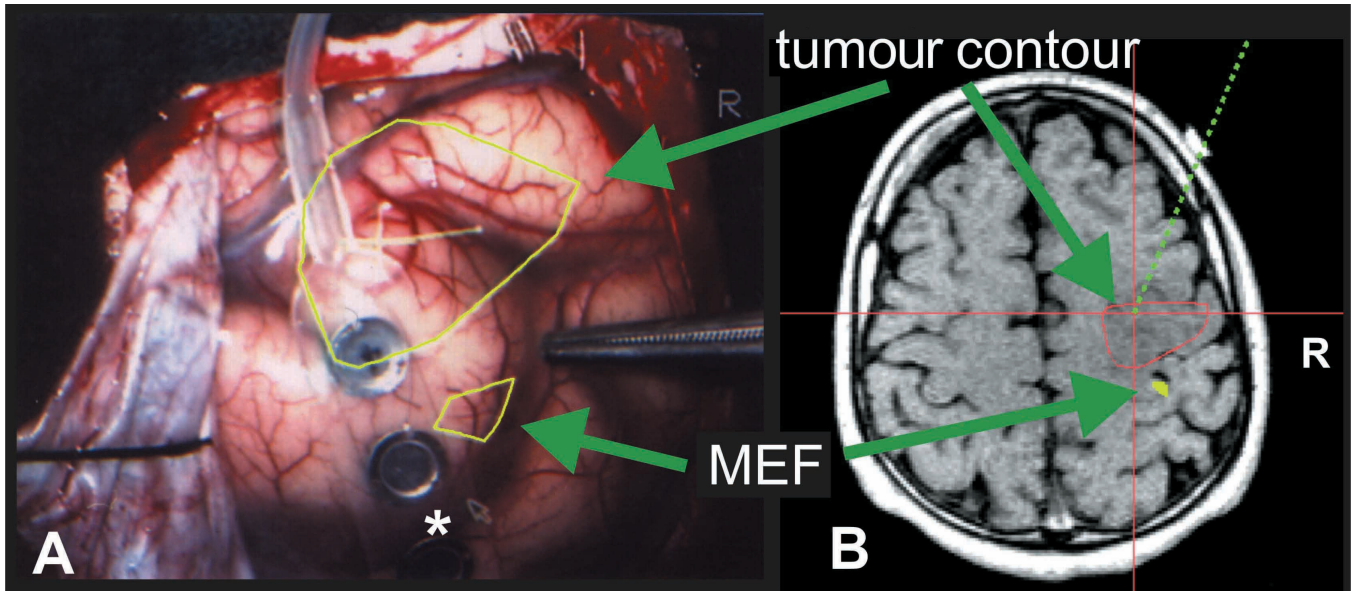

Plate 63.1 (a) Intraoperative view showing that in this patient the MEF dipole representing the motor cortex is displayed on the same gyrus as the tumour, which indicates that a resection is not possible. The white asterisk represents the SEF phase reversal and indicates the central sulcus. (b) Axial MRI showing the tumour countour and MEF dipole yellow triangle in the precentral gyrus, as displayed in the operating theatre for navigation purposes. Reproduced with kind permission from ref. 83.

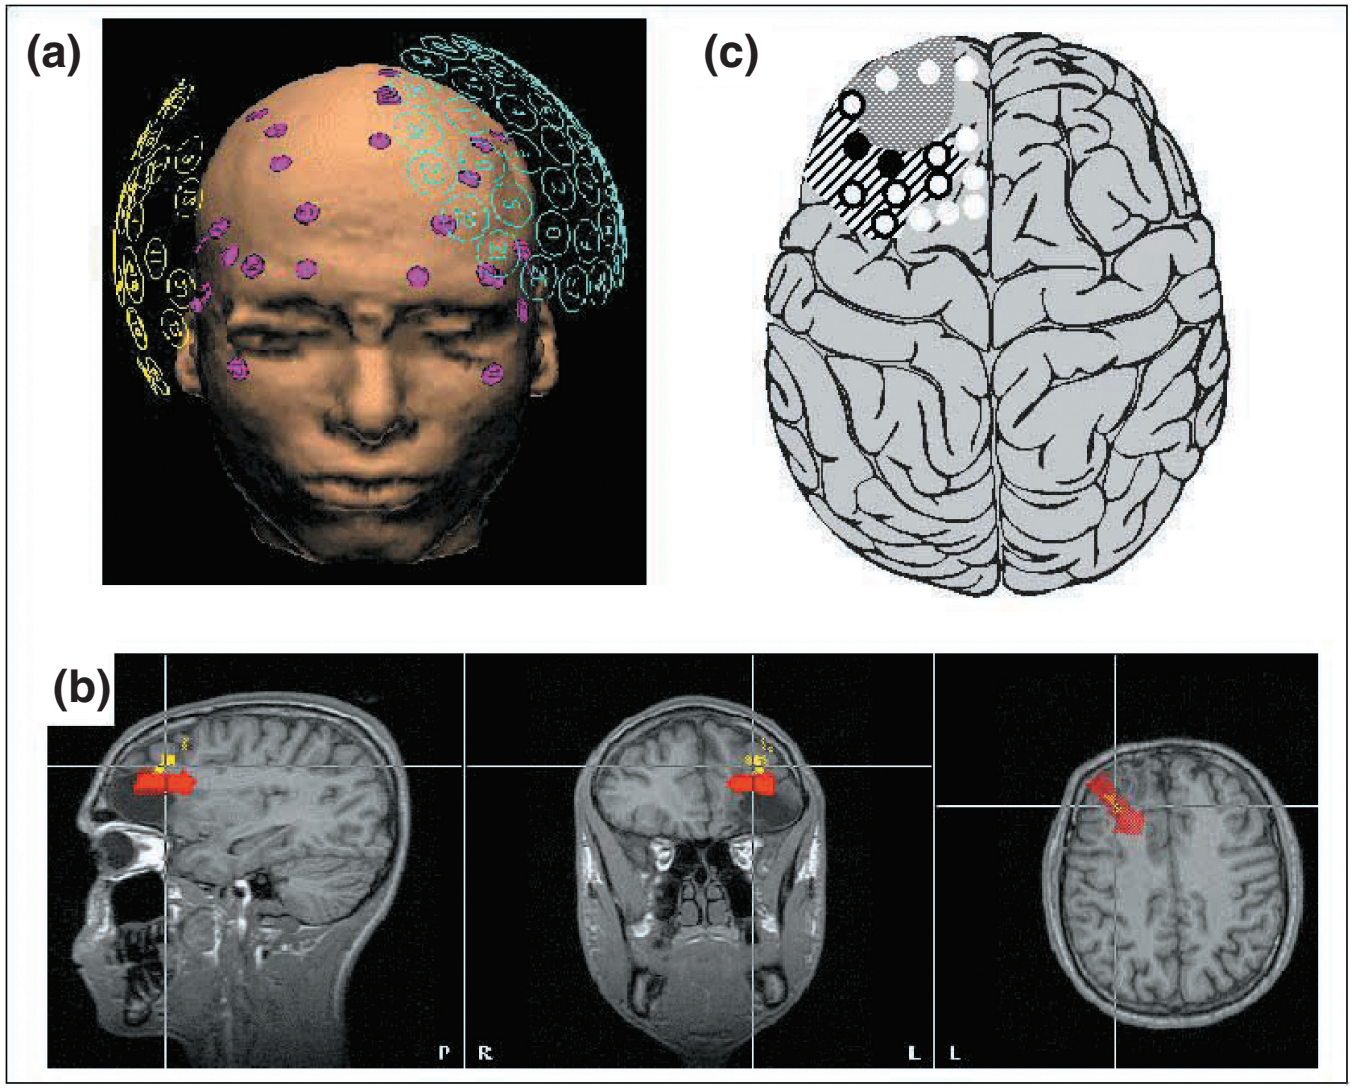

Plate 63.2 MEG and EEG localizations of interictal spikes in a patient with symptomatic frontal lobe epilepsy; with EEG spikes only identifiable after averaging according to MEG templates: (a) EEG electrode (magenta) and MEG sensor (cyan, yellow) locations. (b) Dipole sites, displayed in sagittal, coronal and axial MRI slices. Red: MEG results. Yellow: EEG results (showing higher variability). (c) Sketch of the intraoperative situation. Circles indicate ECoG contacts. Black: maximum spiking activity, in accordance with localization results in (b). White open: no spiking observed. Black-white: medium spiking activity. Shaded area: lesion. Hatched area: resection.

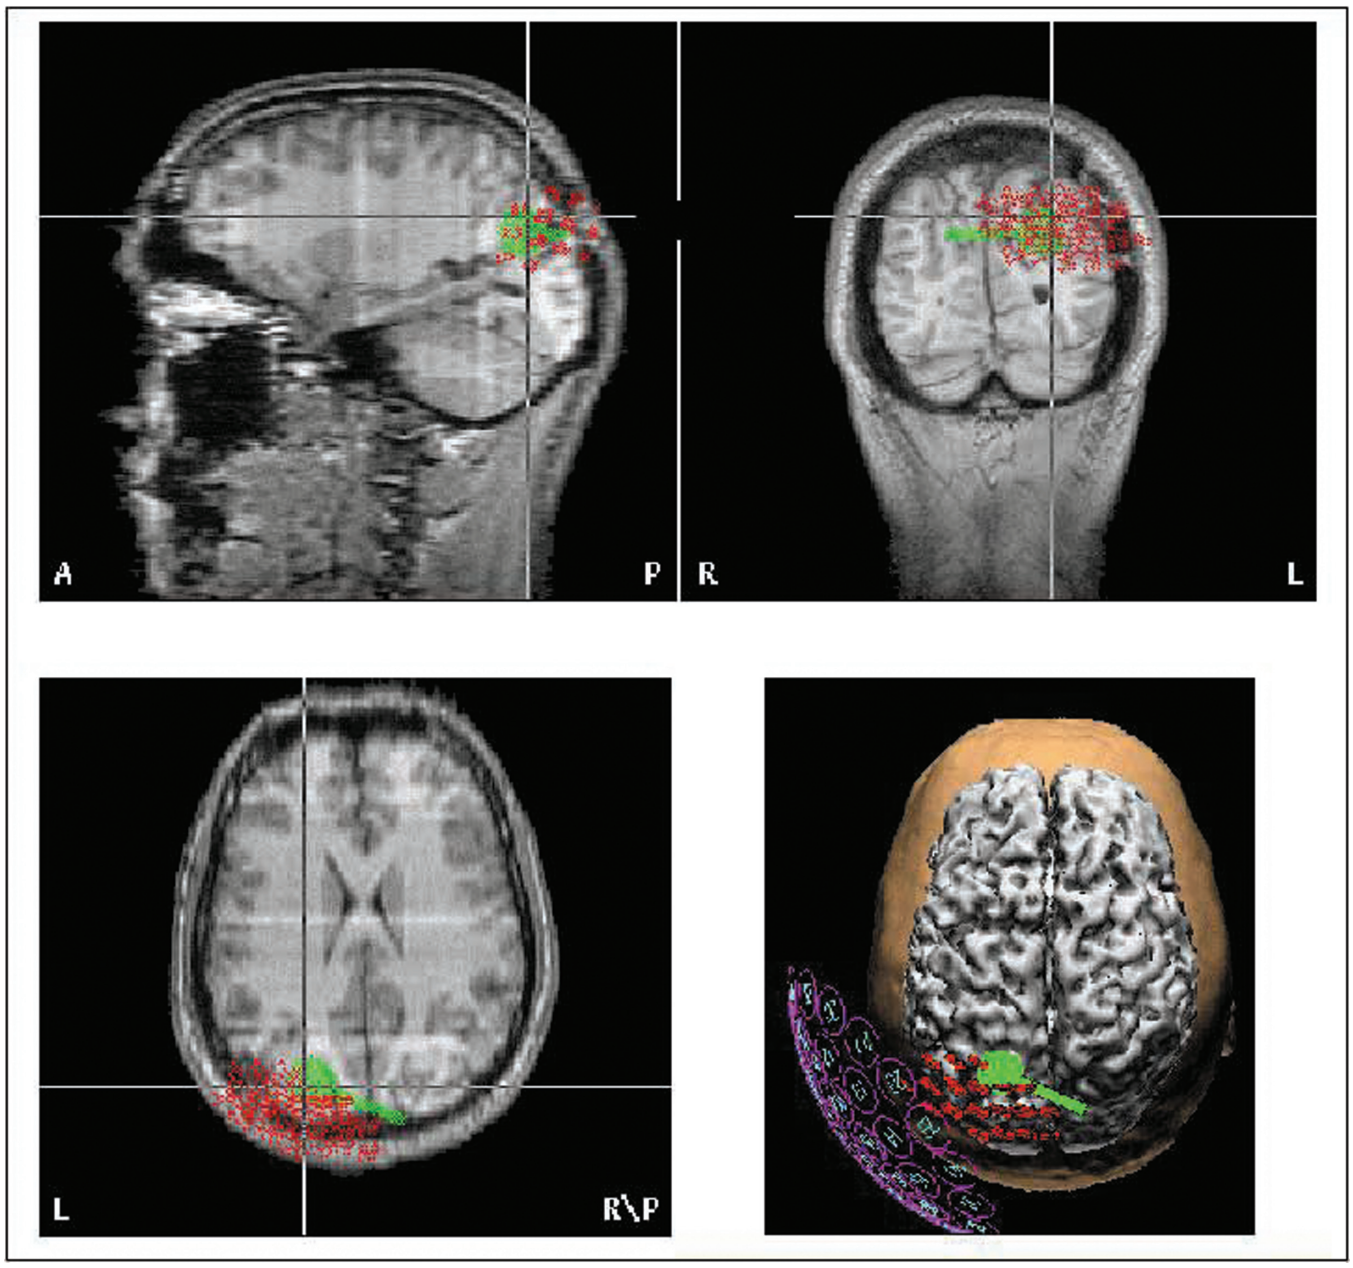

Plate 63.3 Ictal MSI localizations in a patient with symptomatic epilepsy of the left occipito-parietal region, displayed in sagittal, coronal and axial MRI slices (top and bottom left), and in a 3-D reconstruction of the cortex and skin compartments (bottom right). Red: area resulting from current density reconstruction. Green: dipole site. Numbers in magenta circles indicate MEG sensor positions.

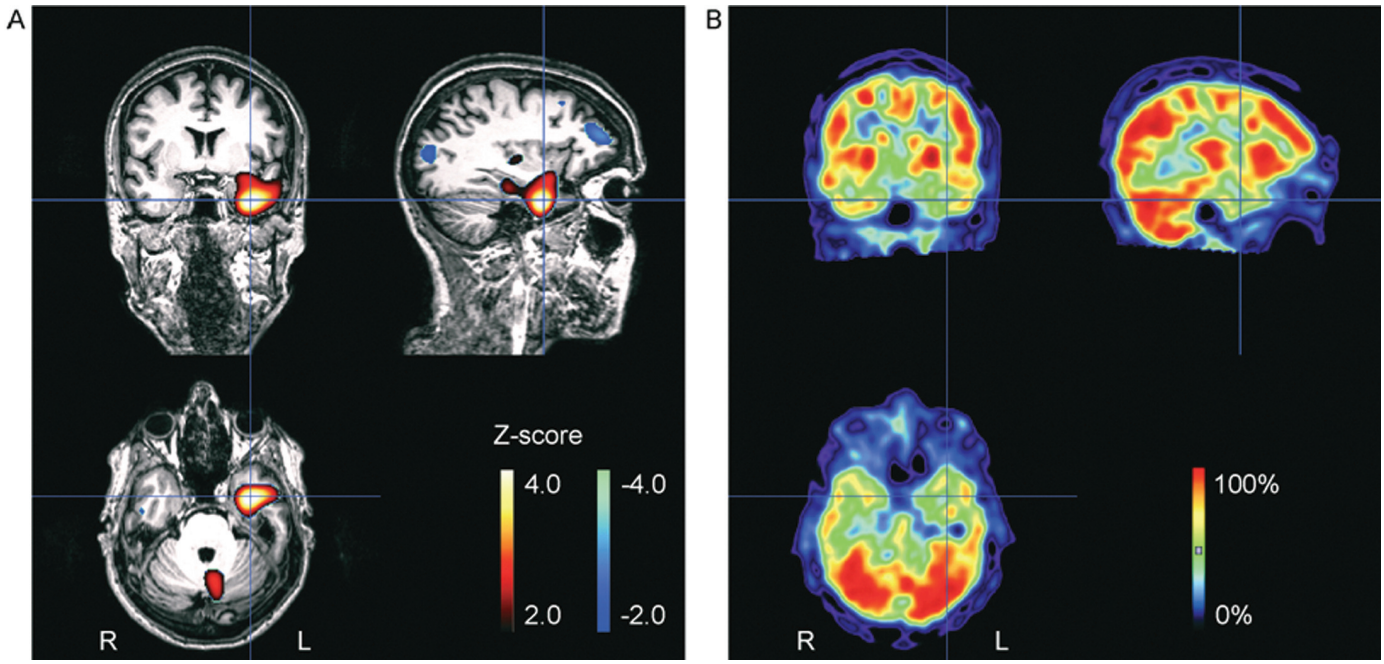

Plate 65.1 SISCOM (a) and FDG-PET (b) images of a 42-year-old patient with left TLE and normal MRI. SISCOM analysis showed a large cluster of ictal hyperperfusion located at the left temporal lobe (indicated by the blue cross). The ictal SPECT injection was given during a complex partial seizure that lasted 67 s, with initiation of the injection 35 s after seizure onset. FDG-PET showed a subtle hypometabolism in the same area. All images were co-registered. These functional imaging data were concordant with electroclinical and neuropsychological data and were considered an important argument to proceed to surgery. The patient underwent a neocortical temporal lobectomy including amygdala, but with sparing of the hippocampus and has remained seizure free. Neuropathological examination did not reveal an epileptic lesion. Reprinted from *Sem Nucl Med* (ref. 87), ©2008 with permission from Elsevier.

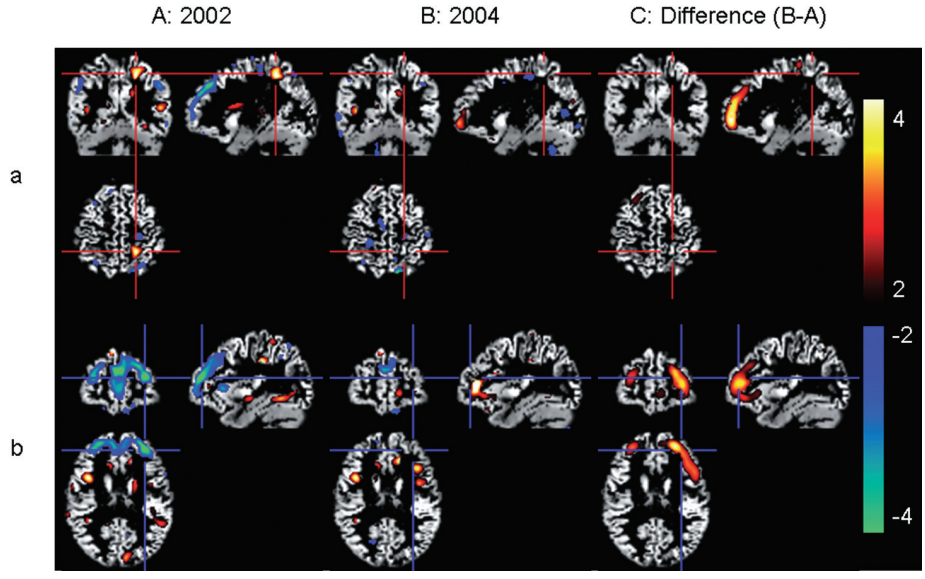

Plate 65.2 Ictal FDG-PET hyper- and hypometabolism during simple partial status epilepticus and recovery of metabolic abnormalities after seizure remission. The patient is a 21-year-old woman with a 3-month history of a simple partial status epilepticus of the left parietal lobe, characterized by continuous paraesthesiae in the right arm. Around 1 week before the ictal FDG-PET, she had a convulsive status epilepticus. The PET images were reconstructed using an anatomy-based reconstruction algorithm analysed semiquantitatively after normalization to white matter activity, and compared with a normal age- and gender-matched control group (for more details see refs 12, 14 and 25). Regions of significantly increased (>2SD, orange-red) and decreased (<2SD, blue-green) metabolism, compared with normal control subjects, are projected on a reconstructed PET image. The top row (a) shows the results in the left parietal region (red crosses) and the bottom row (b) in the left frontal region (blue crosses). FDG-PET during the simple partial SE (A, 12 April 2002) showed hypermetabolism in the left parietal region (a, part A), consistent with ictal activity, and large regions of hypometabolism affecting predominantly the frontal lobes (b, part A). The FDG-PET during remission of epilepsy (B, 2004) showed resolution of the left parietal hypermetabolism (a, part B) and frontal lobe hypometabolism (b, part B). The difference image between the two PET scans (a, part C and b, part C) showed the largest (>2 SD) increases in metabolism (orange-red) in the frontal lobes, left > right (b, part C), during remission of the epilepsy compared with the simple partial SE. This figure illustrates the dynamic, seizure-related character of the metabolic changes, and that ictal hypometabolism is mainly present in seizure propagation pathways, and does not define the ictal onset zone. At the time of scan A, she had severe cognitive deficits, which had normalized at the time of scan B. Reprinted from *Epilepsia* (ref. 45), ©2007 with permission from the International League Against Epilepsy, Blackwell Publishing.

(b)

Plate 65.3 (**a**) Frontal lobe hypometabolism in mesial TLE with HS. (a: part A) Mean image of the normalized FDG PET across a group of patients with TLE due to HS shows that the ipsilateral temporal lobe (white arrows) is more hypometabolic than the contralateral side, and appears to be the most hypometabolic region in the brain. (a: part B) SPM T-map (uncorrected *P*-value < 0.001) shown on the MRI of a single subject in MNI space confirms that a significant asymmetry in interhemispheric metabolism is only found in the temporal lobes. (a: parts C and D) Mean images of the normalized FDG-PET across patients with TLE (a: part C) and control subjects (a: part D), displayed using the same colour table, show a striking hypometabolism in the frontoparietal lobes in patients compared with control subjects. The hypometabolism in the epileptic temporal lobe, on the other hand, is less striking than the changes in the extratemporal regions. (b) Composite SPECT-PET Images. Top row: Images showing voxels in which a significant interictal hypometabolism was seen in combination with a significant ictal hyperperfusion (b: part A, voxels in red) or with a significant ictal hypoperfusion (b, voxels in blue). The results were obtained from a group analysis. Bottom row: Composite images showing the number of patients in a voxel in which hypometabolism (i.e. $z_{PET} < -1$) was seen in combination with ictal hyperperfusion ($z_{SPECT} > 1$) (b: part C) or with ictal hypoperfusion ($z_{SPECT} < -1$) (b: part D). The results were obtained from the individual analysis of each patient. The number of patients in each voxel was projected on the MRI of a single subject available in SPM2, and the right side of the image is ipsilateral to the seizure focus. The colour scales in (b: part C) and (b: part D) indicate the number of patients (maximum: 11). Reprinted from NeuroImage (ref. 25), ©2006 with permission from Elsevier.

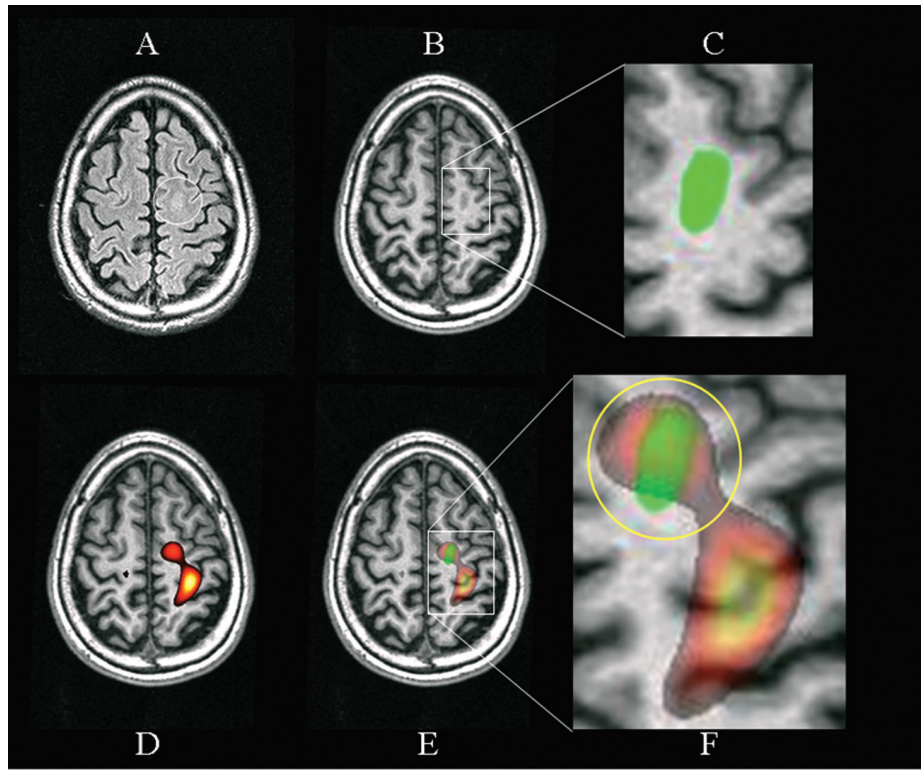

Plate 65.4 Ictal perfusion SPECT propagation pattern 2. A FLAIR image showed an increased signal in the left superior frontal gyrus (a, white circle), and on a T1-weighted image (b), there was blurring of the grey-white matter transition, consistent with an FDL. The FDL was manually outlined in green (c). The ictal perfusion SPECT injection was given during a complex partial seizure that lasted 70 s, with initiation of the injection 18 s after seizure onset. On a SISCOM (d), thresholded at $z = +2$, the cluster with the largest size had the configuration of an hourglass. Co-registration of the manual outline of the FDL and SISCOM (e) showed that the voxel with the lower local maximal *z*-score fell within the FDL, and that the highest *z*-score was at a distance of 28 mm from the FDL, measured from the margin of the manual outline of the FDL. Taking all the information of the presurgical evaluation into consideration, which was concordant, we considered the region containing the FDL and the part of the SPECT cluster with the lower local maximal *z*-score, up to the 'bottleneck of the hourglass' as the epileptogenic zone (f, yellow circle), and decided to operate the patient on the basis of these data. The patient has remained seizure free since the operation with a follow-up of more than 1 year. Reprinted from *Curr Opin Neurol* (ref. 88), ©2007 with permission from Lippincott Williams & Wilkins.

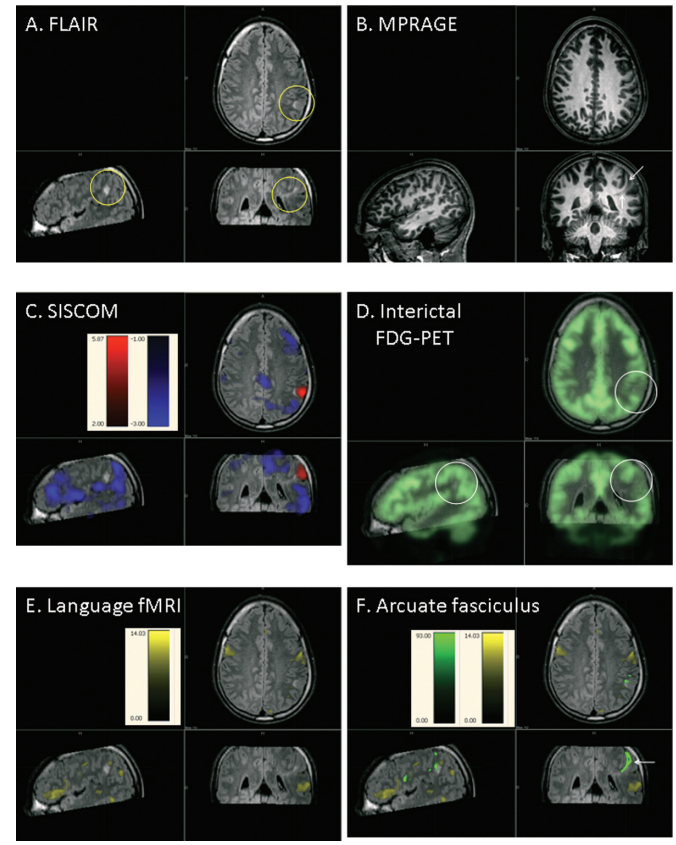

Plate 65.5 Multimodality imaging. The patient had refractory partial epilepsy due to a focal dysplastic lesion in the left supramarginal/angular gyrus, which was visible as a hyperintense lesion with transmantle sign on FLAIR (a, yellow circles) and as thickened cortex with blurred grey–white matter transition on a T1-weighted image (b, white arrows). Patient had an ictal SPECT with injection of the radioligand 5 s after the end of a complex partial seizure that lasted 16 s. The largest and most hyperintense SISCOM hyperperfusion cluster partially overlapped the focal dysplastic lesion (c, red area). Notice the large areas of hypoperfusion (c, SISCOM, blue areas) surrounding the ictal onset zone, which is not seen in *ictal* SISCOMs, which is consistent with the hypothesis of 'surround inhibition'. Interictal FDG-PET showed that the region of the focal dysplastic region was hypometabolic (d, white circles). Language fMRI (e) in this right-handed patient showed a bilateral language network with left-sided predominance. On the left side, Broca's (b) and Wernicke's (W) area were at a distance from the focal dysplastic lesion. Diffusion tensor tractography of the arcuate fasciculus showed that fibres connecting Broca's and the inferior parietal lobule crossed the focal dysplastic lesion (f, green tract, white arrow). Our surgical strategy would be to remove the focal dysplastic lesion and region of overlapping SISCOM hyperperfusion cluster. Although the lesion was outside the classical language areas, i.e. Broca's speech and Wernicke's comprehension centres, and the interconnecting arcuate tract, our imaging data suggested that the lesion was in the indirect pathway of perisylvian language networks [89]. Damage to this region could cause conduction aphasia, necessitating further functional studies preoperatively.

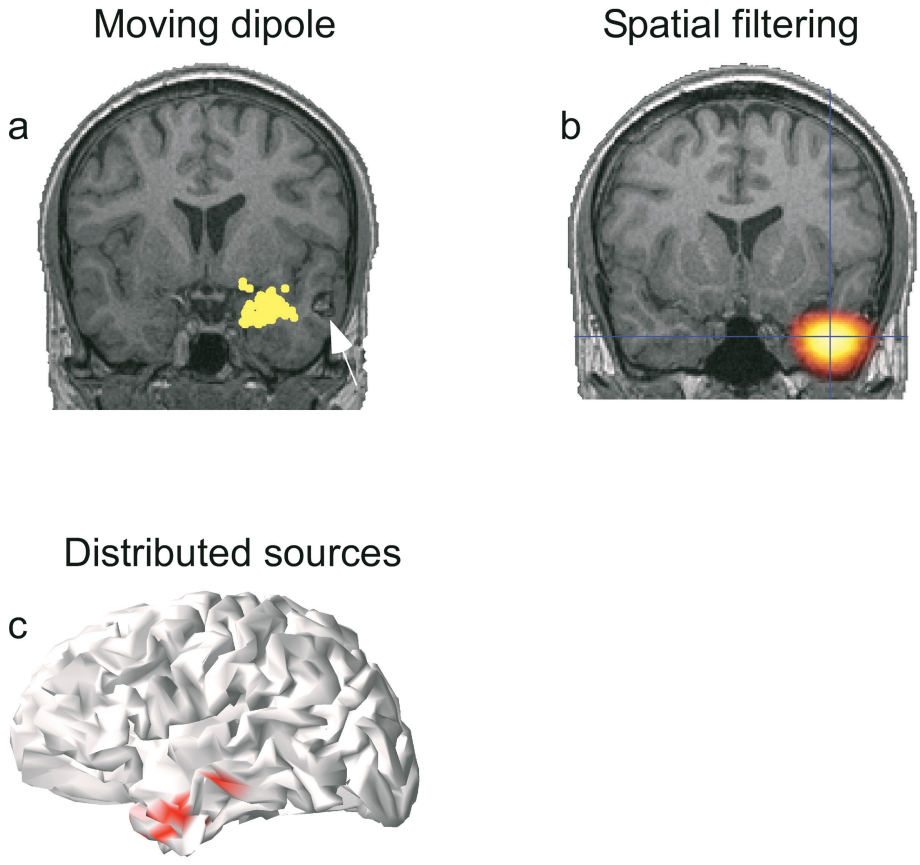

Plate 66.1 Approaches in modelling sources of interictal spikes. The figure shows results of source localization of epileptic spikes using different modelling approaches in the same patient suffering from partial epilepsy related to a left temporal cavernoma (white arrow). (a) Moving dipole: yellow dots represent estimated sources of individual spikes with goodness-of-fit >95%. Each individual source is punctual. (b) Spatial filtering: the pathological volume represents the estimated source extent of spikes. In this approach, the frequency content of the spikes is first estimated (here 65 Hz) and source localization procedures estimate the sources of the frequency content of epileptic spikes. (c) Distributed sources: the pathological volume has been determined with the weighted minimum–norm algorithm applied on averaged spikes. In this approach, dipolar sources are regularly placed along the surface of the cortical mantle obtained following segmentation of the MRI volume and the algorithm estimate the strength of currents underlying epileptic paroxysms for each source.

Plate 73.1 (a) Vertical parasagittal hemispherotomy. (a) Coronal plane demonstrating the cortical parasagittal window to the lateral ventricle (1), followed by the posterior callosotomy (2), which will be pursued towards the splenium. The vertical black bar towards the temporal horn represents the laterothalamic incision. (b) Following resection of the ipsilateral splenium (2), the floor of the ventricular trigone (3) will be sectioned, thus interrupting the foniceal fibres. The laterothalamic incision is then performed (4, 5). Following anterior completion of the callosotomy, the posterior part of the gyrus rectus is resected (6) and, from here, the dissection line is guided laterally across the frontal horn and the caudate nucleus (8), thus completing the disconnection of the entire hemisphere. (c) Postoperative axial MRI in a patient with Rasmussen's encephalitis, demonstrating the line of the laterothalamic disconnection. Figures reproduced with permission from Delalande O, Bulteau C, Dellatolas G *et al*. Vertical parasagittal hemispherotomy: surgical procedures and clinical long-term outcomes in a population of 83 children. *Neurosurgery* 2007; **60**(ONS Suppl. 1): ONS1–ONS32.

Plate 78.3 The Medtronic StealthStation® Axiem™ neuronavigation system in use for biopsy of a tumour. (a) The patient's head no longer needs to be fixed in Mayfield pins. An electromagnetic field is generated around the patient's target anatomy that can be tracked to triangulate the positioning of instruments and patient-tracking devices, so the system is no longer dependent on a camera's line of sight. The fiducial points are carefully loaded into the computer so that image space can be accurately mapped to patient space. (b) The system is then ready for neuronavigation with a flexible instrument tracked at the tip. (c) The trajectory of the probe tip is demonstrated relative to multiplanar preoperative imaging, enabling an accurate trajectory for insertion of the biopsy needle.

1 Definitions and Classification of Epilepsy

Christina A. Gurnett and W. Edwin Dodson
Washington University School of Medicine, St Louis, MO, USA

More than a century and a half ago, Hughlings Jackson defined an epileptic seizure as the clinical phenomenon resulting from 'an occasional, sudden and excessive discharge of gray matter' [1], a definition that has stood the test of time. Over the years, the motor, sensory and autonomic phenomena that are produced by epileptic brain discharges have been identified and classified. Today, as in Jackson's time, seizures remain important signals to the possibility of underlying brain disorders that need to be identified and treated. Seizures are symptoms of abnormal brain function.

Epilepsy, like a seizure, is a symptom of abnormal brain function. Epilepsy is recurrent seizures that are not due to easily reversed, transient metabolic or toxic disorders. Seizures are fundamental elements of epilepsy. Although a causative brain disease can be identified in some cases, in the majority of cases no cause can be found and the best diagnosis possible is only descriptive. Of course, the goal in all cases is to identify the aetiology and pathoanatomical basis for the symptoms, but this is achieved in fewer than one-half of all cases. To summarize, there are two levels of descriptive diagnosis. The most elementary is according to the type of epileptic seizure. The more comprehensive system of descriptive diagnosis categorizes types of epilepsy or epileptic syndromes. The descriptive classifications of seizures and epilepsy are the subjects of this chapter.

Classification of seizure types

The currently used classification of seizures evolved from seminal work undertaken in the mid-1960s, which was published in 1969 [2] and 1970 [3], revised in 1981 [4] and updated in 2006 [5] (Table 1.1). The 1981 product was the result of combined videotaping and electroencephalogram (EEG) recordings of seizures that were reviewed and categorized in workshops convened between 1975 and 1979. Unlike previous schemes, the 1981 classification did not consider evidence of brain pathology, age and aetiology but instead restricted the basis for classification to clinical seizure types plus EEG data. The accepted seizure classification system has as its basis the current knowledge of anatomical substrates and pathophysiological mechanisms, and attempts to be a purely semiological classification system.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Seizures are divided into two primary categories, based on whether the seizure arises in a restricted part of the brain in one hemisphere (focal seizures) or appears to involve both hemispheres from the onset (generalized seizures) [4]. A third category (unclassified seizures) is provided for cases that lack sufficient information for categorization.

Focal seizures

Historically, partial seizures have been subdivided into three groups – simple partial, complex partial or partial secondarily – generalized according to whether consciousness is impaired or the seizure evolves into a generalized convulsion as the epileptic brain discharge extends to involve both hemispheres. Partial seizures are classified as simple if consciousness is unimpaired during the episode. The label complex partial is applied if consciousness is impaired at any point during the ictus. Note that consciousness need only be impaired, not fully lost, to qualify the seizure as complex partial. Secondary generalization of the partial seizure typically overshadows the preceding partial seizure and, for this reason, many secondarily generalized seizures with partial onset go unappreciated by inexperienced observers only to be reclassified accurately after more details are elicited [6]. Hence, it is always important to ask the patient and witness(es) to describe in detail, step by step, the sequence of events that led to a convulsion.

Simple partial (or focal) seizures

The components of epileptic seizures can include any brain-modulated bodily function. Hence, seizures include any movement, sensation, perception or emotion of which humans are capable. However, the behavioural elements of seizures typically are situationally inappropriate, fragmentary manifestations of brain activity and thereby stand apart from smoothly integrated, situationally appropriate behaviours generated by normal brain functioning.

Movements or motor signs in partial seizures depend on the region of brain in which the epileptic discharge takes place. If the seizure is confined to a discrete area, isolated twitching or jerking occurs. If the discharge spreads to contiguous cortical areas, the movement often extends stepwise to involve adjacent functional groups. The progressive spread of an epileptic discharge through the motor strip results in an anatomically contiguous spread of the epileptic jerking called a Jacksonian march or Jacksonian seizure. Partial seizures that affect speech centres may lead to speech arrest. The phenomenon of ictal repetition of syllables or

Self-limited epileptic seizures
Generalized onset
- Seizures with tonic and/or clonic manifestations
  - Tonic–clonic seizures
  - Clonic seizures
  - Tonic seizures
- Absences
  - Typical absences
  - Atypical absences
  - Myoclonic absences
- Myoclonic seizure types
  - Myoclonic seizures
  - Myoclonic astatic seizures
  - Eyelid myoclonia
- Epileptic spasms
- Atonic seizures

Focal onset (partial)
- Local
  - Neocortical
    - Without local spread
      - Focal clonic seizures
      - Focal myoclonic seizures
      - Inhibitory motor seizures
      - Focal sensory seizures with elementary symptoms
      - Aphasic seizures
    - With local spread
      - Jacksonian march seizures
      - Focal (asymmetrical) tonic seizures
      - Focal sensory seizures with experiential symptoms
  - Hippocampal and parahippocampal
    - With ipsilateral propagation to
      - Neocortical areas (includes hemiclonic seizures)
      - Limbic areas (includes gelastic seizures)
    - With contralateral spread to
      - Neocortical areas (hyperkinetic seizures)
      - Limbic areas [dyscognitive seizures with or without automatisms (psychomotor)]
- Secondarily generalized
  - Tonic–clonic seizures
  - Absence seizures
  - Epileptic spasms (unverified)

Neonatal seizures

Status epilepticus
Epilepsia partialis continua (EPC)
- As occurs with Rasmussen's syndrome
- As occurs with focal lesions
- As a component of inborn errors of metabolism

Supplementary motor area (SMA) status epilepticus
Aura continua
Dyscognitive focal (psychomotor, complex partial) status epilepticus
- Mesial temporal
- Neocortical

Tonic–clonic status epilepticus
Absence status epilepticus
- Typical and atypical absence status epilepticus
- Myoclonic absence status epilepticus

Myoclonic status epilepticus
Tonic status epilepticus
Subtle status epilepticus

phrases is called epileptic pallilalia. Continuous partial seizures, often lasting days or longer, are called epilepsia partialis continua.

Transient localized paralysis, lasting between minutes and hours following a partial or secondary generalized motor seizure, is called a Todd's paralysis. In some cases, focal postictal paralysis may be the only clue indicating that a generalized seizure had a partial onset.

Sensory symptoms that are produced by seizures also reflect the normal function of the brain region where the discharge is occurring. Frequently felt sensations include pins-and-needles and numbness. Sensory seizures that originate in visual cortex or auditory cortex produce visual and auditory hallucinations, respectively. As emphasized in the 1981 classification [4], epileptic hallucinations vary in sophistication from ill-formed patterns of light and sound to well-structured images and recognizable sounds such as music [4]. Ictal olfactory hallucinations tend to be vague but are generally disagreeable. Hallucinated tastes are frequently metallic. Vertiginous symptoms, such as hallucinated rotation or spinning, are relatively common. Unlike vertigo of vestibular origin, epileptic vertigo is usually not associated with nausea or severe anxiety and is rarely incapacitating.

When simple focal sensory seizures precede complex partial or secondarily generalized seizures, the premonitory experience is called an 'aura'. Attributed to Galen, the term 'aura' was derived from the Greek word *αερ* or air, meaning breeze, as it was used by a 13-year-old boy who described a sensation that began on his lower leg and 'climbed upwards in a straight line' [7]. Subsequently, the term 'aura' has been applied generally to include any premonitory ictal sensation.

Psychic symptoms

Psychic symptoms are among the most intriguing consequences of partial seizures. These result from discharges that interrupt higher cortical processes and are often associated with impaired consciousness and thereby become components of complex partial seizures.

The most common psychic symptoms are affective, especially the feeling of fear, or in the extreme, terror. These experiences are frequently accompanied by autonomic manifestations including mydriasis, change in skin colour, piloerection and other signs. When epileptic fear or anxiety occurs, the affected person may run to escape or to find a caretaker, seeking assistance. Children who experience ictal fear go to a parent and display fearful facial expressions.

Other affective symptoms include anger, rage, extreme pleasure, sexual sensations and, rarely, ecstasy. These experiences are typically brief and paroxysmal, beginning without warning or provocation, and ceasing abruptly as if an electrical switch were turned on and off. The time-course of the emotion is substantially shorter than normal. Furthermore, seizure-generated affect is usually inappropriate to the social context of the moment. Seizure-induced laughter characteristically sounds automatic, mirthless, hollow or vacuous and is not socially infectious like normal mirthful laughter. Seizures manifest by laughter are known as gelastic seizures.

Ecstatic seizures, also known as 'Dostoevsky seizures', are so rare that it is debated as to whether they truly occur [8]. Described

by the great author Fyodor Dostoevsky [9,10], these are brief moments of 'a contentedness which is unthinkable under normal conditions, and unimaginable for those who have not experienced it'. Dostoevsky went on to write: 'At such times I am in perfect harmony with myself and with the entire universe. Perception is so clear and so agreeable that one would give ten years of his life, and perhaps all of it for a few seconds of such bliss' [8].

Memory distortions are also reported frequently by people who experience complex partial seizures. Representing heightened perceptions of familiarity, déjà vu and déjà entendu refer to the intuition that an experience was previously seen or heard, respectively. Jamais vu and jamais entendu indicate the opposite: the experience is unfamiliar and was never before seen or heard. Panoramic vision is a rapid remembrance of previous life experiences.

Dysphasic psychic epileptic symptoms involve speech. Speech disturbances can occur as either an active part of the seizure (as when words or phrases are repeated) or postictally as transient neurological deficits due to cortical neuronal exhaustion. The latter produce receptive and expressive aphasias of the types seen in cortical deficits of other causes.

Cognitive psychic symptoms include dreamy states, distorted perception of time and reality as well as detachment or depersonalization in which the person feels as if he is outside his body.

Illusions are distorted perceptions. The visual illusions of an object being too large or too small are called macropsia and micropsia, respectively. Analogous distortions affect hearing, resulting in macro- and microacusia. Illusions can affect any simple or complex sensory modality. Examples include monocular diplopia and altered appreciation of limb size and weight.

Complex partial seizures

The *sine qua non* of complex partial seizures is impairment of consciousness. Premonitory sensory or psychic auras (simple partial seizures) frequently forewarn and lead into the complex partial episode. The nature of the sensory experience provides important clues about the origin of the seizure. However, many complex partial seizures begin with sudden impairment of consciousness.

Automatisms – repetitive, patterned, semipurposeful spontaneous movements – are a common feature of complex partial seizures. Gastaut described automatisms as 'more or less coordinated adapted (eupractic or dyspractic) involuntary motor activity occurring during the state of clouding of consciousness either in the course of or after an epileptic seizure, and usually followed by amnesia for the event' [5]. A pathophysiological explanation of automatisms is that these occur when bilateral cortical dysfunction lasts long enough to release the expression of patterned movements that are represented at lower brain levels but which are normally held in check by cortical inhibition [11,12]. As automatisms result from bilateral cortical dysfunction, consciousness is always impaired.

Automatisms are either perseverated continuations of previous movements or are novel behaviours. Common automatisms include chewing or swallowing movements categorized as 'eating'; expressions of emotion (usually fear) categorized as 'mimicry'; picking at or fumbling with garments (gestural automatisms); walking, often in circles (cursive seizures), categorized as 'ambulatory'; and, finally, verbal or repeated items of speech (also called epileptic pallilalia) [5].

Generalized seizures

Generalized seizures are produced by epileptic discharges that affect both hemispheres simultaneously. When this occurs, consciousness is usually lost or impaired.

Absence seizures

In absence seizures, consciousness is lost and regained in an abrupt off–on pattern. Behaviour or movement that is occurring at the onset may be perseverative but usually ceases instantly as the person begins to stare. During the staring, the eyes may gaze straight ahead or deviate upwards while the eyelids twitch faintly and rhythmically. Rarely lasting more than 30 s, absence seizures are usually quite brief, often less than 5 s. Absence seizures need to be differentiated from normal daydreaming and from complex partial seizures. The latter typically have a longer duration and last more than 60 s in untreated cases. In daydreaming, consciousness is intact, although responses to questions or commands may be delayed or slow. In absence and complex partial seizures, consciousness is impaired.

A good way to assess clinically whether consciousness is impaired is to present the person with several words and then ask him or her to repeat what was just said. For example, say to the person, 'Ball, yellow, girl' followed by 'What did I say?' Even young children usually respond correctly to this type of elementary request if consciousness is unimpaired. Repeatedly asking 'Are you alright?' usually does not help to determine whether consciousness was altered during brief staring episodes because if the questioning is repeated enough times, eventually the episode ends and the person answers appropriately. If a verbal response is not promptly forthcoming, gently touching the person can help further evaluate whether consciousness is impaired. When staring due to daydreaming cannot be differentiated from epileptic staring on clinical grounds, video EEG recordings of the episodes are usually diagnostic [13,14].

Atypical absence seizures

Although no single feature differentiates typical from atypical absence, atypical absence seizures are more likely to be associated with the following features: longer duration, decreased postural tone and tonic activity. Atypical absence seizures occur in patients with interictal abnormalities on EEG, multiple seizure types and mental retardation. Although the 1981 classification noted that the onset and cessation of atypical absence were not as abrupt as in the case of typical absence, subsequent investigation found that both types begin and end suddenly. However, postural changes and other features of atypical episodes tend to evolve gradually [2,14,15].

Myoclonic seizures

Myoclonus is a sudden brief involuntary movement (a jerk) that can originate from many regions and levels of the central nervous system [16]. Myoclonic seizures are myoclonic jerks that result from epileptic discharges in the brain. In the 1981 classification, myoclonic jerks were defined as 'sudden, brief, shock-like contractions.' As pointed out by Dreifuss [17], myoclonic seizures

occur in many different epileptic syndromes, which include benign and severe myoclonic seizures of infancy, symptomatic epilepsies due to systemic storage diseases or defects in energy metabolism. On the other hand, non-epileptic myoclonus occurs in spinal disease, cerebellar degeneration, uraemic encephalopathy, subcortical (brainstem) myoclonus and other syndromes. Occurring singly or repeated serially, myoclonic seizures may be generalized or limited to part of the body or a single muscle. Generalized myoclonic seizures that affect the body have been called massive epileptic myoclonus, a term that was introduced in the 1981 classification. Myoclonus epilepsy refers to several progressive disorders in which either epileptic or non-epileptic myoclonus is a prominent feature.

In practice, the terms myoclonic jerks, myoclonus, myoclonic epilepsy and myoclonus epilepsy are confusing because various authorities apply the terms for different purposes. The term myoclonic epilepsy has been used by some authors to describe a particular type of epilepsy and by others to define a group of several epilepsies in which patients have myoclonic seizures plus other features. This ambiguous terminology led Jeavons to comment in 1977 [18] that application of the term 'myoclonic' had become so confusing that he recommended defining the term whenever it was applied to seizures or epilepsy.

In some cases, the epileptic origin of the muscular jerking cannot be discerned on routine EEG but requires event-locked (also called jerk-locked) averaging of cortical potentials for the epileptic discharge to be visualized [19,20].

Clonic seizures

Clonic seizures are those characterized by repetitive, rhythmic jerking. In isolation, a single clonic movement has a rapid phase of contraction followed by a slower relaxation. In clonic seizures this results in an alternating pattern of jerk–relax, jerk–relax, etc. Note, however, that some generalized seizures evolve with the sequence of clonic–tonic–clonic phases.

Tonic seizures

Tonic seizures involve rigid, violent muscular spasms with posturing axial and limb musculature, which typically last 30 s or less with mydriasis plus eye deviation upwards or to the side. Tonic seizures end abruptly with variable to no postictal symptoms. During the seizure, the face is often distorted by the contraction and respiration is disrupted, often leading to cyanosis. Other variable features include slowly progressive alterations of tone, and versive movements with rotation, twisting or turning. As pointed out by Dreifuss [17], these need to be differentiated from non-epileptic dystonia. Isolated tonic seizures seem to be most common during sleep and may go unrecognized.

Tonic–clonic seizures

Tonic–clonic seizure is the term used for a generalized convulsion and was previously referred to as a grand mal seizure. Readily recognized by lay persons as a seizure or fit, it is characterized by a sudden fall and dramatic, violent and involuntary jerking and muscular spasm of the limbs and body. The episode begins suddenly with the simultaneous loss of consciousness and contraction of body musculature; this is the tonic phase during which the person becomes rigid and falls, often traumatizing the head or extensor surfaces of the body (Table 1.2). The tonic contraction first involves flexion and then extension of the axial muscles [21]. Contractions of axial muscles can be sufficiently forceful to cause compression fractures of the vertebrae [22]. Contraction of respiratory musculature leads to forced exhalation and vocalization in the form of a cry or moan. The eyes deviate upwards and pupils dilate. Incontinence can occur during the tonic phase or later when postictal exhaustion leads to relaxation of sphincters. During the tonic phase the individual may bite his tongue or cheek and respiration is disrupted, leading to cyanosis. During the tonic phase the EEG most often is characterized by high-frequency spike activity.

Table 1.2 Behavioural stages of generalized convulsive seizures.

Prodrome
Aura
Tonic phase
Clonic phase
Postictal unconsciousness and hypotonia
Postictal neurological deficit (Todd's paralysis)
Sleepiness
Return to normal functioning

During the maximal tonic contraction of body and limb muscles, the initial rigidity gradually evolves into irregular tremulous shaking, similar to that seen in supramaximal muscular exertion. This in turn evolves into generalized jerking – the clonic phase. In the clonic phase, generalized flexor spasms alternate with relaxation, causing irregular respiration, sometimes with grunting. Salivation is profuse and, when combined with lack of swallowing and an irregular respiratory pattern, leads to frothing at the mouth.

The oscillatory contractions during the clonic phase gradually slow and stop marking the end of the convulsion and the beginning of the postictal period. Although convulsions are frightening and seem long-lasting, most end within 60 s. Those seizures that do last longer than 60 s are statistically uncommon [23].

The postictal phase is characterized by diffuse hypotonia, slow, deep respirations and unresponsiveness. Over time, consciousness slowly returns but is clouded at first as awareness emerges from unconsciousness into partial comprehension with confusion. If the person is restrained or handled forcefully, he may resist combatively. The subsequent recovery over minutes to hours is marked by sleepiness, variable headache and complaints of musculoskeletal soreness upon awakening. Persistent back pain may indicate that a vertebral compression fracture occurred during the seizure.

Atonic seizures

Atonic seizures are those in which there is a sudden reduction or loss of postural tone and in which posture is affected to varying degrees. When the seizure is extensive, postural control is lost and the person drops or slumps to the ground, producing so-called drop attacks or astatic seizures. The latter term, 'astatic seizures', was not part of the 1981 classification but has become widely used since then. In part, this has occurred because most drop attacks are not due to atonic seizures, per se, but rather represent massive myoclonic seizures or combinations of atonic and myoclonic seizures that forcefully thrust down the person. Drop attacks or astatic seizures often result in injury to teeth plus lac-

erations and contusions of the head and face. Some atonic seizures alter tone in a restricted part of the body, causing head nods, head drops or lapses of limb posture. If consciousness is lost in atonic or in astatic seizures, the lapse is quite brief. The difference between partial or brief atonic seizures and so-called epileptic negative myoclonus is unclear [16,24]. As emphasized in the 1981 classification [4], other non-epileptic disorders can cause drops or lapse of posture. Other causes include cataplexy and brainstem ischaemic attacks.

Seizures not classified by the 1981 classification

Epileptic prodrome is the term applied to disturbances in mood and affect that precede seizures by hours or days. More often noted by companions or family members than by the person who has epilepsy, the behavioural characteristics, such as irritability and meanness, cause the observers to look forward to the seizure, after which the person's affect and mood normalize [25].

Classification of epilepsies and epileptic syndromes

The epilepsies, also known as epileptic syndromes, are characterized by other features in addition to seizure type. From the Greek *syn* + *dramein* (meaning to run with), the word syndrome indicates a group of signs and symptoms that occur together. Thus, epileptic syndromes are constellations of epileptic seizures plus concurrent or serially linked symptoms and signs. Seizures are the seminal elements that constitute an epilepsy, but other features largely differentiate the overall disorder or type of epilepsy (Table 1.3). As Professor Fritz E. Dreifuss was fond of saying, 'seizures are to epilepsy as a cough is to pneumonia'.

Complexity and utility of epilepsy syndrome classification

The current classification of epilepsies is empirical. It is the product of expert epileptologists who spent many hours viewing video recordings of seizures, discussing their observations and deliberating about whether clinically similar groups of patients represented discrete clinical entities. At the time the syndromes were being codified, knowledge regarding the genetic neurobiological basis of epilepsy was rudimentary.

Individual metabolic and genetic causes of seizures can produce many different patterns of epilepsy. For example, the epileptogenicity of pyridoxine deficiency was recognized in the 1950s, but it took many years to fully appreciate the heterogeneity of epilepsy syndromes that result from pyridoxine dependency states [26,27]. As a prototype for other epileptogenic diseases, pyridoxine dependency illustrates the principle that discordance between current syndromic classifications of epilepsy and the neurobiology of epilepsy is more often the rule than the exception. For many genetic or congenital epilepsies the age of onset, not a specific epileptic syndrome, is the characteristic feature (Table 1.4).

Initially, pyridoxine dependency was felt to cause only neonatal seizures and drug-resistant neonatal status epilepticus. However, over time the spectrum of epileptic disorders that are attributable to pyridoxine dependency expanded to include epilepsies with onsets ranging from *in utero* to early childhood. Many types of seizures and epileptic syndromes resulted. Seizure types included partial,

Table 1.3 International League Against Epilepsy (ILAE) classification of epilepsies and epileptic syndromes.

Localization related (focal, local, partial epilepsies and syndromes)

Idiopathic (with age-related onset)
- Benign childhood epilepsy with centrotemporal spike
- Childhood epilepsy with occipital paroxysms
- Primary reading epilepsy

Symptomatic epilepsy
- Chronic epilepsia partialis continua of childhood (Kojewnikow's syndrome)
- Syndromes characterized by seizures with specific modes of precipitation

Cryptogenic

Generalized epilepsies and syndromes

Idiopathic (with age-related onset – listed in order of age)
- Benign neonatal familial convulsions
- Benign neonatal convulsions
- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy (pyknolepsy)
- Juvenile myoclonic epilepsy (impulsive petit mal)
- Epilepsy with grand mal (GTCS) seizures on awakening
- Other generalized idiopathic epilepsies not defined above
- Epilepsies with seizures precipitated by specific modes of activation

Cryptogenic or symptomatic (in order of age)
- West syndrome (infantile spasms, Blitz–Nick–Salaam–Krämpfe)
- Lennox–Gastaut syndrome
- Epilepsy with myoclonic–astatic seizures
- Epilepsy with myoclonic absences

Symptomatic

NON-SPECIFIC AETIOLOGY
- Early myoclonic encephalopathy
- Early infantile epileptic encephalopathy with suppression burst
- Other symptomatic generalized epilepsies not defined above

SPECIFIC SYNDROMES
- Epileptic seizure may complicate many disease states. Under this heading are included diseases in which seizures are a presenting or predominant feature

Epilepsies and syndromes undetermined whether focal or generalized

With both generalized and focal seizures
- Neonatal seizures
- Severe myoclonic epilepsy in infancy
- Epilepsy with continuous spike–wave patterns during slow-wave sleep
- Acquired epileptic aphasia (Landau–Kleffner)
- Other undetermined epilepsies not defined above

Without unequivocal generalized or focal features: all cases with generalized tonic–clonic seizures in which clinical and EEG findings do not permit classification as clearly generalized or localization related, such as in many cases of sleep-grand mal (GTCS) that are considered not to have unequivocal generalized or focal features

Special syndromes

*Situation-related seizures (*Gelegenheitsanfälle*)*
- Febrile convulsions
- Isolated seizures or isolated status epilepticus
- Seizures occurring only when there is an acute metabolic or toxic event due to factors such as alcohol, drugs, eclampsia, non-ketotic hyperglycaemia

GTCS, generalized tonic–clonic seizures.
Reproduced with permission from ref. 38.

Table 1.4 Epilepsy syndromes by age of onset and related conditions.

Neonatal period
Benign familial neonatal seizures (BFNS)
Early myoclonic encephalopathy (EME)
Ohtahara's syndrome
Infancy
Migration partial seizures of infancy
West syndrome
Myoclonic epilepsy of infancy
Benign infantile seizures
Dravet's syndrome
Myoclonic encephalopathy in non-progressive disorders
Childhood
Early-onset benign childhood occipital epilepsy (Panayiotopoulos type)
Epilepsy with myoclonic–astatic seizures
Benign childhood epilepsy with centrotemporal spikes (BCECTS)
Late-onset childhood occipital epilepsy (Gastaut)
Epilepsy with myoclonic absences
Lennox–Gastaut syndrome (LGS)
Epileptic encephalopathy with continuous spikes and waves during sleep (CSWS) including Landau–Kleffner syndrome (LKS)
Childhood absence epilepsy (CAE)
Adolescence
Juvenile absence epilepsy (JAE)
Juvenile myoclonic epilepsy (JME)
Progressive myoclonus epilepsies (PME)
Less specific age relationship
Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE)
Familial temporal lobe epilepsies
Mesial temporal lobe epilepsy with hippocampcal sclerosis (MTLE with HS)
Rasmussen's syndrome
Gelastic seizures with hypothalamic hamartoma
Special epilepsy conditions
Symptomatic focal epilepsies not otherwise specified
Epilepsy with generalized tonic–clonic seizures only
Reflex epilepsies
Febrile seizures plus (FS+)
Familial focal epilepsy with variable foci
Conditions with epileptic seizures that do not require a diagnosis of epilepsy
Benign neonatal seizures (BNS)
Febrile seizures (FS)

Reproduced with permission from ref. 3.

multifocal, hemiclonic, infantile spasms, myoclonic and generalized convulsive seizures in infants and young toddlers [28]. The syndromes include uncategorized encephalopathic disorders with partial and generalized seizures along with West syndrome and Lennox–Gastaut syndrome [29–31]. Furthermore, some cases of infantile and early childhood-onset epilepsy caused by pyridoxine dependency respond temporarily to antiepileptic drugs [32,33]. Inadequately treated pyridoxine dependency has been linked to progressive brain atrophy and catastrophic neurological outcomes [34,35].

Contemporary genetic discoveries have further emphasized that individual genetic mutations can result in variable clinical phenotypes. For example, a single gene mutation that causes the syndrome of generalized epilepsy with febrile seizures plus (GEFS+) produces different epileptic syndromes, some benign and some severe, even in different members of the same family [36]. The relationships between epileptic genotypes and phenotypes is to a large extent unpredictable. Moreover, variability in the genotype–phenotype relationships operates in both directions. A single epileptic genetic mutation can often result in different types of epilepsy and a single type of epilepsy sometimes can have different genetic origins. Individual genetic profiles will soon become available as a result of high-throughput diagnostic susceptibility gene testing, but will require astute and knowledgeable clinicians for accurate interpretation. However, environmental exposure and injury also influence the form of the epilepsy and, as a result, the classification of epilepsy will continue to be difficult.

The lessons illustrated by pyridoxine dependency, chromosomal disorders and single-gene disorders that cause 'pure' epilepsy point to the difficulties and invalidity of syndromic classifications. As pointed out by several authorities, syndromes lack clear limits and the boundaries are continuing subjects of debate [37]. In many cases syndromes serve better as descriptive after-the-fact categories of outcomes than as diagnostic entities on which to base prognosis.

Despite their often limited neurobiological validity, syndromic diagnosis is clinically useful. The value of classifying syndromes, as with classifying seizure types, lies in the use of a standard lexicon, which facilitates communication among professionals as well as lay persons. In some cases, syndromic classification provides a basis for fashioning symptomatic treatments. Using a seizure to comprehend aetiology or pathophysiology is similar to trying to guess what is funny from a smile. Standardized, the terminology used for epileptic outcomes for clinically similar groups underpins effective dialogue about the clinical epiphenomena that are being observed. However, the highly variable relationships between aetiologies and epileptic phenotypes suggest that a highly detailed, intricate classification may be futile. To summarize, both seizures and syndromes are symptoms of underlying brain disorders. Both are empirical and descriptive, not aetiological or physiological. As a general rule, individual syndromes have many different aetiologies and mechanisms.

Methods of epilepsy syndrome classification

In classifying the epilepsies, the major division depends on whether the principal seizure type is focal and has localized onset or is generalized. The second axis of categorization is aetiological; is the disorder symptomatic, idiopathic or cryptogenic? Symptomatic epilepsies, also called secondary epilepsies, are those caused by known brain disorders. Cryptogenic epilepsies are those in which a cause is presumed but not identified. Idiopathic epilepsies have no apparent cause, but are believed to be due to 'hereditary predisposition' [38]. In other words, they are thought to be genetic. Defining characteristics of idiopathic epilepsies include age of onset, clinical features, plus characteristic EEG patterns from both interictal and ictal recordings.

The associated clinical features that have been used to define the epilepsies are listed in Table 1.5. Among these, intellectual capacity and motor function and natural history merit special emphasis. Certain syndromes include mental retardation in a high proportion of affected people. When mental subnormality is a key component of a syndrome, the intellectual deficit can either antedate the appearance of epilepsy or develop only after chronic epilepsy with numerous seizures. Conversely, in some syndromes, normal intellect is an expected feature.

Table 1.5 Factors used to characterize the epilepsies or epileptic syndromes.

Seizure type
EEG patterns – both ictal and interictal
Age of onset and remission
Natural history
Associated clinical features
Familial predisposition
Response to or aggravation by specific medications

Table 1.6 Features of frontal lobe seizures.

Brief duration
Complex partial with little or no postictal confusion
Rapid secondary generalization
Prominent tonic or postural movements
Frequent complex gestural automatisms at onset
Frequent falling when discharges are bilateral

Reproduced with permission from ref. 38.

Other factors that appear to affect the evolution of epileptic syndromes include treatment(s), the timing of treatment and the response to treatment. Each can contribute to the eventual clinical syndrome individually and in concert with other factors. Of course, when information about the current clinical picture is incomplete or erroneous the classification can be mistaken. Nonetheless, once syndromic diagnoses are established, 80% hold up over time [39].

The major groupings in the current classification of epilepsies have been validated consensually. In various studies, between one-third and close to all cases of new-onset epilepsy have been categorized according to the 1989 international classification [39–47]. In one study in which patients were reclassified 2 years later, classifications changed in 14%; 4% of changes resulted from evolution of the syndrome and 10% of relabelling resulted from acquisition of new information [17,21,45,48].

There are several impediments to diagnosing epileptic syndromes. When seizures first appear the clinical picture is often incomplete [39,49]. Consequently, some syndromes become discernible only over time after the disorders evolve a sufficient number of features to become distinctive and diagnosable.

Nowhere is the importance of time for sufficient development of distinctive clinical features more apparent than with encephalopathic childhood epilepsies such as infantile spasms and Lennox–Gastaut syndrome. These disorders materialize from a wide variety of premorbid conditions, arising in normal as well as compromised children. Similarly, many epilepsies that evolve into severe epileptic syndromes begin innocently as febrile seizures or occasional idiopathic generalized tonic–clonic convulsions in early childhood.

Localization-related (focal, local, partial) epilepsies and syndromes

In addition to the extensive classification of syndromes presented in the 1989 classification, the authors also described four anatomically defined localization-related epilepsies: temporal lobe, frontal lobe, parietal lobe and occipital lobe. These anatomical groups are considered next, with the major features of each group briefly listed. Localization-related syndromes account for approximately 60% or more of the epilepsies [20,44–46]. In children with epilepsy, 23% are idiopathic and 77% are symptomatic or cryptogenic.

Temporal lobe epilepsies

- Simple partial seizures with autonomic, psychic or certain sensory manifestations include epigastric rising, olfactory and auditory sensations or illusions.
- Complex partial seizures usually lasting more than 1 min, beginning with initial motor arrest followed by oro-alimentary and other automatisms. Other features are amnesia regarding the episode, postictal confusion and gradual recovery to normal.
- Seizures occur in clusters or in isolation.
- Interictal EEG features range from normal to abnormal with various irregularities including spikes, sharp waves, or slowing localized, but not restricted, to the temporal lobe region.
- Ictal EEG abnormalities include appropriately localized alteration of background rhythms, low amplitude, fast activity, spikes or rhythmic slow activity.

The temporal lobe syndromes were further subdivided into two groups: medial basal (amygdalo-hippocampal) and lateral temporal (neocortical). Symptoms pointing to the former location include rising epigastric discomfort, autonomic signs such as pallor, flushing, mydriasis, irregular respiration or respiratory arrest, abdominal borborygmi, eructation, plus fearful, olfactory and gustatory auras. Symptoms of lateral temporal seizures included auditory and/or visual sensory experiences, psychic dreamy states and dysphasias if the speech areas in the dominant temporal lobe were involved.

Frontal lobe epilepsies

Frontal lobe epilepsies are prone to misdiagnosis as psychogenic episodes. They manifest as simple partial, complex partial and partial secondarily generalized seizure types. As defined in the 1989 classification, the notable features of frontal lobe seizures are summarized in Table 1.6.

When seizures originate in specific areas of the frontal lobes they produce symptoms that reflect the normal functions that are mediated by that region. Thus, clinical features of seizures provide clues as to which area(s) of cortex are involved. Many seizures that originate in the frontal lobes are complex partial. However, in frontal lobe epilepsy, rapid spread makes localization on the basis of symptoms much less reliable than with temporal lobe epilepsy.

- Supplementary motor seizures result in fencing postures, focal tonic movement, speech arrest, vocalization.
- Cingulate seizures are complex partial and include affective and autonomic changes plus gestural automatisms.
- Anterior frontopolar seizures include psychic features, and adversive head and eye movements, and tend to cause abrupt loss of consciousness.
- Orbitofrontal seizures begin with motor or gestural automatisms, olfactory symptoms and autonomic signs.

- Dorsolateral frontal seizures are tonic or clonic with eye and head deviation and speech arrest.
- Opercular frontal lobe seizures involve taste, speech and oral–buccal movements. Auras attributed to this area include fear plus gustatory, laryngeal and epigastric sensations. Motor features include chewing, swallowing, speech arrest or clonic facial twitching. Salivation and other autonomic features are produced by seizures from this region.
- Motor cortex seizures tend to be simple partial and reflect the physiological role of the cortex that is producing the seizure. If after the seizure a postictal, so-called Todd's, paralysis occurs, it is an important clue that the seizure originated in the motor area.

Parietal lobe epilepsies

Seizures that originate in the parietal lobe are often sensory at the onset with variable secondary generalization and infrequent evolution to complex partial seizures [38]. Thus, the sensory components may be discretely localized or spread to contiguous areas. Sensations that have been described are mostly tactile and include tingling, electricity, crawling, stiffness, cold or pain/unpleasant dysaesthesias. Visual hallucinations of parietal origin are usually structured. Partial seizures originating in the parietal lobes have variable tendencies to secondarily generalize. Postictally transient neurological deficits that follow parietal lobe seizures are typical of the signs and symptoms that result from permanent parietal damage of other causes. These include asomatognosia, cortical sensory deficits, spatial disorientation and dyscalculia [38].

Occipital lobe epilepsies

Like parietal lobe seizures, when seizures originate in the occipital lobes, they reflect the usual function of that brain region and often involve eye movements, head turning and/or visual hallucinations [38]. Hallucinations that are generated posteriorly tend to be unstructured lights, colours and flashes whereas anterior occipital and temporal–occipital regions generate more structured images or visual distortions such as macropsia or micropsia. Depending on the areas of cortical involvement, visual abnormalities may be restricted to discrete portions of the visual fields.

Idiopathic localization-related epilepsies

Benign partial epilepsy of childhood

The syndrome of benign partial epilepsy of childhood (BPEC) is also called benign rolandic epilepsy (BRE) and benign epilepsy of childhood with centrotemporal spikes (BECTS). The natural history is favourable for normal neurological and cognitive function plus eventual remission of epilepsy in more than 97% [50]. It is characterized by the onset of usually infrequent partial seizures between ages 3 and 13 years. The temporal distribution of seizure favours nocturnal occurrence but seizures can occur at any time of day [51]. An autosomal dominant variant has been described [52]. Prior febrile seizures occur in 10% or less, and family history of seizures of various types in 40%. According to some physicians, half of these cases do not warrant treatment [53].

Although patients with BPEC are typically lesion free, findings that have been reported in patients who manifest the phenotype include hippocampal atrophy [54], cortical dysplasia [55], lesions of corpus callosum, porencephalic cysts and toxoplasmosis [56]. Of course, once a lesion is found, the diagnosis of BPEC usually needs to be changed.

The distinctive seizure type is simple partial, often with onset in the face and orobuccal area, variably followed by secondary generalization. The ictus may be sensory or motor or a combination of the two. Ictal phenomena include clonic jerking, speech arrest, drooling and unilateral tonic or clonic convulsions, or merely episodic dysarthria and drooling [57,58]. In most cases, consciousness is preserved until the seizures secondarily generalize [59]. Typically, examination is normal whereas the EEG is demonstrably abnormal owing to focal spikes that originate most often in the centrotemporal regions, although on repeated EEG recordings, the spikes often wander [60]. When centrotemporal spikes are discovered incidentally in EEGs of children who have not had seizures, most of the children do not go on to have seizures subsequently [61]. In approximately 25% of cases, the EEG occasionally reveals generalized spike–waves [62].

Although the natural history of typical BPEC is for remission of epilepsy and normal development [63,64], numerous reports describe children whose courses deviate from a benign pattern in terms of seizure frequency, seizure severity and occurrence of neuropsychological problems [65–68]. Fejerman *et al.* [69] described 26 children who had atypical evolutions of their epilepsies after presenting with typical clinical pictures of BPEC: 12 developed atypical benign partial epilepsy; three developed acquired epileptic aphasia (Landau–Kleffner syndrome); seven had bouts of status epilepticus; and five evolved mixed pictures of these atypical patterns.

The overlap of BPEC with other epileptic syndromes of childhood illustrates how the boundaries between syndromic entities are blurred and often indistinct. Some cases that present as BPEC evolve into more complicated clinical problems blending into phenotypes overlapping with Lennox–Gastaut syndrome, Landau–Kleffner syndrome and electrical status epilepticus during slow-wave sleep (ESESS) [70–72]. Cases have been labelled atypical benign partial epilepsy (ABPE) or pseudo-Lennox syndrome. Atypical features include bouts of status epilepticus, atypical absence seizures, atonic seizures [69,73] and cognitive and behavioural impairment combined with an EEG pattern of slow spike–wave – all of this along with the core feature of partial seizures. Some investigators have correlated the occurrence of cognitive impairment in BPEC with the abundance of paroxysmal EEG activity [74].

Benign partial epilepsy in infancy

Benign partial epilepsy in infancy, as first described by Watanabe *et al.* in 1987, consists of complex partial seizures appearing in infancy with normal interictal EEG patterns awake and asleep [75]. Subsequently, infants were identified who had both complex partial seizures and secondarily generalized seizures in various combinations [6,76], and, later still, cases were found with vertex spike–wave patterns during sleep [77]. Among those who had developed normally up to the age of 2 years, 90% continued to develop normally when evaluated at age 5 [78].

Childhood epilepsy with occipital paroxysms

Described by Gastaut in 1950, this disorder has prominent occipital epileptiform spike–wave activity that appears after eye closure and is suppressed by eye opening [79,80]. Clinical features include visual symptoms, such as hemianopsias and amaurosis, abstract and complex structured visual hallucinations along with seizures (simple and complex partial, and/or generalized convulsions) and prominent postictal symptoms with migraine headaches accompanied by nausea and vomiting. Subsequent reports indicated that the original cases described by Gastaut were rare and atypical. More typically, features may include severe epilepsy, epilepsy confounded by cognitive difficulties and lesional/symptomatic aetiologies that, in some cases, for instance with mitochondrial encephalopathy with lactic acidaemia and stroke (MELAS), are progressive [81]. These exceptions not withstanding, authoritative opinions regarding this condition emphasized an excellent prognosis. Some of the occipital lobe patients have progressive, degenerative aetiologies – whereas patients with benign rolandic epilepsy virtually never have progressive aetiologies. Key features include onset of episodic vomiting, eye deviation and impaired consciousness with variable secondary generalized convulsions at around 5 years of age. Most seizures are nocturnal. Most affected children have occipital spikes on EEG, but 20% may have spikes elsewhere or not at all [82].

Reading epilepsy

This rare, benign, non-progressive syndrome is characterized by reading-provoked sensorimotor symptoms affecting the oral–buccal–lingual–facial muscles that are involved in reading aloud [83]. However, reading aloud usually is not required to trigger the seizures. As a result, some authorities have recommended renaming the condition language-induced epilepsy [84]. The condition is accompanied by a positive family history of a similar disorder in as many as one-quarter of cases. Described by observers as myoclonic, jerking or tonic movements of the jaw, patients report sensations such as stiffness, numbness or tightness during the seizures. This is a pubertal or postpubertal disorder, with average age at onset being 17 years, with symptoms starting as young 10 years of age in some people [85]. Cases have been described that overlap clinically with BPEC, with juvenile myoclonic epilepsy and with absence epilepsy [86–88]. Some authorities feel that this is part of the idiopathic generalized epilepsy spectrum while others consider it to be a partial reflex epilepsy. Both may be correct as the behaviour can occur in either context.

Symptomatic localization-related epilepsy

There are many causes of symptomatic epilepsy and most lead to localization-related forms of epilepsy. These are considered further in Chapter 3; however, one condition, epilepsia partialis continua, is considered here because of its distinctive clinical presentation.

Chronic epilepsia partialis continua of childhood

Chronic epilepsia partialis continua of childhood (Kojewnikow's syndrome) is linked to two variants of epilepsia partialis continua (continuous partial seizures) and received special mention among various motor seizures in the 1989 classification [38,89,90]. The first type is characterized by a stable neurological picture that is punctuated by infrequent bouts of epilepsia partialis continua that are not linked to progressive brain disease. The second type is linked to progressive diseases caused by various progressive aetiologies. The clinical picture is one of progressive loss of motor and eventually mental function that follows prolonged periods of epilepsia partialis continua. In these cases the localization of the partial seizures migrates, leaving in its wake paralysis of the affected areas [91]. Rasmussen's encephalitis is one cause of the progressive form. A wide variety of aetiologies have been linked to Kojewnikow's syndrome including neoplasia, inborn errors of metabolism (cytochrome C oxidase-induced Leigh's disease) [92], immunoallergic paraneoplastic syndromes [93] and infections [94–96].

Generalized epilepsies and syndromes

Idiopathic generalized epilepsies (with age-related onset)

Benign neonatal familial convulsions

Although most seizures in the neonatal period are symptomatic of perinatal problems, especially hypoxia and ischaemia, idiopathic benign seizures rarely occur in otherwise normal, full-term newborns. Cases occur on both a familial and sporadic basis [97,98].

Inherited in an autosomal dominant pattern, benign familial neonatal seizures typically appear in the first 2 weeks of life [99,100]. The most common semiology is a generalized tonic phase followed by variable patterns of clonic and autonomic activity [101,102]. Approximately 10% develop subsequent epilepsy [103].

In the 1990s the disorder was linked to mutations in two genes (*KCNQ2* and *KCNQ3*) which determine the structure and function of potassium channels and hence influence brain excitability [104]. Other genetic causes are likely to be found.

Benign neonatal convulsions

Also called fifth-day fits, benign neonatal convulsions appear in previously normal newborns [99,104]. Seizure types include apnoeic, partial or generalized clonic, but not tonic. EEG interictal patterns include normal, focal or multifocal spikes and bursts of theta activity in the central regions, the so-called theta pointu alternant. Ictal patterns are mainly rhythmic spikes or rhythmic slow waves [104]. The typical picture is clusters of seizures of 1–3 min in duration, which occur for 24–48 h and then cease. During the cluster of convulsive activity, the seizures are said to be resistant to antiepileptic drugs. For the majority of affected newborns the natural history includes normal development and permanent remission of seizures. However, approximately 10% of newborns have ongoing problems. A few are delayed developmentally, have febrile seizures and/or have persistently epileptiform EEGs. North *et al.* [105] noted that in Australia the syndrome of fifth-day fits was 'epidemic' during the 1970s but disappeared thereafter.

Benign myoclonic epilepsy in infancy

This rare condition appears in infancy in normal children although symptomatic cases have been reported. Features include general-

ized axial, massive myoclonic seizures, interictal EEG pattern of generalized spike waves and a mixed picture developmentally. Persistent uncontrolled seizures are associated with developmental stagnation and psychomotor retardation. It is unclear if this is a phenotypic variant of severe myoclonic epilepsy of infancy (see below) [106,107].

Childhood absence epilepsy (pyknolepsy)

Childhood absence epilepsey (pyknolepsy) appears with the onset of absence seizures in the early and middle years of childhood. This disorder is characterized by female predominance, and affected individuals are usually of normal intellect; there is at least a 40% chance of remission. The absence seizures are quite brief, so brief that, in some cases, they go unrecognized as seizures for long periods. The seizures also tend to occur in clusters. Although absence seizures are the predominant seizure type, other types of seizures occur infrequently. The classical EEG pattern is monotonous, a generalized 3-Hz spike–wave. Clinically, this condition overlaps with several others, especially juvenile myoclonic epilepsy [108]. In a series of 194 patients with typical clinical features and a typical EEG, approximately one-third also had generalized tonic–clonic seizures at some point, and absence status occurred in 15%. When followed up after the age of 18 years, approximately 20% were still having seizures [109].

In population-based studies, absence epilepsies account for less than 3% of newly diagnosed seizure disorders, whereas in paediatric populations they account for 15–20% [40,41,43,110]. Although children with absence epilepsies as a group have an above average intelligence quotient (IQ), in some studies [111] some investigators have found an over-representation of academic and behavioural problems associated with childhood absence epilepsy [112]. As suggested originally by Metrakos and Metrakos [113], childhood absence epilepsy is generally felt to be inherited as an autosomal dominant disorder with variable penetrance.

Boundaries in generalized epilepsies that appear in adolescence are indistinct, suggesting underlying neurobiological relationships [114]. Olsson and Hagberg [115] identified two groups of children with absence epilepsy. Those in whom onset of seizures occurred before the age of 12 years responded to therapy quickly, had a low chance of generalized tonic–clonic seizures and had a high remission rate. On the other hand, juvenile onset after the age of 12 years was associated with a high risk of generalized tonic–clonic seizures and a high relapse rate after discontinuation of antiepileptic therapy. Both groups responded well to antiepileptic drug therapy. In up to one-third of patients with juvenile myoclonic epilepsy, epilepsy begins with absence seizures in early to mid-childhood – well before the peripubertal onset of myoclonic jerks that are diagnostic for juvenile myoclonic epilepsy [116]. When juvenile myoclonic epilepsy presents in this fashion with absence seizures and a 3-Hz spike–wave EEG pattern, it is impossible to differentiate from childhood absence epilepsy.

Many ion channel genes have now been implicated in absence epilepsy and other forms of generalized epilepsy (for a review, see ref. 117) and are too numerous to describe here.

Juvenile myoclonic epilepsy

Juvenile myoclonic epilepsy (JME), also known as impulsive petit mal or Janz's syndrome, includes the following: myoclonic jerks, general tonic–clonic seizures and absence seizures [118,119]. Initially thought to originate in the peripubertal period when the myoclonias usually appear, subsequent studies revealed that approximately 15–30% of people with the disorder experience the onset of absence seizures in childhood, in which case absence seizures always predate the appearance of myoclonic seizures [120–123]. Seizure precipitants include sleep deprivation, stress, alcohol intake and menses, with sleep deprivation being the most common and most important [124]. Interictal EEG patterns vary from a 3-Hz spike–wave to faster patterns of poly-spike–wave at 4–6 Hz; however, EEG patterns may be asymmetrical and misleading [122,125]. Photosensitivity is present in approximately one-third [125].

Juvenile myoclonic epilepsy often goes unrecognized or misdiagnosed. The most common source of these errors is the failure to identify the myoclonic jerks (myoclonias) that are required for the diagnosis or to misinterpret them as partial seizures [126]. Epileptic in origin, the myoclonias are accompanied by polyspikes and spike–wave EEG discharges. Although the jerks can be disruptive and numerous, occurring repeatedly over a period of minutes to hours, consciousness remains intact.

A notable feature of the jerks is that most patients do not report them voluntarily and may attribute them to early-morning clumsiness, nervousness or restlessness. This is surprising given that the jerks are often forceful and dramatic in form. For this reason, a history of myoclonias, especially after awakening, should be directly sought if JME is suspected in anyone who presents with generalized convulsions [127].

The typical natural history includes responsiveness to therapy with valproic acid and vulnerability to an exacerbation of seizures when treated with traditional antiepileptic drugs that modulate use-dependent sodium conductance, such as phenytoin and carbamazepine [128]. The prognosis for seizure control is excellent with medication. However, even if fully controlled, seizures often recur when medication is discontinued [129].

Epilepsy with grand mal seizures (generalized tonic–clonic seizures) on awakening

This condition overlaps considerably with other generalized epilepsies, especially with JME, in which most affected people also have generalized tonic–clonic seizures on awakening. The EEG pattern is generalized spike–wave [122]. Whether this syndrome represents a discrete entity or simply the leftovers from other disorders has been debated for years [130]. At best, the syndrome is indistinct because as noted in the 1989 classification 'If other seizures occur, they are mostly absence or myoclonic.' [38].

Cryptogenic or symptomatic generalized epilepsies (in order of age)

West syndrome (infantile spasms, Blitz–Nick–Salaam–Krämpfe)

The term 'infantile spasms' is used to describe a seizure type as well as an epileptic syndrome, an ambiguity that is avoided by the appellation West syndrome. Synonyms for infantile spasms include Blitz–Nick–Salaam–Krämpfe, massive myoclonic spasms, lightning spasms, flexion spasms, jackknife convulsions and infantile myoclonic epilepsy. West syndrome includes three

features: infantile spasms, developmental arrest and an EEG pattern of hypsarrhythmia.

The EEG is almost always abnormal in these patients [131]. Approximately two-thirds of patients have a pattern of hypsarrhythmia. One-third have focal abnormalities. Less than 2% of patients with infantile spasms have normal EEGs, and if the EEG is normal the diagnosis should be questioned. Young infants who have spasms without EEG paroxysms have an innocent condition called benign infantile myoclonus that does not require treatment [132]. Hypsarrhythymia is a severe epileptic EEG abnormality. There are 'mountainous' high-amplitude, asynchronous delta slow waves intermixed with multifocal spikes or poly-spikes and wave complexes.

The onset of infantile spasms occurs before age 12 months in 85% of cases, and spasms usually cease by age 5 years only to be replaced by other types of seizures [132–135]. In approximately 30% of cases other types of seizures, mostly partial, precede the spasms; in 40% of cases other seizure types appear after the spasms begin [134]. The ictal movements include mixtures of flexion and extension, purely flexor movements, or pure extension, which accounts for 22% of spasms studied by video-EEG monitoring In full form, flexor spasms cause flexion of the neck and trunk with adduction of the shoulders and outstretched arms and variable flexion of the lower extremities, so-called salaam fits. Males account for the majority of patients.

Spasms vary in intensity from subtle to dramatic forms. Often when they first appear they are subtle, but as the child grows older, they tend to become more intense and occur in clusters, during which the infant cries. The clusters are most common on awakening. Aggressive, effective treatment is believed to reduce the chance of developmental stagnation and subsequent retardation [136,137]. Currently, the optimal therapy of infantile spasms appears to be adrenocorticotropin hormone (ACTH), which is initiated within 1 month of the onset of the spasms or aggressive therapy with antiepileptic drugs [136–144].

The aetiology of West syndrome is diverse. In approximately two-thirds of cases the condition is symptomatic of identifiable brain disorders; in approximately one-third, the aetiology is idiopathic or cryptogenic. The most common aetiologies are perinatal asphyxia and tuberous sclerosis. However, any aetiology that results in brain malformation or brain tissue destruction can produce this epileptic picture. Idiopathic cases have the best prognosis [137].

Brain imaging is abnormal in 80% of children with West syndrome [144,145]. The most common abnormalities are atrophic lesions (50%), followed by, in order, malformations, atrophy plus calcification, calcifications and porencephaly. Occurring almost exclusively in females, Aicardi's syndrome includes agenesis of the corpus callosum, chorioretinitis, vertebral anomalies, cortical heterotopias and severe learning diffulties [146–148].

The prognosis in West syndrome is related to the underlying brain disorder and to the therapy [137,142,149]. Patients with idiopathic, cryptogenic infantile spasms who receive optimal therapy have the best prognosis; those with severe encephaloclastic disorders have the worst prognosis. Among all patients with West syndrome, 20% die before reaching the age of 5 years and between 75% and 93% have been reported to have learning difficulties; at least 50% have persistent epilepsy and one-half of these individuals develop Lennox–Gastaut syndrome.

Lennox–Gastaut syndrome

Lennox–Gastaut syndrome is an age-dependent syndrome that includes early childhood-onset epilepsy with either mental retardation before seizures start or developmental stagnation, leading to retardation that accumulates during the period that epilepsy remains uncontrolled [150,151]. The syndrome overlaps clinically with other severe myoclonic epileptic syndromes [152,153]. Approximately 25% of cases of Lennox–Gastaut syndrome evolve from infantile spasms or West syndrome [135,154].

In Lennox–Gastaut syndrome, tonic and atypical absence seizures are the most common seizure types, occurring in 71% and 49% of patients, respectively. Generalized tonic–clonic seizures (GTCSs) and astatic seizures (drop attacks) occur in approximately one-third of patients, whereas partial seizures occur in about one-quarter [155]. The distinctive interictal EEG pattern is a slow spike–wave with frequencies of 2.5 Hz. During sleep, bursts of 10-Hz activity occur.

Lennox–Gastaut syndrome shares many features with myoclonic astatic epilepsy, also called Doose syndrome [156]. Multiple seizure types typify both syndromes, and the evolution of the disorders, resulting in mental retardation when seizures are uncontrolled, is similar. Not surprisingly, there has been debate and confusion about the boundaries of Lennox–Gastaut syndrome and other myoclonic epilepsies with encephalopathy [153,157].

Epilepsy with myoclonic astatic seizures

This disorder is also called 'myoclonic astatic epilepsy of early childhood': it usually appears in children who were previously without any disorder. Even although it is listed here among cryptogenic or symptomatic conditions, it is an idiopathic disorder with a strong genetic component and a positive family history of epilepsy in more than one-third of patients [157]. The epilepsy usually starts with generalized tonic–clonic seizures occurring with or without fever. Over time, other seizure types appear. These include myoclonic seizures, astatic seizures (usually atonic), atypical absence seizures and generalized tonic–clonic seizures but not daytime tonic seizures. However, in Doose's 1992 report [158], 30% of 109 cases had tonic seizures, most of which were nocturnal. Minor motor status occurred in 36%. The EEG is abnormal owing to generalized patterns of spike and wave rhythms of 4–7/s and photosensitivity but not multifocal patterns [107,159,160]. The prognosis for normal development is related to the extent of seizure control. The risk of mental deterioration is increased by onset of epilepsy before the age of 2 years, bouts of minor motor status, tonic seizures, failure to respond to anticonvulsant therapy, and the failure to develop a normal alpha rhythm on the EEG. Children with persistent frequent seizures experience developmental stagnation that results in eventual learning difficulties.

Epilepsy with myoclonic absences

This uncommon disorder is characterized by absence seizures that are accompanied by dramatic bilateral myoclonic jerks that occur in synchrony with an EEG pattern of 3-Hz spike–wave. The onset

is during middle childhood, and a male predominance has been described [109,161]. Approximately one-half of the affected children have learning difficulties and karyotypic abnormalities are common [162]. However, in the absence of structural brain abnormalities, development may be normal [163].

Symptomatic generalized epilepsies and syndromes: non-specific as to aetiology (age-related onset)

The next four conditions overlap considerably phenotypically and share many aetiologies, including a wide range of inborn errors of metabolism and structural brain abnormalities, such as hemimegalencephaly and other disorders of neuronal migration. All are associated with a high risk of severe developmental impairment and persistent epilepsy and are generally resistant to treatment. As a group they support the general concept that the earlier the onset of symptomatic epilepsy, the more extensive the neuropathology is likely to be and the more grave the prognosis [164–166]. Taken collectively, these syndromes, which include early myoclonic encephalopathy, early infantile epileptic encephalopathy with suppression burst, West syndrome and Lennox–Gastaut syndrome, constitute a spectrum of age-dependent epileptic encephalopathies through which the severely epileptic child graduates from one syndrome to the next as brain maturation leads to evolving epileptic phenotypes [167].

Early myoclonic encephalopathy

With onset in the first 3 months of life, this syndrome results from various metabolic, malformative and encephaloclastic diseases that affect the brains of newborns. More than one-half of patients who manifest this severe epileptic phenotype do not live past 12 months [168]. If they do survive infancy, the clinical picture often evolves into infantile spasms or West syndrome. All affected infants present with profound developmental delay. The EEG shows a burst–suppression pattern [38]. As described by Aicardi [169], the seizures present as variable and erratic multifocal myoclonic jerks, but as the infants' brains mature, tonic spasms typical of West syndrome become predominant, only to be superseded by Lennox–Gastaut syndrome as the child ages.

Early infantile epileptic encephalopathy with burst–suppression

Beginning before the age of 6 months, this disorder is characterized by tonic axial spasms and burst–suppression EEG patterns. It is also known as Ohtahara's syndrome [167]. The same continuum of aetiologies produce this syndrome as produce early myoclonic encephalopathy, but tonic spasms rather than myoclonic seizures predominate in Ohtahara's syndrome [170]. For this reason, some regard this syndrome as an early-onset variant of West syndrome [171]. Often evolving into West syndrome, the seizures are therapy resistant and psychomotor retardation is the rule.

Additional idiopathic generalized epilepsies not yet codified by the ILAE

With careful clinical observations, additional epilepsy syndromes are being identified; one of these is Jeavons' syndrome, in which eyelid myoclonia is predominantly manifested and a characteristic EEG abnormality presents upon eye closure. The recognition of some of these epilepsy syndromes, reviewed in Panayiotopoulos [172], may be facilitated by the identification of specific genetic abnormalities that will simplify their diagnosis.

Epilepsies and syndromes undetermined whether focal or generalized

Neonatal seizures

Classification schemes for neonatal seizures and epilepsies do not conform to the same patterns as seizures and epilepsy in older patients. These are considered separately in Chapter 13.

Severe myoclonic epilepsy in infancy

First described by Dravet in 1978 [173], severe myoclonic epilepsy has its onset before the age of 1 year, when the patient presents with febrile convulsions, either generalized clonic or hemiclonic, that are often prolonged. Like fever, hot baths can also precipitate seizures in affected infants [174]. Prior to the onset of the epilepsy, development is normal but encephalopathy eventually develops [175]. After variable numbers of febrile seizures, afebrile seizures of various types appear. These include myoclonic seizures, either focal or generalized with concomitant EEG generalized spike–wave or poly-spike–wave patterns, atypical absence seizures, generalized tonic–clonic seizures and partial seizures in about one-half of affected children. Initially, the interictal EEG is normal but, over time, it becomes progressively epileptic with generalized fast spike–wave, focal and multifocal abnormalities. When severe, the myoclonic seizures cause the children to fall down and thus qualify for the descriptor astatic seizures. As seizure frequency increases, development stagnates, resulting in mental subnormality. Ataxia appears in half of these children [161]. The seizures continue despite aggressive therapy with antiepileptic medications and are associated with shortened life expectancy. Severe myoclonic epilepsy in infancy has been linked to mutations in the sodium channel gene *SCN1A* [176].

Several disorders have been described that are linked to severe myoclonic epilepsy of infancy because they evolve from febrile seizures and have mutations in the sodium channel gene. Collectively, the epilepsies have been named generalized epilepsy with febrile seizures plus (GEFS+) [177,178]. Other disorders, such as high-voltage slow-wave grand mal syndrome (HVSW-GM), overlap clinically, but whether the molecular pathogenetic mechanisms overlap remains to be determined [179]. Other clinically overlapping syndromes include early infantile epilepsy with generalized tonic–clonic seizures, cases of myoclonic astatic epilepsy and childhood absence epilepsy with generalized tonic–clonic seizures [180].

Epilepsy with continuous spike–waves during slow-wave sleep

This condition is defined by a continuous spike–wave EEG pattern during 85% or more of slow-wave sleep [181]. Synonyms and abbreviations include electrical status epilepticus during sleep (ESES) and continuous spikes and waves during slow-wave sleep (CSWS). The central features are cognitive and behavioural deterioration that follow the appearance of various types of epileptic seizures [182,183]. The types of seizures that have

been described include partial, absence, astatic and generalized tonic–clonic.

Several syndromic phenotypes have been described with ESES including typical Landau–Kleffner syndrome of acquired epileptic aphasia (see below) and frontal opercular syndrome, variants of benign partial epilepsy of childhood (BPEC) plus less discrete clinical pictures [184,185]. Some investigators feel that Landau–Kleffner syndrome and ESES represent the same condition [186]. Frontal opercular syndrome consists of episodic dysarthria, dysphagia, drooling and variable degrees of hand apraxia and hemi- or monomelic paralysis [187,188]. ESES occurs on both an idiopathic/cryptogenic and symptomatic basis, with several reports noting polymicrogyria and shunted hydrocephalus as causes [189,190].

Acquired epileptic aphasia (Landau–Kleffner syndrome)

Appearing in early childhood, usually before the age of 5 years, in previously normal children, the syndrome of acquired epileptic aphasia [191] presents abruptly or subacutely, with mutism, apparent deafness, behavioural abnormalities, an epileptiform EEG pattern and seizures in approximately two-thirds [38,192,193]. However, hearing is normal when evaluated by evoked response audiometry, pointing to verbal auditory agnosia as the proper diagnosis instead of deafness [194]. Multiple types of seizures occur, including partial, generalized tonic–clonic and absence seizures. Typically, the EEG is abnormal owing to generalized or multifocal spike and spike–wave patterns, although clinical investigations with positron emission tomography, magnetoencephalography and occasional electroencephalography studies point to temporal lobe dysfunction [195–197]. In sleep, continuous spikes and waves during slow-wave sleep are common. For this reason, some investigators have concluded that ESES and acquired epileptic aphasia represent a spectrum within the same condition [187]. The seizures tend to be resistant to drug therapy but abate with advancing age. Between 25% and 50% of patients experience much improved to normal language function when followed up in adolescence or later, but an EEG pattern of ESES lasting longer than 36 months [198,199] or persistently abnormal EEG patterns have been linked to continual language impairment [200,201].

Special syndromes: situation-related seizures *(Gelegenheitsanfälle)*

Febrile convulsions

Febrile seizures are the most common epileptic syndrome, occurring in more than 3% of children. Fever from any cause can provoke seizures in susceptible infants and toddlers. The seizures may be partial or generalized, brief or lengthy, single or repeated. Interictal EEGs are either normal or have non-specific irregularities. Following febrile seizures, the risk of subsequent afebrile seizures (epilepsy) is increased from two- to sevenfold in various studies [202–205]. Although heightened risk of later epilepsy has been linked to many historical and demographic factors in affected children, since 1995 genetic discoveries about the links between febrile seizures and later epilepsy have provided insight into the neurobiology of epilepsy. Various family members who are affected by the same, single point mutation may develop a heterogeneous array of epileptic syndromes [178,206].

Genetic studies in febrile seizures have identified several mutations that lead to febrile seizures and later generalized epilepsy, a group of disorders that has become known as generalized epilepsy and febrile seizures plus (GEFS+) [207]. Recently discovered causes of GEFS+ include mutations involving two genes for voltage-gated sodium channels (*SCN1A* and *SCN1B*) [208,209] along with mutations of the genes that encode the GABA-A receptor [210,211]. In addition, digenic inheritance has been described [212]. However, among familial GEFS+, mutations affecting *SCN1A* and *SCN1B* accounted for only 17% of cases, indicating that many more genetic mechanisms await discovery [213].

To date, most of the discoveries regarding inherited forms of epilepsy have resulted from investigations of families in which epilepsy occurs as the result of mutated genes that are inherited according to simple mendelian genetics. Berkovic and Scheffer [214] have estimated that 95% of genetic epilepsies are inherited in complex patterns owing to the combined effects of single or multiple genes that interact with environmental and experiential variables. Research endeavours involving thousands of well-characterized epilepsy patients will be required to fully understand the significance of both rare gene mutations and common gene polymorphisms in human epilepsy.

2 Epidemiology and Prognosis of Epilepsy

Lars Forsgren[1] *and Dale Hesdorffer*[2]

[1] Umeå University Hospital, Umeå, Sweden
[2] Gertrude H. Sergievsky Center, Columbia University, New York, NY, USA

Epidemiological studies of epilepsy are important for many reasons, including the provision of fundamental information on the magnitude of the disorder, its causes and its consequences. They can also be used to quantify the impact of important variables, such as the risk for further seizures, the chance of becoming seizure free, and the risk of dying from seizures. Furthermore, they can identify factors that are associated with a low or high risk for intractability.

Prevalence studies of well-characterized epilepsy populations provide valuable information for planning purposes. How many have epilepsy? How many have mild or severe epilepsy? How frequent is epilepsy in different ages? How many have concomitant disorders, and of what type? This and related information make it possible to estimate the number affected individuals, the levels of care needed and the resources that will be required.

There are many sources for identifying epilepsy populations; these include diagnostic registries at hospitals and electroencephalogram (EEG) laboratories as well as registries of groups with conditions that increase the risk for epilepsy, such as mental retardation. When registries, which partly overlap, have identified the vast majority of persons with epilepsy in the study area, the study is considered to be population based (or community based) and thus representative of the general epilepsy population in the study area. The use of hospitals as the sole source for identification can bias the sample, resulting in an underestimation of the number affected and an overestimation of severe cases.

Epidemiological studies often categorize countries as developed and developing, based on such socioeconomic criteria such as level of industrialization and the presence of a mature market economy. This, of course, can be at times difficult and arbitrary. Furthermore, all countries change and are, in that sense, developing. In this chapter, countries in Europe, North America and Australia are classified as developed and the countries of Central and South America, Africa and Asia as less developed. Of course this is an oversimplification since some countries in the less developed parts of the world are socioeconomically more advanced than some of the more developed countries.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

General epidemiology

The size of the epilepsy population: prevalence

In order to compare the prevalence of epilepsy across different groups, the definition of epilepsy should be the same across studies. The definition recommended by international guidelines for epidemiological studies of epilepsy states that seizures should be recurrent (i.e. at least two seizures) and unprovoked by any immediate identified cause [1]. Epidemiological studies of epilepsy are mainly interested in active epilepsy, defined as a condition in which individuals with epilepsy have had at least one seizure during the last 5 years and/or are still being treated with antiepileptic drugs (AEDs).

More developed countries

Several population-based European studies that include all ages report that the prevalence of active epilepsy per 1000 population ranges from 6.2 to 7.6: in children it is generally lower, 3.6–5.3 (Table 2.1). In North America, studies from Rochester, Minnesota, report a prevalence per 1000 of 6.8 in 1980, the same as that reported from the southern states. A study on children and adolescents found a prevalence per 1000 of 4.7. Thus, the prevalence of epilepsy is similar in Europe and North America; prevalence in children is slightly lower (Table 2.1) [2–12].

Less developed countries

Studies from countries in South and Central America, Africa and Asia report larger differences in prevalence of active epilepsy than found in more developed countries [13–19]. Prevalence seems to be higher in South and Central America than in other parts of the world. Many of these studies are small but a large study also reported a high prevalence (Table 2.2) [13].

Several African studies report a high prevalence; many of these studies are small or include cases with provoked and/or inactive epilepsy. Larger population-based studies find prevalence similar to what is found in more developed countries (Table 2.2). The country in Asia where the largest number of studies has been carried out is India. There, a meta-analysis of 20 studies [18] found an overall prevalence per 1000 population of 5.3 with a 95% confidence interval (CI) of 4.3–6.4. Higher prevalence has been reported from other Asian countries (Table 2.2).

It is often claimed that epilepsy is more common in the less developed parts of the world. From the literature. this appears likely for South and Central America, possibly so for sub-Saharan Africa and less likely for Asia. From the age-specific prevalence,

Table 2.1 Prevalence of active epilepsy in more developed countries.

Country, year [ref.]	Prevalence per 1000 people		Age	No. of cases
	Not age-adjusted	Age-adjusted[a]		
Italy, 1983 [2]	6.2	6.7	All ages	278
Faeroe Islands (Denmark), 1986 [3]	7.6	7.8	All ages	333
USA, 1986 [4][b]	6.8	7.0	All ages	160
USA, 1991 [5]	6.8		All ages	383
Finland, 1989 [6]	6.3		Adults	1233
Sweden, 1992 [7]	5.5	5.7	Adults	713
Norway, 2000 [8]	5.3		Children 6–12 years	205
Sweden, 1996 [9])	4.2		Children 0–16 years	155
Finland, 1997 [10]	3.9		Children 0–15 years	329
Estonia, 1999 [11]	3.6		Children 0–19 years	560
USA, 1989 [12]	4.7		Children 0–19 years	1159

[a] Age-adjusted to the US population.
[b] Includes 22% with 'possible epilepsy'.

Table 2.2 Prevalence of active epilepsy in less developed countries.

Country, year [ref.]	Prevalence per 1000 people	Age	No. of cases
Chile, 1992 [13]	17.7	All ages	314
Bolivia, 1999 [14]	11.2	All ages	112
Ethiopia, 1990 [15]	5.2	All ages	316
Tanzania, 1992 [16]	10.2	All ages	185
Tunisia, 1993 [17]	4.0	All ages	141
India, 1999 [18]	5.3	All ages	3207
Pakistan, 1994 [19]	10.0	All ages	241

it can be estimated that globally more than 10 million children, close to 30 million adults and close to 3 million elderly have active epilepsy, a total of 43 million people. This means that children constitute one-quarter, adults two-thirds and the elderly 7% of the global epilepsy population. Of those with epilepsy, around 80% live in less developed countries. Since the largest population increase occurs in the elderly, both in more and less developed countries, it is expected that the elderly will constitute a growing part of the epilepsy population.

Gender

Most studies have found epilepsy to be more common in males [2–4,6,7]. However, there are exceptions. In a study from the USA covering a 50-year period, prevalence was higher for males between 1940 and 1970 but more common in females in 1980 [5]. The increase in prevalence of active epilepsy during the 50-year period was largely due to an increasing prevalence in females. Studies in children often report higher prevalence in males, but higher prevalence has also been found in females. Interestingly, the larger prevalence studies from South America report higher prevalence in females [14] or no difference [13]. In Asia most, but not all [19], studies report slightly higher prevalence in males. In Africa the situation is the same, with most [15,17], but not all [16], studies finding slightly higher prevalence in males. The difference in prevalence found between genders is rarely statistically significant [2,6], and in individual studies the dominance by females and males shifts between age groups. Thus, epilepsy probably is slightly more common in males but several studies find the opposite and therefore uncertainty remains as to whether there is a true gender difference in active epilepsy.

Ethnicity

Only a few prevalence studies have been conducted in racially heterogeneous populations and the effect of ethnicity is difficult to assess independent of socioeconomic factors. A study of childhood epilepsy in the USA found higher rates in the black than in the white population [12], restricted to children under the age of 10 years. In a population with all ages included, prevalence was higher in the black population, among both males and females, except for children aged 5 years or younger [4].

Socioeconomic factors

Using an index for material deprivation, a strong correlation was found between the prevalence of epilepsy and social deprivation in a study from Wales [20]. The correlation remained when patients with coexisting psychiatric illness or learning disability were excluded from the analysis. The authors considered whether social deprivation was a cause or a consequence of epilepsy and concluded that epilepsy was likely a consequence of social deprivation, because a high correlation with prevalence was found already in those under age 20 years, an age when the drift down the social scale as a result of epilepsy should be minor. Confirmation comes from an Icelandic study showing that low socioeconomic status is associated with an increased risk for developing epilepsy [21].

Seizure types

Modern epidemiological studies on seizure types have used the International Classification of Epileptic Seizures. However, this classification requires EEG and clinical data for accurate seizure typing and in many epidemiological studies this is not possible. For instance, many generalized convulsive seizures have a focal onset and rapidly generalize, precluding observation of focal onset. The results of these may be liable to error.

In more developed countries patients with partial seizures or localization-related epilepsies account for 33–65% of the epilepsy population, those with generalized seizures account for 17–60% and in 2–8% seizures are unclassifiable.

Studies in adults find that 55–60% have partial seizures (or localization-related epilepsies), 26–32% have primarily generalized seizures and 8–17% have seizures that are unclassifiable [6,7]. In studies of childhood epilepsy 36–66% have focal seizures/epilepsies, 30–62% have primarily generalized seizures and 2–4% have unclassifiable seizures [8,11,12]. Another study found that localization-related epilepsies account for 50% of the epilepsies in people under 40 years of age and account for 75% of epilepsy among people aged 75 years and older [5].

To summarize, partial seizures are more common than generalized seizures in both children and adults although the preponderance of partial seizures is more pronounced in adults. However, it should be remembered that many seizures categorized as generalized may have an occult focal onset. In less developed countries focal seizures account for 11–55%, generalized seizures for 26–86%, and unclassifiable seizures for 0–19% of patients [13–16,18]. Combining electroencephalography results with clinical diagnosis increases the proportion of seizures classified as partial from 20% to 26% in Ethiopia [15] and from 34% to 53% in Bolivia [14].

New cases with epilepsy: incidence

Incidence studies measure how many new patients develop epilepsy. The incidence rate is expressed as the number of new cases observed annually per 100 000 people (or 100 000 person-years). There can be a delay of months to years between the initial seizure(s) and contact with the health authorities and diagnosis. Thus, annual incidence rates provide information on newly diagnosed cases, whether or not the initial seizure(s) occurred prior to or during the investigation period. The index seizure is the seizure leading to the diagnostic contact. Some incidence studies of epilepsy include single unprovoked seizures. In studies on seizure prognosis it is important to be aware of whether the starting point is the time of the first seizure or the time of diagnosis.

Specific countries

In the USA, the UK, the Faeroe Islands, Sweden and Switzerland, annual incidence rates are around 50 : 100 000 [3,22–25] (Table 2.3). A study from Chile has reported the highest rate worldwide [13] (Table 2.3). The two existing studies on incidence of epilepsy from Africa report slightly higher incidence rates than found in more developed countries [16,26] (Table 2.3). However, when incidence is adjusted for age, using the US population, the incidence in Africa is similar to that found in more developed countries – around 50 : 100 000.

Age-specific incidence

Age-specific incidence forms a U-shaped curve, with the lowest incidence in people between the age of 30 and 40 years and the highest incidence in the elderly (Fig. 2.1) [3,22,25,27,28]. In the few studies from less developed countries, incidence is higher in children and (with a single exception) lower in the elderly than in more developed countries [13,16,26]. Globally, an estimated 3.5 million people develop epilepsy annually; 40% are children under the age of 15 years, another 40% are adolescents and adults 15–64 years old, and close to 20% are elderly. Thus, the majority of people who develop epilepsy do so after childhood.

Table 2.3 Annual incidence of epilepsy.

Country, year [ref.]	Incidence per 100 000 person-years	Age	No. of cases	Comments
Faeroes, 1986 [3]	43	All ages	118	
Sweden, 1996 [22]	56	Adults <16 years	160	SS included
Switzerland, 1997 [23]	46	All ages	176	SS included
UK, 2000 [24][a]	46	All ages	31	
USA, 1993 [25][b]	48	All ages	275	
Chile, 1992 [13]	113	All ages	102	
Tanzania, 1992 [16]	73	All ages	122	
Ethiopia, 1997 [26]	64	All ages	139

[b] Data for the period 1975–84.

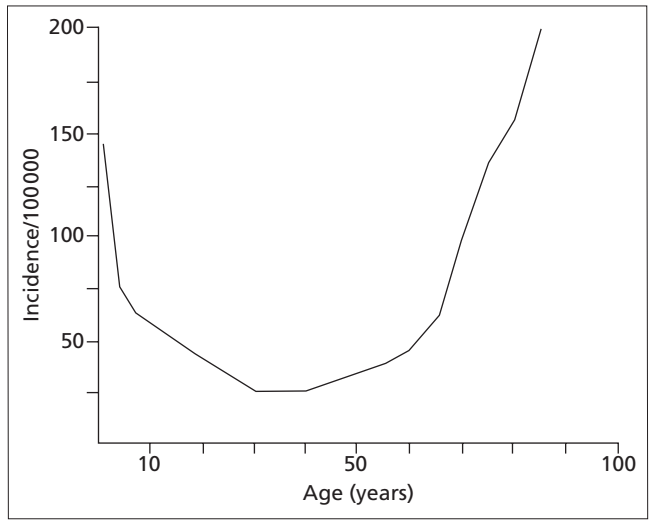

Fig. 2.1 Age-specific incidence of epilepsy based on studies from the USA, the Faeroe Islands and Sweden (single unprovoked seizures included in the Swedish studies) [3,22,25,27].

Cumulative incidence

The cumulative incidence is the summation of age-specific incidence and gives the proportion of a population that develops a disease during a specified period. In the USA, the cumulative incidence is 1.2% up to the age of 24 years, 3% up to the age of 74 years and 4.4% up to the age of 85 years [25]. When single unprovoked seizures are included, the cumulative incidence increases to 4.1% up to the age of 74 years. In Sweden,

the cumulative incidence up to age 74 years, with single unprovoked seizures included, was 4.1%, and 5.8% up to age 84 years [22]. Thus, approximately every 30th person is expected to have epilepsy during some part of his or her life, and every 25th person will have at least one unprovoked seizure.

Gender

Like prevalence studies, newly diagnosed epilepsy is more common in males than females, although the difference is rarely statistically significant [5]. Some studies find minor or no difference between gender and a few find a higher frequency in females.

Ethnicity and socioeconomic factors

In an incidence study in an urban area in the USA, new onset epilepsies were more common in black than white children [29]. Febrile and other provoked seizures, and neonatal seizures were included in the epilepsies. This study also reported an excess of epilepsy in both black and white children living in lower socioeconomic areas.

Seizure types in incidence populations

Partial seizures are most common and are found in 51–68% of incidence populations. In studies in which lower frequencies are found, the most likely explanation is that a proportion of partial seizures with secondary generalization was misclassified as generalized. Seizures were generalized in 16–69% and unclassifiable in 0–17% [3,13,25,26,28].

Causes of epilepsy

The aetiologies of epilepsy are best explored in population-based studies of newly diagnosed patients. Prevalence studies are less well suited for aetiological analysis, because several causes of epilepsy are themselves associated with increased mortality, and such epilepsies will be underrepresented in prevalence cohorts. Also underrepresented are individuals with the most benign epilepsies that rapidly enter remission.

The most commonly identified aetiology in all population-based studies from more developed countries is stroke, accounting for approximately every sixth patient who develops epilepsy (Table 2.4) [22,25,27,28,30]. Other common causes are neoplasm and congenital disorders. Congenital disorders mainly include patients with mental retardation, cerebral palsy and/or a developmental malformation of the brain. Other fairly common causes of epilepsy are trauma and degenerative disorders. The most common neurodegenerative disorder causing epilepsy is Alzheimer's disease, which causes generalized tonic–clonic seizures (GTCSs) in 10–16% of patients [31,32], predominantly during the late stage of the disease [32], at which point many also develop myoclonic seizures [31]. Partial seizures have also been reported in Alzheimer's disease.

In less developed countries, the proportion of patients with epilepsy with unknown causes is large, over 70%, in population-based incidence studies [26]. While the aetiologies of epilepsy are found in all countries, some aetiologies, for example head trauma, infections, pre- and perinatal causes, may be more common in less developed countries. In these countries, there are additional causes such as neurocysticercosis, an infection of the central nervous system (CNS) contracted by eating pork, fruits or vegetables contaminated by the pork tapeworm *Taenia solium*, which is endemic in South America, parts of Africa, India and China. In a study from Ecuador [33] on newly diagnosed patients with epilepsy, the proportion with identified causes was similar to more developed countries, but neurocysticercosis was found in 8% of these patients.

Table 2.4 Population-based studies estimating the proportion (%) of identified presumed causes of epilepsy.

Aetiology	Study				
	Iceland [28]	Sweden[a,b] [22,27]	UK[b,c] [30]	USA [25]	Range
Vascular	9	21	15	11	9–21

[c] Includes 15% with acute provoked afebrile seizures.
[d] Includes 6% with alcohol-related seizures.

Associated disabilities (co-morbidities)

Most people with epilepsy do not have other disabilities, but conditions that cause epilepsy often also produce other disabilities that may have a minor impact compared with epilepsy, or may be the major disability. Cognitive disabilities are more common than motor disabilities in studies of prevalent epilepsy. In newly diagnosed patients, however, motor disabilities are more common than cognitive disabilities.

Learning disabilities

Learning disability, also called mental retardation, is the most common associated disability in epilepsy in children and adults. Mental retardation is found in 38–49% of children [8] and in 23% of adults [7] with active epilepsy. Similar frequencies were reported from India, and in Ethiopia 8% were severely mentally retarded [15].

The degree of mental retardation is clearly related to the risk for epilepsy. Among children with mild mental retardation [intelligence quotient (IQ) of 50–70] epilepsy is found in 7–18% and among children with severe mental retardation (IQ < 50) in 35–44%. In a population with mental retardation including all ages, active epilepsy was found in 20%, corresponding to a prevalence of 1.2 per 1000 people [34]. This study also shows a clear relationship between the degree of mental retardation and frequency of epilepsy, with epilepsy occurring in 11% of the mildly mentally

retarded and 12% of moderate, 23% of severe and 59% of profoundly retarded individuals [34].

Cognitive disability is also found in people with epilepsy due to stroke or dementia. Among adults with newly diagnosed unprovoked seizures, 18% were demented [22].

Cerebral palsy

Cerebral palsy is common in patients with epilepsy: present in 15–21% of children and 9% of adults [7,8]. The vast majority, 89–100%, of children with epilepsy and concurrent cerebral palsy are also mentally retarded [8]. Likewise, the combination of mental retardation and cerebral palsy increases the risk for epilepsy to 48%, compared with 11% when either of these disabilities occurs alone [35]. Epilepsy is more frequent in the most severe form of cerebral palsy, tetraplegia, occurring in 94% of patients with tetraplegia compared with 23% of patients with hemiplegia.

Mental retardation and cerebral palsy should not be regarded as causes (or consequences) of epilepsy, as sometimes stated in the literature. Instead, any combination of these three disorders should, with a few rare exceptions, be considered as different manifestations of a prior brain insult, usually one that occurred early in life.

Seizure frequency

In unselected prevalent seizure populations, an estimated 40–50% have been seizure free during the last year, about 30% have up to one seizure per month and another 20–30% have seizures more frequently than once a month [7–10].

In patients with epilepsy and mental retardation, the proportion with very frequent seizures is much higher than in the general epilepsy population. About 10% have daily seizures and another 15% have one seizure or more per week, which means that one-quarter have at least weekly seizures [34].

Studies from less developed countries find a larger proportion of people with epilepsy having frequent seizures, probably largely because many patients do not receive treatment; studies in Ethiopia, for instance, find that less than 2% receive treatment, and from Bolivia only 11% [14,15]. Another contributory reason may be the underascertainment of patients with low seizure frequency.

Epidemiological time trends

Overall, the incidence of epilepsy was relatively stable in Rochester, Minnesota, USA, for a 50-year period [25,36]. However, age-specific incidence rates have changed significantly. The incidence in children younger than 10 years decreased successively by 40–50% between 1935 and 1984 with a slight increase during the last decade studied (1975–1984) [25,36]. The reason for this decrease is unknown but improved ante- and perinatal care may be partly responsible. Similar trends were observed in Sweden and the UK.

The study from Rochester also found an increase in incidence in those over the age of 60 years that almost doubled during the 50-year study period [36]. The secular trend with an increased incidence in the elderly may be a result of better survivorship from stroke, a group with increased risk for epilepsy, and also may be a result of more accurate case ascertainment.

Prognosis of seizures

Almost all studies on the prognosis of epilepsy published before 1970 were cross-sectional studies in hospital populations. These were biased by an overrepresentation of patients with severe epilepsy and the seizure prognosis observed was considerably worse than for general epilepsy populations. The Guidelines for Epidemiologic Studies on Epilepsy define epilepsy in remission as no seizures for 5 or more years [1]. Depending on whether the patient is receiving AED treatment or not at the time of ascertainment, remission is further specified as occurring with or without treatment. Terminal remission refers to patients still in remission at the end of a follow-up period. Temporary remission refers to patients in whom remission has occurred for a defined period earlier during the follow-up period, followed by a relapse. Permanent remission is not well defined but could be used for patients in terminal remission for a long period, for example 20 years, and judged to be very unlikely to relapse. The term could also be used for patients with specific syndromes with good prognosis once a certain age is reached, for example in patients with benign epilepsy of childhood with centrotemporal spikes (BECT) after the age of 18 years. Cumulative remission refers to the proportion that has been in remission at any time during the follow-up period, i.e. patients in both temporal and terminal remission. Some studies have used the term temporary remission for cumulative remission.

Early prognosis

The risk for a second seizure following a first unprovoked seizure has been investigated by several studies, discussed in detail in Chapter 10. When two unprovoked seizures have occurred, the person by definition has epilepsy. While a minority will have a second seizure following a first seizure, the proportion with a third or fourth unprovoked seizure following a second is considerably higher, 73% and 76%, respectively [37]. Seizure recurrence following a first, second or third seizure mainly occurs within 1 year [37].

Late prognosis: overall remission

In population-based studies of newly diagnosed epilepsy from more developed countries, the vast majority of patients are treated with AEDs. Thus, these studies give the prognosis of treated epilepsy and not the natural history of epilepsy. Results from studies are very similar despite some variation in methods (Table 2.5) [38–42]. At 10 years' follow-up, 5-year cumulative remission was 58–65% in studies from the USA and the UK including all ages [38–40] and from Sweden including adults [41]. Terminal 5-year remission at 10 years' follow-up was 61% [38]. Higher remission rates are found in children, of whom 74% achieve 3–5 years' remission at 12–30 years' follow-up [42]. In a prospective study with patients mainly collected by paediatric neurologists, 10% of children developed intractable epilepsy with more than monthly seizures during 18 out of the first 24 months following diagnosis [43]. The only study including all ages with a follow-up exceeding or of similar length as the childhood studies found a terminal 5-year remission rate of 70% at 20 years [38]. Fifty per cent were seizure free without antiepileptic treatment and 20% with treatment. Thus, at least 30% of patients will eventually achieve long-term remission, and about 75% of children.

Table 2.5 Population-based studies on epilepsy prognosis.

Country, year [ref.]	In remission (%)[a]	Years of remission	Follow-up (year)	Number followed	Age group	Comments
USA, 1979 [38]	65, 61	5	10	458	All	Incidence cohort, population based
	76, 70	5	20			
UK, 1995,97 [39,40]	86, 68	3	7	564	All	Incidence cohort, population based
	68, 54	5	7			
	82	3	7	397		SS and APS excluded
	62	5	7			SS and APS excluded
Finland, 1993 [42]	76	3	30	178	Child	Incident and prevalent
	74	5	30			
Sweden, 2001 [41]	64	3	10	107	Adults	Incidence cohort, population based, SS
	58	5	10			

APS, acute provoked afebrile seizures; SS, single seizures.
[a] First number refers to temporary remissions and second to terminal remissions.

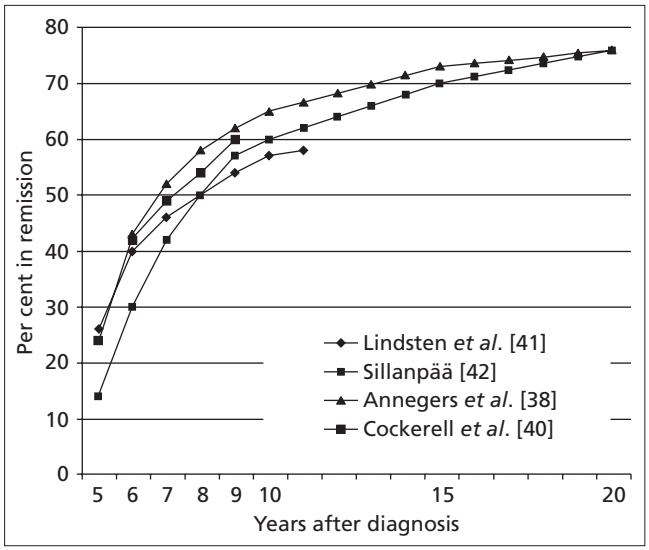

Fig. 2.2 Cumulative 5-year remission of epilepsy years after diagnosis. Population-based studies.

Time to enter remission

All studies on remission in newly diagnosed patients find that most patients enter seizure remission early, although one study has reported a waxing and waning of remission [44]. The longer patients continue to have seizures, the lower the probability for subsequent remission. Curves from studies depicting the relationship between remission and years after diagnosis have the same form with minor deviations (Fig. 2.2).

Initial seizure frequency

The seizure frequency during the first 6 months greatly affects the chance to achieve long-term remission. In the UK, 1-year remission by 6 years' follow-up was found in 95% of patients with up to two seizures during the first 6 months following diagnosis and in 75% of patients with 10 or more seizures during the same period [45]. The corresponding rates for 5-year remission by 6 years were 47% and 24%. In children, high initial seizure frequency also predicts the development of intractable epilepsy, defined as more than one seizure per month for at least 18 months, despite trials with at least three different AEDs during the first 2 years following diagnosis [43]. Only 12% of children achieved 1-year remission during a mean follow-up period of 38 months.

Predictors of seizure remission

Gender

Gender appears not to influence seizure prognosis [38,45].

Age at onset

Age at onset of epilepsy is not a significant predictor of remission. In Rochester, Minnesota, the proportion that achieved 10-year remission decreased with increasing age at onset [38]. Other studies found small or no effect [40].

Aetiology

Overall, idiopathic/cryptogenic epilepsy has a better prognosis than symptomatic epilepsy. Studies on aetiology as a potential predictor for seizure prognosis have used the term idiopathic/cryptogenic for cases with epilepsy of unknown cause. A study from Rochester, Minnesota, reported higher 5-year remission rates without medication for idiopathic/cryptogenic epilepsy (36% and 42% after 10 and 15 years, respectively) than in the remote symptomatic group (remission rates 19% and 30%) [38]. However, after 20 years, 5-year remission was slightly more frequent in the remote symptomatic group (54%) than in the idiopathic/cryptogenic group (47%), a change attributed to increased mortality in the remote symptomatic group leaving a subgroup with better prognosis. The difference was even larger at 20 years when all cases in remission (with and without medication) were included; 74% of the idiopathic/cryptogenic cases and 90% of the remote symptomatic cases were in remission for 5 or more years.

In a Finnish study of childhood-onset epilepsy, remote symptomatic aetiology was a predictor for seizure intractability [42].

Studies from the UK and Sweden did not find aetiology to be a significant predictor for remission, with more than 60% of both the idiopathic/cryptogenic and remote symptomatic groups achieving cumulative 5-year remission at 9 or 10 years' follow-up [39–41,45].

Co-morbidities

Mental retardation and cerebral palsy make up the vast majority of disorders in this group, with neurological dysfunction present since birth, often called the neurodeficit group or the group with early brain damage. This group has the worst prognosis for seizure remission. In Rochester, Minnesota, 5-year remission at 20 years was found in less than half (46%) of the study group; this was achieved without medication in only 15% and 30% at 10 and 20 years' follow-up, respectively [38]. In childhood-onset epilepsy the neurodeficit group also have less chance of achieving long-term seizure remission [42].

Specific aetiological factors

Stroke

Following stroke, acute symptomatic seizures (ASS) occur in 1.8% during the first 24 h [46] and in 4–6% during the first 1–2 weeks [47]. ASS should be classified as acute provoked seizures if they occur during the first week following stroke [1]. Most ASS, defined as acute provoked seizures that occur during the first week after the stroke, occur largely during the first 24 h in 78–87% of population-based studies [46,47].

By 5 years after a stroke, approximately 10–12% of patients will have seizures, either early, late or both [46,47]. Most patients with ASS do not go on to have late unprovoked seizures or epilepsy. At 5-year follow-up, 36% with ASS went on to have seizures whereas only 7% without ASS developed epilepsy [46]. Epilepsy is more common following a late seizure, found in almost 55–60% after ischaemic stroke. Early seizures do not predict 30-day mortality [46,47] when stroke severity has been accounted for. Status epilepticus occurs in one-quarter of stroke patients who have ASS [47].

The characteristics of the stroke affect the occurrence and prognosis of seizures. Haemorrhagic stroke more often results in seizures than ischaemic stroke. Population-based studies report ASS in 2–3% with ischaemic stroke, in 3–7% with haemorrhagic stroke and in 6–8% with subarachnoid haemorrhage (SAH) [46,47]. When ischaemic stroke patients were followed for 5 years the cumulative risk for seizures increased during the whole 5-year period and reached 10% [46]. After primary intracerebral haemorrhage and subarachnoid haemorrhage all seizures occurred by the third year, with a cumulative risk of 26% and 34%, respectively. ASS seizures as a result of stroke are mostly focal, but generalized seizures without obvious focal onset occur in one-quarter of patients [47] and were reported in 50% within 24 h of the onset of stroke [46].

Trauma

Seizures occur in 4–5% of patients with head trauma [48]. Late unprovoked seizures (late is defined as occurring more than 1 week after the insult) occur in 2% of patients: three-quarters of these will be recurrent, i.e. epilepsy [48]. Late seizures follow ASS in 10–15%, mostly in adults with moderate to severe head injury. In multivariate analysis, ASS do not predict late seizures [48].

The risk for seizures varies according to the severity of head trauma and time since head trauma. For all degrees of head trauma the elevated risk decreases with time. Mild head trauma (loss of consciousness or amnesia ≤30 min) results in a very minor increase for late seizures, which are only seen during the first 5 years following trauma [48]. Moderate head trauma (loss of consciousness or amnesia 30 min to 24 h, or skull fracture) causes a threefold increase in seizures compared with the general population during the first 10 years following trauma but not thereafter. Severe head trauma (loss of consciousness or amnesia >24 h, brain contusion or intracranial haematoma) increases risk 17-fold, and the increased risk persists beyond 10 years.

Central nervous system infections

Central nervous system (CNS) infections predispose to subsequent epilepsy that may appear many years later. In a population-based study of people with CNS infections followed up after an average of more than 10 years, ASS was observed in 19% [49], and by 20 years the cumulative risk for late unprovoked seizures was 7%. The majority, 58%, of late seizures occurred in patients with previous ASS. In 98% (all but one patient) late seizures were recurrent. Thus, prophylactic antiepileptic treatment is unwarranted in CNS infections and ASS, but should probably be started after a late unprovoked seizure.

Viral encephalitis with ASS carries the highest risk for later epilepsy, found in 10% by 5 years and 22% by 20 years' follow-up [49]. Without ASS, the cumulative risk of epilepsy after viral encephalitis is 10% by 20 years. The corresponding rates of epilepsy after bacterial meningitis are 13% with ASS and 2% without ASS, and 2% for aseptic meningitis at 20 years' follow-up. The low cumulative incidence of epilepsy following bacterial meningitis without ASS and following aseptic meningitis is no greater than expected in the general population [49].

Neurological deficits

Early brain damage causing neurodeficits is a strong predictor for long-term seizure prognosis. Studies have found neurological abnormalities to be associated with increased risk for persistent epilepsy. This has been substantiated in childhood-onset epilepsy [42] and in hospital-based studies of newly diagnosed cases.

Seizure type

By 20 years' follow-up, 5-year remission was found in 85% of patients with idiopathic/cryptogenic GTCS (50% off medication) and in 80% with absences, in Rochester, Minnesota [38]. A lower remission rate, of 65%, occurred in patients with complex partial seizures (CPS) (35% off medication) although the CPS figures may be low because of underascertainment of mild cases. At 20 years' follow-up, the highest remission rates, 77%, occurred in patients with generalized seizures and seizure onset before age 20 years. The lowest remission rate, 59%, was found in patients with PS and onset after age 20 years. In other studies seizure type was an inconsistent predictor for remission [40,41,43,45]. However, hospital-based studies on newly diagnosed cases have reported that multiple seizure types and partial seizures worsen long-term seizure prognosis.

Status epilepticus

In childhood-onset epilepsy followed for 30 years, status epilepticus (SE) is a predictor for not achieving remission [42]. Prior acute symptomatic or neonatal SE, but not unprovoked or febrile SE, predispose to the development of intractable epilepsy [43].

Electroencephalogram

The absence of generalized epileptiform activity on the first EEG was a significant predictor for cumulative 5-year remission (different analysis of data from reference 38). Whereas focal epileptiform activity and generalized non-epileptiform activity were not of prognostic value in children with epilepsy, focal slowing on the EEG was a predictor of intractable epilepsy [43].

Relapse after achieving remission

Relapse can occur despite achieving long-term remission, and a mean annual relapse incidence of 1.6% has been reported [38]. Relapse occurred in 8% during the first 5 years following 5-year remission and in 15% at 10 years after remission. By 20 years following remission almost one-quarter (24%) had relapsed. Relapse by 20 years is most frequent in patients with CPS (32%) and became more common with increasing age in this study. Relapses following 5-year remission occurred at diagnosis in 13% of patients aged 9 years or younger, in 22% of patients aged 10–19 years, and in 32% and 45% of patients aged 20–59 years and 60 years and above, respectively [38]. Recurrence of seizures is common when AEDs are discontinued, often necessitating treatment for several decades or lifelong [50].

Mortality

Measures of mortality

Mortality rate is the number of deaths during a specified period divided by the number of persons at risk of dying during the period. Studies on mortality rates in epilepsy often use death certificates to identify deaths related to epilepsy.

Mortality in epilepsy is often expressed as the ratio between the observed and expected numbers of death – the standardized mortality ratio (SMR). Expected deaths are calculated by applying the death rates of a reference population to the age distribution of to the study population. When there is no difference in mortality between the study and reference population the SMR is 1; a 95% CI that includes 1 indicates that the SMR is not statistically significant. The SMR cannot be compared between studies when age distributions and age- and sex-specific death rates differ.

Case fatality is the proportion of the cohort with epilepsy that dies over a specified time period: it is expressed as a percentage.

Overall mortality in population-based studies

Population-based studies of mortality in cohorts with newly diagnosed unprovoked seizures or epilepsy are shown in Table 2.6. Most studies included persons who presented with incident single unprovoked seizure [51–55]. SMRs in population-based studies vary from 1.6 to 4.1 (Table 2.6), which means that in unselected epilepsy populations the excess mortality is 60% to 310% of that in the control population without epilepsy.

Table 2.6 Standardized mortality ratios in population-based studies of epilepsy, by aetiology.

Country, year [ref.]	All (95% CI)	Idiopathic[a]	Aetiology	
			Remote symptomatic	Neurodeficit
USA, 1980 [51]	2.3 (1.9–2.6)	1.8 (1.4–2.3)	2.2 (1.8–2.7)	11.0 (6.9–16.4)

France, 1999 [54]	4.1 (2.5–6.2)	1.5 (0.4–3.9)[b]	6.5 (3.8–10.5)	–
Sweden, 2000 [55]	2.5 (1.6–3.8)	1.1 (0.5–2.4)	3.3 (2.4–4.5)	–
Range (SMR)	1.6–4.1	1.1–1.8	2.2–6.5	–

SMR, standardized mortality ratios.

[a] Includes cryptogenic.

[b] Includes all cases with seizures of unknown aetiology: idiopathic and cryptogenic.

Overall mortality in selected epilepsy populations

Mortality has also been studied in selected epilepsy populations, such as those with cancer, but the impact of selection bias results in a tendency to overestimate mortality in these studies. Generally, the SMRs in these selected populations are higher than in the general population and this may be partly because selected epilepsy populations contain more people with severe epilepsy than unselected general epilepsy populations.

Epilepsy mortality in less developed countries

No studies have specifically investigated mortality in epilepsy populations from less developed countries because standardized population mortality rates are less available for comparison. Case series in some countries, however, show that falls, burns, SE and drowning are the most common causes of death in these epilepsy populations. In Ethiopia, 20 patients out of 316 in a prevalence population with epilepsy died during an observation period of 2 years, with 45% of the deaths being seizure related, mainly SE [15]. The crude annual death rate was doubled in the epilepsy population compared with the general population of the study area [26].

Mortality by aetiology

In population-based studies, the mortality is lower in the idiopathic/cryptogenic group than in the remote symptomatic group (static encephalopathy) (Table 2.6). Most studies report little or no increase in mortality in the idiopathic/cryptogenic group [52–55]. In the remote symptomatic group mortality was two to six times greater than in the general population. The group with neurodeficits carries the highest mortality with SMRs of between 11 and 25 [51,52].

Mortality by age and gender

The majority of studies [51,53,55] report higher mortality in males than in females with epilepsy. Age is another factor

affecting the relative mortality. The relative mortality of epilepsy populations compared with reference populations is higher at all ages. Most studies have found an inverse relation between SMR and age. The highest SMRs are found in children, and decreasing SMRs are found with increasing age [51]. The high SMR in children and young adults with epilepsy is partly a reflection of two factors, the low mortality in the reference population and the high mortality in children with epilepsy and neurodeficits [51].

Although the highest SMRs are found in children, the highest excess mortality is found in the elderly. In the Rochester, Minnesota, study [51], the lowest excess mortality due to epilepsy, 6:1000, was found in children, in whom the SMR is highest [51]. The highest excess mortality, 47:1000, or eight times higher than in children, was found in the oldest age group, 75 years and older [51]. In Iceland, 81% of the study population had idiopathic/cryptogenic epilepsy. When mortality was analysed by age at onset of epilepsy, no increase in mortality was found in any age group with idiopathic/cryptogenic epilepsy [53].

Mortality by duration of epilepsy

The increase in mortality is most marked during the initial years following diagnosis [51–55] because of progressive pathologies. However, in longstanding epilepsy, mortality remains higher than that in the general population supporting the assumption that other determinants besides aetiology contribute to mortality. Seizure frequency and seizure severity could be some of these factors.

Mortality by seizure type

Generalized tonic–clonic seizures

A significantly increased mortality was reported from the USA for idiopathic/cryptogenic generalized tonic–clonic seizures (GTCS), with SMRs of 3.5 and 2.4 at 5 and 30 years, respectively, following diagnosis [51]. In Iceland, mortality was not increased in patients with idiopathic/cryptogenic GTCS without generalized spike–wave activity on the EEG (SMR 1.0) [53]. The use of EEG criteria in the Icelandic study excluded a large portion of the primary GTCS from the idiopathic/cryptogenic GTCS group. In Swedish males, with GTCS following either idiopathic/cryptogenic or remote symptomatic epilepsy, there was a statistically significant risk for death (SMR 3.9, 95% CI 2.3–6.8) [55]. Rates for GTCS in the cited studies are not fully similar owing to differences in inclusion [51,53,55].

Partial seizure with or without secondary generalization

Data regarding the relationship between partial seizure (PS) and mortality rates have been inconsistent. In some studies mortality was not significantly increased in patients with complex PS with or without generalization or in idiopathic/cryptogenic cases with PS (all types combined) [51,53]. However, one study reported increased mortality in PS in both males and females (SMR 2.1, 95% CI 1.2–3.6) [55].

Other seizure types

A significantly increased mortality was reported for myoclonic seizures (SMR 4.1), whereas no deaths were observed in patients with absence seizures with or without GTCS [51].

Table 2.7 Causes of death in epilepsy: proportionate mortality ratio (%).

Cause of death	Study		
	USA [51]	UK [52]	France [54][a]
Cerebrovascular	14	12	17
Heart disease	19	8	
Neoplasm, all	20	26	
Brain tumours	8	9	53
Pneumonia	8	14	
Suicide	1.6	0.5	
Accidents	6		
Seizure related	6	3	
SUDEP[b]		0.5	
Other	25	16	30

SUDEP, sudden unexpected death in epilepsy.

[a] Unprovoked seizures + progressive symptomatic.

Cause-specific mortality

Population-based studies with a control population

Population-based studies have found that persons with epilepsy have a significantly increased mortality due to cerebrovascular disease, SMR 2.6–4.2, neoplastic disorders, SMR 2.9–4.8 [51,52,55], and pneumonia, SMR 3.5–10.3 [51,52] (Table 2.7). The increased risk for death from neoplasm remained after exclusion of brain tumours [51,52]. An increased mortality due to accidents and non-heart/cerebrovascular circulatory disorders has also been reported [51]. Suicide is very uncommon in population-based studies of epilepsies [51,52,55].

Epilepsy and seizure-related mortality

Seizure-related death comprises death during SE, accidents and drowning caused by seizures and sudden unexpected death in epilepsy (SUDEP). Suicide in persons with epilepsy is sometimes categorized as epilepsy related.

The pathophysiological mechanisms in SUDEP are presently unknown but believed to be seizure related. Rates of SUDEP vary between different epilepsy populations, from 0.35 per 1000 person-years in an unselected population-based study [56], to around 1 per 1000 person-years in fairly unselected epilepsy populations [57–59], but are higher in more selected populations drawn from hospital series, and 10-fold the population rates annually in patients referred to epilepsy surgery or with continued seizures following surgery. In the only population-based study of SUDEP, 1.7% of all deaths in the epilepsy cohort and 8.6% of deaths in the 15–44 years group were due to SUDEP [56]. Between the ages of 20 and 40 years, SUDEP exceeded the expected rate of sudden death in the general population by nearly 24 times.

A study of childhood-onset epilepsy in Australia reported 22% of deaths to be seizure related [60], higher than other incidence cohorts, in which 0.9–5.5% of deaths were seizure related [51,52]. In prevalent epilepsy and mental retardation, seizure-related deaths are also rare, despite higher mortality noted generally in patients with frequent severe seizures. This may indicate that seizure frequency/severity in patients with neurodeficits in most

cases represent markers of the severity of the underlying aetiology that contribute to mortality, and less often are directly responsible for death.

Overall, it is reasonable to conclude that epilepsy doubles or triples mortality in people with epilepsy, mainly owing to the underlying causes of epilepsy and less often as a direct result of seizures. Thus, the potential to reduce mortality in epilepsy through reduction or elimination of seizures may be limited in the general epilepsy population but substantial in adolescents and younger adults with intractable epilepsy in whom SUDEP most often occurs [56].

There is no ready explanation for the late rise in mortality found in the Rochester, Minnesota, study 25–29 years after onset of epilepsy [51]. It may be seizure related, due to underlying diseases, due to late effects of antiepileptic treatment, or due to a combination of these and other factors. The increased mortality observed during the first 5 years following remission of seizures also indicates the contribution of non-seizure-related factors to mortality in epilepsy [51].

Mortality trends over time

During the last century a major improvement in the standard of living and availability of medical care has taken place. Although one would anticipate that this has decreased mortality in epilepsy, it is difficult to know for certain because of the lack of reliable data on epilepsy mortality over time. Studies evaluating trends in epilepsy mortality are based on death certificates, causing the methodological problems discussed above.

The annual mortality rates for epilepsy declined from the 1950s to the 1970s [61]. A study of epilepsy mortality in the UK and the USA for 1959–94 found similar secular trends for both countries and for both sexes [62]. Epilepsy mortality declined profoundly after 1950 among people younger than age 20 years. A less marked decline was found in adults while mortality in the elderly declined between 1959 and 1974 but then increased. A marked birth cohort effect was found, with a fall with each successive birth cohort indicating that aetiological risk factors varied by generation [62]. The birth cohort effect could be due to a decrease in incidence in epilepsy which, as mentioned earlier, has been found for childhood epilepsy. The increase in mortality during the last decades in the elderly with epilepsy could be an effect of the high incidence of epilepsy in the elderly, which almost doubled during a 50-year interval (see section on epidemiological time trends).

Life expectancy

The higher mortality rates in people with epilepsy are reflected in reduced life expectancies. In the UK, life expectancy was found to be reduced by up to 2 years for people with idiopathic/cryptogenic epilepsy, and by up to 10 years in people with symptomatic epilepsy [63]. Reductions were highest at the time of diagnosis and diminished with time.

Prognosis in largely untreated populations

If epilepsy were a truly chronic condition without increased mortality or remission, the prevalence rate of active epilepsy would be similar to the cumulative incidence rate, but in fact it is much lower. To what extent can this discrepancy be explained by increased mortality and by seizure remission? It is known that mortality is increased in epilepsy, both in more and in less developed countries. The relative mortality may be similar in developed and developing countries, reflecting a two- to threefold increase. However, the highest mortality of general populations is found in less developed countries, and multiplying that mortality two to three times means that the annual mortality is much higher in epilepsy populations of less developed countries than in epilepsy populations elsewhere. A large proportion, probably the majority, of untreated people with epilepsy anywhere in the world are no longer counted as having epilepsy not because of death but because seizures remit spontaneously. Studies of largely untreated populations with longstanding epilepsy in developing countries indicate that the duration of epilepsy before treatment does not seem to affect the likelihood of remission [64].

3 Aetiology of Epilepsy

Simon D. Shorvon
UCL Institute of Neurology, University College London, London, UK

Epilepsy is often multifactorial [1]. Even in the presence of a major aetiology, other factors (genetic and environmental) can play a part in its clinical manifestations. Lennox recognized this in 1960 [2] with his picturesque analogy of *the river* (Fig. 3.1). He also used the analogy of a reservoir in which the

> Causes may be represented as the sources of a reservoir. At the bottom is the already present volume of water, which represents the person's predisposition, a fundamental cause. But the reservoir is supplied also by streams which represent the contributory conditions, such as lesions of the brain acquired since conception, certain disorders of bodily function and emotional disturbances.

It is usual to differentiate the aetiology of epilepsy from factors that contribute to seizure precipitation in patients who already present with the propensity to epilepsy. Here, this convention will be maintained, albeit recognizing that this is a relative not absolute distinction.

The range of aetiology varies in different age groups, patient groups, and geographic locations. Broadly speaking, congenital and perinatal conditions are the most common causes of early childhood-onset epilepsy, whereas in adult life epilepsy is more likely to be a result of external non-genetic causes, but this distinction is by no means absolute. In late adult life, vascular disease is increasingly common. In certain parts of the world, endemic infections are common causes – including tuberculosis (TB), cysticercosis, human immunodeficiency virus (HIV) and viral diseases. The specific 'epilepsy syndromes' are also highly age dependent. The approximate frequencies of different aetiologies in a typical Western population are shown in Table 3.1.

Epilepsy as a result of genetic or developmental causes

Heredity plays a very important role in the production of epilepsy, but mechanisms are complex. Gene expression can be variable and influenced by environmental factors, and the epilepsies are often also age dependent. Single-gene disorders probably underlie only 1–2% of all epilepsies, and usually in these conditions there are additional neurological or systemic features. It is useful to consider the 'pure' epilepsies separately from the epilepsies associated with other neurological defects, although this distinction, like most in medicine, is somewhat artificial and transitional cases occur in a grey area between categories. Epilepsies as a result of some developmental anomalies have genetic and acquired forms but are included here for the sake of convenience.

Pure epilepsies as a result of single-gene disorders

Pure epilepsies resulting from single-gene disorders are generally rare conditions, described in families (sometimes single families), but are potentially important for the mechanistic light they may throw on the more common polygenic epilepsies. Interestingly, almost all of the genes identified that contribute to susceptibility to epilepsy are genes that code for ion channels [3] (Table 3.2) [3,4]. In this sense, epilepsy has been recognized in recent years to be one of a burgeoning group of neurological disorders with intermittent symptoms, which have underlying ion channel genetic defects.

Benign familial neonatal convulsions

The syndrome of benign familial neonatal convulsions is a condition that is inherited in an autosomal dominant fashion and is due to mutations of voltage-gated potassium channel genes *KCNQ2* and *KCNQ3* [5]. The abnormalities of these genes result in reduced potassium conductance and hence enhanced neuronal excitability. Why the effects are restricted to the first few weeks of life is unclear. One plausible hypothesis is that the mutated channels are replaced by other potassium channels that are up-regulated early in life.

Autosomal dominant nocturnal frontal lobe epilepsy

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) was the first 'pure epilepsy' in which the causal gene was found [6,7]. Various mutations in the α_4- and β_2-subunits of the nicotinic acetylcholine receptor have been identified in families with this interesting condition. There is often a strong family history and, when investigated, even apparently unaffected members in a family can have subtle nocturnal events, mistaken as simply restlessness or normal sleep phenomena.

Generalized epilepsy with febrile seizures

Generalized epilepsy with febrile seizures plus (GEFS+) is a heterogeneous form of epilepsy inherited in an autosomal dominant fashion, with age-specific manifestations and variable penetrance (penetrance of about 60% was found in the original families) [8,9]. Many different mutations have been described in either the α- or β-subunits of the voltage-gated sodium channel genes *SCNIA* and *SCNIB*, and more recently the γ2-subunit of the $GABA_A$ receptor *GABRG2* gene in families from many places in the world. Functional studies have confirmed that these mutations confer abnormal membrane excitability.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

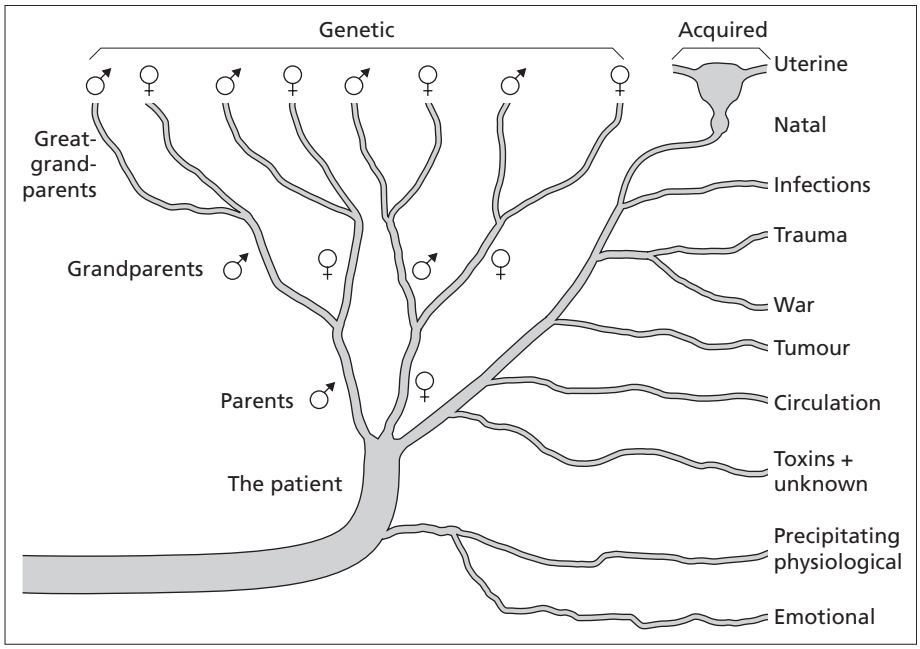

Fig. 3.1 The multifactorial nature of epilepsy was illustrated by Lennox as the analogy of a river in which many different streams (causes) contribute to the occurrence of a seizure.

Table 3.1 Approximate frequency of different causes of epilepsy in a general Western population.

Cause	Approximate frequency (%)
Idiopathic (probably oligogenic)	10–30
Vascular	10–20
Congenital	5–10
Neurodegenerative/other neurological disorder	5–10
Hippocampal sclerosis	5–10
Brain tumour	5–10
Trauma	5
Childhood epilepsy syndrome	5
Infectious metabolic, toxic causes	5
Single-gene disorder	1–2
Unknown cause (cryptogenic epilepsy)	30

Dravet's syndrome

Dravet's syndrome [severe myoclonic epilepsy of infancy (SMEI)] is a severe form of epilepsy in which many (but not all) patients have mutations in the *SCNIA* gene, the same gene that causes the more benign GEFS+, and indeed there are families in which both phenotypes coexist [10]. Furthermore, despite the frequency of a family history, curiously, the mutations are in the vast majority of cases *de novo*.

Other single-gene 'pure epilepsy' syndromes

A rag-bag of other single-gene epilepsy syndromes have been described, in either single or a few families, and include [11]: familial adult myoclonic epilepsy (in a few families from Japan), familial autosomal recessive idiopathic myoclonic epilepsy of infancy (in an Italian family), X-linked infantile spasms, benign familial infantile convulsions, familial partial epilepsy with variable foci (linked to 22q), autosomal dominant epilepsy with auditory features (linked to 10q), familial temporal lobe epilepsies, and autosomal recessive rolandic epilepsy with paroxysmal exercise-induced dystonia and writer's cramp. Autosomal dominant rolandic epilepsy with speech dyspraxia (ADRESD) is a rare condition with an unknown genetic basis but which exhibits anticipation, suggesting that it may be a triplet repeat syndrome.

Pure epilepsies with complex (presumed polygenic) inheritance

Pure epilepsies with complex inheritance are far more common than the single-gene epilepsies. Categories of idiopathic and cryptogenic epilepsy, both focal and generalized, exist with a strong presumption of a polygenic genetic basis (i.e. with complex inheritance, which does not follow simple mendelian rules). These conditions are divided into the idiopathic generalized epilepsies (IGE) and the benign partial epilepsies of childhood, and have been the subject of intensive genetic study, but to date no common susceptibility genes have been identified [12].

The extent to which other cryptogenic epilepsies have a genetic basis is less clear (e.g. febrile convulsions, cryptogenic West syndrome and cryptogenic Lennox–Gastaut syndrome). The conditions are probably best conceptualized as polygenic disorders in which the phenotype is the result of interactions between susceptibility genes and environmental effects. There is often no strong family history, and genetic studies have to be conducted using case–control methodology in large populations. The phenotypes are wide, and the susceptibility genes may also have a widely varying polymorphism. In this context, the concept of epilepsy syndromes as discrete entities that are clinically homogeneous and biologically distinct cannot be sensibly sustained. More attractive is the concept of the neurobiological continuum, in which there are widely varying phenotypes with similar genetic defects and also overlapping phenotypes caused by differing gene abnormalities. To confuse the picture further, many of these phenotypes can result from a range of identifiable acquired and congenital brain disorders (symptomatic cases). In this sense, the epilepsy

Table 3.2 Single genes found to be the cause of pure epilepsy.

Human epilepsy	Affected gene	Affected current	Effect on the current	Main functional mechanism
BFNC	*KCNQ2, KCNQ3*	M-current	Loss of function	Decreased expression or modifications of gating kinetics that reduce K^+ M-current induced hyperpolarization
Focal familial seizures and myokymia	*KCNA1*	Delayed rectifier	Loss of function	Decreased delayed rectifier K^+ current by various mechanisms
Generalized epilepsy and paroxysmal dyskinesia	*KCNMA1*	I_{KCa}, (BK)	Gain of function	Enhanced Ca^{2+} sensitivity (cell hyperexcitability may be caused by rapid action potential repolarization and enhanced recurrent firing)
BFNIC	*SCN2A*	I_{Na}	Gain of function	Increase of current by various modifications of voltage dependence of gating
GEFS+ type 1	*SCN1B*	I_{Na}	Gain of function	Variable according to the expression system, often loss of modulation of I_{NaT} inactivation
GEFS+ type 2	*SCN1A*	I_{Na}	Gain or loss of function	Variable according to the mutation, expression system, and complementary DNA used Slowed time course of I_{NaT} inactivation and faster recovery from inactivation Decreased use-dependent inactivation Enhanced I_{NaP} fraction and decreased fast inactivation of I_{NaT} Hyperpolarizing shift of both I_{NaT} activation and inactivation causing a hyperpolarizing shift of window current Reduced current and enhanced recovery from slow I_{NaT} inactivation Depolarizing shift of I_{NaT} steady-state inactivation because of altered interaction with β1 subunit
SMEI	*SCN1A*	I_{Na}	Gain or less of function	No current Enhanced I_{NaP} fraction
ICEGTC	*SCN1A*	I_{Na}	Gain or loss of function	No current Various effects on gating properties according to the mutation
FS	*SCN1A*	I_{Na}	Loss of function	Decreased current, pocitive shift voltage dependence of activation
Absence epilepsy and episodic ataxia	*CACNA1A*	I_{Ca} (P/Q)	Loss of function	Decreased P/Q Ca^{2+} current by reduced membrane targeting
CAE	*CACNA1H*	I_{Ca} (T)	Gain or loss of function	Various effects on gating properties of T-type Ca^{2+} channels
IGE and episodic ataxia	*CACNB4*	I_{Ca}	Gain of function	Decrease in the fast inactivation time constant when co-expressed with α subunit
IGE with absences and convulsions	*CLCN2*	I_{Cl}	Loss of function	Complete loss of function causing decreased transmenbrane Cl gradient (and GABA inhibition) Changes in voltage-dependent gating (membrane depolarization?)
GEFS+ type 3	*GABRG2*	I_{GABA}	Loss of function	Decreased current amplitude by reduced membrane targeting and receptor assembly
CAE and FS	*GABRG2*	I_{GABA}	Loss of function	Loss of benzodiazepine sensitivity
JME	*GABRA1*	I_{GABA}	Loss of function	Reduced GABA sensitivity and altered channel gating
ADNFLE type 1	*CHRNA4*	nAChR	Loss of function	Various effects
ADNFLE type 3	*CHRNB2*	nAChR	Gain of function	Slower desensitization Increase in acerylcholine sensitivity

BFNC, benign familial neonatal convulsions; BFNIC, benign familial neonatal–infantile convulsions; I_{Na}, sodium current; GEFS+, generalized epilepsy with febrile seizure plus; I_{NaT}, transient sodium current; I_{NaP}, persistent sodium current; SMEI, severe myoclonic epilepsy in infancy; ICEGTC, intractable childhood epilepsy with generalized tonic–clonic seizures (a disorder similar to SMEI); FS, febrile seizures; CAE, childhood absence epilepsy; IGE, idiopathic generalized epilepsy; JME, juvenile myoclonic epilepsy; ADNFLE, autosomal dominant nocturnal frontal lobe epilepsy; nAChR, nicotinic acetylcholine receptor.

syndrome can be thought of as a genetically determined end-point response of dysfunctional brain tissue to an acquired insult.

Epilepsies in other single-gene disorders

At least 240 single-gene and chromosomal disorders result in neurological disorders in which epilepsy is part of the phenotype. Most are rare or very rare, manifest initially in childhood and present for diagnosis to paediatric neurological services rather than to an epilepsy specialist. In only a few of these conditions does epilepsy have distinctive features or is a predominant or consistent feature: exceptions are the progressive myoclonus epilepsies and some neurocutaneous syndromes. Conditions associated with epilepsy are shown in Table 3.3.

Table 3.3 Risk for epilepsy in genetic disorders.

Category	No increase in risk	Slight increase in risk (5–20%)	High risk (>20%)
Chromosome disorders	Cri-du-chat syndrome Sex chromosome disorders	Trisomy 21 syndrome Other chromosome anomalies	Fragile X syndrome Trisomy 13 syndrome Trisomy 18 syndrome Wolf–Hirschhorn syndrome
Contiguous gene disorders		Prader–Willi syndrome	Angelman's syndrome Miller–Dieker syndrome
Metabolic disorders	Endocrine disorders Exocrine disorders Glycogen storage disease Mucopolysaccharidoses	Acute intermittent porphyria Leukodystrophies	Amino acid disorders Glycogen storage disorders Homocystinuria Krabbe's disease Leigh's syndrome Menkes' disease Mitochondrial disorders Organic acidurias Peroxisomal disorders Pyridoxine-dependent seizures
Genetic syndromes			
Short stature	Bloom's syndrome Cockayne's syndrome Dubowitz's syndrome Hallermann–Streiff syndrome Noonan's syndrome	Brachmann–de Lange syndrome Robinow's syndrome Rubinstein–Taybi syndrome Smith–Lemli–Opitz syndrome Xeroderma pigmentosum (de Sanctis–Cacchione variant)	
Early overgrowth	Marshall–Smith syndrome Smith–Golabi–Behmel syndrome Sotos' syndrome Weaver's syndrome	Bannayan–Riley–Ruvalcaba syndrome Beckwith–Wiedemann syndrome Cohen's syndrome	Borjeson–Forssman–Lehmann syndrome
Skeletal dysplasias	Achondroplasia Apert's syndrome Metaphyseal dysplasias Osteochondrodysplasias Osteopetrosis Saethre–Chotzen syndrome	Albright's osteodystrophy Crouzon's syndrome Hypophosphatasia Pfeiffer's syndrome	Christian's syndrome
Facial defects	Moebius sequence Oculo-auriculo-vertebral syndromes Treacher Collins syndrome Other branchial arch syndromes	FG syndrome Langer–Giedion syndrome Progressive hemifacial atrophy	Acrocallosal syndrome Cardiofaciocutaneous syndrome Coffin–Lowry syndrome
Connective tissue disorders	All except homocystinuria		
Neurocutaneous disorders	Neurofibromatosis-2	Neurofibromatosis-1	Encephalocraniocutaneous lipomatosis Epidermal naevus Hemimegalencephaly Incontinentia pigmenti Sturge–Weber syndrome Tuberous sclerosis
Ectodermal/mesodermal dysplasias	All disorders		
Disorders of brain development	Posterior fossa disorders		Agenesis of corpus callosum syndromes Holoprosencephaly Lissencephaly Other disorders of neuroproliferation, migration and connectivity
Neurodegenerative disorders	Ataxias Parkinson's disease and variants	Alzheimer's disease Hallervorden–Spatz disease Wilson's disease	Ceroid lipofuscinosis Dentato-rubro-pallido-luysian atrophy (myoclonus epilepsy form) Juvenile-onset Huntington's disease Neuroacanthocytosis Rett's syndrome

From ref. 142, with permission.

The *inborn errors of metabolism* are conditions in which biochemical defects are inherited, usually in an autosomal recessive fashion, and in which the epilepsy is one symptom within a much broader spectrum of learning disability, neurological and systemic features [13]. These include conditions with intermittent or persistent metabolic changes, including hypoglycaemia, hyperammonaemia, hypocalcaemia, hyperglycinaemia, metabolic acidosis, ketoacidosis, abnormal amino acid or oligosaccharide profile, mucopolysaccharidoses and lipid storage diseases. Epilepsy is particularly found in Angelman's syndrome [14], Tay–Sachs disease, Niemann–Pick disease type C, Krabbe's disease, amino acid disorders and glycogen storage disorders. In a substantial number of cases presenting with epilepsy and learning disability, on a congenital basis, no cause can be identified. Porphyria is another important cause with geographical variation [15].

Progressive myoclonic epilepsy (PME)

Progressive myoclonic epilepsy (PME) has a rather specific phenotype, which can be caused by a variety of genetically determined neurological disorders (Table 3.4). In most parts of the world, there are six leading underlying conditions: mitochondrial disorders, Unverricht–Lundborg disease, dentato-rubro-pallido-luysian atrophy (DRPLA), Lafora body disease, neuronal ceroid lipofuscinosis (NCL) and sialidosis.

Baltic myoclonus (Unverricht–Lundborg disease)

Baltic myoclonus is the most benign form of progressive myoclonic epilepsy. It is an autosomal recessive disorder due to mutations in the *EPM1* gene coding for the cystatin B protein, a protease inhibitor. The most common mutation is an unstable expansion of a dodecamer repeat. Diagnosis can be made by genetic testing [16,17].

Table 3.4 Causes of progressive myoclonic epilepsy (PME).

Most common causes
Baltic myoclonus (Unverricht–Lundborg disease)
Ceroid lipofuscinoses
Dentato-rubro-pallido-luysian atrophy (DRPLA)
Lafora body disease
MERRF, mitochondrial disease
Sialidoses
Rarer causes
Alpers' disease
Alzheimer's disease
Biotin-responsive progressive myoclonus
Coeliac disease
Gaucher's disease
GM2 gangliosidosis (juvenile type)
Hexosaminidase deficiency
Huntington's disease
Juvenile neuroaxonal dystrophy
Menkes' disease
Non-ketotic hyperglycinaemia
Phenylketonuria
Tetrahydrobiopterin deficiencies
(In some patients, no cause can be identified)

From ref. 1, with permission.

Dentato-rubro-pallido-luysian atrophy

Dentato-rubro-pallido-luysian atrophy is inherited in an autosomal dominant fashion. It occurs with markedly varying frequency around the world, being particularly common in Japan (a frequency of 0.2–0.7 per 100 000 persons) and in northern Europe. It is a triplet repeat disorder involving the *DRPLA* gene which is of uncertain function. The normal repeat number is between 6 and 35 and the condition is present with full penetrance when the repeat number is greater than 48. The diagnosis of DRPLA rests on positive family history, the characteristic clinical findings, and the detection of an expansion of a CAG/polyglutamine tract in the *DRPLA* gene. The CAG repeat length in individuals with DRPLA ranges from 48 to 93 base units. Molecular genetic testing is widely available. Diffuse high-intensity areas deep in the white matter are often observed on T2-weighted MRI in individuals with adult-onset DRPLA of long duration.

Lafora body disease

Lafora body disease, an autosomal recessive condition mostly reported from southern Europe, is characterized by the presence of Lafora bodies, which are periodic acid–Schiff (PAS)-positive intracellular polyglucosan inclusions found in neurones, sweat glands and a variety of other sites. A mutation in the *EPM2A* gene on chromosome 6q24, which codes for a putative protein tyrosine phosphatase gene, is sometimes responsible. Fourteen different mutations in 24 families are now known. The diagnosis can be confirmed by histological examination of skin (which should include eccrine glands), liver or muscle biopsy material, but genetic testing has now rendered this largely unnecessary [18].

Mitochondrial cytopathy

Mitochondrial cytopathy [myoclonic epilepsy with ragged red fibres (MERRF)] is caused by a range of point mutations or deletions of mitochondrial DNA, or nuclear genes linked to mitochondrial function, which result in dysfunction of the mitochondrial respiratory chain [19–21]. On the inner mitochondrial membrane there are over 70 different polypeptides that form the respiratory chain and 13 of these polypeptides are encoded by mitochondrial DNA; defects have been described in all of these. Two classic phenotypes [MERFF and mitochondrial encephalopathy with lactic acidaemia and stroke (MELAS)] occur, in which seizures are a common and important symptom, although intermediate and transitional cases are not uncommon. In a third mitochondrial disorder, the Leigh syndrome and neuropathy, ataxia and retinitis pigmentosa (NARP) continuum, seizures are also common but not a predominant feature. Alpers' disease has now been found to be due to a mitochondrial defect, inherited by nuclear DNA mutations. The diagnosis of MERRF is made by the findings of ragged red fibres on muscle biopsy in 80% of cases, and biochemical analysis will show decreased activity in respiratory chain enzymes. MRI may show atrophy, T2 signal change and also basal ganglia calcification. In 90% of cases, the genetic defect is an A→G transition at nucleotide 8344 in the $tRNA^{lys}$ gene of mtDNA, and some other cases are caused by *T8356C* or *G8363A* mutations. Genetic testing is available. Heteroplasmy is responsible for some of the phenotypic variation and can complicate genetic diagnosis.

Neuronal ceroid lipofuscinosis

The NCLs are a group of inherited lysosomal storage disorders that may present with progressive myoclonic epilepsy, and mental and motor deterioration [22]. These are the commonest of the hereditary progressive neurodegenerative diseases, occurring generally in about 1:25 000 live births, but with marked geographic variation with a particularly high frequency in Finland. The phenotypes are categorized by age of onset: infantile neuronal ceroid lipofuscinosis (INCL), late-infantile (LINCL), juvenile (JNCL), adult (ANCL) and northern epilepsy (NE). Myoclonic epilepsy is a feature of all types. Almost all cases are inherited in an autosomal recessive manner although an autosomal dominant form of adult-onset NCL has been described. Carriers show no symptoms. The diagnosis of a NCL is based on clinical findings, electron microscopy of biopsied tissues, and, in some instances, assay of enzyme activity or enzyme levels, and molecular genetic testing. Causative mutations in a variety of genes (NCL and MFSD8 genes) have been identified, which vary geographically. MRI shows atrophy and sometimes T2 hyperintensity, and visually evoked responses (VEPs) and electroretinogram (ERG) responses are abnormal. White cells are vacuolated. Electron microscopy of white blood cells, skin, conjunctiva, or other tissues typically reveals lysosomal storage material manifest as fingerprint, curvilinear profiles, or granular osmophilic deposits. The levels of enzyme products of each of the six genes can also be assayed. There are six causative genes – *PPT1*, *CLN2*, *CLN3*, *CLN5*, *CLN6* and *CLN8* – and over 140 mutations described. There is a marked geographic variation in the genetic abnormalities, with *CLN8* abnormalities for instance found only in Finland. Genetic testing, and also prenatal testing, for each is available.

Sialidosis

Sialidosis is less common than the other causes of progressive myoclonic epilepsy. There are at least two variants [23]. All cases are inherited in an autosomal recessive manner. Type 1 sialidosis (cherry-red spot myoclonus syndrome) is due to *N*-acetyl neuraminidase deficiency: a gene has been mapped to chromosome 6p21.3. In Type 2 sialidosis (also known as galactosidase), there are defects in β-galactosidase activity in addition to those in *N*-acetyl neuraminidase. One gene has been mapped to chromosome 20. The genetic basis of this disorder is complex and not completely elucidated, and involves both the gene for Neu-1 and the gene for cathepsin A, which forms a complex with Neu-1. Diagnosis is confirmed by finding elevated urinary sialyloligosaccharides and by assaying enzyme activity in leucocytes and cultured skin fibroblasts.

Epilepsies in neurocutaneous syndromes

The so-called neurocutaneous conditions often result in epilepsy [24,25]. Tuberous sclerosis complex, Sturge–Weber syndrome and neurofibromatosis (type 1) are the most important, and are not uncommonly encountered in epilepsy clinics. Other rare conditions causing epilepsy include hypomelanosis of Ito, epidermal naevus syndrome, hereditary haemorrhagic telangiectasia, midline linear naevus syndrome, incontinentia pigmenti and Klippel–Trenaunay–Weber syndrome.

Tuberous sclerosis

Tuberous sclerosis (synonym: tuberous sclerosis complex, TSC) is a common and important cause of epilepsy [26,27]. The incidence may be as high as 1:5800 live births and there is a high spontaneous mutation rate (1:25 000). It is inherited in an autosomal dominant fashion and is usually caused by mutations of the *TSC1 or TSC2* genes: both are tumour suppressor genes. There is no obvious phenotypic difference between individuals with mutations in either gene. To date, about 300 unique *TSC1* or *TSC2* mutations have been identified in nearly 400 separate patients/families. The mutations are primarily small deletions, insertions or nonsense mutations; in contrast, *TSC2* mutations also include significant numbers of missense mutations, large deletions and rearrangements. Between 60% and 80% of patients with TSC enrolled in research studies have an identifiable *TSC1* or *TSC2* mutation. The condition is a form of cortical dysplasia, and the histological appearances of the tumours show similar features to other forms of focal cortical dysplasia. There is considerable clinical variability in the manifestations of tuberous sclerosis, and the extent to which some other forms of cortical dysplasia represent *form fruste* cases will no doubt be established by modern genetic studies. Molecular genetic testing for diagnostic confirmation and prenatal testing of the *TSC1* and *TSC2* genes is available but complicated by the large size of the two genes, the large number of disease-causing mutations and the high rate of somatic mosaicism (10–25%).

Neurofibromatosis (type 1)

Neurofibromatosis type 1 (NF1) is a common dominantly inherited genetic disorder, occurring in about 1:3000 live births. Almost one-half of all cases are new mutations. The mutation rate for the *NF1* gene is about 1:10 000, among the highest known for any human gene. It is a large gene, and many different mutations have resulted in the clinical manifestations. Although the penetrance is essentially complete, the clinical manifestations are extremely variable. In NF1, the incidence of epilepsy is about 5–10% [28]. Genetic counselling and testing is available but it is complex and needs to be carried out by those who have experience of the condition.

Sturge–Weber syndrome

Sturge–Weber syndrome is an uncommon sporadic developmental disorder of uncertain causation. The principal clinical features are a unilateral or bilateral port wine naevus, epilepsy, hemiparesis, mental impairment and ocular signs. This is a highly characteristic clinical constellation, and diagnosis is clinically based. Severe seizures in this condition result in neurological deterioration and are an argument for early surgical intervention [29]. Diagnosis is made on clinical and radiological grounds.

Epilepsies in disorders of chromosome structure

Epilepsy is also a feature of two common chromosomal abnormalities: Down syndrome and fragile X syndrome [30]. It also takes a highly characteristic form in the rare ring chromosome 20. Other uncommon chromosomal abnormalities in which epilepsy is found include trisomy 12p, 8, 13; ring chromosome 14; partial monosomy 4p (Wolf–Hirschhorn syndrome); inverted duplication of pericentromeric chromosome 15; and Klinefelter's

syndrome (where epilepsy occurs in about 10% of cases). In all these conditions, there are additional behavioural and intellectual disabilities and characteristic dysmorphic features. The seizures often take multiple forms, including myoclonus, and are of variable severity. Genetic testing is available for most conditions.

Down syndrome

The Down phenotype occurs in about 1:650 live births. It is usually caused by trisomy of chromosome 21, and triplication of 21q22.3 results in the typical phenotype. In 95% of cases, the cause is a non-disjunction, and in about 4% an unbalanced translocation. About 1% of cases are mosaics. The risk of trisomy increases with maternal age. Epilepsy is present in up to 12% of cases and electroencephalogram (EEG) abnormalities in more than 20% [31]. Genetic testing and prenatal screening are available.

Fragile X syndrome

Fragile X syndrome is a condition due to increased number of CGG codon repeats (typically >200) in the *FMR1* gene (at Xq27.3) accompanied by aberrant methylation of the gene. It is an X-linked condition in which the presenting symptom is usually mental retardation, which is moderate in affected males and mild in affected females. Epilepsy is a common feature. Fragile X syndrome occurs in about 1:4000 male births and is the most commonly identified cause of mental retardation. The carrier rate in unaffected females with the permutation (CGG codon repeats of <200) may be as high as 1:250, with some geographic and racial variation. Repeat numbers vary, and mosaicism is common, and these may account for the variable clinical features. Genetic and prenatal testing are widely available. The methylation status of the gene can also be identified using Southern blot. Identification of the abnormal protein is not usually required.

Ring chromosome 20

Ring chromosome 20 is a rare condition but one in which epilepsy is the predominant feature and has a highly characteristic phenotype [32]. The locus of fusion between the deleted short and long arms of the chromosome is at p13q13, p13q13.3.3 or p13q13.33. This is a sporadic condition, and can be identified by genetic testing. Mosaicism is common and at least 100 mitoses may need to be examined before excluding the condition.

Epilepsies as a result of developmental anomalies of cerebral structure (the 'cortical dysplasias')

Cortical dysplasia (synonyms: cortical dysgenesis, malformations of cortical development) is a term that is applied to developmental disorders of the cortex producing structural change. A minority of these conditions are caused by identifiable genetic abnormalities. Others are caused by environmental influences such as infection, trauma, hypoxia or exposure to drugs or toxins. In most cases the cause is unclear. The form of dysplasia consequent on environmental insults depends not only on the nature of the insult, but also on the stage of development at which it occurred. Cortical malformations can be due to abnormal neuronal and glial proliferation, abnormal neuronal migration or abnormal synaptogenesis, cortical organization or programmed cell death [33–35].

The true prevalence of these conditions, previously thought to be rare, has only become apparent with the widespread use of MRI, which can detect cortical dysplasia in cases previously classified as cryptogenic epilepsy. Epilepsy is a leading feature of these conditions, usually, but not always, in association with learning disability and other neurological findings.

Hemimegalencephaly

Hemimegalencephaly describes a gross structural abnormality which can be the end result of various cerebral processes and insults [36]. One cerebral hemisphere is enlarged and is structurally abnormal with thickened cortex, reduced sulcation and poor or absent laminar organization. Giant neurones are found throughout the brain and in 50% of cases balloon cells are found. The condition can occur in isolation, associated with other cortical dysplasias or as part of other syndromes (notably tuberous sclerosis or other rarer neurocutaneous syndromes, such as epidermal naevus syndrome, Klippel–Trenaunay–Weber syndrome, neurofibromatosis type 1 or hypomelanosis of Ito). The restriction of the abnormality to one hemisphere may be a result of somatic mosaicism, and it has been suggested that the condition is due to defects in the process of programmed cell death (apoptosis) in early fetal life.

Focal cortical dysplasia

Focal cortical dysplasia is a common form of dysplasia, important to identify because of its potential for surgical therapy [37,38]. The term encompasses a variety of subtypes with different histological appearances, possibly a result of formation at different stages of embryogenesis. In some, the cortical lamination is normal, but in others there may be associated macrogyria and polymicrogyria. Focal dysplasia can occur in any part of the cortex, and varies greatly in size. There are often widespread minor dysplastic abnormalities, associated with some forms of focal cortical dysplasia, although in the Taylor form, diagnosed by the histological presence of 'balloon cells', the dysplastic changes are more limited.

Schizencephaly

Schizencephaly refers to the presence of clefts in the cortex, stretching from the surface to the ventricle [39]. The clefts are subdivided into open-lip schizencephaly (in which the walls of the cleft are separated) and closed-lip schizencephaly (in which the walls of the cleft are not separated). The clefts can be unilateral or bilateral and they are usually perisylvian in location. Schizencephaly is often associated with polymicrogyria and less often with other focal cortical dysplastic anomalies, corpus callosum agenesis or septo-optic dysplasias. The cortex may or may not have normal lamination. The pathogenesis in some cases is a failure of migration and in others an environmental insult causing focal necrosis of developing cortex. The causes are heterogeneous, and include germline mutations of the homeobox gene *EMX2* and environmental insults during development, including radiation, infection and ischaemia.

Agyria–pachygyria band spectrum

Lissencephaly, pachygyria, agyria and subcortical band heterotopia are descriptive terms denoting abnormalities of cortical gyration, and are grouped together as they show an interconnected genetic basis: in all of these, the gyration is simplified and the cortex is thickened. Lissencephaly (literally meaning smooth

brain) is the most severe form, in which gyration is grossly diminished or even absent. Subcortical band heterotopia (synonym: subcortical laminar heterotopia, band heterotopia, double cortex syndrome) denotes the presence of a band of grey matter sandwiched by white matter below the cortical grey matter. The band may be thin or thick and can merge with overlying cortex, in which case the cortex takes a macrogyric form. When the bands are thin and clearly separated from the cortical ribbon, the ribbon itself may appear normal. Thicker bands are usually associated with macrogyria. *Macrogyria* refers to thickened cortex and can occur as an isolated phenomenon. It is variable in extent and, when focal, it is indistinguishable on clinical or imaging grounds from some forms of focal cortical dysplasia.

Most forms of lissencephaly occur without other non-cerebral malformations [isolated lissencephaly sequence (ILIS)] [40]. Isolated lissencephaly is present in 12 of one million live births. Sixty to eighty per cent of cases of isolated lissencephaly are caused by identifiable mutations in *LIS1*, on 17p13.3, or in X-linked dominant lissencephaly (XLIS) (in *DCX*) on Xq22.3–q24: in 40% the entire gene is deleted. *LIS1* lissencephaly is predominantly posterior in location, and the condition occurs in both sexes and is sporadic. Conversely, XLIS cases occur almost always in boys and the brain anomaly tends to be anterior in location. Genetic testing is available for both forms.

Other forms of lissencephaly have more widespread associations. The best known is *Miller–Dieker syndrome*, which is caused by large deletions of *LIS1* and of several other contiguous genes on 17p13.3. Genetic testing is available.

Subcortical band heterotopia is caused in about 80% of cases by germline deletions in the *DCX* (XLIS) gene and occurs almost always (but not exclusively) in females. The pachygyria and bands are anteriorly predominant. The genetic anomaly in the other 20% of cases has not been identified. The rare cases of *subcortical band heterotopia* in boys are probably caused by missense mutations in *DCX* or *LIS1*.

Agenesis of the corpus callosum

Agenesis of the corpus callosum is a dysplastic anomaly that occurs in various genetic and congenital disorders. Epilepsy is an invariable association, and often a leading symptom. In *Aicardi's syndrome*, the corpus callosum agenesis is associated with periventricular heterotopia, thin unlayered cortex and diffuse polymicrogyria. It is observed only in females (the only exception being males with two X chromosomes) and is X-linked with male lethality. The causal gene has not yet been identified but linkage to Xp22.3 has been reported. The syndrome may be due to skewed X chromosome inactivation. Other syndromes with agenesis of the corpus callosum exist, and this anomaly may co-exist with other dysplastic features. The *L1 syndrome* is associated with mutations in the *L1CAM* gene and presents as hydrocephalus, mental retardation, spasticity and epilepsy.

Polymicrogyria

The appearance of small and prominent gyri, separated by shallow sulci, is known as polymicrogyria. It can be diffuse or localized, and varies in severity as well as extent. The underlying cortex is invariably thickened, and can be unlayered or show an abnormal four-layered structure. The former may be a migrational defect in weeks 13–18 of fetal life, and the latter the result of ischaemia or perfusion failure between weeks 12 and 24 of fetal life. Epilepsy is the leading clinical feature, associated with learning disability and focal neurological signs. No gene is yet discovered, but linkage has been reported to X28p in 22q11.2m and in other cases due to 22q11 deletion and mutations of the *AHI1* gene.

Periventricular nodular heterotopia

The presence of subependymal nodules of grey matter, located along the supralateral walls of the lateral ventricles, is known as periventricular nodular heterotopia [synonyms: bilateral periventricular nodular heterotopia (BPNH), subependymal nodular heterotopia (SENH)]. The heterotopia is usually bilateral, although not always. It is much more common in females and conforms to X-linked dominant transmission, and is probably the most common of all the cortical dysplasias. Almost all cases have shown mutations in the *FLN1* (filamin-1) gene [41,42].

Other dysplasias

Various other types of dysplastic lesion exist, including sheets of abnormal neurones forming linear streaks in the white matter, abnormal cortical patterning (including stellate-like gyral formations), isolated clusters of grey matter within white matter and microdysgenesis. The last term refers to abnormally placed microscopic clusters of heterotopic neurones often associated with abnormal lamination of the cortex. Normal brains have occasional heterotopic cells, and distinguishing the truly pathological from the normal is, to an extent, a subjective judgement. Because of this, widely varying estimates of the frequency of microdysgenesis have been made. At one extreme is a study showing microdysgenesis in 38% of postmortem specimens in epilepsy compared with a frequency of only 6% in control subjects.

Epilepsy as a result of an acquired disorder

Epilepsy resulting from an acquired injury or disorder is sometimes known as symptomatic epilepsy. Almost any condition affecting the cerebral grey matter can result in epilepsy, but here only the more common forms of acquired epilepsy will be mentioned. The mode of diagnosis depends on the cause but MRI is a central investigation showing the site and location of the cerebral lesion and often providing reliable or near-reliable clues to pathology.

Hippocampal sclerosis

Hippocampal sclerosis is the most common cause of temporal lobe epilepsy [43–45]. It is found in up to one-third of patients with refractory focal epilepsy attending hospital clinics in whom there is no other structural lesion. However, it is less frequent in population-based cohorts and in patients with mild epilepsy. Hippocampal sclerosis typically causes complex partial seizures and the clinical features and symptom complex associated with the syndrome of mesial temporal lobe epilepsy. The pathogenesis of hippocampal sclerosis is probably multifactorial. There is a very clear association with a history of childhood febrile convulsions and one postulation is that the febrile convulsions, especially if

prolonged or complex, damage the hippocampus and result in hippocampal sclerosis. There is also evidence that, in some cases, hippocampal sclerosis may be a congenital lesion, and its frequent association with forms of cortical dysplasia (particularly subependymal heterotopia) adds some strength to the view that hippocampal sclerosis itself may sometimes be a form of cortical dysgenesis. The lesion is also common after severe brain trauma and in vascular damage.

Prenatal and perinatal injury

Epilepsy has traditionally often been thought to occur as a result of perinatal injury, although it is now recognized that many such cases have in fact genetic or other prenatal developmental pathologies causing the epilepsy. In most children with epilepsy, minor perinatal problems are quite irrelevant to the subsequent development of epilepsy, or indeed are themselves the result of the underlying defects. In controlled studies, only severe perinatal insults have been found to increase the risk of subsequent epilepsy, for example perinatal haemorrhage and ischaemic–hypoxic encephalopathy. Factors such as toxaemia, eclampsia, forceps delivery, being born with the 'cord round the neck', low birth rate or prematurity have only a very modest association, if any, with subsequent epilepsy (Table 3.5). Factors reported in some studies are not confirmed in others, but in one large case–control study, early

gestational age, vaginal bleeding during pregnancy, birth by Caesarean section and socioeconomic factors were found to confer a small risk of subsequent epilepsy [46–55].

Cerebral palsy

Cerebral palsy encompasses many pathologies, both prenatal and perinatal and both genetic and acquired. The term therefore has little specificity, although it is in widespread use. Whatever the cause, cerebral palsy is indicative of cerebral damage and thus is strongly associated with epilepsy. The US National Collaborative Perinatal Project, a prospective cohort study of infants followed to the age of 7 years, found epilepsy to occur in 34% of children with cerebral palsy: cerebral palsy was present in 19% of children developing epilepsy. In the same cohort, the risk of learning disability (associated with cerebral palsy) was 5.5 times higher among children developing epilepsy following a febrile seizure than in children with a febrile seizure alone. Learning disability (IQ < 70) was present in 27% of children with epilepsy, and seizures were present in about 50% of children with mental retardation and cerebral palsy.

Post-vaccination encephalitic encephalomyelitis

The possible role of vaccination (particularly pertussis vaccination) in causing a childhood encephalopathy and subsequent epilepsy and learning disability has been the subject of intense study, with contradictory claims [56]. There is a fairly general consensus now that the risk of vaccine-induced encephalopathy and/or epilepsy, if it exists at all, is extremely low. Risk estimates in the literature have included risk of a febrile seizure, 1:19496 vaccinations; risk of an afebrile seizure, 1:76133 vaccinations; risk of encephalopathy after pertussis infection, 0–3 cases per million vaccinations. The situation is complicated by the findings of a recent study which showed that encephalopathy in 11 out of the 14 children studied, although previously attributed to vaccination, was in fact due an inherited genetic defect of the *SCN1A* gene, which codes for the voltage-gated neuronal sodium channel [57]. Suggestions that MMR (mumps, measles, rubella) vaccine increases the risks of autism and epilepsy are now thought to be unfounded. Currently, the vaccine with the greatest risk is the smallpox vaccination, with a rate of 10–300 cases per million of post-vaccination encephalomyelitis, although safer vaccines are under development. The vaccines in which there is a possible association with post-vaccination encephalomyelitis are smallpox, measles, DPT (diphtheria, pertussis and tetanus), Japanese B encephalitis and rabies.

Degenerative diseases and dementia

Epilepsy is a common feature of degenerative neurological disease that involves the grey matter, but is seldom a leading symptom in pure leucodystrophy. Six per cent of persons over the age of 65 years have dementia, and the rate increases exponentially as a function of age [58,59]. Five per cent of patients with Huntington's disease have epilepsy, usually in the later stages. Epilepsy is more common in the juvenile form, and occasionally takes the form of a progressive myoclonic epilepsy. Epilepsy, and indeed status epilepticus, can be the presenting feature of Creutzfeldt–Jakob disease.

Post-traumatic epilepsy

Head trauma is an important cause of epilepsy [60–65]. Estimates of frequency of injury and of the risk of post-traumatic epilepsy have varied widely in different studies, partly because of different definitions and changes in diagnosis and management. The figures given below are best-guess estimates based on modern practice. It is customary to draw a distinction between open head injury, in which the dura is breached, and closed head injury, in which there is no dural breach. Post-traumatic seizures are traditionally subdivided into immediate, early and late categories. Immediate seizures are defined as those that occur within the first 24 h after injury, early seizures are those that occur within the first week and late seizures occur after 1 week. Early seizures occur in about 5% of all those admitted to hospital with head injury and are more common in children than in adults.

Closed head injuries are most common in civilian practice, usually from road traffic accidents, falls or recreational injuries. In different series, closed head injuries have accounted for between 2% and 12% of all cases of epilepsy [64]. Mild head injury – defined as head injury without skull fracture and with less than 30 min of post-traumatic amnesia – is, in most studies, not associated with any markedly increased risk of epilepsy. Moderate head injury – defined as a head injury complicated by skull fracture or post-traumatic amnesia for more than 30 min – is followed by epilepsy in about 1–4% of cases. Severe head injury – defined as a head injury with post-traumatic amnesia of more than 24 h, intracranial haematoma or cerebral contusion – is followed by epilepsy in about 10–15% of patients, in most studies. In a recent population-based study, the relative risk for epilepsy was 2.22 (95% CI 2.07–2.38%) in the presence of mild brain injury and 7.40 (95% CI 6.16–8.89%) in the presence of severe brain injury.

Post-traumatic epilepsy is much more frequent after open head injury [6]. This is particularly so in penetrating wartime injuries, with between 30% and 50% of patients suffering subsequent epilepsy. Overall, the risk of late epilepsy, if early epilepsy is present, is about 25% compared with 3% in patients who did not have early seizures. In patients admitted to hospital, the risk of late epilepsy is about 35% if there is an intracranial haematoma and about 5% if not, and about 17% if there is a depressed skull facture and 4% if not. If there is neither haematoma nor depressed skull fracture, the risk of epilepsy is 1% if there were no early seizures and 26% if there were early seizures. The risk of late epilepsy after open head injury is greatest if the extent of cerebral damage was large and involved the frontal or temporal regions. About 50–60% of patients have their first (late) seizure within 12 months of the injury, with most patients developing epilepsy within 4–8 months after the injury, and 85% within 2 years. There is a subsequent slight excess risk for 5 years.

The pathophysiology of post-traumatic epilepsy is complex and multifactorial. The kinetic energy imparted to the brain tissue produces pressure waves that disrupt tissue and lead to histopathological changes, including gliosis, axon retraction balls, wallerian degeneration, neurological scars and cystic white matter lesions. In addition, iron liberated from haemoglobin generates free radicals that disrupt cell membranes and have been impli-

cated in post-traumatic epileptogenesis. Iron and other compounds have also been found to provoke intracellular calcium oscillations. Hippocampal damage following head injury also seems common (over 80% of one series) and this may be due to enhanced excitability secondary to death of inhibitory dentate hilar neurones. Such hyperexcitability can last for months, following trauma, with reorganization of excitatory pathways, such as mossy fibre sprouting.

Epilepsy after neurosurgery

The incidence of seizures varies according to the nature of the underlying disease process, its site and its extent (Table 3.6) [66,67]. A large retrospective study found an overall incidence of 17% for postoperative seizures in 877 consecutive patients undergoing supratentorial neurosurgery for non-traumatic conditions. The patients had no prior history of epilepsy and the minimum follow-up was 5 years. The incidence of seizures ranges from 4% in patients undergoing stereotactic procedures and ventricular drainage to 92% for patients being surgically treated for cerebral abscess. The risk of craniotomy for glioma was 19%, for intracranial haemorrhage 21% and for meningioma removal 22%. All of these risks were greatly enhanced if seizures occurred preoperatively. Among patients developing postoperative seizures, 37% did so within the first postoperative week, 77% within the first year and 92% within the first 2 years. If early seizures occurred (i.e. those occurring in the first week), 41% of patients developed late recurrent seizures.

Studies after unruptured aneurysm show an overall risk of about 14%. The risk of a middle cerebral aneurysm resulting in epilepsy is 19%, and anterior communicating aneurysms and posterior communicating aneurysms carry a risk of about 10%. If the aneurysm has bled, causing an intracranial haematoma, the incidence of epilepsy is much higher, as it is if patients have perioperative complications including hemiparesis or meningitis, implying parenchymal damage. The overall postoperative risk of epilepsy depends on the site. In patients with no deficit, low-risk sites (risk under 5%) include aneurysms on the anterior communicating and posterior communicating arteries and a moderate risk (about 10%) in operations on the middle cerebral artery aneurysm. If there is a preoperative deficit, the risk of postoperative seizures increases to 20–30% in all these sites. An overall risk of epilepsy following shunt procedures is about 10%, although this depends on the site of the shunt insertion. As is the case following cerebral trauma, the risks of epilepsy following neurosurgery are greatest in the first postoperative year although a substantial proportion of cases (perhaps 25%) experience their first seizures in the second postoperative year.

Cerebral tumour

Brain tumours are responsible for about 6% of all newly diagnosed cases of epilepsy [68]. The rate is greatest in adults, and about one-quarter of adults presenting with newly developing focal epilepsy have an underlying tumour compared with less than 5% of children. Seizures occur in about 50% of all brain tumours. Metastases from non-CNS tumours often present with epilepsy or status epilepticus. The frequency of seizures is high in tumours in the frontal, central and temporal regions, lower in posterior cortically placed tumours and very low in subcortical tumours.

Glioma

Gliomas are the most common form of brain tumour causing epilepsy [69–71]. Slow-growing low-grade well-differentiated gliomas are the most epileptogenic lesions. In the Montreal series of 230 patients with gliomas, seizures occurred in 92% of those with oligodendrogliomas, 70% of those with astrocytomas and 37% of those with glioblastomas. Overall, slow-growing or benign tumours account for about 10% of all adult epilepsies, and fewer in children. The history of epilepsy will often have extended for decades, sometimes even into infancy. In chronic refractory tumoral epilepsy, oligodendrogliomas account for between 10% and 30%, dysembryoplastic neuroepithelial tumours (DNETs) account for 10–30%, astrocytomas account for 10–30%, gangliogliomas account for about 10%–20% and hamartomas for between 10% and 20%. These tumours are sometimes associated, particularly if situated in the temporal lobe, with hippocampal sclerosis.

Ganglioglioma

These are mixed tumours that are composed of neoplastic glial and neuronal cell types and constitute 10% of the neoplasms

removed at temporal lobectomy. Seizures are the primary presenting symptom in 80–90% of patients with gangliogliomas [72–75].

Dysembryoplastic neuroepithelial tumour

The dysembryoplastic neuroepithelial tumour (DNET or DNT) is a pathological entity only recently differentiated from other forms of 'benign gliomas'. They are, in fact, a relatively common cause of 'tumorous epilepsy', accounting for 10–30% of resected tumours in the temporal lobe [76–78].

Hamartoma

These benign tumours account for 10–20% of tumours removed at temporal lobectomy. These are more common in children. Their pathological features include proliferation of glial and neuronal elements, and they can be associated with other types of cortical dysplasia. Indeed the distinction between cortical dysplasia, hamartomas and relatively indolent neoplasms, such as DNET, can be blurred. The classic clinicopathological finding in *tuberous sclerosis complex* is the periventricular glial nodule or subependymal tuber. Histologically, these lesions are hamartomas and consist of foci of gliosis, which include both glial cells and neurones.

Hypothalamic hamartoma (and gelastic epilepsy)

The hypothalamic hamartoma is a particular form of hamartoma [79,80]. These are benign tumours, usually small and sometimes confined to the tuber cinereum. They develop in young children, and characteristically present with gelastic seizures, learning disability, behavioural disturbance and later with precocious puberty. They are diagnosed by MRI scanning but the lesions can be very subtle, especially if small, without mass effect and isodense on both T1 and T2 sequences.

Meningioma

Epilepsy is the first symptom of meningioma in 20–50% of cases. Meningiomas are more likely to cause epilepsy when located over the convexity, parasagittal/falx and sphenoid ridge, and with evidence of peritumoral oedema. There is no relationship between the presence of epilepsy and histological type.

Central nervous system infection

Central nervous system (CNS) infections are a major risk factor for epilepsy. Seizures can be the presenting or the only symptom, or one component of a more diffuse cerebral disorder [81,82].

Meningitis and encephalitis

The risk of chronic epilepsy following encephalitis or meningitis is almost seven times greater than that in the general population. The increased risk is highest during the first 5 years after infection, but remains elevated for up to 15 years. The risk is much higher after encephalitis [relative risk (RR) 16.2] than bacterial meningitis (RR 4.2) or aseptic meningitis (RR 2.3) [83].

The most common forms of bacterial meningitis are now due to *Streptococcus pneumoniae* (pneumococcal meningitis) and *Neisseria meningitidis* (meningococcal meningitis) [82,84]. *Haemophilus influenzae* type b (Hib) used to be a leading cause but new vaccines have virtually eradicated the condition in Western countries. Meningococcal meningitis is the most serious common form. Its incidence varies and in Europe, for instance, the highest incidence is in Scotland and Iceland. Ninety-five per cent of cases are due to serogroups B and C, and the case fatality rate is between 5% and 10%.

Table 3.7 Causes of infectious encephalitis.

Causes of infective encephalitis in the immunocompetent patient
Viral
Herpes simplex virus (HSV) type 1, other herpes virus (e.g. varicella, HSV type 2, CMV, EBV, HSV type 6), measles, mumps, rubella, rabies, arbovirus (e.g. Japanese B, St Louis, West Nile, equine and tick-borne virus), adenovirus, HIV, influenza (A,B), enterovirus, poliovirus
Bacterial and rickettsial (uncommon)
Bartonella spp., *Borrelia burgdorferi, Brucella* spp., *Leptospira interrogans, Listeria monocytogenes, Mycobacterium tuberculosis, Mycoplasma pneumoniae, Rickettsia rickettsii*, Q fever and other rickettsial infections, *Treponema pallidum*, leptospirosis, *Nocardia actinomyces, Salmonella typhi, Legionella*
Protozoal (uncommon)
Malaria (*Plasmodium falciparum), Toxoplasma gondii*, *Naegleria fowleri, Acanthamoeba* spp.., cysticercosis, *Echinococcus* spp., *Trypanosoma* spp., schistosomiasis
Fungal (uncommon)
Blastomycosis, coccidioidomycosis, histoplasmosis, cryptococcus, aspergillosis, candidiasis
Causes of infectious encephalitis in the immunocompromised patient
Viral
Enterovirus, cytomegalovirus, HSV types 1,2,6, JC virus, measles, rubella, varicella
Protozoal
Amoebic meningoencephalitis, toxoplasmosis
Fungal
Cryptococcus neoformans, coccidioidomycosis, blastomycosis, histoplasmosis, *Aspergillus, Candida*

From ref. 1, with permission.

Encephalitis is most commonly due to viral infection, but other infectious agents can cause post-encephalitic epilepsy (Table 3.7) [85]. The most common serious viral encephalitis is due to herpes simplex virus type 1 (HSV-1). The incidence of severe HSV-1 encephalitis is about 1 per million persons per year, but it is possible that more minor infection occurs which escapes detection. It is often assumed that the many cases of epilepsy, currently considered cryptogenic, are due to occult viral infection – although hard evidence in support of this point is entirely lacking. Viral encephalitis needs to be differentiated from acute disseminated encephalomyelitis (ADEM), which can present with a very similar picture, and also from the increasingly recognized autoimmune encephalopathies, particularly those associated with voltage-gated potassium channel antibodies or antithyroid antibodies (Hashimoto's disease).

Patients with acquired immunodeficiency syndrome (AIDS) and other immunocompromised states have a different range of pathogens, and cerebral infection is a common feature of the condition; the most common opportunistic CNS infections are cryptococcal meningitis, toxoplasmosis, tuberculosis and cytomegalovirus (CMV) encephalitis [83,86,87]. Seizures may also be

a sign of progressive multifocal leucoencephalopathy in human immunodeficiency virus (HIV), although usually a minor aspect of the clinical presentation.

Cerebral malaria

Seizures and typically status epilepticus are particularly common in the acute phase of cerebral malaria [88–90]. Chronic epilepsy is common after cerebral malaria, particularly if seizures occurred in the acute phase, and one study has shown a 9- to 11-fold (CI 2–18) increase in risk of epilepsy in children with malaria compared with children without malaria. This risk is at least double the risk of epilepsy after complex febrile seizures.

Pyogenic cerebral abscess

Pyogenic cerebral abscess is an uncommon but serious cause of infective epilepsy [91]. Abscesses range in size from microscopic foci of inflammatory cells to major encapsulated necrotic areas of a cerebral hemisphere exerting significant mass effect. The species of bacteria responsible for brain abscess depends on the pathogenic mechanism involved. Commonly isolated organisms are streptococci, including aerobic, anaerobic and microaerophilic types. *S. pneumoniae* is a rarer cause of brain abscesses, which are often the sequel to occult cerebrospinal fluid (CSF) rhinorrhoea and also to pneumococcal pneumonia in elderly patients. Enteric bacteria and *Bacteroides* are isolated in 20–40% of cases and often in mixed culture. Anaerobic organisms have become increasingly important organisms and in many instances more than a single bacterial species is recovered. Gram-negative bacilli rarely occur alone. Staphylococcal abscesses account for 10–15% of cases and are usually caused by penetrating head injury or bacteraemia secondary to endocarditis. Clostridial infections are most often post-traumatic. Rarely, *Actinomyces* or *Nocardia* species are the causative agents in a brain abscess.

Neurocysticercosis

Worldwide, neurocysticercosis (NCC) is the most common parasitic disease of the CNS and it is a major cause of epilepsy in endemic areas such as Mexico, India and China. Epilepsy is the most common clinical manifestation and a usual presenting feature of NCC [92–94]. The condition is a helminthiasis caused by the encysted larval stage, *Cysticercus cellulosae*, of the pork tapeworm *Taenia solium*. Parenchymal cysts usually lie dormant for many years and symptoms usually coincide with larval death and an intense inflammatory response caused by the release of larval antigens. The solitary cerebral parenchymal lesion is a common form of presentation, but lesions are often multiple. Over time, the cysts shrink progressively and then calcify or disappear completely. Seizures are the most common symptom and develop when a cyst is degenerating or around a chronic, calcified lesion. In the racemose form of NCC, the cysts can obstruct CSF flow and present with mass effect, hydrocephalus or basal arachnoiditis. Diagnosis is made by imaging and by serological tests. The results of CSF and EEG examination are rather non-specific. Newer enzyme-linked immunoelectron transfer blot (EITB) assays on CSF or serum appear to have higher sensitivity (98%) and specificity (100%) in multiple cysticercosis. Its superiority to enzyme-linked immunosorbent assay (ELISA) is due to its ability to detect up to seven glycoproteins specific to *T. solium*. Recently, an antigen detection ('capture') assay specific for viable metacestodes in CSF has been designed.

Tuberculoma

Tuberculosis remains a major problem in developing countries and the incidence is also rising in industrialized countries, with increasing migration and also the spread of HIV. The most common form of tuberculosis is pulmonary infection, and the incidence of intracranial tuberculoma (tuberculous abscess) has decreased, particularly in Western countries, owing to the BCG vaccination programme. In the early twentieth century, tuberculomas accounted for about one-third of all space-occupying lesions. The incidence fell dramatically throughout the century, although recently rising again. For example, today, tuberculomas account for about 3% of all cerebral mass lesions in India, and 13% of all cerebral lesions in patients with HIV [95,96]. Diagnosis depends on the clinical context, imaging, serology, and histological examination of biopsy material.

Cerebrovascular disease

Epilepsy can complicate all forms of cerebrovascular disease. Stroke is the most commonly identified cause of epilepsy in the elderly, and occult stroke also explains the occurrence of many cases of apparently cryptogenic epilepsies in aged individuals. A history of stroke has been found to be associated with an increased lifetime occurrence of epilepsy [odds ratio (OR) 3.3; 95% CI 1.3–8.5]. Among the other vascular determinants, only a history of hypertension was associated with the occurrence of unprovoked seizures (OR 1.6, 95% CI 1.0–2.4) [97,98]. The risk of unprovoked seizures rises to 4.1 (95% CI 1.5–11.0) in subjects having a history of both stroke and hypertension [99]. Status epilepticus occurs in the acute phase of about 1% of all strokes, and 20% of status epilepticus is due to stroke.

Cerebral haemorrhage

The reported risk of chronic epilepsy due to intracranial haemorrhage has varied greatly from series to series, but is generally in the region of 5–10%. The incidence of early epilepsy (seizures in the first week) is higher, up to 30% in some series with status epilepticus in about 10%. Early seizures do not necessarily lead to chronic epilepsy, although they increase the long-term risk, and about one-third of those with early seizures continue to have a liability to epilepsy. Epilepsy is common after large haemorrhages and haemorrhages which involve the cerebral cortex: they are less common in deep haematomas and rare after subtentorial haemorrhage. The epilepsy almost always develops within 2 years of the haemorrhage. The risk of seizures after subarachnoid haemorrhage is approximately 25% and has been claimed to be independent of residual deficit. If early seizures occurred, the risk of subsequent epilepsy is over 70% [100,101].

Cerebral infarction

After cerebral infarction, epilepsy occurs in about 6% of patients within 12 months and 11% within 5 years of the stroke [97,98]. Epilepsy is more common in cerebral infarcts located in the anterior hemisphere, and involving cortex. The standardized mortality ratio (SMR) for epilepsy after infarction has been found to be

5.9 (95% CI 3.5–9.4), and the risk of developing seizures is highest during the first year, and higher if there is a history of recurrent stroke. In a multivariant analysis, early seizures and recurrent strokes were the only clinical factors shown to predict the occurrence of epilepsy after infarction. The risk of epilepsy is about 17–20 times greater than in non-stroke control subjects. As in head injury, the occurrence of early seizures results in a greater (8–16×) increase in risk of subsequent epilepsy than in patients with stroke and no early seizures, and about 35% of those with early seizures develop subsequent epilepsy. Other factors associated with a greater risk of epilepsy in various studies are severity, size of infarct, haemorrhagic transformation, cortical versus subcortical site of the stroke and, in some studies, an embolic stroke.

Occult degenerative cerebrovascular disease

Epilepsy can also complicate occult cerebrovascular disease [3]. Late-onset epilepsy can be the first manifestation of cerebrovascular disease. Between 5% and 10% of patients presenting with stroke have a history of prior epileptic seizures in the recent past, and, in the absence of other causes, new-onset seizures should prompt a screen for vascular risk factors [102].

Arteriovenous malformations

An arteriovenous malformation (AVM) is a racemose network of arterial and venous channels that communicate directly, rather than through a capillary bed [103]. Between 17% and 36% of supratentorial AVMs present with seizures [104], with or without associated neurological deficits, and 40–50% with haemorrhage. Smaller AVMs (<3 cm diameter) are more likely to present with haemorrhage than large ones. Conversely, large and/or superficial malformations are more epileptogenic, as are AVMs in the temporal lobe. About 40% of patients with large arteriovenous malformations have epilepsy, and epilepsy is the presenting symptom in about 20%. Irrespective of the initial presentation, a significant proportion of patients with cerebral AVMs will develop epilepsy after diagnosis. The risk of seizures seems to be higher the younger the patient is at the time of diagnosis. In one study, among patients aged between 10 and 19 years, there was a 44% risk of epilepsy by 20 years. This risk declined to 31% for patients aged 20–29 years and to 6% for patients aged 30–60 years. The annual risk of bleeding of an AVM is in the region of 2–4%, irrespective of whether the malformation presented with haemorrhage, and the average mortality is about 1% per year. The risk is dependent on the size of the AVM, its growth, the presence of aneurysms, the type of feeding and draining vessels and the anatomy. The risk of surgical resection depends on the anatomy, size and site of the AVM, and is potentially hazardous: endovascular therapy and focused radiotherapy are also used. Arteriovenous malformations also show highly characteristic MRI appearances, with high signal on T2-weighted images often with a notch-like configuration, and areas of decreased signal intensity representing previous intralesional bleeding.

Cavernous haemangioma

Cavernous haemangiomas (cavernoma) are well-circumscribed hamartomatous lesions consisting of irregularly walled sinusoidal vascular channels. They are located within the brain but without intervening neural tissue and have large feeding arteries or draining veins. Pathologically, they consist of endothelial cell-lined caverns filled with blood and surrounded by a matrix of collagen and fibroblasts. They have the potential to haemorrhage, calcify or thrombose and are multiple in 50% of cases. They account for 5–13% of vascular malformations of the CNS and are present in 0.02–0.13% of autopsy series. The majority of these lesions present in the third and fourth decades of life, but 20–30% present earlier in childhood or early adult life. Cavernomas can increase in size and number over time, particular in genetically determined cases and in those in whom cavernoma have developed after cerebral irradiation. However, in most cases, the factors influencing the development of new lesions or growth of existing lesions are unknown. At least 15–20% of patients remain symptom free throughout their lives. Patients present with seizures (40–70%), focal neurological deficits (35–50%), non-specific headaches (10–30%), and cerebral haemorrhage [105,106]. Retinal, skin, and liver lesions have occasionally been reported, presumably on a genetic basis. Familial clustering can be found in 10–30% of cavernous haemangiomas and familial cases have been found to be linked to genes at three different loci: the *CCM1, CCM2* and *CCM3* genes. Overall, 40% of familial cases are linked to *CCM1*, with higher rates among Hispanic cases. Genetic testing is available. The lesions are usually diagnosed on MRI, whereas cerebral angiography often shows no abnormality. On T2-weighted images the typical appearance of cavernomas is that of a reticulated core of mixed signal representing blood in various states of degradation surrounded by a hypointense haemosiderin halo. T1 images show a similar pattern but they are less sensitive. There is slight contrast enhancement in some cases.

Other vascular disorders

Cortical venous infarcts are particularly epileptogenic, at least in the acute phase, and may underlie a significant proportion of apparently spontaneous epileptic seizures complicating other medical conditions and pregnancy, for instance. Seizures also occur with cerebrovascular lesions secondary to rheumatic heart disease, endocarditis, mitral valve prolapse, cardiac tumours [107] and cardiac arrhythmia, or after carotid endarterectomy. Infarction is also an important cause of seizures in neonatal epilepsy. Epilepsy is also common in eclampsia, hypertensive encephalopathy and malignant hypertension and in the anoxic encephalopathy which follows cardiac arrest or cardiopulmonary surgery. Unruptured aneurysms occasionally present as epilepsy, especially if large and if embedded in the temporal lobe, for example a giant middle cerebral or anterior communicating aneurysm. Epilepsy with a vascular basis also occurs in antiphospholipid syndrome, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL), Moyamoya disease, collagen disease (e.g. Ehlers–Danlos syndrome, Marfan's syndrome), Behçet's disease and amyloid angiography. Other rare causes of epilepsy include temporal arteritis, polyarteritis nodosum, Takayasu's disease, Fabry's disease and the hyperviscosity syndrome.

Other neurological disorders

Rasmussen's encephalitis

Rasmussen's encephalitis is a rare progressive neurological disorder of unknown cause. Pathologically, there is severe unilateral hemisphere atrophy with histological evidence of perivascular lymphocytic infiltration, neuronal loss and microglial nodule formation. The pathological changes are strikingly unilateral and, where changes do occur in the opposite hemisphere, these are usually minor [108–110]. The cause is unclear, although viral and immunological factors have been implicated. The genomes of various viruses have been found in biopsy tissue, including the Epstein–Barr and herpes simplex viruses, and IgG, IgA and C3 have been found. Glu-R3 antibodies have been reported in the sera of some patients. None of these findings though appears to be consistently present. Diagnosis is on the basis of the clinical and MRI findings.

Demyelinating disorders

Several clinical series reported an association between epilepsy and multiple sclerosis (MS). In one small population-based study from Iceland, patients with multiple sclerosis had a threefold but non-significant increase (SMR 3.0; 95% CI 0.6–8.8) in the risk of epilepsy compared with the general population [111]. In another series, the cumulative risk of epilepsy in patients with multiple sclerosis was found to be 1.1% at 5 years, 1.8% by 10 years and 3.1% by 15 years. The mean interval until the onset of epilepsy is about 7 years after the onset of multiple sclerosis [111,112].

Acute disseminated encephalomyelitis (ADEM) is an acute inflammatory demyelinating disorder that can follow systemic infections, and it is immunologically mediated. Epilepsy is a feature of the acute attack and occurs much more commonly than in an acute attack of MS. ADEM can follow infections with many different viruses (notably measles, mumps, rubella, varicella, HIV, hepatitis A and B, Epstein–Barr and CMV) or other infectious agents (notably mycoplasma, *Streptococcus*, *Borrelia*, *Campylobacter*, *Chlamydia*, *Leptospira* and *Legionella*). The incidence after measles infection is about 1 in 1000, varicella infection 1 in 10 000 and rubella infection 1 in 20 000.

Inflammatory and immunological diseases of the nervous system

Epilepsy can be a complication of many inflammatory and immunological diseases affecting the CNS. The mechanisms of seizures can be a result of the direct effect of immunological processes (for instance in Rasmussen's encephalitis) or an indirect effect owing to vascular disease and cerebral infarction (for instance, in the cerebral vasculitides). In many conditions, the mechanisms are unknown. Epilepsy is a common symptom of all forms of cerebral vasculitis, and particularly in systemic lupus erythematosus. It occurs less often in other vasculitides such as Behçet's disease and in other 'connective tissue disorders', such as Sjögren's syndrome and mixed connective tissue disease. In SLE, seizures occur in about 25% of cases and are particularly common in severe or chronic cases and in lupus-induced encephalopathy. Seizures can also occur as the presenting and only symptom of SLE [113]. Epilepsy can occur in all other forms of large, medium or small vessel vasculitis, sometimes on the basis of infarction. Chronic epilepsy seems to be a particularly common sequel of Henoch–Schönlein purpura, probably on the basis of acute vasculitis. Seizures are the most common neurological complication of the inflammatory bowel diseases (ulcerative colitis and Crohn's disease), occurring in one series in 6% of cases. The epilepsy may be a direct effect or caused indirectly by dehydration or sepsis. Neurological complications occur in about 10% of patients with Whipple's disease, and the condition presents neurologically in 5%. In a series of cases with neurological symptoms, myoclonus occurred in 25% and seizures in 23%. About 10% of patients with coeliac disease have neurological symptoms, and epilepsy is associated with several rather distinctive neurological presentations. Epilepsy in association with occipital calcification can be the presenting symptom of coeliac disease. Epilepsy, myoclonus and cerebellar ataxia or spinocerebellar degeneration, and sometimes dementia is another characteristic neurological syndrome. Myoclonus and seizures are also a prominent feature of Hashimoto's thyroiditis, a relapsing encephalopathy associated with high titres of thyroid antibody [114]. Epilepsy is also a feature, although often not prominent, of the primary granulomatous diseases of the CNS such as sarcoidosis.

There has been recent interest in the occurrence of epilepsy, particularly in the syndrome of limbic encephalitis, associated with high titres of antibodies against voltage-gated potassium channels (VGKCs) [115–117]. The epilepsy usually presents as a subacute illness, associated also with psychosis, neurological signs (e.g. ataxia), memory loss and behavioural change. Other cases of limbic encephalitis have no detectable antibody present (although it is assumed that the cause is immunologically mediated, by an unknown antibody) and some are paraneoplastic. It also remains possible that some chronic temporal lobe epilepsy cases are also due to immune-mediated mechanisms. This is an area of intense research interest.

Seizure precipitants

The precipitant of a seizure can be defined as a factor that, in patients with pre-existing epilepsy, precedes the onset of the attack and is considered to be an explanation of why the seizure happened when it did and not earlier or later. A detailed consideration of these factors is outwith the scope of this chapter. About 50–60% of people with epilepsy claim that precipitants are sometimes identifiable, and the most common factors are listed in Table 3.7. Attention to these factors can dramatically improve seizures in susceptible persons, and this is particularly true of avoidance of alcohol, sleep deprivation and stress.

The reflex epilepsies

The term reflex epilepsy is used to describe cases in which seizures are evoked consistently by a specific environmental trigger. In some cases, the stimulus can be highly specific and in others less so. The term is not usually applied to patients whose seizures are precipitated by internal influences such as menstruation, nor to situations where the precipitating factors are vague or ill-defined (e.g. fatigue, stress), nor to patients with existing epilepsy in

which seizures are more likely to occur as a result of specific precipitants (e.g. sleep deprivation, alcohol); transitional cases, however, occur in what can be a nosological grey area. The reflex epilepsies are sometimes subdivided into simple and complex types. In the simple forms, the seizures are precipitated by simple sensory stimuli (e.g. flashes of light, startle) and in the complex forms they are precipitated by more elaborate stimuli (e.g. specific pieces of music). The complex forms are much more heterogeneous and the syndromes are less well defined than the simple reflex epilepsies. In hospital practice, about 5% of patients show some features of reflex epilepsy. The stimuli most reported to cause seizures include flashing lights and other visual stimuli, startle, eating, bathing in hot water, music, reading and movement.

Visual stimuli, photosensitivity and photosensitive epilepsy

The most common reflex epilepsies are those induced by visual stimuli. Flashing lights, bright lights, moving visual patterns (e.g. escalators), eye closure, moving from dark into bright light, and viewing specific objects or colours have all been described to induce seizures [118–127]. The term photosensitive epilepsy should be confined to those individuals who show unequivocal electroencephalographic evidence of photosensitivity, and differentiated from other, usually more complex, cases in which seizures can be apparently precipitated by visual stimuli but when electroencephalographic evidence of photosensitivity cannot be demonstrated. Photosensitivity (strictly defined) is present in a population with a frequency of about 1.1 : 100 000 persons, and 5.7 : 100 000 in the age range of 7–19 years, and very strongly associated with epilepsy. About 3% of persons with epilepsy are photosensitive and have seizures induced by photic stimuli (usually viewing flickering or intermittent lights or cathode ray monitors, bright lights or repeating patterns). Most patients with photosensitivity have the syndrome termed idiopathic generalized epilepsy, although photosensitivity also occurs in patients with focal epilepsy arising in the occipital region, and some inherited metabolic diseases, and occasionally in other epileptic conditions.

Startle-induced epilepsy

Startle-induced seizures usually occur in patients with a frontal or central focus and usually in lesional epilepsy [128]. The seizures usually take a form similar to a tonic seizure, and the EEG is commonly normal or shows rather non-specific changes. A susceptibility to startle is more common in late childhood and adolescence and may resolve as the patient gets older.

Primary reading epilepsy

Primary reading epilepsy is a specific rare epilepsy syndrome in which clonic jerking of the jaw or perioral muscles, which can evolve to a generalized convulsion, is precipitated by prolonged reading. Some forms may be variants of idiopathic generalized epilepsy [129,130].

Other forms of reflex epilepsy [3]

Other simple reflex epilepsies include cases with seizures induced by movement, touching or tapping. These should be differentiated from paroxysmal kinesogenic choreoathetosis and stimulus-sensitive myoclonus. Hot-water epilepsy, which is common in parts of India but rare elsewhere, is a remarkable syndrome in which seizures are induced by pouring of hot water over the head or immersion in hot water [131]. Complex forms of reflex epilepsies include cases in which seizures are precipitated by the act of eating, hearing certain sounds, hearing certain pieces of music and psychic processes including decision-making, mental arithmetic, chess playing, card playing, drawing, spatial construction and deep thought [132]. These conditions are heterogeneous in terms of aetiology, electroencephalography and seizure types. The mechanisms underlying these (and other) reflex epilepsies are uncertain and specific 'reflex arcs' have not been identified. Prevention of the precipitating cause is sometimes helpful, as is drug treatment along conventional lines.

Acute symptomatic seizures

Acute symptomatic seizures, a somewhat unsatisfactory term, is reserved for seizures in persons who had not previously had seizures, which start in close temporal association to a sudden acute precipitant [133,134]. If the epilepsy can be attributable to a pre-existing, non-acute or static cause it is referred to as remote symptomatic epilepsy but clearly there is a grey area in which the distinction between acute and remote symptomatic epilepsies is rather arbitrary. The boundary is similarly blurred in some cases of reflex epilepsy or cases in which seizures have acute precipitants, such as sleep deprivation or alcohol. Furthermore, if seizures continue after the acute phase, and if the cause remains present (e.g. post-stroke, post-traumatic, tumoral or post-infectious epilepsy), seizures that were initially categorized as acute symptomatic are reclassified as remote symptomatic. All this makes rather a nonsense of the classification scheme.

The age-adjusted incidence rate of symptomatic seizures, reported in an old study from the record-linkage system in Rochester, Minnesota, was about 40 per 100 000 person-years. The rate was higher in men than in women (52 versus 29 per 100 000 per year), and highest in the first year of life owing to metabolic, infectious and encephalopathic aetiologies. The rate decreases in childhood and early adulthood, with a nadir at 25–34 years, and then increases, producing a second peak at age 75 and older, accounted for mostly by cerebrovascular disorders. The cumulative incidence of acute symptomatic seizures has been estimated to be about 4% up to the age of 80 years.

Metabolic- and endocrine-induced seizures

Many types of metabolic or endocrine disturbances can result in epilepsy [135]. Hyponatraemia is the most common electrolyte disturbance to result in seizures, which typically occur if the serum sodium level falls below 115 mmol/L. Seizures also routinely occur in the presence of hypernatraemia, hypocalcaemia, hypercalcaemia, hypomagnesaemia, hypokalaemia and hyperkalaemia. Ten per cent of patients with severe renal failure have seizures, caused either by the metabolic disturbance, renal encephalopathy, dialysis encephalopathy or dialysis disequilibrium syndrome. Asterixis may develop into myoclonus and then epilepsy.

Seizures are a common occurrence in hepatic failure. Hepatic encephalopathy may be overlooked and routine liver function

tests can be relatively normal; hyperammonaemia is sometimes diagnostically helpful. Reye's syndrome should be considered in patients with liver failure, especially in children, in whom it is associated with aspirin intake.

Hypoglycaemia is a potent cause of seizures, which can occur if the blood sugar levels fall below 2.2 mmol/L. This is commonly a result of insulin therapy in patients with diabetes but can also be due to insulinoma and drugs such as quinine and pentamidine. Non-ketotic hyperglycaemia frequently causes seizures. Levels of blood sugar as low as 15–20 mmol/L can cause seizures if there is associated hyperosmolarity. The seizures in non-ketotic hyperglycaemia are focal and this implies the presence of cerebral pathology (usually cerebrovascular disease). Diabetic ketoacidosis does not frequently result in seizures.

Thyroid disease can result in seizures that are due either to immunological mechanisms, or directly to hormonal change or hormonally induced metabolic change. Twenty per cent of patients with severe myxoedema have seizures. Hashimoto's encephalopathy, a steroid-responsive encephalopathy associated with high levels of antithyroid antibody, is an immunologically determined condition that results in altered consciousness, focal signs and other features of encephalopathy, including myoclonus and tonic–clonic seizures.

Alcohol- and toxin-induced seizures

Alcohol abuse is a potent cause of acute symptomatic seizures, and indeed of epilepsy, in many societies [136–138]. There are various mechanisms. Binge drinking can result in acute cerebral toxicity and seizures. Alcohol withdrawal in an alcohol-dependent person carries an even greater risk of seizures. Withdrawal seizures occur typically in a tonic–clonic form, occurring 12–24 h after withdrawal, and are associated with photosensitivity. Seizures can also be caused by the metabolic disturbances associated with binge drinking (notably hypoglycaemia, hyponatraemia and hepatic failure), cerebral damage owing to trauma, cerebral infection, subdural haematoma, chronic neurotoxic effects of chronic alcohol exposure or acute Wernicke's encephalopathy due to thiamine deficiency. It has been estimated that 6% of patients with alcoholism investigated for epilepsy have an additional identifiable causative lesion.

The risk of a first generalized tonic–clonic seizure in chronic alcoholics is seven times greater than in non-alcoholic control subjects, and in the USA, for instance, 15% of patients with epilepsy have alcoholism. The risk of seizures is increased only with a daily alcohol intake of 50 g/day or more, and the higher the intake the higher the risk. Odds ratios according to alcohol intake have been calculated to be 3.0 (95% CI 1.7–5.4) for a daily intake of 51–100 g/day, 7.9 (95% CI 2.9–21.9) for 101–200 g/day, and 16.6 (95% CI 1.9–373.4) when the intake is more than 200 g/day.

Seizures can also be provoked by exposure to many different toxins. Potent causes include heavy metal poisoning and carbon monoxide poisoning (in which carboxyhaemoglobin levels are above 50%). Although acute toxic exposure causes seizures, these are usually part of an acute encephalopathy. Whether low-grade long-term exposure to carbon monoxide, lead or to other heavy metals carries any risk is quite unclear. To what extent organophosphate poisoning can result in seizures is equally contentious, and reliable data seem to be absent.

Drug-induced seizures

A wide range of drugs, toxins and illicit compounds can cause acute symptomatic seizures and epilepsy, although seizures accounted for less than 1% of 32 812 consecutive patients prospectively monitored for drug toxicity [139–141]. As many as 15% of drug-related seizures present as status epilepticus. In a population-based survey from Richmond, Virginia, drug overdose was the reported cause in 2% of children and 3% of adults with status epilepticus. Drugs can cause seizures if the following conditions are present: intrinsic epileptogenicity, patient idiosyncrasy, antiepileptic drug interactions, impairment of the hepatic or renal drug metabolism, drug withdrawal phenomena and direct cerebral toxicity (especially in an intentional overdose). Some authorities also include febrile seizures in this category but others do not.

Almost any psychotropic drug carries a risk of inducing seizures. The risk is highest with the aliphatic phenothiazines [e.g. chlorpromazine (1–9% risk), promazine or trifluoperazine]. The use of clozapine is associated with a 1–4% risk of seizures and with interictal epileptiform abnormalities. The piperazine phenothiazines (acetophenazine, fluphenazine, perphenazine, prochloperazine and trifluoperazine), haloperidol, sulpiride, pimozide, thioridazine and risperidone are thought to have the lowest epileptogenic potential, although firm data are lacking. The risk of seizures with antidepressant drugs ranges from <1% to 4% and varies with the drug category. Agents accompanied by a high risk of seizures include clomipramine and the second-generation antidepressants amoxapine, maprotiline and bupropion. The risk of seizures with tricyclic antidepressants (other than clomipramine), citalopram, moclobemide and nefazodone is thought to be lower. The seizure risk with the selective serotonin reuptake inhibitors (fluoxetine, sertraline, paroxetine), monoamine oxidase inhibitors and trazodone is probably lower although definitive data are lacking. All of these drugs in overdose carry a significant (>10%) risk of seizures. The narcotic analgesic meperidine is metabolized in the liver to normeperidine, a potent proconvulsant, which tends to accumulate after prolonged administration and renal failure. The monocyclic antidepressant bupropion, which is used to assist the cessation of smoking, provokes seizures in 1 in 1000 patients. Pethidine can also result in seizures, especially in the presence of renal impairment or in combination with monoamine oxidase inhibitor (MAOI) drugs. Lidocaine-related neurotoxicity is common with intravenous use, especially with advanced age, congestive heart failure, shock, and renal and hepatic failure. The anaesthetics enflurane, propofol and isoflurane can be proconvulsant. Quinine and the other antimalarial drugs, especially mefloquine, can provoke acute seizures, and are relatively contraindicated in epilepsy. Various traditional remedies, including morning primrose oil and some Chinese and Indian herbal medicines, can provoke seizures.

Neurotoxic reactions may occur frequently with β-lactam antibiotics (semisynthetic penicillins and cephalosporins), probably due to GABA antagonist action. Benzylpenicillin, cefazolin and imipenem/cilastatin have the higher neurotoxic potential (with increased risk at higher doses) in the presence of renal failure, blood–brain barrier damage, pre-existing CNS disorders, comedication with nephrotoxic agents or drugs lowering seizure threshold. Isoniazid can be induced by antagonizing pyridoxal phosphate (the active form of pyridoxine), which is involved in

GABA biosynthesis. Seizures have also been reported, especially in elderly patients, in relation to aminoglycosides, metronidazole, quinolones and amantadine. Quinolones (nalidixic acid, norfloxacin, ciprofloxacin) probably enhance seizure activity by inhibiting GABA binding to membrane receptors. The tetracyclines seem less proconvulsant than these other antibiotics. Zidovudine and other antiviral agents have caused seizures in patients with HIV. Seizures (and non-convulsive status epilepticus) have been reported after administration of intravenous contrast media, and the risk is as high as 15% in patients with brain metastases.

The anti-cancer chemotherapeutic agents can provoke seizures, especially chlorambucil (95%), and ciclosporin (1–3%), asparaginase, tacrolines and busulfan, but also the platin drugs, vinca alkaloids, bleomycin, anthracyclines and azathioprine.

Theophylline is a potent convulsant that can result in seizures or status epilepticus, possibly as a result of the antiadenosine action. β-Blockers and other antiarrhythmic agents have been reported to precipitate seizures, particularly in overdose. Cimetidine, levodopa, insulin, thiazide diuretics, lidocaine, salicylates, chemotherapeutic agents, L-asparaginase and baclofen have been reported to cause seizures. The non-steroidal analgesics also predispose to seizures [for example, non-steroidal antiinflammatory drugs (NSAIDs), tramadol, diamorphine and pethidine].

Seizures may be precipitated after sudden withdrawal of any antiepileptic drug but seem a particular problem in benzodiazepines, carbamazepine and barbiturate withdrawal.

Recreational drugs can cause seizures. The greatest risk is with the stimulant drugs, such as cocaine, amphetamine and 'ecstasy' (3,4-methylenedioxymethamphetamine, MDMA). The hallucinogens, such as phencyclidine (angel dust) and lysergic acid diethylamide (LSD), less commonly cause seizures. The opiates and the organic solvents are least epileptogenic, although past or present heroin use has been shown to be a risk factor for provoked and unprovoked seizures (OR 2.8; 95% CI 1.5–5.7). Of the performance-enhancing drugs, erythropoietin has strong epileptogenic potential. By contrast, in one study, marijuana use in men was shown to have a protective action against non-provoked seizures (OR 0.4; 95% CI 0.2–0.8) and provoked seizures (OR 0.2; 95% CI 0.1–0.8).

4 Differential Diagnosis of Epilepsy

Mark Cook

University of Melbourne, St. Vincent's Public Hospital, Melbourne, Australia

Introduction

Episodic disorders of consciousness or behaviour are a common cause of visits to emergency departments, family physicians and neurologists. Although the diagnosis of an epileptic disorder may be straightforward, it is frequently difficult, especially if the event is unwitnessed, or if the history is incomplete. Among the wide variety of neurological and non-neurological conditions that may be mistaken for epilepsy, the most frequent and challenging distinction is between epileptic events and syncope or presyncope.

In my experience, 20–30% of new patients attending a specialty epilepsy clinic have a diagnosis other than epilepsy. A number of studies have shown that syncope is commonly misdiagnosed as epilepsy, largely through ignorance of the complex prodrome that may occur, and the sometimes dramatic nature of a clinical event that shares many features with epileptic convulsions [1]. Migraine, non-epileptic seizures (pseudoseizures), hyperventilation and vertigo are other conditions commonly misdiagnosed as epilepsy. Less common disorders that are confused with epilepsy include cerebral ischaemia or paroxysmal symptoms of demyelinating disease, raised intracranial pressure, Tourette's syndrome and other movement disorders. Patients presenting with behavioural symptoms most often have a primary psychiatric diagnosis but are often thought to be suffering a seizure disorder. The surprising abundance of misdiagnosed epilepsy has been confirmed in a number of studies, and is cause for much concern [2].

Epilepsy remains primarily a clinical diagnosis. The incorrect diagnosis is often catastrophic for the patient, resulting in significant restriction to social activity and employability, as well as administration of unnecessary medication, with all the problems that entail. Loss of driving privileges is often the most immediate and traumatic component for patients whose livelihood may depend on a valid driving licence. From all perspectives, the diagnosis of epilepsy requires clinical skill and judgement, and it is incumbent on the clinician to attach a definite diagnosis only if certain.

General approach to episodic disturbances

As an enormous variety of conditions can cause episodes of transiently disturbed consciousness or function, the major component of clinical management consists of separating out the various causes, usually on clinical grounds. Determining the nature of events can be very challenging, particularly when the event has been unwitnessed or when the patient is an inadequate historian.

Obtaining a clear account of the nature of the attack is the most important single component of the assessment. Ascertain precisely the circumstances of the event, any warning that occurred, the duration of the attack, exactly what occurred during the event, the nature and speed of recovery and as well as whether there were any focal or lateralizing signs after the event. There is no substitute for a detailed history of the attack from both the patient and any eye-witnesses, and obtaining a detailed account of the circumstances of the event as well. What was the patient engaged in the day and evening prior to the event? Was there sleep deprivation or were there other medical problems? Was there unusual stress or anxiety [3]? Obtaining an eye-witness account is crucial and the telephone is now an invaluable device in this regard, particularly now mobile telephones are so widely owned (half the world's population at last count, many with video-cameras). Dramatic disparity is often noted between the eye witness's and patient's stories. Whereas the patient may recall a simple fall or brief loss of consciousness, an eye-witness may provide a detailed account of generalized convulsion with postictal confusion, tongue biting and so on, for which the patient is often amnesic. In other situations there may be deliberate concealment. Clinical examination may provide useful information, particularly if undertaken in the hours after the event, but is most often non-contributory. Supportive investigations including electroencephalograms (EEGs) and structural imaging may provide additional evidence for the diagnosis, but interpreting all these factors requires clinical skill and judgement. EEGs are often normal interictally in the adult patient with epilepsy and, conversely, on interictal traces around 20% of people have minor and irrelevant abnormalities that are frequently misinterpreted as confirming a diagnosis of epilepsy.

Events that occur in particular circumstances should always raise the suspicion of syncope. There are obvious causes, such as sudden pain, venesection, emotion, standing for long periods or watching unpleasant movies. However, mechanical causes, such as cough, urination or defecation, may also provoke syncope; the differences between syncope and epilepsy are detailed below. Episodes of loss of consciousness occurring with postural change are more likely to be syncopal. Shock, fright or extreme emotion can precipitate syncope also but these are frequently recognized to be non-epileptic events. Other physical alterations, such as change in head position, rolling in bed, looking up at a high shelf or

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

bench, precipitating an attack would suggest a vestibular basis. Relationship to eating might establish a hypoglycaemic basis.

Events that occur from sleep, even if only some of the time, are almost always epileptiform. Sleep disorders enter the differential diagnosis. Non-epileptic seizures (NESs) never occur from sleep, although some patients maintain they were asleep when they occurred, and this can be hard to resolve without video-electroencephalography (VEEG) monitoring [4]. Seizures are sometimes linked to particular phases of the menstrual cycle, and whilst once interpreted as a functional element, this is very common in women with organic episodes and should always be taken seriously.

Episodes that occur when under emotional stress, if in difficult circumstances, particularly in the cognitively impaired, might relate to behavioural problems rather than seizure activity; however, the distinction is sometimes difficult, and this can be further complicated when it is suggested that the behavioural alterations are a feature of a postictal state.

The symptoms in the immediate moments prior to the event are diagnostically critical. Those who describe focal neurological symptoms, such as clonic jerks, olfactory or gustatory hallucinations, rising epigastric aura, intense déjà vu or similar phenomena, are likely to be experiencing seizures; however, some symptoms can be fairly non-specific, such as light-headedness and dizziness. True vertigo is rarely a feature of epileptic attacks but it is not always easy to distinguish vertigo from brief seizures. A visual aura can be epileptiform but more often is migrainous. If a typical account of shimmering scotomatous deficit evolving over some minutes with or without a headache following, and possibly associated with other neurological symptoms, is described then migraine becomes a strong possibility.

The duration of attacks is probably the best single guide when considering the nature of the episodes. Epileptic events are almost always seconds to minutes in duration. Migrainous neurological symptoms are usually 15–20 min in duration; the subsequent headache can last for hours but may occasionally be absent, and if so there is a much greater likelihood that they will be misdiagnosed as seizures. With epileptic events, there is often some warning and gradual build-up to maximal deficit whereas, with ischaemic vascular episodes, the onset is abrupt and typically maximal deficit at the outset with gradual resolution. Since consciousness is usually unimpaired in focal cerebrovascular events involving the hemispheres, altered consciousness during attacks of this type is more suggestive of an epileptic aetiology. Generalized tonic–clonic seizures typically last 40–90 s but occasionally longer. Reports of attacks lasting hours, whether considered to be complex partial events or generalized tonic–clonic attacks, should always raise the suspicion of non-epileptic episodes. Although status epilepticus, both convulsive and non-convulsive, can certainly be prolonged it is a relatively uncommon event among people with chronic seizures.

After an event, rapid recovery, perhaps with sweatiness or nausea and vomiting, is more typical of syncope than of epilepsy. Tonic–clonic seizures are almost always followed by a period of confusion. Occasionally there is marked alteration in mood and behaviour postictally; less often a true psychosis occurs postictally which, although typically self-limiting, sometimes dominates the presentation.

Activity during the event often helps clarify the nature of the attack. If absences are typical with abrupt cessation of activity and prompt resumption of activity at the end of the few-second-long episode then the diagnosis is usually clear. Classical complex partial seizures with a warning followed by loss of contact, oral and manual automatisms and postictal confusion, sometimes with lateralizing signs noted during or after the event, are obviously clear cut. Generalized convulsive activity can be more difficult to distinguish from syncope. Generalized tonic–clonic seizures may or may not be preceded by a warning; the event usually lasts less than a minute or two, lateral tongue biting and incontinence are common, the eyes are often noted to be open with the eyeballs rolled upwards and there is often marked confusion postictally. The total absence of confusion after a generalized convulsive event should immediately raise the suspicion that the event was not epileptic.

During a seizure, well-organized motor activity is uncommon, though automatisms can sometimes be preservative and simple activities are continued, although in an incomplete and sometimes clumsy manner. The purposeless nature of motor activity during the events usually draws the attention of those around the patient. The normal performance of complex activity, such as driving a car, or riding a bicycle, suggests that the attacks are non-epileptic. Partial seizures of temporal lobe origin are usually associated with altered consciousness, at least to some degree, though this is often not perceived by the patient. There are accounts of patients suffering generalized tonic–clonic convulsions and being able to recall events around them after the episode. When this occurs, it is usually because the motor activity is actually caused by partial seizures of frontal or parietal origin, when consciousness can sometimes be preserved despite the bilateral symmetry of the motor activity [5].

Similarly, seizures of extratemporal origin, particularly those originating in the frontal lobes, sometimes have bizarre features that may be similar to non-epileptic events. Furthermore, VEEG monitoring with scalp electrodes can be unremarkable during these events, obscuring the issue diagnostically. Helpful clues are the stereotypic nature of attacks, which often cluster, and that they may occur from sleep. If unusual events occur in association with a structural cerebral pathology, the diagnosis is usually clear. Great caution must be exercised diagnosing non-epileptic events in patients with bizarre clinical events that have a structural pathology demonstrated on MRI, particularly if it is extratemporal in location.

Prolonged ‘absences’, typically occurring during driving, are a common reason for referral to the epilepsy clinic. The patient describes driving or walking some distance, and then finding themselves at their destination (or just missing it), and not able to recall how they got there. If they have made the trip without difficulty, arrived at their destination and there is no sign of damage to the vehicle, it is highly unlikely such activity occurred during a seizure. These patients – and the referring doctors – are typically very anxious about the event (in contrast to many patients who have had complex partial seizures whilst driving!). It can be difficult to provide satisfactory reassurance that this is a benign phenomenon experienced to some degree by many people.

Neurological examination is rarely helpful in patients who present with episodic disorders. Stigmata of a phakomatosis, the

finding of a significant hemiatrophy, lateralized weakness or reflex change and, of course, transiently lateralizing signs immediately postictally can be very useful. Directly after a seizure, the most useful physical sign is perhaps the observation of petechiae over the upper trunk and face in particular, sometimes a quite striking phenomenon but usually subtle. Tongue bites and evidence of incontinence might be present if the patient is seen early enough. Although most tongue bites are lateral after epileptic seizures (lateral tongue biting is a highly characteristic feature of an epileptic seizure and rarely due to other causes), lacerations of the tip of the tongue and occasionally even the lips or cheeks can occur. Injuries such as fractures and bruising are not so helpful, often occurring through loss of consciousness with syncope for example. Shoulder dislocation, particularly posterior dislocation, and crush-fractured vertebrae are almost diagnostic of a seizure and are never seen in syncope or non-epileptic events. Back pain or radicular pain post event should always be investigated with radiography of the region; these injuries are often not diagnosed correctly and can lead to significant problems in returning to normal activity.

Tests for vestibular abnormalities might be performed and sometimes provoke attacks. Cardiac examination might disclose features to suggest an alternative aetiology for episodic disorders. Cardiac bruits, valvular heart disease, cardiomegaly or postural hypotension, tics and other movement abnormalities might be detected during the physical examination. Occasionally patients have seizures whilst being examined; most often, these episodes are non-epileptic. Hyperventilation might be induced deliberately having informed the patient of your purpose, but other floridly non-epileptic attacks are sometimes brought on by simple tests, such as deep tendon reflexes, fundoscopy or suggestion. Great caution must be exercised when interpreting such events, but most often they provide strong primary evidence as to the true nature of the episodes. Vulnerable patients with epilepsy may easily be induced to have non-epileptic events in some circumstances, particularly if they believe the organic nature of events is being questioned. There is considerable pressure to 'perform' for some, whether during the examination and history or VEEG monitoring. Thus, the use of suggestion and other provocative procedures should only be performed in special circumstances [6]. Procedures such as the injection of saline are deceitful and unethical.

Laboratory tests, such as biochemistry and haematological screens, add little to the diagnosis of epilepsy. Occasionally, a primary metabolic disturbance such as hyponatraemia is found but this almost always occurs in a specific clinical setting and in the context of other recognized metabolic abnormalities. Elevation in creatine kinase and white blood cell (WBC) count might transiently occur after a seizure [7]. Serum prolactin levels rise transiently after seizures, reaching a peak at about 15 min after the event and returning to normal after around an hour. Obtaining a blood prolactin level can be useful then in the diagnosis of events of uncertain type, provided it is done close enough to the episode. Prolactin levels are elevated following generalized convulsions in about 90% of cases, following complex partial seizures in probably only about 50% and not elevated following simple partial episodes. There is some uncertainty as to how prolactin changes might be interpreted in other settings, such as syncope and migraine. Elevations of similar order of magnitude have been found in vasovagal syncope as in seizures [8]. Also, numerous medications and other pathological conditions can cause changes in prolactin levels, although these generally do not cause transient fluctuations like seizures do [9,10]. Although in principle serum prolactin ought to be a useful test, it is difficult to implement because of the time scale and the fact that most seizures do not occur in circumstances where obtaining an acute sample is possible. At times, though, serum prolactin estimation provides useful supportive information. It is not appropriately used as the primary diagnostic modality [7].

Other tests that can be useful include structural imaging, CT or MRI. Visualization of a focal cerebral pathology involving the cortex may provide useful supportive evidence for a diagnosis of epilepsy, but finding a structural pathology does not prove attacks are epileptiform. Conversely, not finding a structural pathology does not exclude a diagnosis of epilepsy, even if the symptomatology is focal. The sensitivity of MR scans particularly with quantitative measure is now so great that it is uncommon in focal seizures of long standing not to find a relevant abnormality. However, in some patients abnormalities are never demonstrated, perhaps because they are too small or subtle or because it is not a focal syndrome. The aetiology of these seizure types is often unknown and many appear to have a relatively good prognosis.

Functional imaging tests such as single-photon emission computerized tomography (SPECT) and positron emission tomography (PET) are more appropriately done in conjunction with VEEG monitoring or as part of surgical workup in specialty epilepsy units. They are rarely helpful as a diagnostic procedure.

Electroencephalograms (EEGs) and VEEG monitoring are extremely useful tests but need careful interpretation. Unfortunately EEGs show an enormous range of minor abnormalities, benign variants, artefactual change and other confusing features that are often misinterpreted as evidence that there is a cerebral disturbance of some sort [6,11–13]. Although EEG can provide confirmation of precisely the type of epilepsy, and occasionally the location of a structural pathology, more often it leads to erroneous diagnosis of epilepsy when minor changes are misinterpreted. The EEG should never be substituted for a good clinical history; EEG changes, even if epileptiform, should be interpreted cautiously. There is a very strong case to be made for not doing studies like EEG if the primary diagnosis is non-epileptic, provided there are strong clinical grounds for an alternative diagnosis. This is particularly true if the episode was unequivocally syncopal clinically, when minor EEG abnormalities may lead the otherwise confident clinician (and patient!) to less certainty. VEEG monitoring is as close to a gold standard as is available. Actually capturing events, witnessing directly the physical accompaniment of the attacks and observing the EEG changes that occur with this, often allows a specific diagnosis or the exclusion of epilepsy. However, simple partial events, extratemporal episodes, particularly from the frontal lobes even if associated with altered consciousness, are sometimes not associated with clear changes on the EEG. On the other hand, all most complex partial events and all generalized convulsions will show diagnostic EEG changes. The scalp EEG is very often normal in simple partial

seizures, particularly those involving sensorimotor cortex, even if the seizure activity is continuous.

Repeated observations over time also help make the correct diagnosis. Clinicians often feel obliged to arrive at the correct diagnosis immediately and at first consultation in episodes where alteration in consciousness has occurred, but when the diagnosis is unclear it is better to leave the diagnosis open. An erroneous diagnosis of epilepsy has serious implications for the patient. The concern with unexplained episodes of altered consciousness generally relates to safety, driving and perhaps in the work place, and these activities might need to be restricted if the nature of episodes is uncertain but this will depend on specific circumstances and the frequency of attacks and their character. Even if activities do need to be restricted to some degree, this is a much better precaution than the so-called 'therapeutic trial' of anticonvulsant that often gives rise to uncertain and confusing results, sometimes leading to the de facto diagnosis of epilepsy. Much more harm is done through the incorrect diagnosis of epilepsy than by keeping an open mind and reviewing the situation when more information is to hand, after implementing appropriate safety precautions.

Syncope

Syncope is defined as an abrupt but transient loss of consciousness, with loss of postural tone and followed by rapid recovery, due to sudden reduction of cerebral perfusion. It is common, can have serious cause, and is frequently complicated by injuries. It may be very disabling. The cost of syncope is extremely high, with patients seeing on average three physicians to reach a diagnosis, at an estimated cost of US$5000 per admission, and over US$20 000 to get to a definite diagnosis of syncope after admission [14]. Epidemiologically, syncope has many features in common with epilepsy. It appears often in late childhood and teenagers, with a second peak in the elderly. The lifetime incidence of syncope is 3–5% [15,16], with slightly more women affected than men. Because many do not present to physicians, the true incidence is likely to be much higher; some have estimated a 20–30% lifetime risk of a syncopal episode. It is more frequent in the elderly, with an annual incidence of 6% in those over 75 years old, who have a higher risk of injury. Neurocardiogenic (vasovagal) syncope is most common in early life; cardiac causes become more common later on. Whereas syncope due to cardiac disease is potentially life threatening, syncope as a result of other causes is generally benign [17]. The recurrence rate is at least 50% in those who present for evaluation.

There are a variety of causes of syncope (Table 4.1) but in over 25% of patients no cause can be identified [18,19]. There has been considerable interest in the syndrome of ictal arrhythmias, with a syncopal event complicating a subclinical epileptic discharge. Well reported in a relatively small number of cases, this situation is probably a rare cause of syncope. In patients studied with VEEG monitoring, it is rare to see symptomatic syncope complicating the frequently observed but usually minor disorders of cardiac rhythm that may occur during the ictus [20]. When this does occur, it is more likely in patients with temporal lobe foci. It may be the presenting feature of the seizure syndrome, and is thought to require cardiac pacing as well as anticonvulsant therapy if symptomatic [21–23].

Psychiatric causes
Unknown cause (SUO)

SUO, syncope of unknown origin.

Any seizure that occurs in specific circumstances should be regarded with suspicion. These are sometimes erroneously diagnosed as 'reflex seizures'. An excellent example is the patient who arrives with a referral describing seizures that only occur during or immediately after venesection (often when having blood taken for anticonvulsant levels!). Episodes occurring during micturition, defecation, coughing or with Valsalva, whether during weightlifting or deliberate, should suggest a diagnosis of syncope [24]. Often the precipitant for a syncopal event is not obvious and the patient will reveal it only if specifically questioned. Male patients particularly may be embarrassed to disclose painful or emotional precipitants, especially if they perceive that the circumstances are relatively minor. Good examples of this include syncopal events occurring in cinemas during violent or bloody scenes, during venepuncture, or watching minor surgical procedures. Even visiting hospitals, discussing medical procedures, reading an unpleasant book or reminiscing on a painful or unpleasant experience can be sufficient stimuli. The last example particularly applies to children, and events that have occurred under these circumstances should be considered syncopal until proven otherwise [25]. It is of course more obvious if the patient is undergoing a surgical procedure, or has seizures in the setting of some acute medical illness, but it is surprising how often epilepsy is misdiagnosed under such circumstances. Syncopal events related to primary cardiac disease less often have a well-defined aura than syncope due to neurocardiogenic episodes [26–28]. Cardiogenic syncope leads to sudden collapse and usually lacks situational precipitants.

In the lead-up to syncope, the patient has sometimes been unwell, sleep deprived or is 'run down'. It may be in the cooling down period after vigorous exercise, with a combination of vasodilatation and erect immobility, resulting in transient hypotension. At home, events are often in the kitchen, when prolonged standing is common, or in the bathroom, again associated with standing immobile for long periods but also with micturition or defecation. Standing in a hot shower, in supermarket queues and waiting for tickets, standing at church or at assembly are also common situations. They may be in a crowded warm environment such as a cinema or club. Alcohol has often been consumed, and this is frequently associated with a late night. The patient is often standing at the onset of the event, but syncope may occur while seated although rarely while recumbent. In the latter situation there is often some specific precipitant (i.e. pain). Familial

predisposition to syncope is common, and migraine frequently co-exists in these patients [29].

At the onset of the event frequent symptoms are nausea, often with a rising quality, light-headedness and sweating. There is often the urge to get outside into cool air. Anxiety and claustrophobia may dominate the account. Patients often describe 'I knew I had to get out' or 'I had to get some air quickly'. Anxiety is often marked at this point, leading the episodes to be confused with panic attacks. Witnesses may observe pallor and sweating, and may report the subject to be confused or semiresponsive. The event may progress no further than this, so-called 'presyncope', or go on to a more typical event with collapse. Immediately prior to loss of consciousness symptoms such as an auditory disturbance with noises 'sounding distant' or 'as if from down a tunnel' are frequently reported, then flaccid collapse. More complex auditory and visual hallucinations are surprisingly common, seen in 36% and 60% respectively of Lempert's series [26]. Visual hallucinations are sometimes quite complex, and may involve figures and scenes, and be associated with familiarity or even déjà vu [28,30,31]. 'Out of body' experiences have been described [26]. Auditory hallucinations are usually of ringing or roaring, sometimes voices are described though, and, as with partial seizures, these often have a familiar but unidentifiable quality about them.

Generalized stiffening and then clonic limb movements are frequently described by witnesses. The limb movements are usually asynchronous but multifocal, and sometimes seen to involve one limb or side asymmetrically, rarely exclusively. Facial involvement with the myoclonic limb movement is common. Head turning is rarely seen, but that and asymmetric dystonic limb posturing are certainly recognized. Estimates of the frequency of tonic and clonic components range from 40% to 90%, and depend on the quality of the witnessed account [32,33]. Medical or paramedical personnel are perhaps most prone to confuse the events with epileptic convulsions, testimony to the often dramatic nature of the convulsive activity. Eyes are usually open during the event, and sometimes oral and perseverative manual automatisms can occur. Automatisms of this type may be seen in the presyncopal phase also [27]. Head turning is a feature more often seen with seizures, but can be seen in syncope, as can dystonic posturing of the upper limbs, which may be asymmetric. Salivation may be noted also [34].

Typically, the duration of the convulsive activity is less than 15–20 s but, rarely, prolonged convulsive activity may be provoked. This is more likely if the subject is held upright during the event, usually by well-meaning bystanders, or if there is an underlying cause that persists. Urinary incontinence is not uncommon in syncope, a fact surprisingly little known among physicians. Respiration is seen to briefly cease in some instances. On recovery the patient is usually quite lucid, and in the elderly confusion postictally can be marked with syncope. Patients often report feeling 'washed out', occasionally for prolonged periods after the event, and will often prefer to sleep. Tongue biting is seen very rarely, perhaps when a hypoxic seizure has complicated syncope, but can certainly occur. Shoulder dislocation and bony injuries are rare. Lateralized neurological signs should not be seen in the postictal phase. Vomiting and marked diaphoresis are often reported in the postictal phase and the patient often appears grey and unwell. Cyanosis is rare, in contrast with epileptic events [24]. The marked confusion and drowsiness that follow epileptic convulsions are not usually confused with these features, but sometimes it is a difficult distinction, particularly if the patient sustained a significant blow to the head during the episodes. Syncopal episodes often occur in clusters, sometimes one after another, frequently as the patient is helped up from the first collapse. Where the sitting position is forced through restraint, such as with a car seatbelt, quite prolonged reflex anoxic seizures sometimes occur. A similar situation may be observed after cardiopulmonary arrest, when delayed seizures may be pronged and recurrent.

Examination is typically unrewarding; patients usually have normal resting blood pressure and appropriate postural responses between episodes. Even if measured immediately after the event, no abnormality is the rule, although contributing factors should be looked for including a primary arrhythmia, hypotension, inappropriate bradycardia and carotid sinus hypersensitivity. Fall-related injuries may be noted, usually in the form of facial trauma. Elevated creatine kinase levels, although more typical of a generalized convulsion, may be seen with syncope (even after those with trauma are excluded), although typically levels are much higher [35]. Elevated CK-MB levels have also been reported in syncope [36].

Features of syncope that should alert the clinician to the possibility of a serious underlying cardiac condition include a history of coronary artery disease or congestive cardiac failure, precipitation by exercise, palpitations at the onset or the occurrence of the events at the peak of exertion, an abnormal ECG, family history of sudden death and breathlessness with the episodes. Scoring systems to define those at higher risk in the emergency department have been devised [37].

If the history is typical, extensive investigation should generally be avoided in patients with syncope. However, if there is diagnostic uncertainty, or if the events are frequent, cause anxiety, limiting activity, or if a cardiac arrhythmia is suspected then investigations are appropriate. If the event can be induced by reproducible stimulus (i.e. venepuncture or pain) then it may be practical to induce an event when under electroencephalography or electroencephalography monitoring in order to document the typical features of neurocardiogenic syncope with ictal bradycardia or asystole associated with profound slowing of EEG patterns. Routine ECG tracing, echocardiography and chest radiography may be indicated. Because events are rarely frequent enough for spontaneous episodes to be recorded during inpatient monitoring, ambulatory studies with Holter monitoring, or more recently implantable loop recorders, may be more appropriate. Loop recording can be done for periods of up to 18 months, and is clearly the investigation of choice in many of these patients. A recent study demonstrated a surprisingly high rate of primary cardiac arrhythmias in patients misdiagnosed as suffering from refractory epilepsy [38].

Tilt table testing has been available for some time but its use remains controversial, particularly in relation to provocative drugs used to increase the sensitivity of the test, and interpretation of the results. Although this is a valuable adjunct to diagnosis in many patients, the wide range in results between centres should be recognized [39]. Carotid sinus massage may be helpful in the diagnosis, but this finding has low specificity in the elderly

population where it is most often found. Cerebral imaging may be useful in some cases, and finding a cerebral cortical pathology suggesting an epileptic basis will be helpful in management of a patient with refractory syncope.

Treatment of syncope depends on the cause. If a clear cardiac cause is demonstrated, specific therapy is obviously indicated. Most people, however, have neurocardiogenic syncope, and their treatment consists primarily of reassurance and avoidance of precipitating circumstances. When typical premonitory symptoms are recognized, preventative measures should be promptly undertaken. Usually this consists of lying or sitting with the head between the knees, and rising cautiously and slowly after the episode seems to have abated. Attention to hydration is an important element in many, as may be avoiding alcohol. Other drugs, such as antihypertensives, may require adjustment. The patient should be counselled about other agents that may provoke or precipitate syncope: alcohol, calcium channel blockers, ACE inhibitors, beta-blockers, barbiturates, prazosin, diuretics and sildenafil citrate are some of the more frequent offenders. Other conservative measures include increasing salt consumption and 'tilt training' [40], although the role of the latter is uncertain [41]. Isometric exercises of the upper limbs (squeezing a ball such as a darning ball, leg crossing) are often utilized, and have been shown to be effective in neurocardiogenic syncope [42].

Therapeutic data from large randomized controlled trails relating to neurocardiogenic syncope are very limited [43]. Evidence for the use of lipophilic beta-blockers remains controversial, but the recent prevention of syncope trial (POST) study did not find evidence of efficacy for metoprolol [44]. Serotonin reuptake inhibitors [45], ACE inhibitors [46] and midodrine [47] are the only agents that have been shown to be effective in randomized controlled trials. A large RCT with fludrocortisone is currently in progress [48]. Elastic stockings, with or without fludrocortisone, are used widely but, like disopyramide, have not been shown to be effective. Cardiac pacing had been shown effective in two randomized controlled trials [49] for the treatment of refractory neurocardiogenic syncope, but is now felt perhaps to represent the non-blinded nature of these studies and a reflection of expectation rather than real benefit [50].

Post-concussive events [51], in which tonic posturing, clonic movements or confusion stares are seen shortly after a concussive injury, are felt by some to represent a syncopal event, although there is some evidence to suggest such injuries have an epileptic basis. Either way, the prognosis is excellent and recognition of this distinctive syndrome important, particularly in the emergency department setting.

Non-epileptic seizures

Non-epileptic seizures (NESs) has become the preferred term to describe the events referred to often as pseudoseizures, psychogenic seizures or hysterical seizures, as it lacks the pejorative implications of the older names. Definition of these episodes is difficult; convulsive activity is witnessed but has no electrical correlate and is felt to reflect psychological stresses of some sort, though these are rarely specifically identified [52]. These episodes may be extremely difficult to distinguish from epileptic events, even by experienced observers. As a result, one of the most useful applications of VEEG monitoring has been to recognize and clarify these events. Although in some series up to 40% of patients with refractory seizures have NES, a more realistic proportion is 5–10% [6,11,12,52–54]. Patients with NES consume a disproportionate amount of resources at epilepsy centres – the patients present frequently and dramatically, often have inpatient stays and seek more consultations with neurologists. They typically consume more medications than those with organic seizures alone. Often they receive health benefits of some sort, are unemployed and require high levels of care at home [52].

There is no consensus on the mechanism of these events from a psychiatric point of view, and often no specific psychiatric diagnosis can be made; the disorder itself seems to be the sole clinical manifestation of the problem [55]. Recent work has suggested the events are best considered as a manifestation of a personality disorder [56]. Munchausen's syndrome by proxy, in which the description of seizures in the child is fabricated by the caretaker, is a form of child abuse and represents a different situation [57].

The clinical features of NES vary enormously. Although it is often precipitated by emotional stress or specific circumstance, this is not always the case. There is sometimes a family history of epilepsy, of epilepsy earlier in life or of personal encounters with epileptics, perhaps in a paramedical situation or as a carer. Events are usually very disruptive and dramatic, typically leading to multiple hospital admissions, and have a propensity to occur in public where they may be readily observed. Although there are many reports of a high rate of co-existence of NES and epilepsy, this is in fact a very uncommon occurrence [11].

The events themselves may consist of loss of contact, flaccid collapse and immobility or florid motor activity, often with side-to-side head shaking, pelvic thrusting and back arching. Variability from one event to another is common, making the lack of stereotypy a valuable clinical feature. The prolonged duration of many of the episodes is the most obvious clue to their non-organic nature. It is not uncommon for episodes to wax and wane from 30 min to hours in duration. Crying and screaming may be striking features of the episodes, and complex organized activity may be seen. Eyes are usually held closed during the episodes. Cyanosis is infrequent, but can be seen in some patients who may have what appears to be an adult version of breath-holding attacks. Tongue biting and urinary incontinence are sometimes reported (but rarely confirmed), although mainly by patients with a long history of this disorder. Interestingly, almost exclusively this group of patients reports fecal incontinence. After the event recovery is usually rapid and often accompanied by emotional distress. However, not all events resolve rapidly, and prolonged unresponsiveness with normal vital signs may follow. The lack of tachycardia during this phase is a helpful feature diagnostically but may be complicated by the sometimes frenetic motor activity of the episode. This may cause elevated creatinine kinase levels on testing, helping to reinforce the organic basis of the episode to emergency department staff and intensivists, who frequently deal acutely with such patients.

Typically, many anticonvulsant medications have been prescribed without benefit. Furthermore, some patients have been treated urgently with parenteral benzodiazepines or even paraly-

sis and intubation in a critical care setting. In many centres, NES is the most common cause of uncontrolled seizures in the intensive care environment and should always be considered as the diagnosis when a patient with chronic seizures presents in status without obvious cause.

Some non-epileptic events are embellished organic syndromes, such as syncope or hyperventilation. The clinical scenario occurs in a hysterical or anxious person who experiences syncopal symptoms, hyperventilates and then evolves into a very complex and clearly non-organic behaviour that attracts attention while the prodrome becomes lost in the drama.

Confirming the diagnosis may be a challenge unless monitoring (VEEG) is utilized. Patients who refuse monitoring, or those who have no events while being monitored, present a very difficult diagnostic problem, but most will have typical events in hospital. Often they can be encouraged by suggestion to produce episodes. Some centres have used other provocative manoeuvres, such as saline injection, but this may make interpretation of the events more difficult because there is considerable pressure on the patient to 'perform' and typical attacks may not be evoked [38,58]. As part of the illness involves the drama and frequency of the seizures, usually outpatient VEEG monitoring will be sufficient to make the diagnosis [53,58].

Epileptic seizures that are commonly mistaken for NES are frontal lobe seizures and simple partial seizures. Seizures originating in the frontal lobe can be bizarre, frequent, and associated with preserved awareness, and they are often refractory to medication. The stereotypic nature of the events, many of which may occur from sleep, and usually some response to acute parenteral therapy provide clues. However, VEEG may not demonstrate significant change during these episodes and movement artefact frequently obscures interpretation.

A diagnosis of simple partial seizures may be difficult to be certain about as the seizures are often not accompanied by scalp electroencephalography changes. In these situations the finding of a relevant structural abnormality on imaging studies supports the diagnosis of seizures, but negative imaging studies do not exclude it.

Management of NES is complex and difficult [52,55,56,59]. Engaging the patient in a therapeutic relationship is the most valuable component, followed by an explanation of the non-electrical basis of the events and recognizing that the condition causes disability. Confirming this belief with the patient takes much of the tension out of the situation. Confronting patients with a diagnosis of functional illness does little for their long-term care and often leads to re-presentation to other hospitals, with the consequent risk of inappropriate therapy. A face-saving compromise is often required, with an agreement by the patient to reduce or withdraw anticonvulsant therapy, avoid hospitalization and, where appropriate, to seek help from a psychiatrist to address underlying issues, such as depression. Accepting the care of one neurologist, or at least of one centre, is a major component of the clinical management plan [56]. However, controversy exists as to whether these patients should be managed by neurologists at all (in my view psychiatrists have little to offer these patients) and the temptation to treat with anticonvulsants is too great in the primary care setting. Engaging the patient in a positive therapeutic relationship minimizes risk, enables the anticonvulsant medications to be managed appropriately, and can lead to a good long-term outcome.

Panic disorder

Panic attacks can appear very similar to seizures They are episodes of fear or discomfort that are often accompanied by somatic symptoms such, as palpitations, dizziness, light-headedness and epigastric sensation, which may have a rising element [60,61]. The attacks have an abrupt onset, typically reaching a peak within 10 min. Hyperventilation is often prominent. Fearful patients want to escape and feel that the episodes indicate a life-threatening disorder. The attacks can be situational but most often occur spontaneously without a clear precipitant. As with seizures, attacks can be nocturnal and can cluster, occurring many times daily after long breaks between episodes. Overlap with the symptomatology of both complex partial seizures and syncope is marked, and seizures are not infrequently initially misdiagnosed as panic attacks, rather than the reverse [62].

Lifetime prevalence has been estimated at around 2%, with a higher risk for women. There is a significant familial incidence. Although the condition is usually diagnosed in young adults, it has been described in children and the elderly. Highly variable in severity, these episodes are often disruptive and overlap considerably with other psychiatric syndromes, particularly agoraphobia and depression. At least 50% of patients with panic disorder develop a significant depressive illness during their life; the majority are depressed when they present for treatment [63].

Management consists of a reassurance directed at specific unfounded concerns regarding underlying illnesses and psychiatric therapy of the phobic and depressive elements [63].

Migraine

Migraine is surprisingly often mistaken for epilepsy, particularly when the headache is mild or absent [64]. Migrainous aura may have visual, sensory or motor features that are suggestive of seizure activity and alertness is sometimes impaired. Postictal headache is common in epilepsy and often has a vascular quality, which may further complicate the diagnosis. Migraine and epilepsy may share a common pathophysiological basis [65].

Some unusual types of seizures, particularly those that originate in the occipital lobe, can be difficult to distinguish from migraines because features such as visual disturbance occur in both disorders [66,67]. Because there is no diagnostic test for migraine, the diagnosis is clinical. Migraines are more common among those who suffer syncope and there is often some overlap with the symptoms. Although visual disturbances are the most common neurological feature of migraine, sensory or motor change, speech disturbance, amnesia or confusion and even loss of consciousness may occur.

Migraine may have specific triggers, such as foods, medication, emotional stress or visual stimuli. Sensory or visual symptoms generally build up slowly and typically spread over minutes, progressing stepwise from one affected cortical region to the next, with resolution of the symptoms occurring as each new region

becomes involved. Typical symptom duration is 15–30 min, although occasionally episodes last longer and may not be followed by headache.

As epilepsy and migraine are both common, one might anticipate encountering them occasionally in the same patient. This has been studied by a number of authors [68] with differing results. There seems to be no excess of epilepsy among patients with migraine overall [69]. Marks and Ehrenberg [70] showed 20% of 395 patients with epilepsy had migraine, and 3% had migrainous phenomena immediately preceding seizures, for which they coined the term 'migralepsy' [71]. They also noted that there seemed to be a particular link between catamenial epilepsy and migraine with aura. Some authors have postulated that migraines might be a seizure equivalent [72].

Postictal migraine is well recognized and may have some lateralizing value [69,73]. Seen in focal and generalized syndromes, it more often occurs after a tonic–clonic convulsion. Ito *et al.* [74] showed that migraine-type headaches were more common in those with occipital and temporal epilepsies than in events of frontal lobe origin [74]. The increased cerebral blood flow that is induced by seizure activity is felt to be responsible for this headache. Often these types of headaches occur in patients who suffer migraines at other times. However, the patient who presents with new-onset headache and seizure obviously requires the exclusion of an acute neurological problem, such as intracranial haemorrhage or infection.

Seizures of occipital origin have many features of migraine, with visual hallucinations or amaurosis often complicated by headache. Benign partial epilepsy with occipital paroxysms is a syndrome of childhood to teenage years [75,76]. Hallucinations are typically simple in nature but can be complex and followed by complex partial or generalized convulsions [77], after which come the headache with nausea and vomiting. The diagnosis depends on observing the distinctive interictal EEG pattern. Occipital seizures resulting from structural pathologies, such as coeliac disease and mitochondrial encephalomyelopathies, may share these features [78].

Non-specific EEG changes occur with migraine, but specific epileptiform abnormalities are rare [75]. Finding interictal spikes in patients with migraine suggests an alternative diagnosis, such as benign occipital epilepsy in children or the possibility of a structural lesion in adults. As a rule, electroencephalography is not useful in typical migraine. Minor abnormalities seen during episodes need to be interpreted with great caution.

The diagnosis of migraine is clinical and rests on recognizing the typical progression of symptoms, the duration of attack (tens of minutes rather than seconds), and gradual resolution. Response to anticonvulsant therapy is an unreliable basis for making the diagnosis.

Sleep disorders

A review of the many abnormalities that arise from sleep is outside the scope of this brief chapter. However, sleep disorders, such as periodic limb movements of sleep, rapid eye movement (REM) sleep disorders, narcolepsy and cataplexy, can be confused with seizures [79,80]. On the other hand, some epilepsies arise exclusively from sleep and there is a propensity for partial seizures to occur in sleep or shortly after waking [81]. Benign rolandic epilepsy is an example of a seizure syndrome that is associated with sleep.

The parasomnias, including sleep walking, night terrors, restless legs, nocturnal myoclonus, bruxism and REM sleep disorder, can be more difficult to differentiate from seizures [82], whereas disorders with hypersomnolence rarely present diagnostic problems. Sleep disorders are common, particularly in the elderly. Obstructive sleep apnoea has been recognized to precipitate seizures in the elderly with epilepsy [83], and REM sleep disorders have been recognized to be more common in patients with epilepsy, perhaps because of a shared pathological substrate, thus often causing diagnostic confusion [84].

Although the classic tetrad of narcolepsy involves excessive daytime sleepiness, cataplexy, hypnogogic or hypnopompic hallucinations and sleep paralysis, not every component occurs in a given individual. The diagnosis is based on sleep latency studies in which REM sleep begins abnormally early. Cataplexy, sudden episodes of sleep, and hallucinations are sometimes misidentified as seizures [85]. Rarely, cataplexy precipitated by laughter is mistaken for a gelastic seizure.

Paroxysmal nocturnal dystonia presents as an often dramatic movement disorder from sleep. Typically, there is arousal and then vigorous motor activity. Episodes typically last 30–60 s, followed quickly by sleep [86]. There is amnesia for the episodes. Many patients originally diagnosed with this condition have since been recognized to have frontal lobe epilepsies [80,87]. The diagnosis is made all the more difficult by movement artefact obscuring EEG traces made during the episodes. Video, without electroencephalography, is often helpful in differentiating the two conditions. The history of daytime seizures is also helpful in confirming a diagnosis of epilepsy.

Night terrors (*pavor nocturnus*) are a childhood parasomnia. Children wake from sleep screaming and crying inconsolably for many minutes, after which they go back to sleep and are amnesic of the episode. Autonomic features may be prominent and there are sometimes vocalizations. Events usually occur from slow wave sleep, typically 30 min to 4 h after going to sleep. Rarely, night terrors persist into adult life. If the diagnosis is in doubt, ictal EEG recordings can confirm that these do not have an epileptic basis [88,89]. Sleepwalking is a related problem, and the features are well known to the general population [90]. The automatic activity of wandering is sometimes less florid, featuring motor activity that may imitate the automatisms of complex partial seizures, with repetitive hand movements.

Bruxism, or tooth grinding, can be a very striking nocturnal phenomenon. It is a benign disorder that requires no specific therapy. Hypnogogic myoclonus, although a normal event most have had experience of, sometimes brings patients to the epilepsy clinic, often through the observations of an anxious partner and sometimes in the setting of recognized epilepsy. Pathological fragmentary myoclonus, in which fragments of myoclonus of early stage sleep persist into stages 3 and 4, may be seen with any cause of disrupted sleep.

Periodic movements of sleep are so distinctive that it is rare for them to be confused with seizures [91]. They are characterized by repetitive flexion and extension, sometimes quite vigorously,

of hip, knee, ankle and toe for a period of 30 s or so. The episodes frequently recur throughout the night, troubling the bed partner but not the patient.

The REM behaviour disorders are much more complicated. These episodes occur from REM sleep and consist of the individual acting out components of dreams. Sometimes dramatic and prolonged, the activity can be complex, violent or aggressive and accompanied by agitation and vocalizations. Typically recurrent, the attacks present a risk of injury for the partner. Causes include structural brain injury, such as subarachnoid haemorrhage. In some situations REM behaviour disorder might be difficult to distinguish from postictal confusion [88].

Although most parasomnias can be distinguished from epileptic disorders by their distinctive clinical features, polysomnography allows definitive diagnosis in most instances [92].

Vertigo

Vertigo with brief episodes of dysequilibrium is often misinterpreted as seizure activity, at least by referring physicians. This is because many patients describe the episode as involving loss of awareness, although this is not confirmed by witnesses. Although vertigo may rarely occur as a feature of focal seizures, especially those originating in frontal or parietal regions [93,94], other non-specific symptoms, such as light-headedness and dizziness, are more often reported as a feature of convulsive episodes.

In vertigo caused by peripheral vestibular causes, the episodes are often provoked by head movement, as in benign positional vertigo, and are associated with nausea and vomiting. Sometimes eye signs can be seen during the attacks. Although witnesses typically observe consciousness to be preserved during episodes of vertigo, it is not uncommon for patients to report the sensation of loss of awareness briefly during a severe brief vertiginous episode. In so far as attacks sometimes lead to falls, they imitate epilepsy. Careful history, provocative manoeuvres such as the Hallpike test and, sometimes, vestibular testing may be required to make the diagnosis. True vertigo is a very uncommon feature of epileptic seizures.

Movement disorders

A number of movement disorders can imitate epilepsy. Paroxysmal choreoarthetosis or dystonia, both kinesogenic and non-kinesogenic forms [95], are movement abnormalities with striking posturing or chorea that are precipitated by sudden movement, surprise or startle, stress or rapid movement. Some forms are aggravated by alcohol, caffeine and fatigue. These are often unilateral and consciousness is preserved during the attacks. The episodes are often mistaken for focal motor seizures and the description of hemitonic seizures with preserved consciousness should raise the possibility of a paroxysmal dyskinesia. Similar symptoms might be secondary to demyelinating disease or other primary cerebral pathologies. The so-called tonic seizures of multiple sclerosis may be unilateral or bilateral and are sometimes precipitated by movement. Occasionally these entail what is interpreted as clonic movements, particularly as the attacks resolve [96]. Inability to speak during the episode may be interpreted by witnesses as altered awareness. The abrupt onset and extent of the attacks, as well as the lack of focal onset and typical rhythmic activity at the onset, are clues as to the true nature of the episodes. However, seizures, particularly those of frontal lobe origin, occasionally can cause abrupt tonic posturing.

Epileptic seizures precipitated by startle (startle seizures) often take the form of asymmetric posturing and collapse. These occur usually in epilepsy of frontal lobe origin. Sensitivity to startle often occurs in late childhood and recedes in later life. The episodes usually occur in cognitively impaired patients [97]. Often a hemiparesis is present, and other seizure types occur. The startle attacks might progress to more obvious convulsive seizure activity. Startle seizures can be mistaken for non-organic events and for paroxysmal dyskinesias. Hyperekplexia is a rare disorder of infancy, where an exaggerated startle response occurs in response to unexpected stimuli, particularly auditory events. After the initial startle, with exaggerated blinking and generalized stiffening, there may be vigorous limb jerks and head extension. Hypertonicity is often noted on handling of these infants. A variety of other features have been described, including periodic limb movements in sleep. The condition gradually improves. The condition spontaneously remits in the first years of life. Autosomal dominant and recessive forms of the disease have been described and a variety of genes have been associated with the condition.

Cerebral ischaemia

Vascular disturbances typically produce an abrupt onset of negative motor and/or sensory phenomena, speech disturbance or visual abnormality without alternation of consciousness. When this occurs in an elderly person at risk for cerebrovascular disease, the diagnosis is usually clear. Recurrent episodes of limb weakness, speech disturbance or paraesthesia in a limb have much in common with focal seizures. Ischaemic attacks tend to be maximal at the onset, last for a period of seconds to minutes, do not affect consciousness, and do not progress to more typical seizure activity. Neuroimaging, including echocardiography and carotid Doppler or angiographic studies, might allow a definitive diagnosis. Clonic jerking of the limb has been reported with transient ischaemic episodes and there may be some overlap here with seizure activity occasionally resulting from cortical ischaemia [98]. In general, the differentiation of cerebral ischaemia from seizure activity is straightforward. However, the most frequent seizures in the elderly are complex partial and thus can be missed by the unwary evaluator.

Endocrine and metabolic abnormalities

Disturbances of hormones, glucose, fluids and electrolytes can cause seizures or seizure-like events [99]. When occult abnormalities such as insulinomas present with seizures, the diagnosis can be challenging. The most common cause of transiently altered awareness due to endocrine abnormality is hypoglycaemia related to insulin therapy of diabetes. This can cause confusional episodes, generalized tonic–clonic convulsions and sometimes

episodes imitating focal seizures. Although hypoglycaemia is common, it usually presents to the primary treating doctor rather than to a neurologist.

Hypoglycaemic episodes can be mistaken for vasovagal syncope or seizures. Other than insulin therapy, causes of hypoglycaemia include alcohol, insulin-producing tumours, rare inborn metabolic abnormalities, such as the congenital deficiencies of gluconeogenic enzymes, and renal or hepatic disease [100,101]. Reactive hypoglycaemia may occur postprandially, or in association with other enzyme abnormalities, such as hereditary fructose intolerance.

The symptoms of hypoglycaemia include altered vision, diaphoresis, confusion, coma and altered behaviour in addition to partial and generalized seizures. Perioral and peripheral paraesthesiae, dysarthria, ataxia, tremor and palpitations are common features. Occasionally, true vertigo occurs. Some patients describe the symptoms as 'anxiety', or in otherwise non-specific terms. There is usually a prodromal period with prominent hunger. The behavioural change can be extremely bizarre, and hypoglycaemia should be considered in any patient with periods of unusual or prolonged episodes.

The relationship of symptoms to eating or fasting provides clues about the cause. The diagnosis is confirmed by measurement of serum glucose at the time of the event. Sometimes the rate of change of serum glucose levels is more important than the absolute glucose level. Hyperglycaemia can cause seizure-like activity and focal seizures are well described as features of hyperglycaemic states [102], sometimes in association with other neurological symptoms, such as movement disorders or lateralized weakness [103]. Hypocalcaemia can produce paraesthesia, carpopedal spasm, laryngeal stridor or convulsions [104]. Consciousness is preserved unless a generalized tonic–clonic seizure occurs. Hypocalcaemic sensory disturbances are sometimes misinterpreted as an aura.

Seizures rarely complicate a number of other endocrine abnormalities, including hypocalcaemia, hypo- and hyperthyroidism, generally only when the disorders are extreme. Phaeochromocytoma and other catacholamine-producing tumours can produce paroxysmal symptoms that might be mistaken for presyncope, anxiety or seizures. Flushing and palpitations due to phaeochromocytoma usually last longer than the autonomic features of seizures. Menopausal symptoms, such as hot flushes and paroxysmal sweating, are sometimes misinterpreted as seizure related. Seizures might be aggravated by hormonal change, such as those who suffer seizures in relation to the menstrual cycle, but again this is generally fairly clear [105].

Transient global amnesia

Transient global amnesia is an illness of uncertain aetiology. Some authorities feel it represents cerebrovascular disease, others attribute it to migraine and still others regard it as an epileptiform phenomenon [106]. Most would agree, however, that it is not an epileptic event. These stereotypic events are quite characteristic and easily recognized by the experienced clinician [107]. Amnesic episodes are recurrent in 8% of these patients.

The patient typically presents in a confused state, unsure of what they are doing or where they are going. Although they have little awareness of their current circumstances, they typically retain personal information. The episodes can last up to hours, after which small islands of memory start to return of what went on during the amnesic period. However, some never recover any memory for the time that was involved. As a result, these episodes typically cause great anxiety to those around them.

Although slightly perplexed or agitated during the attacks, no focal neurological abnormalities are found. EEGs and structural imaging are normal and blood tests provide no clues. However, the description of events is so characteristic that the diagnosis is generally straightforward. Most patients have a history of migraine and sometimes the episodes are followed by headache [108]. Rare causes include lacunar strokes.

The condition can be confused with the confusion after a generalized tonic–clonic seizure in cases where the seizure was not noticed. However, postictal confusion is generally global and lacks the peculiar specificity of the true transient global amnesic attack [109]. Patients with transient global amnesia need no further investigation and no other specific therapy besides strong reassurance.

5 Mechanisms of Epileptogenesis

Giuliano Avanzini and Silvana Franceschetti

C. Besta Foundation, Neurological Institute, Milan, Italy

Over a century and a half ago, Hughlings Jackson [1] defined epileptic seizures as 'an occasional, sudden and excessive discharge of grey matter'. This statement can be viewed as the culmination of a series of previous studies of animal electricity started by Luigi Galvani [2] and von Humbolt [3], and subsequently pursued using cortical stimulation experiments by Fritsch and Hitzig [4] and the clinical observations of Todd [5]. The scientific quality and prescient ideas of Jackson's work, however, mark the beginnings of the modern era of epileptology. Since then, increasingly refined investigatory techniques have provided a great deal of information about how epileptic discharges are generated and propagated within the central nervous system, and the many different ways in which they manifest themselves that we have learned to recognize from clinical observation. David Prince coined the term of 'epileptogenesis' [6] to describe the various pathogenetic mechanisms of epilepsy. Subsequently, owing to the emphasis given to the progressive course of some of these mechanisms, the term epileptogenesis has often been employed to define the process whereby an initial event leads to the constitution of a persistent epileptic condition. This section is devoted to the important concept of epileptogenesis as a process and the term *epileptogenesis* will be used in Prince's original context, irrespective of whether the mechanisms that we are referring to are the result of a progressive process or not.

As in the case of many other pathological conditions, experimental models made a major contribution to our understanding of epileptogenesis. The term 'experimental models' should be restricted to animals presenting spontaneous or experimentally induced epileptic seizures, whereas *in vitro* or computer models are more properly called models of epileptogenic mechanisms. This is not just a question of semantics, because the relevance of experimental results to the advances made in our understanding of epilepsy depends on how suitably the experiment has been designed for this purpose. Operationally, it is enough to say that an experimental preparation should be referred to as a model (of epilepsy, seizures, or epileptogenic mechanisms) only if it has been demonstrated that it faithfully reproduces the clinical and electroencephalographic characteristics of human epilepsies or seizures, or the biological changes that are known to be associated with them. Over the last few years, animal experiments have been effectively supplemented by human tissue studies of brain specimens surgically removed for the treatment of drug-refractory epilepsies. Experimental studies have shown that a number of different agents that affect excitatory or inhibitory neurotransmission, intrinsic cell excitation mechanisms or the ionic microenvironment can induce seizures.

A key to the investigation of cellular epileptogenic mechanisms came from studies of Matsumoto and Ajmone Marsan [7] (who were among the first to observe them in penicillin cortical foci). They showed that neurones belonging to an epileptic neuronal aggregate consistently discharged in the form of particularly protracted 'bursts' (Fig. 5.1), which are referred to as paroxysmal depolarization shifts (PDS). In a normal brain, this phasic type of cell discharge can also be seen in some 'intrinsically bursting' (IB) cell subpopulations of the neocortex and in area 3 of Ammon's horn (CA_3) in the hippocampus: both are particularly involved in synchronizing cortical activity. In both experimental epileptogenic foci and epileptic human tissue, spontaneous or stimulus-evoked PDSs have been found to occur commonly in physiologically nonbursting neurones, and can therefore be considered reliable hallmarks of an active epileptogenic process [6].

Epileptogenic procedures, such as the blockade of γ-aminobutyric acid (GABA)-mediated inhibitory neurotransmission by bicuculline, picrotoxin and penicillin or the potentiation of excitatory amino acid (EAA)-mediated transmission by the kainate, ibotenate or *N*-methyl-D-aspartate (NMDA)-selective agonists, are all capable of inducing generalized phasic PDS-like activity in cortical cells. Similar effects can also be obtained by means of epileptogenic agents acting on the intrinsic mechanisms responsible for membrane excitability, such as Na^+ or Ca^{2+} depolarizing current activators [veratridine or ethylene glycol tetraacetic acid (EGTA) and 1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,-*N*′,*N*′-tetra-acetic acid (BAPTA)] or the inhibitors of hyperpolarizing K^+ currents (tetraethylammonium, intracellular Cs^{2+}, 4-aminopyridine).

In this chapter, particular attention will be given to the epileptogenic mechanisms that putatively account for naturally occurring animal and human epilepsies.

Membrane ion channels

The excitability of nerve cells depends on the movement of ions through specific voltage-dependent or receptor-activated membrane channels. The kinetics of transmembrane ion currents has been extensively investigated by means of various types of voltage-clamp recordings, whereas the effects of ion currents on cell membrane potential can be detected by means of current clamp recordings.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

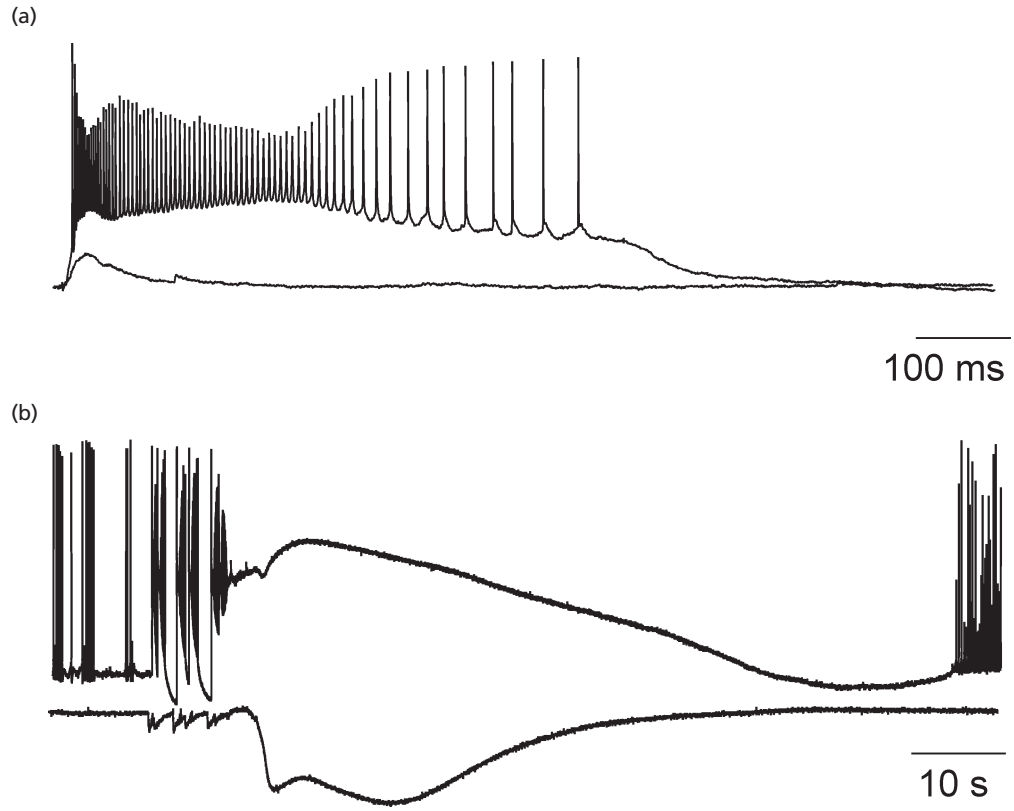

Fig. 5.1 (a) Intracellular recording from a neocortical pyramidal neurone perfused with the GABA antagonist bicuculline reveals a paroxysmal depolarization shift (PDS) evoked by an afferent synaptic stimulus. Note that a subthreshold stimulus evokes a normal excitatory synaptic potential. (b) Uppermost trace: same display as in (a) at a different time scale to show in the same cell the transition from interictal PDS to a sustained ictal discharge. Note spontaneous recurrent PDS eventually merging in a long depolarization lasting about 10 s, which is considered to represent an ictal event at cellular level. Lower trace: field recording of the discharge synchronously involving a large neuronal population.

Ion channels are hetero-oligomeric membrane proteins, typically consisting of 2–6 subunits including transmembrane segments that are assembled in a variable number of domains. This is seen in Fig. 5.2, which shows the subunit structures forming ligand- and voltage-gated channels. Fig. 5.2 also shows the disposition of N and C termini: from the extracellular side of the membrane in ligand-gated channels (receptors), and from the cytoplasmic side in voltage-gated channels. The N-terminal region is particularly important in beginning the process of subunit association that leads to channel assembly, a process that is facilitated by the presence of accessory subunits and significantly influenced by a large number of different environmental influences. It leads to the formation of channels with different degrees of permeability to the various ions and different opening and inactivating kinetics, depending on the type of subunits assembled, their stoichiometric characteristics, and the relative position of each subunit within the hetero-oligomeric complex. The contribution of channel–receptor-mediated transmembrane currents to the generation of action potential and PDS is schematically depicted in Fig. 5.3.

The identification of the molecular structure of the various subunits and their corresponding coding genes has revealed a surprising multiplicity of distinct subunits, of which the pattern of assembly can lead to a considerable number of channel subtypes with different properties [8]. When investigating the elementary determinants of neuronal excitability (e.g. ionic channels), it must be remembered that most epileptic seizures are either due to discharges generated in different parts of the neo- or paleocortices (partial seizures), or seem to arise diffusely from a large part of the cerebral cortex of both hemispheres, with the possible involvement of thalamic structures (generalized seizures). The topographic expression pattern of putative epileptogenic dysfunctions should therefore be carefully investigated, not only at structural but also at cellular and subcellular level.

Voltage-gated channels

These form a category of ion channels that undergo voltage-dependent conformational changes leading to transitions from the closed to open state or vice versa.

Na^+ channels

The molecular structure of the pore-forming α-subunit of Na^+ channels is shown in Fig. 5.2. Each domain contains six transmembrane segments, the fourth one being the voltage sensor, and the loop between the fifth and sixth forming the ion-selective pore. The cytoplasmic loop between the third and fourth domain is the inactivation point. This structure satisfactorily correlates with the functional properties demonstrated by electrophysiologi-

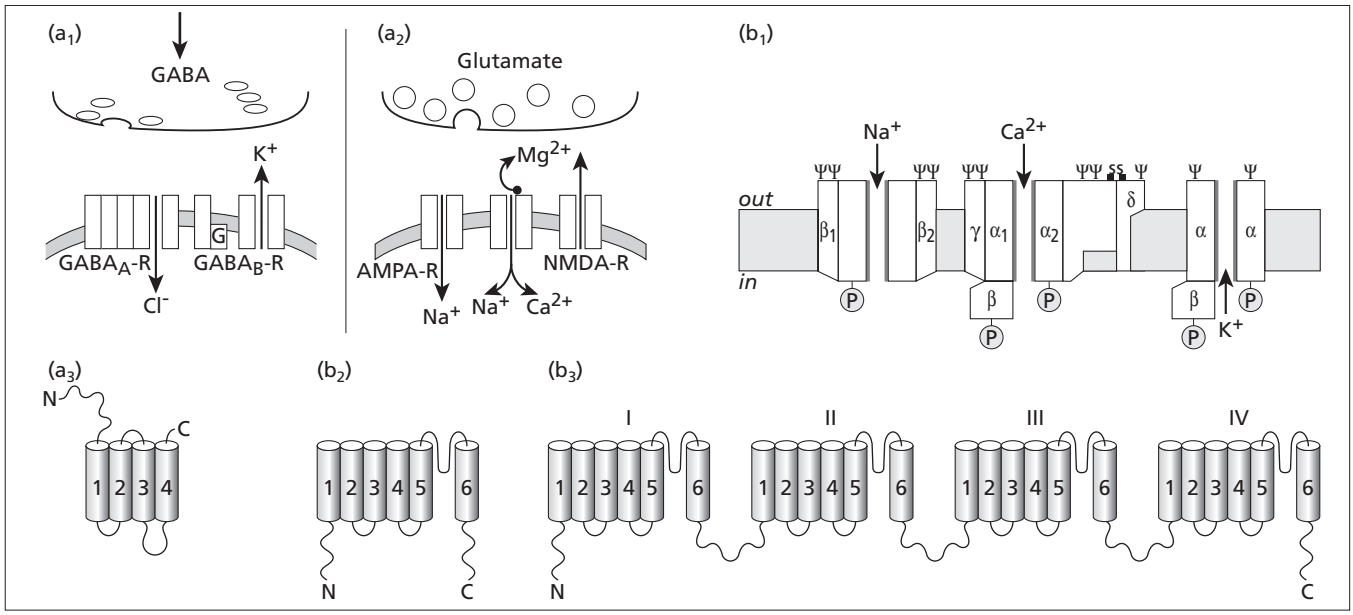

Fig. 5.2 Ligand-gated and voltage-gated channels largely involved in the paroxysmal depolarization shift (PDS) generation. The upper panels schematically represent GABAergic (a_1) and glutamatergic (a_2) synapses and Na^+, Ca^{2+} and K^+ channels (b_1). Flat and round vesicles are respectively recognizable in GABA- and glutamate-containing presynaptic endings. Ionotropic receptors (R) are depicted on the postsynaptic membrane. The lower part of the figure shows a schematic representation of the molecular structure of pore-forming subunits of ligand-gated (a_3), voltage-gated K^+ (b_2) and Na^+/Ca^{2+} (b_3) channels.

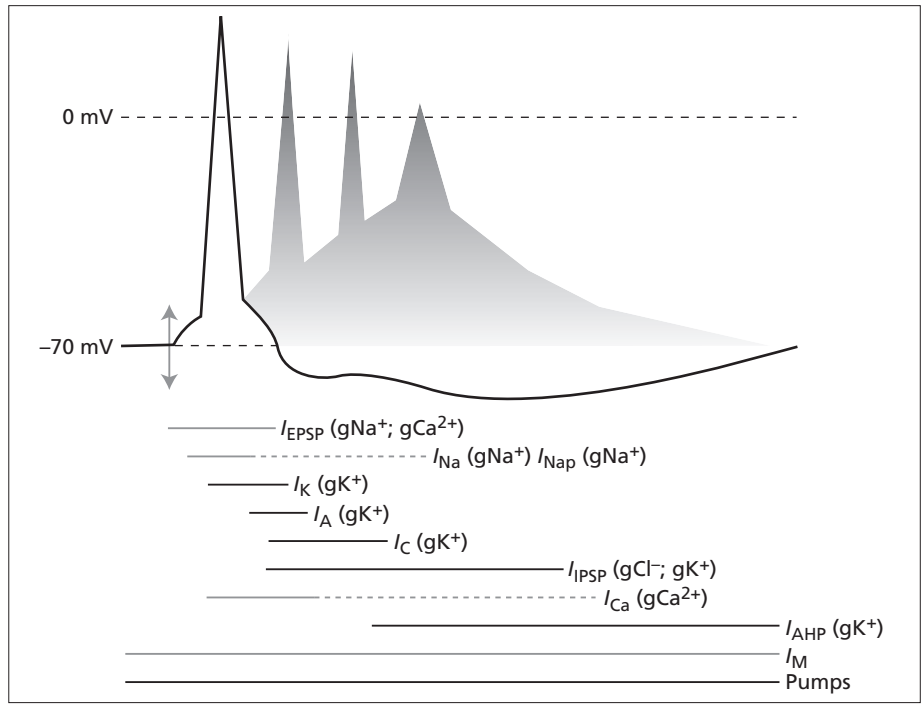

Fig. 5.3 The contribution of different transmembrane currents to the generation of action potential and paroxysmal depolarization shift (PDS). The broken line indicates the level of 0 mV membrane potential. Owing to the effect of ion pumps in resting conditions, membrane potential is kept around –70 mV. The lines below the tracings depict the time course of ion currents with different kinetics. Grey lines indicate currents that tend to depolarize the membrane and black lines indicate currents that polarize it. Particularly effective in inducing the transition from simple action potential to PDS are the currents with slow kinetics (I_{Nap}, I_{Ca}).

cal recordings, which allow characterization of the activation and inactivation kinetics of the main transient component of Na^+ current (I_{NaT}) and of the persistent Na^+ component (I_{NaP}), owing to a fraction of Na^+ channels that fail to inactivate.

Experiments with toxins that block Na^+ channel inactivation (thus considerably enhancing its persistent I_{NaP} component) have demonstrated that this effect is sufficient to switch the firing of neocortical pyramidal neurones from regular spikes to bursts [9]. The possible role of Na^+ changes in the pathophysiology of human epilepsies was first suggested on the basis of indirect arguments, such as the blocking effect of clinically effective antiepileptic drugs (AEDs) on Na^+ currents [10] and particularly I_{NaP} [11,12]

(for a review, see Stafstrom [13]). In the last 10 years, a vast amount of data revealed changes of Na^+ channel molecular structure in cases of familial generalized epilepsies with febrile seizures plus (GEFS+) (for a review, see Meisler and Kearney [14]) or simple febrile seizures [15]. The discovery of *SCN1A* mutations in patients with the non-familial severe myoclonic epilepsy of infancy (SMEI or Dravet's syndrome) [16], a drug-resistant epileptic encephalopathy [17], further indicated the importance of channel pathologies in human epilepsies and suggested that channel mutations may cause neurological disease even in the absence of a positive family history.

Heterogonous expression studies of different mutations of SCN1A channel subunits showed a large spectrum of functional effects. Many of these effects were consistent with a gain of function of Na^+ channels, and thus with a pathologically increased membrane excitability [14,18]. However, the effects of other mutations are unclear, or conversely indicate a complete loss of function. Experiments aimed at clarifying this apparently paradoxical defect suggested that the prominent presence of the mutated channel subunit on inhibitory interneurones [19,20] reduces interneurone firing, eventually resulting in the increased excitability of 'released' pyramidal neurones. This interesting topic shows the complex scenario of channel pathology and highlights the need for further investigation aimed at understanding the effect of sodium channel mutations at circuitry level rather than in individual neurones.

Another point needing clarification arises from the observation that families with identical mutations show heterogeneous phenotypes, ranging from mild expression with febrile seizures to more severe epilepsies such as myoclonic–astatic epilepsy [21]. Furthermore, even if most SMEI mutations are *de novo*, in a few cases they have been inherited from mildly affected parents [16,22]. Therefore, concomitant factors (e.g. primary non-pathogenetic factors involving other channel subunits or modulating mechanisms) are probably crucial in shaping the final effect of the mutated channels to appear as a more or less severe phenotypic expression. Recently, it has been found that molecular interactions with modulatory proteins or drugs can partially rescue the function of Na^+ channels with mutations that normally lead to a complete loss of function [23]. This evidence further shows that more research is needed to clarify the functional effects of channel mutations *in vivo* and the variability of the phenotypes resulting from Na^+ channel mutations.

K^+ channels

Unlike Na^+ and Ca^{2+} channels, which are large monomeric proteins that include four homologous repeats, K^+ channels are made by the assembly of four proteins, the basic structure of which are shown in Fig. 5.2. These assembled proteins each contain six transmembrane domains. The resulting structure is similar to that of Na^+ and Ca^{2+} channels, but the number of possible subtypes is much higher because of the large number of possible combinations. Although it is assumed that there are subtle functional differences between the different subtypes, the currents flowing to the K^+ channels are grouped in a relatively limited number of physiological categories. Other than the 'delayed rectifier', first described by Hodgkin *et al.* [24] and characterized by slow activation kinetics, the most important types of K^+ current are I_A (rapid kinetics with activation range between –65 and –40 mV); $I_{K(Ca)}$ (Ca^{2+} dependent); I_{AR} (activation in hyperpolarization); I_H (activation in hyperpolarization, carried by Na^+ and K^+); $I_{K(ATP)}$ (voltage-independent, and blocked by ATP); I_M (activation range from –60 to –20 mV, blocked by acetylcholine binding to muscarinic receptors); $I_{K(Na)}$ (activated by a high concentration of intracellular Na^+) and; I_R (inward rectifier, whose physiological significance in the central nervous system is still not completely understood).

With the exception of the I_R, all of the K^+ currents are outward currents, which means that their effect is to move the membrane potential towards the more negative value. This reduces the probability of cell discharge and/or limits the amplitude and duration of depolarizing events, whereas membrane repolarization after an excitatory event (i.e. an action potential) is the prerequisite for further action potential generation. This was first recognized by Hodgkin *et al.* [24], who used the term 'delayed rectifier' to indicate the characteristics of the repolarizing K^+ current in the giant axon of the squid. The definition was intended to denote the fact that the increase in membrane conductance (rectification) due to the opening of the corresponding K^+ channel is delayed in comparison with that of the Na^+ channel in terms of the beginning of the depolarizing pulse current used to evoke the action potential. Owing to the rich repertoire of K^+ channels with which the neurone is endowed, the K^+ currents flowing through them can modulate membrane excitability and shape excitatory events in a highly sophisticated manner.

Of particular interest here are the limiting effects of K^+ currents on the sustained depolarization underlying PDS and the high-frequency discharges of action potentials. This is probably due to the combined influence of I_K, I_A, $I_{K(Ca)}$ and $I_{K(Na)}$. However, because it is active at about the resting potential, I_M is particularly effective in distancing the threshold of the membrane potential for the generation of the high-frequency action potentials characterizing the neurones belonging to epileptic neurone aggregates. Epileptiform discharges can be easily obtained in *in vitro* preparations by perfusion with K^+ blockers such as extracellular tetraethylammonium, by intracellular Ca^{2+} or simply by increasing the K^+ concentration in extracellular fluid, which reduces the strength of the outward K^+ currents by decreasing the intracellular–extracellular K^+ concentration gradient that provides the driving force for K^+ outflow.

It has been suggested that disrupted K^+ channel function is involved in the epileptogenesis in some spontaneously occurring human epilepsies. In benign neonatal familial convulsions (BNFC), Biervert *et al.* [25] and Wang *et al.* [26] have demonstrated the pathogenetic role of a genetically determined I_M defect. Interestingly, these studies showed that two K^+ channel subunits (KCNQ2 and KCNQ3) contribute to the native M current, and that mutations of either of the genes coding for these subunits (located at the 20q13 and 8q24 chromosomal loci, respectively) lead to an impairment in the M current associated with the BNFC phenotype. The M current depends on a slowly activating and inactivating K^+ conductance; the range of this activation (–60 to –20 mV) makes the I_M particularly suitable for controlling subthreshold membrane excitability and the responsiveness to synaptic inputs.

The above studies have stimulated a new interest in K^+ currents as possible targets for new antiepileptic drugs (AEDs), as seen in a review by Rogawski [27]. The recent identification of molecules acting as KCNQ channel activators and the advances in defining the activator-binding sites have provided a new possible therapeutic strategy. Indeed, some of these drugs are capable of inducing conformational channel changes and subthreshold opening that lead to a 'gain of function' of the hyperpolarizing currents flowing through these channel types [28] and nominally to restore postexcitatory repolarization.

Ca^{2+} channels

Like Na^+ channels, the Ca^{2+} α-subunit is a large monomeric protein that includes four homologous repeats (Fig. 5.2). The characterized high-voltage activated Ca^{2+} currents are I_L (a slow current with an activation level positive to −30 mV), I_N, $I_{P/Q}$ and I_R (fast currents, activation positive to −20 mV), and it has been found that they are differently expressed in brain cells and other excitable tissue. In addition, a low-threshold I_T current that is inactive at resting membrane potential and *reactivated* by membrane hyperpolarization (activation level positive to −70 mV) has been found to be particularly pronounced in some regions of the central nervous system, such as the inferior olivary nucleus and the thalamic nuclei (see ref. 29 for a review).

As Ca^{2+} is a divalent cation, its cross-membrane movements are particularly effective in depolarizing the membrane, and so the possible role of Ca^{2+} currents in sustaining the pronounced depolarization underlying PDS has been repeatedly hypothesized. However, this is difficult to prove experimentally for three reasons: (1) given its paramount importance for protein synthesis and metabolism, a considerable amount of Ca^{2+} is stored in the cytoplasmic reticulum and any artificial change in its concentration in an experimental preparation can mobilize it from the storage compartment to the ionized free fraction, thus leading to complex effects on cell excitability that are further complicated by metabolic effects, which are often difficult to resolve; (2) the role of Ca^{2+} in promoting vesicle fusion at nerve terminals adds a presynaptic effect that has to be taken into account when evaluating membrane excitability as a function of Ca^{2+} concentration; and (3) a number of the Ca^{2+}-dependent K^+ currents contributing to cell excitability (see above) may be impaired when Ca^{2+} concentration is artificially lowered, thus leading to indirect and somehow unpredictable consequences that may obscure the direct effect of Ca^{2+} movement across the membrane.

The main evidence of the possible involvement of Ca^{2+} channels in the pathogenesis of naturally occurring epilepsies comes from experimental studies of the generalized non-convulsive epilepsies that occur in rats (the Genetic Absence Epilepsy Rat from Strasbourg, GAERS) [30], WGJ [31], mutant tottering, lethargic, stargazer and ducky mice with absence epilepsy, cerebellar degeneration and ataxia (see ref. 32 for a review).

Experiments carried out in our laboratory [33–36] indicate that overexpression of the low-threshold Ca^{2+} current in reticular thalamic nucleus (Rt) cells could be responsible for GAERS spike–wave (SW) discharges according to a mechanism which will be further specified below. Although no genetic basis for this Ca^{2+} channel dysfunction has yet been demonstrated in GAERS, mutations have been found in the genes that code for the $\alpha 1_A$-, β4-, γ2- and α2δ-subunits of the calcium channel in mutant tottering, lethargic, stargazer and ducky mice with SWs [32].

Furthermore, the role of the I_T current in the generation of SW discharges has recently been confirmed by experiments in mice lacking α1 GT-type Ca^{2+} channel [37].

Investigations aimed at confirming the role of Ca^{2+} channel mutation in the most frequent types of human non-convulsive generalized epilepsies (childhood and juvenile absence epilepsies) have been inconclusive so far; however, the evidence of a mutation of the gene *CACNA1A* coding for the P/Q Ca^{2+} channel has been recently reported in a child with early-onset absence epilepsy and cerebellar ataxia [37].

Ligand-gated channels

Ligand-gated channels, or receptors, are molecular complexes that include a pore region or ionophore, which becomes permeable to some ions when the relevant ligand binds to a specific binding site. Ligand-gated channels are classified according to a scheme based on the ligand (neurotransmitter or neuromodulator), with a number of functionally distinct subtypes being differentiated in each category based on pharmacological (affinity for artificial ligands) or physiological criteria (selective ion permeability). Increasing knowledge of the molecular structure of receptor subunits is providing grounds for defining subtypes on the basis of their structure–function relationships.

The ion currents flowing through the receptor-associated ionophores can significantly affect membrane potential and cell excitability, and so these channels too are implicated in epileptogenesis and as possible targets for AEDs. Pharmacological agents acting on receptors can affect not only the primary epileptogenic process, but also its effects in regions beyond the epileptogenic area.

Excitatory amino acid receptors

The amino acids glutamate and aspartate are the two main excitatory neurotransmitters in the cerebral cortex and act through various receptor subtypes, the subunit composition of which determines the selective ionic permeability and kinetics of the respective ionic currents [38]. From the functional point of view, two main receptor types have been identified. AMPA and NMDA are respectively named after the two ligands α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid and *N*-methyl-D-aspartic acid (Fig. 5.2). The ionophores associated with both receptor types are permeable to Na^+, but the NMDA receptor is also permeable to Ca^{2+} and is blocked by Mg^{2+} in a voltage-dependent manner; consequently, the inward Na^+/Ca^{2+} current flowing through it can be activated by ligand-receptor interaction only when the membrane potential is depolarized enough to remove the Mg^{2+} block. As Ca^{2+} is a divalent cation, the NMDA-dependent I_{EPSP} is very powerful in depolarizing the membrane and can significantly enhance and prolong excitatory postsynaptic potentials (EPSPs).

The potential epileptogenic effect of EAA systems is demonstrated by the fact that a number of EAA agonists (kainic and hybotenic acids, NMDA) are currently used to induce various types of epilepsies in animals. In humans, evidence of structural changes in EAA receptors leading to AMPA or NMDA

epileptogenic hyperactivity in the dysplastic cortex has been provided by Najm *et al.* [39]. Moreover, the occurrence of circuitry rearrangements leading to a selective facilitation of the NMDA-dependent I_{EPSP} has been demonstrated in temporal lobe epilepsy and will be further discussed below.

γ-Aminobutyric acid receptors

There are two main types of GABA ionotropic receptors (A and B), which are respectively coupled to Cl^- and K^+ ionophores, as well as a metabotropic receptor that can indirectly modulate membrane excitability. Recently a third type of ionotropic receptor, $GABA_C$, has been demonstrated. The inflow of Cl^- and outflow of K^+ promoted by GABA binding to *ionotropic* receptors both lead to a membrane hyperpolarization that results in inhibitory postsynaptic potentials (IPSPs). GABA-mediated IPSPs are very effective in preventing neuronal discharges because they are associated with a dramatic drop in membrane input resistance. Local inhibitory circuits consisting of Golgi type 2 GABAergic neurones are ubiquitously present in the cerebral cortex as a mechanism controlling the main population of pyramidal neurones. $GABA_A$ blockers (bicuculline, penicillin and picrotoxin) are well-known epileptogenic agents currently being used in experimental studies. As far as human epilepsies are concerned, the evidence of a decrease in GABAergic neurones in brain tissue resected for the treatment of refractory epilepsies [40,41] has not been unequivocally confirmed by subsequent studies. The idea of the functional impairment of structurally intact GABAergic circuitry proposed by Sloviter 1991 [42] under the attractive name of the 'dormant basket cell hypothesis' was also not confirmed by recordings made of human hippocampi during presurgical evaluation for refractory temporal lobe epilepsies [43], which showed enhanced rather than impaired inhibition. Furthermore, the hyperexcitable dentate gyrus removed from patients with temporal lobe epilepsy retains bicuculline-sensitive synaptic inhibition [44]. A more recent systematic analysis of tissue specimens from cortical dysplasias revealed significant disarrangements in GABAergic circuitry [45], but their functional significance is still unclear.

One variant of the GEFS+ syndrome has been reported to be associated with a mutation of the *GABRG2* gene that codes for the γ2-subunit of the $GABA_A$ receptor [46,47], and a defect in the *GABRB3* gene that codes for the β3-$GABA_A$ receptor subunit is thought to account for the epileptic symptoms of Angelman's syndrome [48]. GABA receptor genes and their relation to idiopathic generalized epilepsies have been repeatedly investigated but the results derived from the study of individual large families or few smaller families have been still contradictory (see ref. 49 for a review). On the other hand, the GABA function plays a varying role in different brain structures or in different developmental epochs. It is certainly well known that impairment of cortical GABAergic transmission obtained by the application of GABA receptor antagonists or by targeted genetic mutations induces epileptic seizures. However, various drugs increasing GABAergic transmission are currently used for antiepileptic therapy in humans. The antiepileptic and proepileptogenic effects of GABAergic drugs in subcortical structures, namely in the thalamus, are still not clearly understood. Various studies indicated a proepileptogenic role of $GABA_B$ in absence seizures, probably depending on the complex interaction between pre- and postsynaptic receptors [50].

A special form of GABA-dependent excitation occurs in early developmental stages, when GABA release, occurring before synapse formation, plays as a neurotrophic factor rather than a neurotransmitter and regulates neuronal migration [51]. In early life, GABA neurotransmission matures sooner than glutamate neurotransmission and has a plastic effect. However, owing to the presence of an immature distribution of Cl^- across the membrane, the immature GABA depolarizes the neuronal membrane, thus acting as an excitatory neurotransmitter (see ref. 52 for a review). A similar paradoxical GABA-dependent depolarization, resulting in an excitatory action, can reappear in the adult brain in specific epileptogenic conditions [53].

Acetylcholine receptors

Acetylcholine (ACh) receptors are present ubiquitously in the central nervous system, but their role in controlling brain excitability is much less known than that of the receptors in the peripheral nervous system, where ACh is the main excitatory neurotransmitter at neuromuscular junctions. As it could be obtained in very large quantities from the electric organ of the *Torpedo marina*, the ACh receptor was the first to be purified and characterized [54]. Its pore region has a pentameric structure consisting of various hetero- or homologous combinations of eight α-subunits and three β-subunits.

Phillips *et al.* [55] identified a large Australian family including 27 subjects affected by autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) with a linkage for locus 20q13.2 in 1995 and, subsequently, Steinlein *et al.* [56] discovered the mutation of the *CHRNA4* gene that codes for the α4-subunit of the nicotinic ACh receptor, and thus provided the first demonstration of a human epilepsy due to a genetically determined channel alteration. It has been shown that mutations of the *CHRNB2* gene coding for the β2-subunit of ACh receptors lead to similar phenotypes. The effect of these mutations on ACh receptor gating remains to be determined, as does their role in neuronal hyperexcitability. As the α4-subunit is widely distributed in the mammalian brain, it is puzzling how the mutation can cause a focal hyperexcitability syndrome.

Circuit involvement in epileptogenesis

Although an alteration in neuronal excitability is a primary prerequisite for epileptogenesis, epileptic discharges cannot be due to the abnormal activity of individual neurones, but require the synchronous activation of large populations of hyperexcitable neurones. The generation and spread of epileptic discharges therefore needs to be considered.

Local circuits

The special role of the physiologically bursting IB neocortical and hippocampal neurones mentioned in the introduction depends not only on the power of their excitatory output, but also on their pattern of connectivity, which makes them particularly suitable for the synchronization of large populations of synaptically connected neurones.

Layer V intrinsically bursting pyramidal neurones of the neocortex

Chagnac-Amitai and Connors [57] have shown that one-third of the layer V pyramidal neurones of the rat neocortex are endowed with intrinsically determined bursting properties and generate axon collaterals running tangentially to the cortical surface, which establish synaptic connections with a large number of neighbouring pyramidal neurones. They also demonstrated that pyramidal IB neurones consistently fire in association with highly synchronized electrocorticographic potentials, thus confirming their presumed synchronizing ability. It is interesting to note that the bursting discharges of neocortical IB neurones are determined by the persistent fraction of the Na^+ current I_{NaP} [58,59] and so it can be expected that inherited or acquired changes in Na^+ channels (the putative epileptogenic role of which has been discussed above) may also enhance the IB-dependent synchronizing mechanism, especially if they affect Na^+ channel inactivation.

Taken together, the available data suggest that the synchronizing circuitry established by layer V IB pyramidal neurones of the neocortex plays an important role in recruiting the 'critical mass' of neurones required to create an epileptogenic area.

Intrinsically bursting neurones of CA3

All cornu ammonis area 3 (CA3) neurones have an intrinsically determined bursting property, which, unlike that of neocortical IB neurones, is Ca^{2+} dependent [60]. However, in functional terms, CA3 and neocortical IB neurones are similar in so far as their connectivity enables them to synchronize the activity of synaptically connected neuronal populations. The anatomical basis is the Shaeffer's collateral of the CA3 neuronal axons, which establish a rich synaptic connectivity with the dendrites of the pyramidal neurones of cornu ammonis area 1 (CA1). The effectiveness of this synaptic organization can be easily demonstrated in *in vitro* hippocampal slices by placing a stimulation electrode on the CA3 stratum radiatum, after which the synchronized CA1 output is conveyed to the hippocampal–entorhinal circuitry that creates the reverberating loop involving dentate gyrus–CA3/CA1–entorinal cortex–dentate gyrus. Dreier and Heinemann [61] have developed a technique for preparing *in vitro* slices including the full circuit, and demonstrated that it is necessary and sufficient to sustain persistent epileptic activities (Fig. 5.4). The physiology of this multisynaptic system and its relevance to epilepsy have been a focus of intense research.

In addition to the Na^+ and K^+ conductance responsible for action potentials, both the granule cells making up the principal population of the fascia dentata and the pyramidal cells of Ammon's horn also possess a broad repertoire of Ca^{2+} and K^+ conductance (including Ca^{2+}-dependent K^+ conductance) that contribute towards modulating their firing properties. In particular, the Ca^{2+} conductance is responsible for generating the depolarizing afterpotential (DAP) that follows the action potential, whereas the Ca^{2+}-dependent K^+ conductance is essentially responsible for the pronounced afterhyperpolarizing potential (AHP) that follows individual or repetitive (burst) action potentials. The CA3 pyramidal cells have a marked DAP, which keeps the membrane depolarized and determines burst discharges with a much greater degree of probability than that observed in CA1. In contrast, the granule cells have much shorter DAPs and, under physiological conditions, rarely produce burst discharges. They are therefore particularly suited to the production of graduated activities that are linearly correlated with the intensity of the stimulus, whereas the CA3 cells can act as amplifiers capable of having a secondary effect on the CA1 cells through Schaeffer's collateral projection that make up the exit stage of the circuit. Both the fascia dentata and Ammon's horn contain GABAergic interneurones that are activated directly by the fibres in arrival (feed forward inhibition) as well as by the axonal collaterals of the principal cells (feedback inhibition). An important property of the hippocampal–entorhinal circuit is plasticity and it will be discussed in the next section.

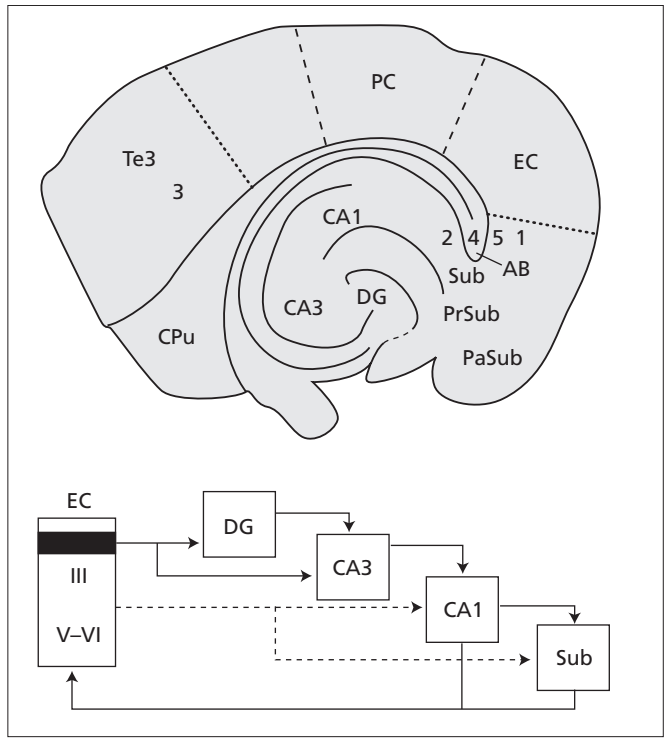

Fig. 5.4 Uppermost part: brain slice of the hippocampal formation prepared according to the Dreier and Heinemann technique. Te3, neocortical temporal area 3; PC, parahippocampal cortex; EC, entorhinal cortex; hippocampal formation with the dentate gyrus is shown in areas CA3 and CA1; Sub, PrSub, PaSub, subiculum, pre- and para-subiculum; CPu, caudat putament. In the lowermost part of the figure, the reciprocal connections of the above structures creating the hippocampal–entorhinal circuitry are represented by a wiring diagram. From ref. 61, with permission.

There is no evidence of primary functional or anatomical CA3 neuronal alterations in human epilepsies but CA3 and its efferent connections can be secondarily involved as a consequence of other circuit changes occurring in human mesial temporal lobe epilepsy (MTLE), as is discussed in the next section.

Systems

Thalamocortical system

It has long been known that thalamocorticothalamic circuits play a role in the generation of SW discharges [62,63]. The results

obtained in rodents presenting with absences associated with 7-Hz SW [64,65] have shed some light on the SW-released rhythmogenic properties with which thalamocortical circuitry is endowed [34–36,66].

A key role is played by the reticular thalamic (Rt) nucleus, a laminar structure enfolding the anteroventral and lateral aspects of the dorsal thalamus that is entirely made up of GABAergic neurones. Rat neurones have a low-threshold Ca^{2+} current (I_T) that is particularly effective in generating sequences of 7–9 Hz Ca^2/K^+-dependent bursts after hyperpolarizing complexes [33,67]. The resulting rhythmic GABAergic output is fed into the thalamocortical relay (TCR) neurones, which are therefore recruited in rhythmic firing with a reciprocal time relationship. A simplified sequence of the events occurring during an SW discharge is schematically illustrated in Fig. 5.5. Both the thalamic nuclei and the cortex are necessary to sustain the SW-related oscillatory mode of thalamocortical circuitry as selective lesions or functional block of either thalamic nuclei [34] or cortex can suppress SW discharges. Moreover mice lacking α(1G) T-type Ca^{2+} channels show a lack of the burst firing of thalamocortical relay neurones and resistance to absence seizures [37]. Whether SW-related thalamocortical activity is initiated in the thalamus [36] or in the cortex [68] has long been debated. Recent results [69,70] support a crucial role of facial somatosensory cortex as a trigger area of SW-related oscillatory activity in thalamocortical systems of rodents. Recent evidence indicates that a non-inactivating Na^+ current component may act synergistically with the T-type Ca^{2+} current [71].

Limbic system

The series of structures located at the edge of the cerebral mantle and surrounding the hilum of the hemisphere was first called the limbic lobe (grand lobe limbique) by Broca in 1878 [72]. The limbic system is involved with the integration of emotions and autonomic functions. The main limbic structure and its interconnections are schematically depicted in Fig. 5.6. Among the subcallosal, cingulate and parahippocampal circumvolutions, the hippocampus and dentate gyrus and the amygdala are involved in generation and propagation of those epileptic seizures that are characterized by autonomic symptoms and often referred to as limbic seizures.

Hippocampus and parahippocampal cortex

The hippocampus is the main part of the archicortical component of the oligostratified cortex or archicortex. Some information concerning the significance of integrative hippocampal activities has come from studies of the correlations between cell activities and behaviour. Above all, these have demonstrated a fundamental relationship between the discharging properties of hippocampal

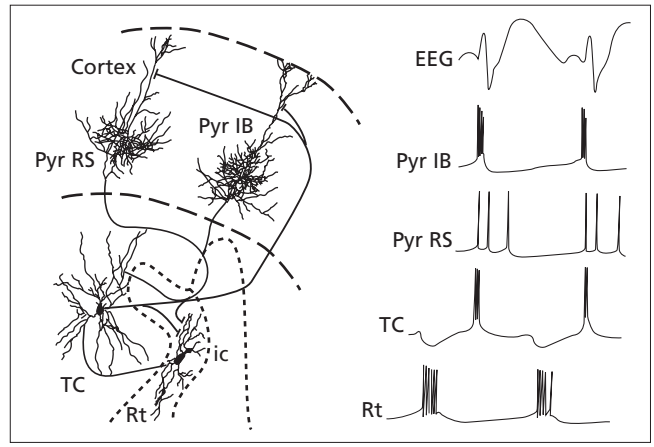

Fig. 5.5 The reverberating thalamocorticothalamic circuit putatively responsible for spike–wave (SW) discharges. Low-threshold Ca^{2+} current in reticular neurones (Rt) gives rise to particularly pronounced burst-hyperpolarization sequences which induce rhythmic inhibitory post-synaptic potentials (IPSPs) in thalamocortical (TC) neurones. The resulting membrane hyperpolarization allows activation of a low-threshold Ca^{2+} current in TC neurones that sustain rebound burst in reciprocal time relationship with Rt. The TC excitatory output propagates to the cortex where both regular spiking and intrinsically bursting pyramidal neurones (PyrRS, PyrIB) are excited simultaneously and send their rhythmic output back to thalamic Rt and TC neurones. The synchronous discharges of cortical neurones are 'seen' by the electroencephalograph scalp electrodes as rhythmic spike–wave complexes. SW discharges are thought to result from a pathological enhancement of the oscillations in the circuitry. From ref. 35.

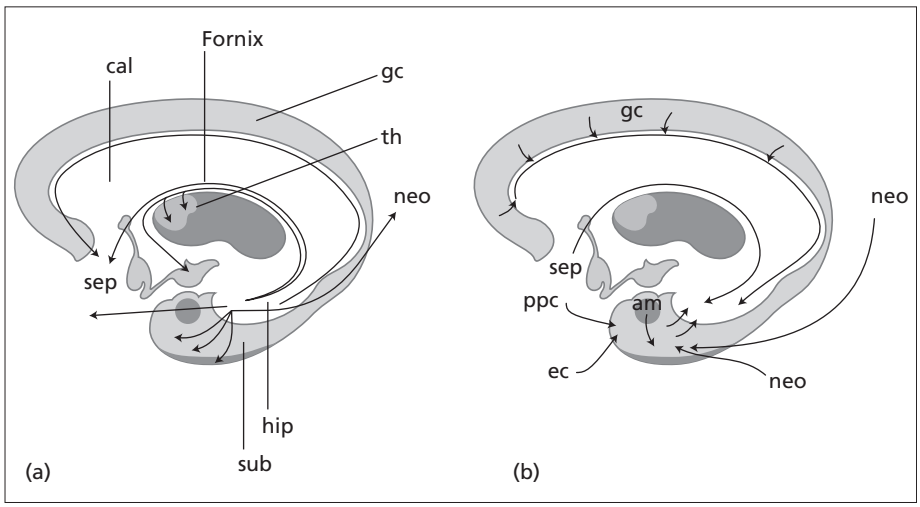

Fig. 5.6 Limbic circuitry. The arrows in parts (a) and (b) indicate efferent and afferent connections, respectively. am, amygdala; cal, corpus callosum; ec, entorhinal cortex; gc, gyrus cinguli; hip, hippocampus; neo, neocortex; ppc, prepyriform cortex; sep, septum; sub, subiculum; th, anterior thalamic nuclei.

cells and arousal, the most important finding being the modifications created during the acquisition of conditioned responses. These modifications are the expression of a synaptic plasticity that was experimentally characterized by Bliss and Lømo [73], who demonstrated that high-frequency stimuli of the entorhinal cortex could persistently increase the effectiveness of synaptic transmission to granule cells and termed this effect *long-term potentiation* (LTP). Thanks to these properties, the limbic (and particularly hippocampal) circuits are capable of recording and storing traces of information originating from the various sensory systems by constructing a cognitive map that is continuously updated on the basis of experience [74]. The relevance of hippocampal plasticity in the pathophysiology of temporal lobe epilepsies was first demonstrated by Graham Goddard [75]. Goddard coined the term *kindling* to describe the phenomenon whereby the repeated subthreshold stimulation of susceptible structures induces an epileptiform EEG and increasingly prolonged and severe behavioural abnormalities. Eventually spontaneous seizures occur. The role of such an epileptogenic plasticity in determining the progressive course of some types of epilepsies will be discussed further in the next section.

Amygdala

The amygdaloid complex includes various nuclei that are involved in integrative activities connected with the association of emotional and neutral stimuli, with the control of homeostasis and with the utilization of current and memorized experiences [76]. Sensory information reaches the amygdala through the lateral nucleus and is then distributed in parallel to the various other nuclei by means of a system of highly organized intra-amygdaloid circuits. Amygdala discharges are often associated with oral feeding automatisms (chewing movements) that are sometimes accompanied by salivation [77], less frequently with unmotivated fear and even more rarely with emotional expressions of anger and aggressiveness described in classic animal studies [78].

Cingulate gyrus

The cingulate region appears to be involved in conditioned responses presumably connected with the acquisition of avoidance reactions. The symptomatology of epileptic seizures originating from the anterior cingular region includes terror, screams, aggressive verbal expressions, complex gestural automatisms, vegetative disturbances and visual hallucinations associated with only partial alterations in consciousness [79]. The anatomical basis underlying the motor expression of the responses are the connections between this region and the caudate nucleus, the ventral pontine nuclei, the ventral part of the periaqueductal grey matter, and the deep strata of the superior colliculus. The posterior or retrosplenial cingulate region seems to be particularly involved in the processes of spatial discrimination associated with visual information.

Other fibre systems

Corticocortical connections can provide epileptic discharges with a number of propagation pathways that may account for the large variety of epileptic phenomena. Specific mention should be made of the role of frontal callosal projections in the interhemispheric synchronization of epileptic discharges. Marcus and Watson [80] reported that bilateral frontal homotopic epileptogenic foci in rhesus monkeys produced bilateral discharges resembling bilateral synchronous SW, but symmetrical foci located in other parts of the cortex were usually independent. They obtained different types of pseudogeneralized discharges depending on the location of the bilateral frontal loci, a finding that correlates well with the marked tendency towards the bilateral expression of seizures with a frontal origin in humans.

Epileptogenesis as a process

In several instances epilepsy, i.e. a chronic condition of the brain characterized by an enduring propensity to generate epileptic seizures, seems to be the result of a process that develops progressively from an initial event. The biological mechanisms responsible for this progressive course of the epileptogenic process have been extensively investigated as potential targets of strategies to prevent the development of epilepsy. One important question is whether the seizures themselves can activate mechanisms capable of facilitating epileptogenesis. The obvious difficulty is with the differentiation of cause and effect, i.e. to determine whether epilepsy becomes progressively worse owing to high seizure frequency or whether high seizure frequency is the expression of an epileptogenic process which is, per se, severe from the beginning.

There is evidence that the progressive course of epileptogenic changes in excitable mechanisms (i.e. ion channels and receptors) and circuitry may account for a progression of epilepsy towards a more severe condition with a reduced sensitivity to AED treatment.

Channels and receptors

Changes in Na^+ channel subunit expression have been reported in the hippocampal tissue from experimental animals [81,82] and from patients with temporal lobe epilepsy [83]. These molecular changes result in the enhancement of Na^+ current, which can contribute to epileptogenesis [82]. Relevant to epileptogenesis are the changes in expression of glutamate and GABA receptor subunits reported in human tissue from experimental animals [84,85] and patients with temporal lobe epilepsy [86,87]. Moreover, complex changes in neurotransmitter and neuromodulator systems have been reported (see ref. 88 for review), which can participate in epileptogenic mechanisms. Particular attention has been devoted to the neuromodulatory action of neuropeptides, namely neuropeptide Y, which is overexpressed in the hippocampus of various seizure models. Neuropeptide Y inhibits glutamatergic transmission and has been proposed to act as an endogenous anticonvulsant [89] and could therefore be a privileged target for gene therapy [90].

Circuitry

An impressive number of data demonstrate that in several instances epileptogenesis is associated with circuitry reorganization. The first evidence was provided by Sutula *et al.* [91], who first demonstrated that the kindling process is associated with the sprouting of a mossy fibre pathway that reorganizes synaptic connections in the dentate gyrus, and then that a similar picture can be observed in the surgically resected hippocampus of patients with epilepsy [92]. These findings have been confirmed by others [93]. Mossy fibre sprouting had been previously observed after

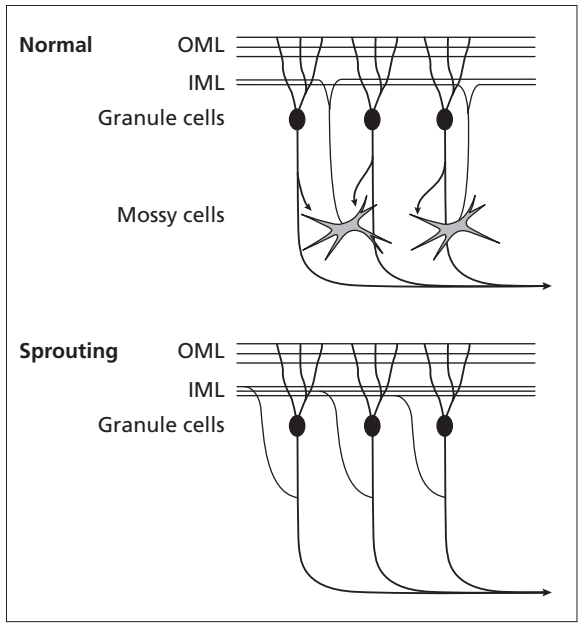

Fig. 5.7 Schematic representation of granule axon sprouting in hippocampal sclerosis. According to the current interpretation, the inner molecular layer, deprived of the mossy fibres because of the degeneration of hilar mossy cells, is reoccupied by newly formed axon collaterals of granule cells. IML, inner molecular layer; OML, outer molecular layer.

experimentally induced status epilepticus accompanied by extensive neural damage (e.g. in the kainic acid model [94]), but the kindling paradigm demonstrated that repeated brief seizures can induce sprouting in the absence of initial extensive brain damage [95]. In human MTLE, mossy fibre sprouting is consistently associated with hippocampal sclerosis and cell loss, and it is thought that the degeneration of mossy cells of the hippocampal hilus significantly contributes to the circuitry rearrangement (Fig. 5.7).

Experiments in various animal models have shown that sprouted mossy fibres make synaptic contacts in ectopic locations, and thus provide an excitatory feedback circuit [96–98]. The excitatory effect of the aberrant recurrent fibres is further enhanced by the facilitation of NMDA receptor-mediated conductance, which has been demonstrated in dentate granule cells in slices prepared from the surgically excised temporal lobe tissue of epileptic patients [99]. Recurrent axon collaterals also make synaptic contacts with inhibitory interneurones, leading to an enhanced inhibition [100] that, rather than preventing the generation of epileptic discharges, contributes to it by promoting synchrony [101]. The main dentate granule axon target is CA3 (which is therefore secondarily involved in the hyperexcitable state) but it is not known to what extent the sprouted collaterals of granule axons inside CA3 contribute to the enhanced excitability in postsynaptic neurones, nor the contribution of sprouting phenomena occurring elsewhere in the hippocampal-entorhinal circuit, such as in CA1 [102].

In general, it can be said that the study of circuit reorganization in MTLE has provided important insights into its biological bases but left a number of unanswered questions. Comparisons of human and animal studies have shown that brief seizure episodes can set in motion a cascade of events leading to sprouting and neosynaptogenesis, which may account for the tendency of MTLE to progress towards a condition of medical intractability.

In both humans and experimental animals (kainic and pilocarpine models), there is a typical biphasic time course, with a more or less prolonged latent interval between the initial event and the chronic epileptic phase, during which the activation of Ca^{2+}-dependent proteases, protein kinase C, Ca^{2+}/calmodulin kinase systems and the immediate early gene [103] promotes circuit remodelling. The most frequent initial event in the clinical history of MTLE is a prolonged febrile seizure during the first 2 years of life that can be likened to the status epilepticus induced by kainic acid and pilocarpine in experimental animals. Once established, the aberrant hippocampal circuitry creates a condition of hyperexcitability that leads to chronic epilepsy, which is often difficult to treat.

However, a number of other observations do not support this linear interpretation. First of all, experimental interventions that prevent sprouting do not impair the acquisition of epileptic properties [104]. Second, although PDS-like discharges can easily be recorded from dentate granule cells in *in vitro* sclerotic hippocampal slices and putatively interpreted as the result of newly formed glutamatergic synapses, *in vivo* recordings taken from the epileptogenic hippocampi of patients indicate that bursting neurones are only rarely encountered and that it is difficult to demonstrate their synchrony [105,106]. Third, the role of the putatively seizure-dependent cell loss in determining the sprouting is still unclear, as is that of the excess of zinc caused by the sprouting of zinc-containing mossy fibres upon glutamatergic and GABAergic synaptic transmission [107]. Finally, the relevance of seizure-stimulated modulations of adult neurogenesis in the dentate gyrus to human MTLE [108] remains to be clarified.

Whichever is its role in MTLE pathogenesis, sprouting remains an important morphological correlate of epileptogenesis and a better knowledge of its neurobiological mechanisms can advance our understanding of epileptogenesis. Much effort is being devoted to identify investigational tools by which the development of epileptogenesis could be monitored. Staba *et al.* [109] have recently shown a correlation between histopathological changes found in hippocampal sclerosis and high-frequency oscillations (fast ripples) recorded with depth electrodes from patients with medically intractable MTLE. Should it be possible to record such activities with non-invasive methods, fast ripples could provide an interesting marker of the epileptogenic process.

In recent years the role of inflammation in epileptogenesis has been intensively investigated [110,111], prompting Annamaia Vezzani and her group [112] to propose a novel anticonvulsant strategy based on the inactivation of the interleukin-converting enzyme caspase-1.

Another modern approach is aimed at identifying genes that may affect the development of an epileptogenic process set in motion by a non-genetic mechanism. A recent review of Lukasiuk *et al.* [113] reveals that epileptogenic insults induce time-specific expression of genes relevant to different aspects of epileptogenesis, such as cell death and survival, neural plasticity and immune responses, suggesting novel lines of research that may advance our understanding of epileptogenesis.

Conclusions

Many different types of experimental manipulations affecting neuronal excitable properties can induce epileptic discharges in various *in vivo* and *in vitro* models of epilepsy. Over the last few years, a number of cell mechanisms involving voltage-dependent and ligand-operated channels have been found to be relevant to human epilepsies. An important step was the identification of some monogenic epilepsies due to mutations of genes coding for ion channels or receptors (epileptogenic channelopathies). This has led to a greater understanding of how these elementary alterations can affect brain circuitry in some common types of human epilepsies. The term 'system epilepsies' has recently been proposed to describe this [114]. The data relating to seizure-related brain plasticity are particularly interesting because they shed further light on the biological bases for epileptogenesis and for the tendency of some epilepsies to progress towards a condition of medical intractability. New data on brain inflammation in epilepsy and epileptogenesis indicate that a better understanding of the genetic basis of these phenomena will likely open the way to further exciting progress in the not too distant future.

6 Antiepileptic Drug Discovery

H. Steve White
University of Utah, Salt Lake City, UT, USA

Epilepsy affects more than 50 million people worldwide and consists of more than 40 clinical syndromes [1]. At the present time, treatment strategies are symptomatic, rather than curative, in nature and aimed at the suppression of clinical seizures with one or more of the available antiepileptic drugs (AEDs). Since the early 1990s, 10 new AEDs have been approved for the add-on treatment of partial seizures. Moreover, there are several more AEDs in late-stage clinical development. This has been an exciting era for the physician treating patients suffering from seizure disorders, and for the patient with epilepsy the introduction of the new drugs continues to provide renewed hope for complete seizure control and lessening of their AED-associated side-effect profile. Never before has there been so many new AEDs available for the management of epilepsy.

As with any other class of drugs, the discovery and development of new AEDs rely heavily on the preclinical employment of animal models to establish efficacy and safety prior to their introduction in human volunteers. Obviously, the more predictive the animal model for any given seizure type or syndrome, the greater is the likelihood that an investigational AED will demonstrate efficacy in human clinical trials. Unlike many other central nervous system (CNS) disorders, epilepsy has benefited from reasonably predictive animal models, particularly models that predict efficacy against primary generalized and partial seizures. Nonetheless, one of the most often discussed issues has focused on what model(s) is most appropriate when attempting to screen for efficacy against human epilepsy.

This chapter will review the different approaches employed in the AED discovery process and how each of these has led to the successful identification of clinically effective AEDs. In addition, it will address some of the issues surrounding the development of more appropriate models of pharmacoresistant seizures. An extensive discussion of these issues is beyond the scope of this chapter. Where possible, the reader will be referred to pertinent reviews for a more detailed discussion.

Characteristics of the ideal model system

In a perfect world, the 'ideal' screening model should reflect similar pathophysiology and phenomenology to human epilepsy. In addition, seizures should evolve spontaneously in a developmental time frame consistent with the human condition and display a pharmacological profile that is resistant to existing AEDs. Given the limitless potential of combinatorial chemistry to identify potential therapies, it would be preferable if a given animal model were amenable to high-volume screening. Unfortunately, human epilepsy is a heterogeneous neurological disorder that encompasses many seizure phenotypes and syndromes. As such, it is highly unlikely that any one animal model will ever predict the full therapeutic potential of an investigational AED. This necessitates the evaluation of an investigational AED in several syndrome-specific model systems.

The current era of antiepileptic drug discovery

Since 1974, the National Institutes of Neurological Disorders and Stroke (NINDS) has played a pivotal role in stimulating the discovery and development of new chemical entities for the symptomatic treatment of human epilepsy, through its Anticonvulsant Screening Project, which, since its inception, has accessioned over 30 000 investigational AEDs from academic and pharmaceutical chemists worldwide. The majority of these investigational AEDs have evolved from one of the following strategies: random drug screening and efficacy-based AED discovery; structural modification of a clinically effective pharmacophore; and mechanistic-based AED development. The University of Utah Anticonvulsant Drug Development Program uses a battery of well-defined animal models to provide initial characterization of the anticonvulsant and behavioural toxicity profile [2–5]. The remainder of this chapter will review the current systematic screening process employed by the Anticonvulsant Drug Development Program at the University of Utah and discuss some of its inherent advantages and limitations. Subsequent discussion will focus on some of the emerging models that may be more likely to identify the truly 'novel' AED for the treatment of pharmacoresistant partial epilepsy.

The current era of AED discovery was ushered in by Putnam and Merritt [6] in 1937, when they demonstrated the feasibility of using the maximal electroshock seizure (MES) model to identify the anticonvulsant potential of phenytoin. Since then, different animal models have been used. A number of new AEDs have been developed since 1993 and are currently in development (second-generation AEDs). Although they have improved therapy, these drugs have not altered the percentage of patients with 'therapy-resistant' partial epilepsy; e.g. there has been no

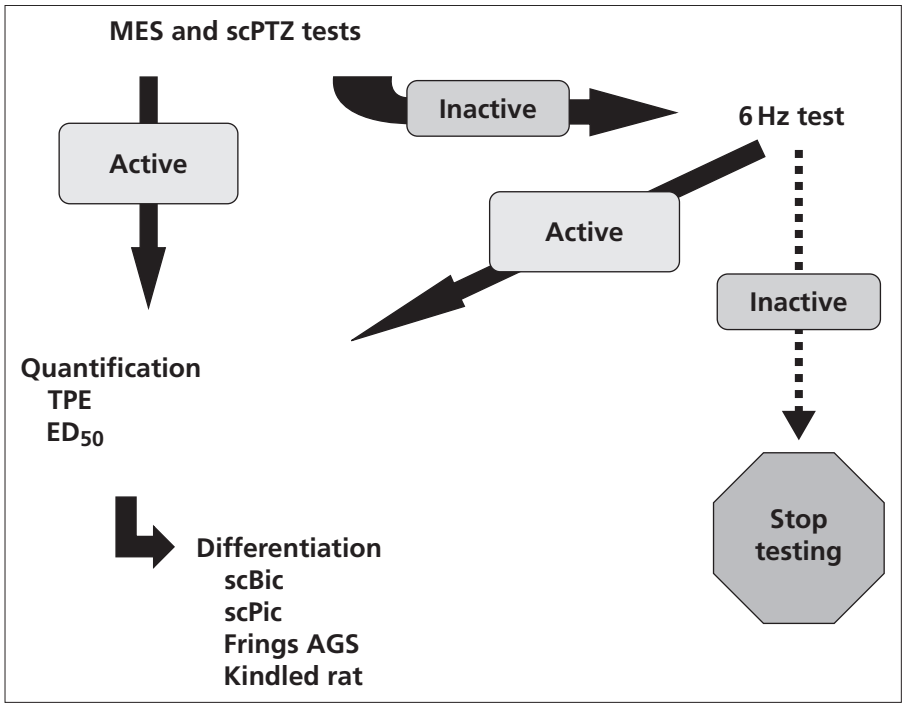

Fig. 6.1 The initial identification screen of the University of Utah Anticonvulsant Screening Project. Once accessioned, an investigational AED is screened for efficacy in both the MES and scPTZ tests. The activity of those compounds (median effective dose, ED_{50}) with demonstrated efficacy and minimal behavioural toxicity is quantitated at the time to peak (TPE) anticonvulsant effect. Compounds found inactive in the MES and scPTZ tests are subsequently evaluated in the 6-Hz seizure test. The activity of those compounds with demonstrated efficacy in the 6-Hz test is then quantitated at their respective time to peak effect. All compounds found active in one or more of these three identification screens are then differentiated on the basis of their activity in the subcutaneous bicuculline (scBic) test, the subcutaneous picrotoxin (scPic) test, the Frings audiogenic seizure-susceptible (AGS) mouse, and the hippocampal kindled rat model of partial epilepsy.

significant change since the early 1970s and the percentage remains between 25% and 40% [7].

Identification of anticonvulsant activity

As shown in Fig. 6.1, the University of Utah Anticonvulsant Screening Project undertakes three primary screens in their initial identification studies. These are the MES, subcutaneous pentylenetetrazol (scPTZ), and 6-Hz psychomotor seizure tests. Each of these evoked seizure models provides valuable information regarding the potential anticonvulsant spectrum of an investigational AED.

Maximal electroshock seizure and subcutaneous pentylenetetrazol tests

The MES and scPTZ seizure models continue to represent the two most widely used animal seizure models employed in the search for new AEDs [5,8,9] and currently remain as the primary screens of the Anticonvulsant Screening Project (Fig. 6.1). As mentioned above, Putnam and Merritt [6] successfully used the MES test in a systematic screening programme to identify phenytoin. This observation, when coupled with the subsequent success of phenytoin in the clinical management of generalized tonic–clonic seizures, provided the validation necessary to consider the MES test as a reasonable model of human generalized tonic–clonic seizures. In 1944, Everett and Richards [10] demonstrated that PTZ-induced seizures could be blocked by trimethadione and phenobarbital but not by phenytoin. A year later, Lennox demonstrated that trimethadione was effective in decreasing or preventing petit mal attacks in 50 patients but was ineffective or worsened grand mal attacks in 10 patients [11]. Trimethadione's success provided the necessary validation to establish the PTZ test as a model of petit mal or generalized absence seizures. With these observations, the current era of AED screening using the MES and scPTZ tests was launched.

The MES and scPTZ tests are routinely conducted with either mice or rats. For the MES test, individual animals receive an electrical stimulus that is delivered through either corneal or pineal electrodes for a 0.2 s duration. The stimulus is of sufficient intensity (e.g. 50 mA in mice and 150 mA in rats) to induce a tonic extension seizure characterized by hindlimb extension. This stimulus intensity is typically three to five times greater than the threshold current necessary to evoke a maximal seizure. An investigational drug is said to offer protection in the MES test if it displays an ability to block the hindlimb tonic extensor component of the seizure.

In the scPTZ test, PTZ is administered subcutaneously in a dose sufficient to produce a minimal clonic seizure of the vibrissae and/or forelimbs that persists for at least 5 s. A drug is said to be effective in the scPTZ test if it is able to block the minimal clonic seizure described above. It is important to note that higher doses of PTZ can produce myoclonic jerks, repeated clonic seizures of the vibrissae, forelimbs and hindlimbs without loss of righting reflex, clonic seizures of the limbs with loss of righting reflex and loss of righting reflex followed by tonic extension of the forelimbs and hindlimbs [12]. These different endpoints are associated with different pharmacological profiles [12,13]. For example, ethosuximide and phenytoin (two AEDs with markedly different clinical profiles) will both block threshold tonic extension seizures induced by scPTZ [13].

The anticonvulsant activity of those AEDs found to be active at non-toxic doses in the initial identification studies is then quantitated in a larger population of mice or rats. For these studies, the MES and scPTZ tests are routinely conducted at the predetermined time to peak effect of the investigational

Table 6.1 Correlation between anticonvulsant efficacy and clinical utility of the established and second-generation AEDs in experimental animal models.[a]

Experimental model	Clinical seizure type			
	Tonic and/or clonic generalized seizures	Myoclonic/generalized absence seizures	Generalized absence seizures	Partial seizures
MES (tonic extension)[b]	Carbamazepine, phenytoin, valproate, phenobarbital (felbamate, gabapentin, lamotrigine, pregabalin, topiramate, zonisamide)			
scPTZ (clonic seizures)[b]		Ethosuximide, valproate, phenobarbital[c], BZD (felbamate, gabapentin, tiagabine[c], pregabalin, vigabatrin[c])		
Spike–wave discharges (absence seizures)[d]			Ethosuximide, valproate, BZD (lamotrigine, topiramate, LVT)	
Electrical kindling (focal seizures)				Carbamazepine, phenytoin, valproate, phenobarbital, BZD (felbamate, gabapentin, lamotrigine, pregabalin, topiramate, tiagabine, zonisamide, LVT, vigabatrin)
6 Hz (44 mA)[e]				Valproate (LVT)

[a] BZD, benzodiazepines; CBZ, carbamazepine; ESM, ethosuximide; FBM, felbamate; GBP, gabapentin; LTG, lamotrigine; LVT, levetiracetam; PB, phenobarbital; PHT, phenytoin; PGB, pregabalin; TGB, tiagabine; TPM, topiramate; VGB, vigabatrin; VPA, valproic acid; ZNS, zonisamide.

[e] Data summarized from ref. 16.

drug following oral or intraperitoneal administration to either mice or rats. Numerous technical, biological and pharmacokinetic factors have been identified which can 'qualitatively' affect the results obtained in a drug test [12,14,15]. These factors, albeit important, are not likely to overlook an active drug in the MES and scPTZ tests but can contribute to false conclusions regarding the potency and duration of action of an active drug.

The MES and scPTZ tests are easily conducted with a minimal investment in equipment and technical expertise. They provide valuable data regarding the potential anticonvulsant activity of an investigational drug, and with one exception, levetiracetam, all of the currently available AEDs and AEDs in clinical development have been found to be active in one or both of these tests (Table 6.1). Furthermore, both tests are amenable to high-volume screening with widely available, relatively inexpensive, normal rodents. As the MES and scPTZ tests are conducted in 'pathologically normal' rodents, there is no guarantee that they will be equally effective in 'pathologically abnormal' rodents. The best example to illustrate this point is levetiracetam. As mentioned above, the MES and scPTZ tests failed to identify levetiracetam's anticonvulsant activity. Subsequent investigations demonstrated that levetiracetam was active in 'pathologically abnormal' models of partial and primary generalized seizures [16–20]. In this regard, levetiracetam has, since its discovery, been considered to represent the first 'truly' novel AED identified in recent years and has underlined the need for flexibility when screening for efficacy and the need to incorporate levetiracetam-sensitive models into the early evaluation process.

As shown in Table 6.1, neither of these seizure models possesses a pharmacological profile consistent with therapy-resistant human epilepsy. The MES test is sensitive to all of the first-generation AEDs effective in the treatment of generalized tonic–clonic seizures (e.g. phenytoin, carbamazepine, valproate and phenobarbital) and a number of the second-generation AEDs (e.g. felbamate, gabapentin, pregabalin, lamotrigine, lacosamide, topiramate and zonisamide). Likewise, the scPTZ test is sensitive to those first-line AEDs used in the management of generalized absence seizures (i.e. ethosuximide, valproate and the benzodiazepines) and some second-generation compounds (felbamate, gabapentin, pregabalin, tiagabine and vigabatrin). However, these two models were initially validated using the older, established AEDs phenytoin, phenobarbital and trimethadione [4,8] and it could be argued that the continued use of these methods leads to the identification of only drugs with a similar pharmacological profile (see refs 4 and 8 for historical review and discussion). However, when initially used, there was a limited armamentarium of AEDs available and several of the drugs possessed significant teratogenic properties or safety issues (e.g. trimethadione, bromide and phenobarbital) and there was a clear need for improved products.

One might ask then what, if any, benefit these two tests might provide when screening for novel AEDs. First, both tests provide some insight into the central nervous system bioavailability of a particular investigational AED. Furthermore, both models are

non-selective with respect to mechanism of action. As such, they are very well suited for the early evaluation of anticonvulsant activity because neither model assumes that a particular drug's pharmacodynamic activity is dependent on its molecular mechanism of action. For example, the MES test predicts efficacy for a broad range of mechanistically distinct AEDs including Na^+ and K^+ channel blockers, NMDA (*N*-methyl-D-aspartate) and AMPA (alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) receptor antagonists, and α2δ ligands. Similarly, the scPTZ test has been found to identify T-type Ca^{2+} channel blockers, benzodiazepines, barbiturates, GABA transport blockers, GABA transaminase inhibitors and α2δ ligands.

Lastly, both model systems display clear and definable seizure endpoints and require minimal technical expertise. This, coupled with lack of dependence on molecular mechanism, makes them ideally suited to screen large numbers of chemically diverse entities. Levetiracetam taught the community that lack of efficacy in either of these tests does not translate into lack of human efficacy. As such, there is no longer any reason to limit further screening on the basis of results obtained in the MES and scPTZ. In fact, there is no a priori reason to assume that a novel AED will be active in the MES, scPTZ or other acute seizure tests.

The 6-Hz seizure test

As discussed above, levetiracetam is unique among the clinically available AEDs in that it is inactive in both the MES and scPTZ tests, emphasizing the need to identify and characterize new screening models so as to minimize the risk of missing other potentially novel AEDs. To this end, the Anticonvulsant Drug Development Program is currently utilizing the 6-Hz psychomotor seizure model in its early identification studies (Fig. 6.1) [5,21].

Although the high-frequency (50 Hz), short-duration (0.2 s) stimulation used in the MES test has become a standard for screening AEDs, it was only one of several electroshock paradigms initially developed in the 1940s and 1950s [22]. An alternative stimulation paradigm was the low-frequency (6 Hz) long-duration (3 s) corneal stimulation model that was stated to produce 'psychic' or 'psychomotor' seizures. Instead of the tonic extension seizure characteristic of the MES test, the 6-Hz seizure test was reported to involve a minimal clonic phase followed by stereotyped, automatistic behaviours reminiscent of human partial seizures [23–25]. At the time of its initial description, the authors were attempting to validate the 6-Hz model as a screening test for partial seizures; however, the pharmacological profile was not consistent with the profile observed in clinical practice [25]. For example, phenytoin was found to be inactive in the 6-Hz seizure test. This observation led to the view that it was no more predictive of clinical utility than the other models available at the time (i.e. the MES and scPTZ tests). Subsequent investigations in our laboratory confirmed the relative insensitivity of the 6-Hz test to phenytoin and also to carbamazepine, lamotrigine and topiramate [21]. The relative resistance of some patients to phenytoin and other AEDs in today's clinical setting and the lack of sensitivity of the MES and scPTZ to levetiracetam prompted studies to re-evaluate the 6-Hz seizure test as a potential screen for therapy-resistant epilepsy [21]. Subsequent investigations demonstrated that levetiracetam did afford protection against the 6-Hz seizure at a stimulus intensity at which other AEDs display little to no efficacy (Table 6.2). Of the drugs in late-stage clinical development, efficacy in the 6-Hz test has also been confirmed for brivaracetam, carisbamate, lacosamide and retigabine. This observation clearly demonstrates the potential utility of this model as a screen for novel AEDs that may be useful for the treatment of therapy-resistant partial seizures.

Table 6.2 Effect of stimulus intensity on the anticonvulsant efficacy (ED_{50}, mg/kg i.p.) of phenytoin, lamotrigine, ethosuximide, levetiracetam and valproic acid in the 6-Hz seizure test.

Antiepileptic drug	Stimulus intensity (mA)		
	22	32	44
Phenytoin	9.4 (4.7–14.9)	>60	>60
Lamotrigine	4.4 (2.2–6.6)	>60	>60
Ethosuximide	86.9 (37.8–156)	167 (114–223)	>600
Levetiracetam	4.6 (1.1–8.7)	19.4 (9.9–36.0)	1089 (787–2650)
Valproic acid	41.5 (16.1–68.8)	126 (94.5–152)	310 (258–335)

Results are represented as ED_{50} (95% confidence interval). With permission from ref. 21.

Differentiation of anticonvulsant activity

Once the efficacy of an investigational AED is established using either the MES, scPTZ or 6-Hz seizure test, a battery of further tests are employed to characterize the anticonvulsant potential of the test substance. These include assessing the ability of the investigational AED to block audiogenic seizures in the Frings audiogenic seizure-susceptible mouse, limbic seizures in the hippocampal kindled rat and acute clonic seizures induced by the γ-aminobutyric acid A ($GABA_A$) receptor antagonist bicuculline or the Cl^- channel blocker picrotoxin [3,5,8].

Of these tests, the kindled rat is the only chronic model currently employed by the Anticonvulsant Drug Development Program. Kindling is defined as the progressive increase in electrographic and behavioural seizure activity in response to repeated stimulation of a limbic brain region such as the amygdala or hippocampus with an initially subconvulsive current [26]. The kindled rat is a useful chronic model for identifying those AEDs that are likely to be useful for the treatment of difficult-to-control seizure types such as complex partial seizures [27]. To this point, the Anticonvulsant Screening Project has initiated studies to evaluate the efficacy of investigational AEDs in the lamotrigine (LTG)-resistant kindled rat. In addition to its utility in AED discovery, the kindled rat also provides a means of studying complex brain networks that may contribute to seizure spread and generalization from a focus [28]. The kindling process is associated with a progressive increase in seizure severity and duration, a decrease in the focal seizure threshold and neuronal degeneration in limbic brain regions that resemble human mesotemporal lobe epilepsy. The electrographic and behavioural components of the kindled seizure begin locally at the site of stimulation and quickly become secondarily generalized. In 1972, Racine [29] proposed a behavioural scoring system that is still in use today. The Racine scale provides a quantitative efficient mechanism through which to assess the effect of an investigational AED on the focal (stages

1 and 2) or secondarily generalized (stages 3–5) seizure. In addition to the behavioural seizure, one can assess whether the drug of interest also affects the electrographic seizure.

One of the kindling models employed by the Anticonvulsant Drug Development Program is the rapid hippocampal kindling model of Lothman *et al.* [28]. This particular model offers some distinct advantages for the screening and evaluation of new anticonvulsant substances, and provides a framework for assessing, in a temporal fashion, drug efficacy in a focal seizure model. For most drug studies, the candidate substance is evaluated for its ability to block the evoked kindled motor seizure (seizure scores of 3–5) and limbic behavioural seizure (seizure score between 1 and 2) and to affect changes in the afterdischarge duration. The kindled rat is also an important tool that can be used to identify drugs that prevent or attenuate the development of a seizure focus (i.e. antiepileptogenic versus anticonvulsant drugs). Thus, in an acquisition paradigm, animals begin receiving the test substance prior to initiation of the kindling process. The relevance of a drug's ability to delay or prevent the development of kindling to human epileptogenesis remains unknown. Valproic acid, phenobarbital, levetiracetam, topiramate and several NMDA antagonists are among some of the drugs found to delay the acquisition of kindling. Of these, valproic acid has been examined for its ability to prevent the development of post-traumatic epilepsy following closed head injury [30,31]. In this study, valproic acid was quite effective in preventing the acute seizures but it failed to prevent the development of epilepsy. Although not conclusive, this finding would suggest that the kindling model is perhaps not a predictive model of trauma-induced epilepsy. Whether it is more predictive of other acquired epilepsies is not known at the present time. As mentioned above, the AED discovery programme at the University of Utah has utilized the LTG-resistant kindled rat in recent years to differentiate the pharmacological profile of novel AEDs. The LTG-resistant kindled rat model of partial epilepsy was first described by Postma and colleagues (2000) [32]. In this particular model, resistance to LTG is induced when a rat is exposed to low-dose LTG during the kindling acquisition phase. For example, exposure to a low dose (5 mg/kg) of LTG during kindling development leads to reduced efficacy of LTG when administered to the fully kindled rat [32]. A similar phenomenon has been observed for carbamazepine [33]. Perhaps more important is the observation that LTG-resistant rats are also refractory to carbamazepine, phenytoin, and topiramate but not valproate or the investigational $KCNQ_2$ activator retigabine [34–36] or the investigational AED carisbamate [37].

The LTG-resistant kindled rat offers the practical advantage over the phenytoin (PHT)-resistant rat [38,39] that it is not necessary to prescreen a population of rats in order to identify those animals that are pharmacoresistant. It serves as an early model to differentiate novel AEDs from phenytoin, lamotrigine, carbamazepine and topiramate.

Pharmacological profile and potential clinical utility

Although not predictive of therapy-resistant epilepsy, the pharmacological profile of the MES, scPTZ and kindled rat tests does provide some insight into the potential clinical utility of drugs that are found to be active in one or both of these tests. For example, the pharmacological profile of the MES test clearly supports its utility as a predictive model for human generalized tonic–clonic seizures and, to date, all of the clinically evaluated drugs that have demonstrated efficacy in the MES test have been found to possess activity against generalized tonic–clonic seizures. In contrast, the lack of any demonstrable efficacy by tiagabine, vigabatrin and levetiracetam in the MES test argues against its utility as a predictive model of partial seizures. Consistent with this conclusion is the observation that NMDA antagonists are very effective against tonic extension seizures induced by MES; however, they were found to be without benefit in patients with partial seizures [40].

Historically, positive results obtained in the scPTZ seizure test were considered suggestive of potential clinical utility against generalized absence seizures. This interpretation was based largely on the finding that drugs active in the clinic against partial seizures (e.g. ethosuximide, trimethadione, valproic acid, the benzodiazepines) were able to block clonic seizures induced by scPTZ,whereas drugs such as phenytoin and carbamazepine, which were ineffective against absence seizures, were also inactive in the scPTZ test. Based on this argument, phenobarbital, gabapentin and tiagabine should all be effective against spike–wave seizures but lamotrigine should be inactive against spike–wave seizures. However, clinical experience has demonstrated that this is not the case, and, for example, the barbiturates, gabapentin and tiagabine all aggravate spike–wave seizure discharge, and lamotrigine has been found to be effective against absence seizures. Thus, before any conclusion concerning potential clinical utility against spike–wave seizures is made, positive results in the scPTZ test should be corroborated by positive findings in other models of absence, such as the γ-butyrolactone [41] seizure test, the genetic absence epileptic rat of Strasbourg [42] or the lethargic (*lh/lh*) mouse [43,44]. The pharmacological profile of these three models more reasonably predicts efficacy against spike–wave seizures than the scPTZ test (Table 6.1). Another important advantage of all three of these models is that they accurately predict the potentiation of spike–wave seizures by drugs that elevate GABA concentrations (e.g. vigabatrin and tiagabine), drugs that directly activate the $GABA_B$ receptor and the barbiturates.

The 6-Hz seizure test appears to offer some of the same advantages afforded by the MES, scPTZ and kindled rat models. For example, the 6-Hz seizure test, like the MES test, is an acute electrically evoked seizure using standard corneal electroshock. It requires minimal technical expertise and is high throughput. The 6-Hz test differs from the MES tests in two respects, i.e. the frequency (6 Hz vs. 50 Hz) and duration (3 s vs. 0.2 s) of the stimulation used. The seizure that is evoked by this low-frequency, long-duration stimulus is thought to more closely model human limbic seizures and is characterized by immobility, forelimb clonus, Straub tail and facial automatisms [21,25]. In particular, the pharmacological profile of the 6-Hz test clearly differentiates itself from the other models and is dependent on the intensity of the stimulation used. For example, as the stimulus intensity is increased from the CC_{97} (convulsive current required to evoke a seizure in 97% of the mice tested) to twice the CC_{97}, the

pharmacological profile shifted from being relatively non-discriminating to being very discriminating (Table 6.2). For example, at the CC_{97} (22 mA) all of the AEDs tested (phenytoin, lamotrigine, ethosuximide, levetiracetam and valproic acid) were active at doses devoid of behavioural toxicity. In contrast, at a current intensity twice the CC_{97} (44 mA), the 6-Hz seizure was resistant to ethosuximide, phenytoin and lamotrigine but sensitive to levetiracetam and valproic acid, albeit the potency of both drugs at two times the CC_{97} was markedly reduced [21]. The observation that levetiracetam was active at a specific stimulus intensity at which other anticonvulsants display little to no efficacy illustrates the value of the 6-Hz model, as levetiracetam is inactive in the acute seizure models such as the MES and PTZ seizure tests [45,46]. The 6-Hz test may thus represent a potential therapy-resistant model and is a rather inexpensive alternative to the extremely labour-intensive and expensive chronic models such as kindling. The incorporation of this simple acute screen also minimizes the chances of 'missing' a unique drug like levetiracetam, an important consideration when setting up an anticonvulsant testing protocol to evaluate investigational AEDs.

Of the four models discussed in some detail, the kindled rat model offers perhaps the best predictive value. For example, it is the only model that adequately predicted the clinical utility of the first- and second-generation AEDs including tiagabine and vigabatrin. Furthermore, the kindled rat is the only model that accurately predicted the lack of clinical efficacy of NMDA antagonists [47]. The reason for not using the model as a primary screen is logistical. It is extremely labour intensive and requires adequate facilities and resources to surgically implant the stimulating/recording electrode, to kindle and to house sufficient rats over a chronic period of time, and is inherently time-consuming. This severely limits the number of AEDs that can be screened in a timely manner.

Recommendations

Activity of a test substance in one or more of the electrical and chemical tests described above will provide some insight into the overall anticonvulsant potential of the compound. However, a concern voiced in recent years is that the continued use of the MES and scPTZ tests in the early evaluation of an investigational AED is likely to identify 'me too' drugs and is unlikely to discover those drugs with different mechanisms of action. It has been argued that the inclusion of a kindling model into the initial identification screen would provide a mechanism to identify those novel compounds that are active in a chronic model that might be missed by the acute models currently used in the initial identification screens. In this regard, it will be of further interest to assess whether the 6-Hz screen identifies molecules that will be inherently active in the kindled rat model.

A review of the data summarized in Table 6.1 clearly demonstrates the importance of employing multiple models in any screening protocol when attempting to identify and characterize the overall potential of a candidate AED substance, as shown by the example of levetiracetam, tiagabine and vigabatrin [48,49]. Furthermore, as mentioned above, the exacerbation of spike–wave seizures by vigabatrin or tiagabine would have been predicted not by the scPTZ test but by the other models (i.e. GAERS and the *lh/lh* mouse) [44]. What is clear is the need to evaluate each investigational AED in a variety of seizure and epilepsy models. Only then will it be possible to gain a full appreciation of the overall spectrum of activity for a given investigational drug.

What is the future of AED discovery and development?

Since its inception in 1975, the NIH-based Anticonvulsant Screening Project at the University of Utah has screened over 30 000 investigational AEDs in one or more of the animal models discussed above. Of these, the Anticonvulsant Screening Project played a pivotal role in the initial identification of anticonvulsant activity for felbamate, lacosamide and topiramate, and confirmed and expanded the anticonvulsant profile for many of the other AEDs, including gabapentin, lamotrigine and levetiracetam. In addition to the compounds that have been successfully developed, another 16 compounds are in various stages of clinical development. Each of these drugs has brought about substantial benefit to the patient population in the form of increased seizure control, increased tolerability and better safety and pharmacokinetic profiles. Unfortunately for 25–40% of epilepsy patients, there still remains a need to identify therapies that will more effectively treat their therapy-resistant seizures, and there is thus a continued need to identify and incorporate more appropriate models of refractory epilepsy into the AED screening process.

Pharmacoresistant seizure models

The identification and characterization of one or more model systems that would predict efficacy in the pharmacoresistant patient population would be a valuable asset to the epilepsy community. In addition to being useful for therapy development, the ability to segregate animals on the basis of their responsiveness or lack of sensitivity to a given AED would (i) be useful for attempting to understand the molecular mechanisms underlying pharmacoresistance; (ii) be an asset for those studies designed to assess whether it is possible to reverse drug resistance; and (iii) be useful for identification of surrogate markers that might predict which patient will remit and become pharmacoresistant. At the present time, there are no clinically validated models of pharmacoresistant epilepsy. Furthermore, until that first drug or therapy is developed that has a marked effect on this patient population, we will not know what is the 'best' model system to employ in our search for more effective therapies. At the present time, the drug discovery programme at the University of Utah uses two *in vivo* models and one *in vitro* model in its attempt to characterize the full potential of a novel therapy. These include the 6-Hz limbic seizure test, the lamotrigine-resistant kindled rat model (discussed above) and the *in vitro* hippocampal slice model (see ref. 50 for a review and discussion). All three of these models meet the pivotal criteria for 'pharmacoresistance' as defined by the participants of two National Institutes of Health (NIH)/National Institute of Neurological Disorders and Stroke (NINDS)/

American Epilepsy Society (AES)-sponsored Workshops on Animal Models held in 2001 and 2002 [51,52], e.g. all three models 'demonstrate resistance' to two or more of the first-line AEDs employed in the treatment of partial epilepsy.

In addition to the 6-Hz psychomotor seizure model of partial epilepsy [21] and the LTG-resistant kindled rat [32,34–36] a number of additional *in vivo* model systems have been described in recent years which display a phenotype consistent with pharmacoresistant epilepsy (see ref. 53 for review). These include the PHT-resistant kindled rat [38,39], post-status epilepticus models of temporal lobe epilepsy [54–62], and the methylazoxymethanol (MAM) acetate *in utero* model of nodular heterotopia [63]. In addition to the *in vitro* entorhinal cortex–hippocampal slice model [50] and the *in vitro* low-magnesium hippocampal slice preparation [64] several other *in vitro* systems have been described over the years which meet the criteria of pharmacoresistance (see refs 65 and 66 for review and references).

Of the many models currently employed in the discovery and differentiation of investigational AEDs, the post-status epilepticus model of refractory epilepsy is beginning to emerge as an important tool. The post-status model fulfils one very important characteristic of the ideal model system: spontaneous recurrent seizures (SRS) following a species-appropriate latent period [51,52]. This model can be used to evaluate the efficacy of a given treatment on seizure type (i.e. focal or generalized), frequency of seizures, and the liability for tolerance development following chronic treatment. It also provides a mechanism to differentiate a given compound from the established AEDs. Unfortunately, these models are laborious, time-consuming and require a greater level of technical expertise. To date, they have been used in only a few pharmacological studies [54–62].

Lastly, it is important to note that the use of the post-status epilepticus rat and other models of pharmacoresistance has led to the development of novel drug testing protocols in animals that more closely resemble human clinical protocols. Furthermore, these models provide a unique biological platform for gaining greater insight into the mechanisms underlying pharmacoresistant epilepsy, to test novel approaches designed to overcome or reverse therapy resistance and to identify appropriate surrogate markers of pharmacoresistance.

Disease modification

At the present time, there are no known therapies capable of modifying the course of acquired epilepsy. Attempts to prevent the development of epilepsy following febrile seizures, traumatic brain injury and craniotomy with the older established drugs have been disappointing (see refs 30 and 31 for review). Any successful human therapy will necessarily be identified and characterized in a model system that closely approximates human epileptogenesis, and at the present time there are several potential chronic animal models in which spontaneous seizures develop secondary to a particular insult or genetic manipulation (for review and references, see refs 7 and 67). If we are to be successful in identifying a novel, disease-modifying therapy in the near future, we will need to characterize and incorporate such models of epileptogenesis into screening protocols.

Summary

This chapter has focused on the present-day process used by the University of Utah Anticonvulsant Screening Project to evaluate the anticonvulsant efficacy of an investigational AED. An attempt has been made to identify and discuss the advantages and limitations of this approach and the various animal model systems employed. Lastly, the rationale and need to broaden the scope of AED screening protocols to include models of therapy resistance and epileptogenesis has also been discussed in context with the continuing need to identify more efficacious drugs for the 25–40% of patients who remain refractory to the currently available AEDs. The real future of epilepsy research lies in our ability to couple a greater understanding of the pathophysiology of epilepsy at the molecular level with the identification and development of a truly novel therapy that modifies the course of epilepsy or prevents the development of epilepsy in the susceptible individual.

7 Mechanisms of Antiepileptic Drug Action

Matthew C. Walker, Rainer Surges and Andrew Fisher

UCL Institute of Neurology, University College London, London, UK

Despite a burgeoning in epilepsy research, we are still a long way from understanding the mechanisms underlying seizure generation and epileptogenesis. Antiepileptic drugs have been developed either through serendipity, such as the fortuitous discovery of the antiepileptic effects of bromides and phenobarbital, or through screening in animal epilepsy models. Indeed, the recent growth in antiepileptic drug development has been due to extensive screening of over 25 000 compounds in animal epilepsy models. Designing antiepileptic drugs with specific mechanisms of action is a recent approach that has not been particularly fruitful, first, because the drugs turn out to have separate mechanisms of actions (e.g. lamotrigine and gabapentin) and, second, because most of these drugs have been ineffective or have had unacceptable side-effects [e.g. *N*-methyl-D-aspartate (NMDA) antagonists]. Because of this, the mode of action of antiepileptic drugs is multifarious, and often poorly defined. Most antiepileptic drugs have a number of putative targets, and it is often not possible to discern which are the most germane. There may be many complex effects, even when an antiepileptic drug ostensibly has one target [e.g. tiagabine inhibiting γ-aminobutyric acid (GABA) uptake]. Rather than describe the possible mechanisms underlying each antiepileptic drug in turn (this is covered in individual chapters), we have described the more important targets of antiepileptic drugs, and which drugs affect those targets. Those that are most relevant to our present armamentarium of antiepileptic drugs are sodium channels, calcium channels and the GABAergic system. Other putative and potential targets include hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, potassium channels, the glutamatergic system, synaptic vesicle protein SV2A and some amines.

Main targets

Sodium channels

Sodium channels provide the major target for a number of antiepileptic drugs (Table 7.1). Passage of ions through voltage-gated sodium channels is responsible for the rising phase of the action potential in excitable cells and membranes, and the channels are therefore critical for action potential generation and propagation [1]. The sodium channel exists in three principal conformational states: (1) at hyperpolarized potentials the channel is in the resting closed state; (2) with depolarization the channel converts to an open state that conducts sodium ions; and (3) the channel then enters a closed, non-conducting, inactivated state. This inactivation is removed by hyperpolarization (Fig. 7.1). In this manner, depolarization results in a transient inward sodium current that rapidly inactivates. There is also a slow inactivated state which occurs with sustained depolarizations, and from which the channel recovers at hyperpolarized potentials over a matter of seconds [1].

The sodium channel consists of a 260-kDa α-subunit that forms the sodium-selective pore (Fig. 7.2). This α-subunit consists of four homologous domains (I–IV) that each consist of six α-helical transmembrane segments (S1–S6). The S4 segments are responsible for the voltage-dependent activation, as these are highly charged. Inactivation is mediated by a 'hinged lid', consisting of the intracellular loop connecting domains III and IV that can close only following voltage-dependent activation [1].

In the central nervous system, the α-subunit is associated with two auxiliary β-subunits (β_1 and β_2) that influence the kinetics and voltage dependence of the gating. There are at least 10 different sodium channel isoforms ($Na_v1.1$–1.9 and Na_x). Five of these isoforms are present in the central nervous system – $Na_v1.1$–1.3, $Na_v1.5$ (in the limbic system) and $Na_v1.6$. These isoforms have some functional differences that are of physiological importance (see below). In addition, the sodium channel can be modulated by protein phosphorylation, which affects the peak sodium current, and the speed and voltage dependence of channel inactivation [1].

Many drugs, including certain anaesthetics and antiarrhythmics, exert their therapeutic effect by preferential binding to the inactivated state of the sodium channel [1]. This has two effects: first to shift the voltage dependence of inactivation towards the resting potential (i.e. the channels become inactive at less negative membrane potentials) and, second, to delay the return of the channel to the resting, closed conformation following hyperpolarization. Phenytoin, lamotrigine and carbamazepine have a similar mode of action [2]. All bind in the inner pore of the sodium channel, and their binding is mutually exclusive, suggesting binding to identical or common amino acids [2]. There may, however, be differences in the fashion in which drugs interact with adjacent amino acids that can partly explain drug-specific effects [3]. In addition, the kinetics of antiepileptic drug interactions with the sodium channel differ, so that, for example, carbamazepine binds less potently, but faster, than phenytoin [4]. How does this binding mediate their anticonvulsant effect? The conventional

view has been that such binding prevents sustained repetitive firing [5]. The rate at which an axon can 'fire' is critically determined by the rate at which the sodium channels change from the inactivated state to the resting, closed state ready to be opened by a subsequent depolarization. If this time is delayed, then the 'refractory period' is prolonged. Thus, phenytoin, carbamazepine and lamotrigine all prolong the 'refractory period' and so inhibit sustained repetitive firing. In addition, since these drugs bind to channels in their inactive state, the greater the number of channels that have entered this state, the greater the drug binding. This results in a 'use-dependent' phenomenon in which repetitive firing results in greater amounts of the drug bound and so greater inhibition. Since these drugs have a slow rate of binding to the sodium channel, there is little binding of the drug to sodium channels following a single rapid action potential, and more substantial binding only with sustained depolarizations or repetitive firing.

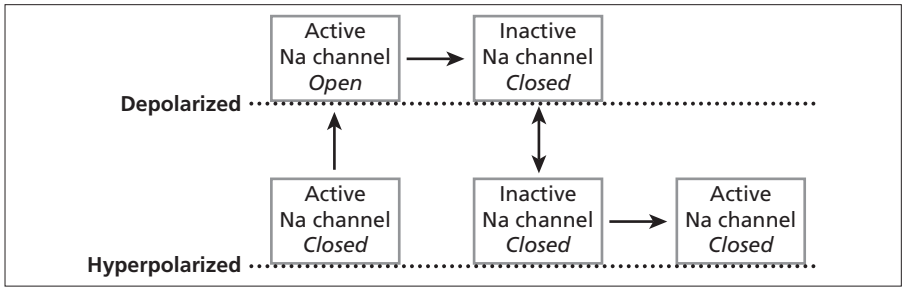

Fig. 7.1 Voltage dependence of sodium channel. In the activated state, the channel is opened by depolarization. The channel then inactivates, and hyperpolarization is necessary for reactivation of the channel.

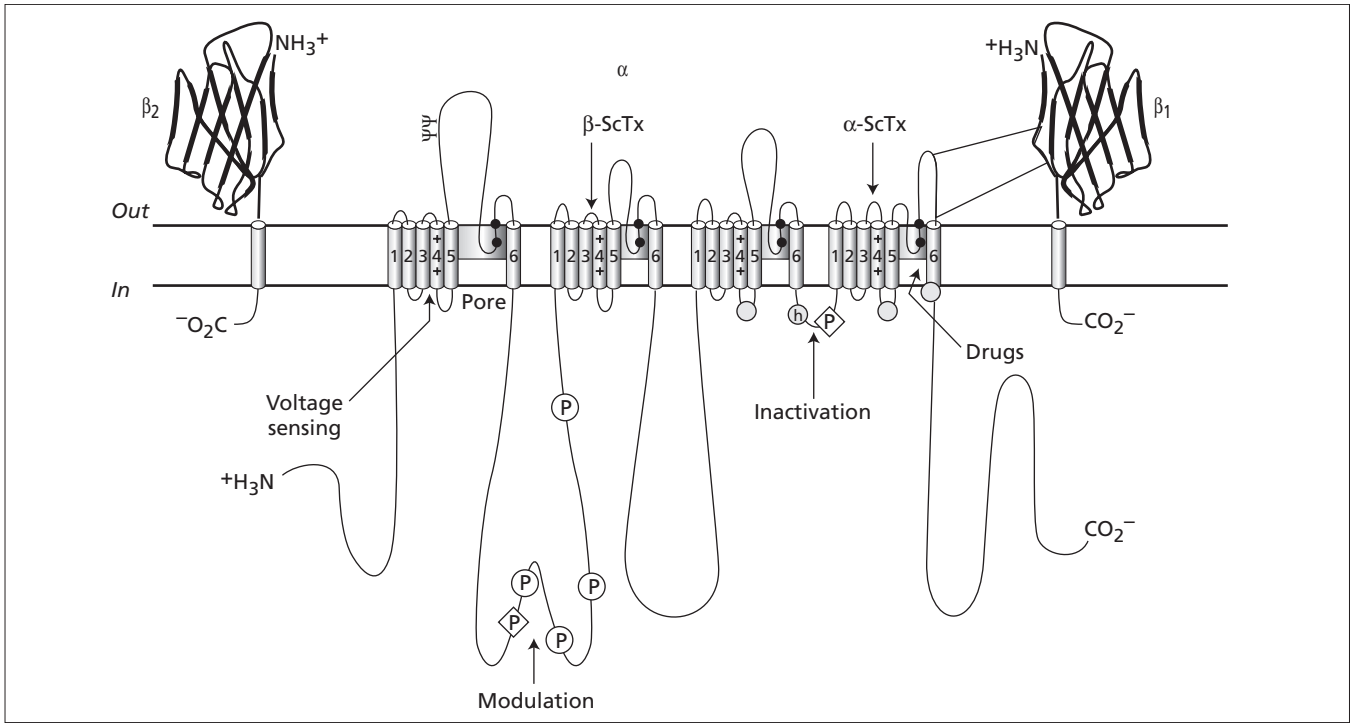

Fig. 7.2 The primary structure of the voltage-gated sodium channel consisting of four homologous six α-helical transmembrane segments (S1–6). P, sites of demonstrated protein phosphorylation by protein kinase A (PKA) (circles) and protein kinase C (PKC) (diamonds); between 5 and 6, pore-lining segments; +4+, S4 voltage sensors; h, inactivation particle in the inactivation gate loop; stippled circles, sites implicated in forming the inactivation gate receptor. Putative site of drug action is shown. From ref. 1.

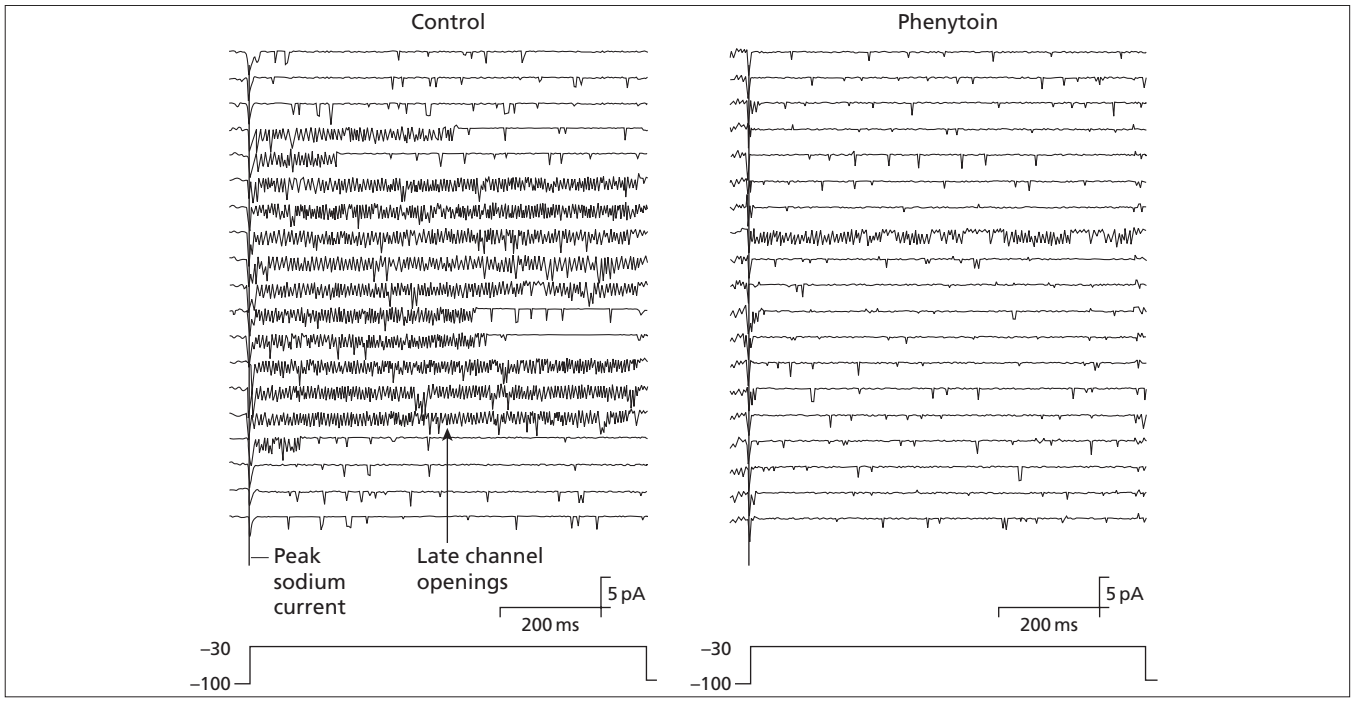

Fig. 7.3 Using outside-out patches from neuronal cultures; each record shows a consecutive trace. Sodium channels open with depolarization (peak current), followed by late channel openings. Phenytoin reduces the initial peak current, but more impressively reduces the late channel openings. From ref. 6.

Although an action on sustained repetitive firing may be one potential antiepileptic action, an action on persistent sodium currents is possibly of greater importance [6].

The persistent sodium current consists of rare late openings of sodium channels following a depolarization. Certain channel subtypes, such as $Na_v1.6$, are more prone to these late openings. Epileptiform activity is reflected, at a cellular level, by persistent depolarizations (paroxysmal depolarizing shifts), and persistent sodium currents can be a significant component of these persistent depolarizations. Prolonged late openings would permit significant drug binding, and, thus, phenytoin, carbamazepine and lamotrigine should affect the persistent current to a much greater degree than the peak sodium current during an action potential. This is indeed the case (Fig. 7.3), and may explain why phenytoin affects burst behaviour to a greater extent than normal synaptic transmission [6].

Why is it that some people require higher serum levels of, or are resistant to, these drugs? Recently, a polymorphism in the *SCN1A* gene which affects the proportion of alternative channel transcripts (neonatal versus adult forms) has been shown to partially explain resistance to phenytoin and carbamazepine [7]. Since lamotrigine, carbamazepine and phenytoin act at the same site in similar fashions, we might expect epilepsy that is resistant to one of these drugs to be be resistant to the others. This does not seem to be the case. Sodium channels from patients with refractory temporal lobe epilepsy may be selectively resistant to carbamazepine [8]. Furthermore, drug resistance may be not only a pharmacodynamic phenomenon, but also a pharmacokinetic phenomenon, and there is some evidence of drug resistance being mediated by multidrug-resistant proteins that 'remove' drugs from the extracellular fluid and thus from their site of action [9].

The fact that the drugs have a similar mode of action could be an argument, in certain circumstances, for their concomitant use. So if seizures partially respond to one of these drugs, but further increases in dose are limited by side-effects, then the addition of a drug that acts at the same site, but has dissimilar side-effects, is likely to have an additional benefit: the effects would be infra-additive (i.e. the efficacy of the combination would be less than the combination of the efficacies). Do other antiepileptic drugs have effects on the sodium channel? Oxcarbazepine and eslicarbazepine probably have similar effects to carbamazepine [10,11]. Valproate seems to inhibit rapid repetitive firing [12], but acts at a different site from that at which carbamazepine, lamotrigine and phenytoin act. Phenobarbital and benzodiazepines may inhibit the sodium channel at high concentrations – concentrations that are not usual in clinical practice, but which may be attained during drug loading for the treatment of status epilepticus. The newer antiepileptic drugs – rufinamide, topiramate and zonisamide – also have actions on sodium channels, the exact nature and importance of which are unclear [13–15]. In addition to these three states of the sodium channel, there is also a slow inactivated state which occurs with sustained or repeated depolarizations. This state is selectively enhanced by the new antiepileptic drug lacosamide [16].

Calcium channels

Calcium channels are putative targets for antiepileptic drugs, although their importance in mediating antiepileptic effects is largely unknown (Table 7.2). The main pore-forming subunit of

calcium channels is similar in structure to that of sodium channels. This α_1-subunit is a 170- to 240-kDa protein, consisting of four homologous domains that each consist of six α-helical transmembrane segments. The pore-forming segments and the mechanism of inactivation are similar to that of the sodium channels [17]. Cloning has uncovered 10 subtypes of the α_1-subunit; these have been named $\alpha_{1A\text{-}I}$ and α_{1s} (this exists only in skeletal muscle), but have now been labelled $Ca_v1.1$–1.4 (L-type), $Ca_v2.1$–2.3 (P/Q-, N- and R-type) and $Ca_v3.1$–3.3 (T-type). In addition, there are associated subunits, $\alpha_2\delta$ and β, that promote channel expression and affect channel kinetics. A third auxiliary subunit, the γ-subunit, is expressed in skeletal muscle, but its expression and relevance in the brain are controversial [17].

In the brain four main classes of voltage-gated calcium channel are expressed: L-, P/Q-, N- and T-type channels [17]. L-, P/Q- and N-type channels are high-voltage-activated channels that require significant depolarization before activation, whilst the T-type channel is a low-voltage-activated channel and is activated at relatively hyperpolarized potentials.

The L-type channels are expressed mainly postsynaptically and are involved in postsynaptic calcium entry upon neuronal depolarization. L-type channels inactivate only slowly (long-lasting channels), thereby permitting sustained calcium entry [17]. L-type channels are typically blocked by dihydropyridines (e.g. nifedipine), and are regulated by protein phosphorylation and by calcium autoregulation [17]. Calcium entry through L-type channels is the major contributor of calcium to trigger the afterhyperpolarization (see below) in certain neuronal subtypes, particularly in the hippocampus, and the somatic expression of L-type channels means that they are ideally placed to open during the depolarization that occurs with an action potential. Calcium entering through L-type calcium channels may also have other effects, including gene regulation and the expression of long-term synaptic potentiation with strong stimulation. Blockade of L-type calcium channels has a variety of effects on epileptic discharges, and can have both anticonvulsant and proconvulsant effects, possibly by inhibiting synaptic potentiation, yet also inhibiting afterhyperpolarization. L-type calcium antagonists are proconvulsant in absence epilepsy models [18]. L-type antagonists may, however, inhibit epileptogenesis by inhibiting the calcium entry that secondarily activates various genes necessary for the epileptogenic process [19]. Some antiepileptic drugs have been proposed to antagonize L-type calcium channels, including carbamazepine [20], topiramate [21] and phenobarbital at high anaesthetic doses [22]. The relevance of this to their antiepileptic effect is difficult to predict, but this antagonism may contribute to their side-effects, including the pro-absence effect of carbamazepine.

N- and P/Q-type channels are expressed at synaptic boutons, where they mediate calcium entry necessary for neurotransmitter release. These channels are rapidly inactivating, resulting in brief calcium transients. This calcium entry then triggers exocytosis of the presynaptic vesicles. N- and P/Q-type channels are primarily regulated by G-proteins; they are thus modulated by G-protein-linked receptors such as $GABA_B$ receptors [17]. Inhibiting these calcium channels inhibits neurotransmitter release. The following antiepileptic drugs have been proposed to inhibit N-type calcium channels: lamotrigine [23,24], levetiracetam [25], phenobarbital at high doses [22] and topiramate [21]. Lamotrigine may also inhibit P-type channels [23], and levetiracetam has some effect on P- or P/Q-type channels [26]. Although only oxcarbazepine has some weak effect on L-type channels [27], the monohydroxy derivative (its main metabolite) inhibits high-voltage-activated calcium channels that are not L-type (presumably P/Q- or N-type channels) [28]. The effect of gabapentin and pregabalin on calcium channels is complex and novel; both show strong and specific binding for the $\alpha_2\delta$ auxiliary calcium channel subunit and may modulate P/Q-type calcium channels [29]. Gabapentin may also inhibit some peripheral L-type channels in a use-dependent manner, but the significance of this for the central nervous system is, at present, unknown [30].

T-type channels are activated at relatively hyperpolarized potentials. They open with small depolarization (low voltage activated), and then rapidly inactivate. T-type channels undoubtedly contribute to the generation of spike–wave discharges associated with absence epilepsy [31]. Hyperpolarization of thalamocortical cells results in the activation of T-type channels, which are then opened by the subsequent repolarization, leading to calcium entry that further depolarizes, leading to action potential generation. Spike activity in the thalamocortical neurones results in the recruitment of neocortical neurones which, via reticular thalamic neurones, inhibit and so hyperpolarize thalamocortical neurones (Fig. 7.4). Ethosuximide, an effective anti-absence drug, has been proposed to inhibit specifically T-type calcium channels [32]. This hypothesis has been challenged in a study that found that ethosuximide has no effect on calcium currents, but instead modulates neuronal bursting by decreasing the persistent sodium current, and perhaps the calcium-dependent potassium current [33]. More recent studies using cloned channels have, however, demonstrated that ethosuximide does inhibit T-type calcium channels at therapeutically relevant concentrations [34]. A possible explanation for these opposing findings is that ethosuximide binds to inactivated T-type channels. Since T-type channels are inactivated at depolarized potentials, then ethosuximide's efficacy is dependent on voltage and will show use dependence [34]. Thus, the inefficacy of ethosuximide at T-type channels found in one study [33] could be

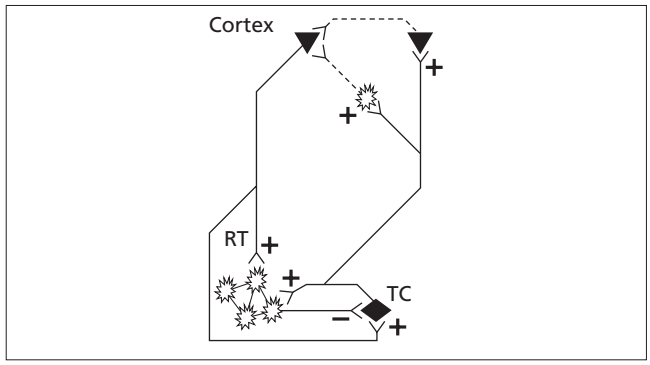

Fig. 7.4 The thalamocortical circuit proposed to underlie spike–wave discharges. RT, reticular thalamic neurones; TC, thalamocortical neurones. Filled, excitatory neurones; open, inhibitory neurones. RT hyperpolarize TC thus activating T-calcium currents that result, on depolarization, in burst firing and so excitation of cortical neurones. These in turn feedback onto RT and so the cycle continues.

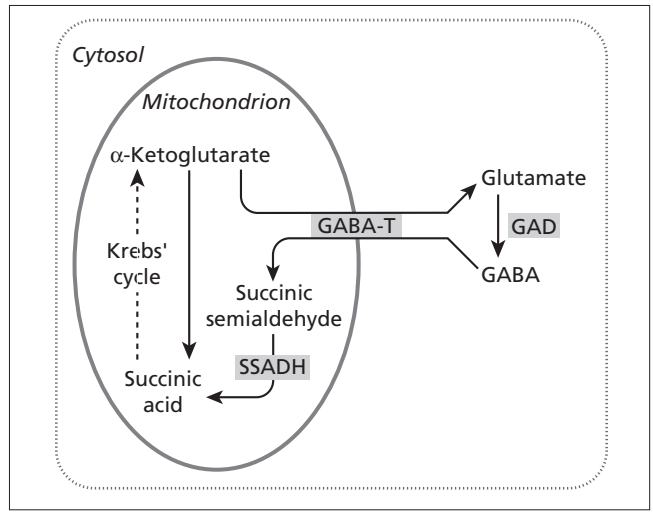

Fig. 7.5 GABA shunt. α-Ketoglutarate and succinic acid are two intermediaries in the Krebs' cycle within the mitochondria. Outside the mitochondria, glutamate is converted to GABA by glutamic acid decarboxylase (GAD). GABA is converted by GABA transaminase (a mitochondrial enzyme) into succinic semialdehyde and then by succinic semialdehyde dehydrogenase (SSADH) to succinic acid; α-ketoglutarate is converted in this reaction to glutamate.

explained by the relatively hyperpolarized potentials that were used (this would result in most T-type channels being in the active, ethosuximide-insensitive state) [34]. Nevertheless, ethosuximide's mode of action is probably more complex than just inhibition of T-type channels [33]. Zonisamide, another drug with anti-absence effects, has been found to inhibit T-type calcium channels [35]. T-type channels can be subdivided into three types, and the expression of these varies between brain regions [17]. Phenytoin and the barbiturates inhibit T-type currents in dorsal root ganglion (valproate has a weak effect), but have minimal effect on thalamic T-type currents [36]. Furthermore, the low-voltage-activated calcium current is not necessarily confined to T-type channels [37]. Thus, some of the effect of phenytoin on low-voltage-activated calcium currents in hippocampal neurones could be because of an effect of phenytoin on other calcium channel subtypes [33]. Some T-type channels may play a part in the bursting of 'epileptic' neurones in the hippocampus, and thus drugs that reduce these T-type channels could be effective in partial epilepsy [38].

GABA and GABA receptors

GABA is the major inhibitory neurotransmitter in the brain. It is formed and degraded in the GABA shunt (Fig. 7.5). Glutamic acid decarboxylase (GAD) converts glutamate to GABA. Promotion of GABA synthesis has been proposed to contribute to the action of some antiepileptic drugs, including valproate [39]. GABA is degraded by GABA transaminase to succinic semialdehyde; α-ketoglutarate accepts the amino group in this reaction to become glutamate (see Fig. 7.5). GABA is transported into vesicles by the vesicular transporter, VGAT, which has been cloned. As this transporter is absent from some GABAergic synapses, then other vesicular transporters probably also exist. GABA acts at three specific receptor types: $GABA_A$, $GABA_B$ and $GABA_C$ receptors. $GABA_C$ receptors are present almost exclusively within the retina, where they are responsible for fast chloride currents. $GABA_C$ receptors have a high affinity for GABA and slowly desensitize, possibly explaining their particular sensitivity of the retina to vigabatrin-induced damage.

$GABA_A$ receptors

$GABA_A$ receptors are expressed mainly postsynaptically within the brain (presynaptic $GABA_A$ receptors have been described within the spinal cord, and at specific synapses in the brain). They are heteropentameric channels constructed from five of at least 16 known mammalian subunits, grouped in seven classes: α, β, γ, δ, σ, ε and π. Each subunit has four transmembrane segments (termed M1–M4), with M2 contributing to the ion-conducting pore (Fig. 7.6). The large number of different subunits permits a large number of putative receptor isoforms, the most abundant in the brain being $GABA_A$ receptors composed of $\alpha_1\beta_2\gamma_2$ (see Fig. 7.6).

The subunit composition determines the specific effects of allosteric modulators of $GABA_A$ receptors, such as neurosteroids, zinc and benzodiazepines. The subunit composition also determines the kinetics of the receptors and can affect desensitization. Importantly, the subunit composition of $GABA_A$ receptors expressed in neurones can change during epileptogenesis, and these changes influence the pharmacodynamic response to drugs [40]. $GABA_A$ receptor activation results in the early rapid component of inhibitory transmission. Since $GABA_A$ receptors are permeable to chloride and, less so, bicarbonate, the effects of $GABA_A$ receptor activation on neuronal voltage are dependent on the chloride and bicarbonate concentration gradients across the membrane. In neurones from adult animals, the extracellular chloride concentration is higher than the intracellular concentration, resulting in the equilibrium potential of chloride being more negative than the resting potential. Thus, $GABA_A$ receptor activation results in an influx of chloride and cellular hyperpolarization. This chloride gradient is maintained by a membrane potassium/chloride co-transporter, KCC2 [41]. Absence of this transporter in immature neurones results in a more positive reversal potential for chloride, and thus $GABA_A$ receptor activation in these neurones produces

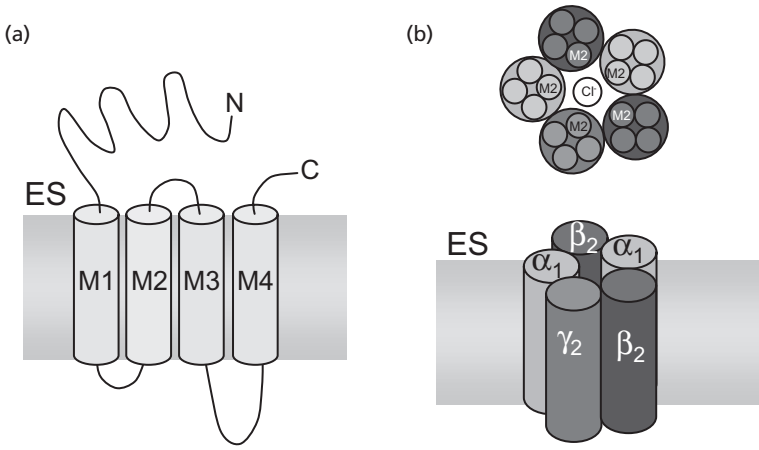

Fig. 7.6 The $GABA_A$ receptor. (a) Membrane topology of a single $GABA_A$ receptor subunit with four transmembrane segments (termed M1–4) and the extracellular NH_2 and COOH termini. M2 contributes to the ion-conducting pore. (b) Pentameric $GABA_A$ receptor composed of two α_1, two β_2, and one γ_2 subunits are the most abundant in the brain (bottom). neuronal depolarization [41]. During excessive $GABA_A$ receptor activation, intracellular chloride accumulation can result in depolarizing $GABA_A$ receptor-mediated responses. Repetitive stimulation can also have a further paradoxical effect in which the hyperpolarizing $GABA_A$ receptor-mediated potential is followed by a prolonged depolarizing potential. This depolarizing potential is partially mediated through an extracellular accumulation of potassium extruded by activation of KCC2 [42]. Thus, under certain circumstances, $GABA_A$ receptors can mediate excitation rather than inhibition. Drugs that inhibit carbonic anhydrase, such as acetazolamide, topiramate and zonisamide, will reduce the intracellular bicarbonate and thus can reduce these depolarizing GABA responses [43].

Benzodiazepines are specific modulators of $GABA_A$ receptors and act at $GABA_A$ receptors that contain an α_1, α_2, α_3 or α_5-subunit in combination with a γ-subunit [44]. Drugs acting at the benzodiazepine site have different affinities for the different α-subunit-containing $GABA_A$ receptors, and this specificity can affect pharmacodynamic response [45]. This is perhaps because of the varied distribution of these receptors in the brain. Thus, α_1-subunit-containing receptors seems to have mainly a sedative effect, and this is perhaps responsible for this side-effect of benzodiazepines [45]. This also explains why zolpidem, a drug that has great affinity for $GABA_A$ receptors containing the α_1-subunit, has marked sedative effects and weak anticonvulsant efficacy [46]. More selective ligands could thus result in benzodiazepine agonists that have a less sedative effect and a greater anticonvulsant potential. The benzodiazepines' main effect is to increase the affinity of $GABA_A$ receptors for GABA, and to increase the probability of receptor opening [47]. Barbiturates are less selective than benzodiazepines, and potentiate $GABA_A$ receptor-mediated currents. The potentiation is partly mediated by prolonging receptor opening times [47,48]. Stiripentol may have a similar mechanism of action [49]. In addition, at high concentrations, barbiturates can directly activate the $GABA_A$ receptor [44]. This partly explains their anaesthetic effect at high concentrations. Other anaesthetic agents, such as propofol, have similar effects on $GABA_A$ receptors [44]. Topiramate can also potentiate $GABA_A$ receptors by an unknown mechanism [50].

$GABA_A$ receptors have other modulatory sites, and can be modulated by zinc [44]. In hippocampi from epileptic brains, $GABA_A$ receptor function is more sensitive to allosteric inhibition by zinc. This zinc-induced inhibition of $GABA_A$ receptors, as well as of glycine receptors, was fully reversed on acute application of levetiracetam in cultured hippocampal neurones [51]. Levetiracetam also prevented the rundown of $GABA_A$ receptor currents in hippocampal tissue from patients with epilepsy following repeated GABA application [52]. Neurosteroids can also modulate $GABA_A$ receptors [44], and variations in neurosteroid levels may explain why seizures occasionally cluster around the time of menstruation [53]. Ganaxolone, a neurosteroid, was, nevertheless, dropped from clinical trials due to lack of efficacy [54].

On occasion, $GABA_A$ receptor agonists can have paradoxical proepileptic effects, perhaps as a result of GABA being excitatory in some circumstances (see above), synchronization of neurones through the interneuronal network or preferential potentiation of GABAergic inhibition of GABAergic interneurones leading to paradoxical disinhibition. $GABA_A$ receptor agonists can also exacerbate absence seizures. Absence seizures are generated within a recurrent loop between the thalamus and neocortex, and their generation is dependent upon oscillatory behaviour mediated by $GABA_A$ receptors, $GABA_B$ receptors, T-type calcium channels and glutamate receptors [55]. One hypothesis is that hyperpolarization of the thalamocortical neurones in the thalamus mediated by GABAergic inhibition leads to activation of T-type calcium currents which open on neuronal depolarization, resulting in repetitive spiking. This activates neurones in the neocortex, which in turn stimulate the thalamic reticular nucleus, leading to GABAergic inhibition of the thalamocortical (relay) neurones (see Fig. 7.4), and so the cycle continues [55]. Within this circuit, clonazepam preferentially inhibits the thalamic reticular neurones, perhaps due to the higher expression of α_3-containing $GABA_A$ receptors [56]. Non-specific $GABA_A$ receptor agonists, $GABA_B$ receptor agonists or agonists of specific $GABA_A$ receptors can all hyperpolarize thalamocortical neurones and so can have a pro-absence effect. This also occurs through the potentiation of GABAergic inhibition with ganaxalone [57].

$GABA_B$ receptors

$GABA_B$ receptors are expressed both pre- and postsynaptically. They are G-protein-coupled receptors, and consist of dimers of either $GABA_{B1a}$ or $GABA_{B1b}$ and $GABA_{B2}$ subunits. Activation of $GABA_B$ receptors results in inhibition of adenylyl cyclase, inhibition of voltage-gated calcium channels and activation of G-protein-linked inwardly rectifying potassium channels (GIRKs). The postsynaptic effect is a prolonged hyperpolarization leading to the late component of inhibitory neurotransmission. At many synapses, postsynaptic $GABA_B$ receptors are located far from the release site, and are activated only by GABA spillover during simultaneous release of GABA from multiple synapses [58]. Although the effects of this would be to decrease the excitability of the system, $GABA_B$ receptor activation may enhance the oscillatory nature of certain structures [58]. Indeed, activation of postsynaptic $GABA_B$ receptors in the thalamus has been proposed to underlie the generation of absence seizures. The presynaptic effect of $GABA_B$ receptors is not only to inhibit GABA release at inhibitory synapses as a process of autoregulation, but also to inhibit glutamate release at excitatory synapses, and thus the effect on the network is complex and difficult to predict. Results with $GABA_B$ receptor agonists have been variable, but they seem to have a pro-absence effect; conversely, $GABA_B$ receptor antagonists have anti-absence effects but can be proconvulsant in other seizure models [59].

GABA uptake and breakdown

Other means of positively modulating GABAergic activity are to inhibit GABA uptake or inhibit GABA breakdown. GABA is mainly metabolized by GABA transaminase to succinic semialdehyde; glutamate is synthesized in this reaction (see above). Vigabatrin irreversibly inhibits GABA transaminase. This results in an increase in intracellular GABA that can produce an increase in vesicular GABA, and so inhibit transmission [60]. In addition, vigabatrin results in an increase in extracellular GABA that can be partly explained by decreased GABA uptake [61]. GABA released into the extracellular space is transported into neurones and glial cells via Na^+/Cl^--coupled GABA transporters (GAT) that can transport GABA against an osmotic gradient [62]. In human and rat, four GAT proteins have been identified and cloned: GAT-1, GAT-2, GAT-3 and BGT-1 [62]. GAT-1 is predominantly present on presynaptic GABAergic terminals and glia, and is the most prevalent GABA transporter in the rat forebrain. In contrast, GAT-3 is localized exclusively to astrocytes and glia, and GAT-2 has a more diffuse distribution. GABA uptake and GAT expression change during development, and are also regulated by protein kinase C (activated by a variety of G-protein receptors), a direct effect of GABA and tyrosine phosphatase [62].

Amongst the most potent of GABA transporter inhibitors is nipecotic acid. Nipecotic acid proved to be a useful tool *in vitro*, but had poor penetration across the blood–brain barrier [63]. Nipecotic acid was thus effective in animal epilepsy models only if it was administered intracerebrally. In order to improve the blood–brain penetration of nipecotic acid and similar compounds, a lipophilic side chain was linked to them via an aliphatic chain. This markedly increased the potency and the specificity of these compounds for the GAT-1 transporter as well as increasing brain penetration [64]. These compounds, in contrast to nipecotic acid, are not substrates for the transporter [65]. One such compound, tiagabine (*R*-[–]-1-[4,4-*bis*(3-methyl-2-thenyl)-3-butenyl]-3-piperidinecarboxylic acid), was selected because of its good preclinical profile. Tiagabine is thus a GAT-1-specific, non-transportable, lipid-soluble GABA uptake inhibitor.

Microdialysis studies have demonstrated an increase in extracellular brain GABA concentrations in various brain regions following systemic or local administration of tiagabine [66,67]. There does, however, appear to be significant differences in the effect of tiagabine on extracellular GABA between brain areas, perhaps secondary to different levels and expression of the different GATs. Thus, the thalamus seems to be less sensitive to the effects of tiagabine than the hippocampus [66]; indeed, the dose of tiagabine that results in an increase in thalamic GABA is much higher than that necessary to mediate an antiepileptic effect and is of a magnitude that has a possible proconvulsive effect [67]. Tiagabine, in contrast to vigabatrin, has no effect on total brain GABA. This and the failure of tiagabine to accumulate in the retina, again in contrast to vigabatrin, may mean that tiagabine will not cause the concentric visual field defects associated with vigabatrin [68].

Although many explanations of vigabatrin's and tiagabine's mode of action concentrate on raising the extracellular GABA concentration, these drugs have other important effects. The time-course of the GABA transit in the synaptic cleft is partly (and variably) determined by GABA uptake; tiagabine can thus prolong the synaptic GABA transient. In addition, by decreasing GABA uptake there is greater spillover of GABA from the synaptic cleft onto extrasynaptic receptors. Each of these mechanisms can have an effect on inhibition, and there is no consensus as to the relative importance of each.

Increasing extracellular GABA can have two opposing effects. Extrasynaptic $GABA_A$ receptors have a high affinity and less propensity to desensitize. Extracellular GABA acting at these receptors can mediate a tonic (continuous) form of inhibition. Such inhibition is developmentally regulated and demonstrates regional and cellular specificity [69]. Since extracellular GABA concentrations can vary and increase during seizures, such tonic inhibition would be expected to demonstrate similar increases during seizure activity. A second effect of increasing extracellular GABA is to desensitize synaptic $GABA_A$ receptors [70]. This can result in smaller amplitude $GABA_A$ receptor-mediated currents [70]. Thus, vigabatrin increases tonic inhibition, but decreases synaptically mediated inhibition (Fig. 7.7) [70].

The effects of inhibiting GABA uptake on the time-course of GABA in the synaptic cleft are dependent upon the extent to which the time-course is governed by uptake as opposed to just diffusion, and is thus dependent upon the affinity, on-rate and density of GABA transporters and the geometry of the cleft and the extracellular space. GABA uptake varies with age and location. Inhibiting GABA uptake has no effect on inhibitory postsynaptic current (IPSC) kinetics at early ages, whilst prolonging IPSCs at later age groups [71]. The effect of changing the time-course of the GABA transient is not immediately predictable. Importantly, at some synapses the decay of the $GABA_A$ receptor-mediated IPSC/P is determined mainly by the spatiotemporal profile of the GABA concentration rather than the kinetics of the $GABA_A$ receptors [72]. At these synapses, prolonging the

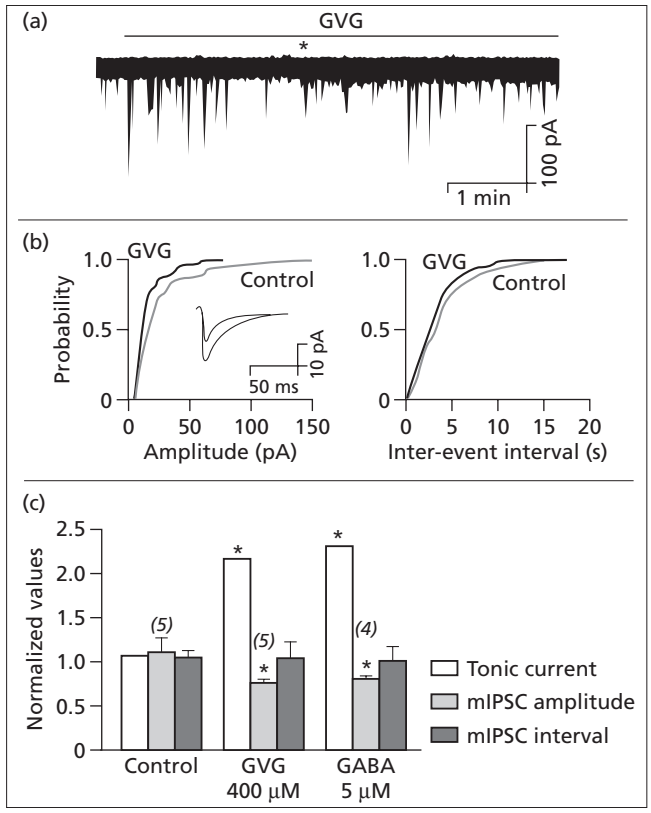

Fig. 7.7 Acute vigabatrin (GVG) or GABAs reduces miniature inhibitory postsynaptic currents (pIPSC) amplitude, but increases tonic inhibition. (a) GVG (400 μmol) applied to an untreated slice produced an increase in tonic current that was apparent after a couple of minutes (*) and increased gradually throughout the experiment. (b) GVG reduced the mIPSC amplitude in all cases, without affecting the interevent interval. (c) The tonic current was increased by GVG or GABA (experiments performed with $GABA_B$ receptors blocked). From ref. 70.

time-course of the synaptic GABA transient prolongs the duration of the IPSC/P [72]. This results in an effect on the current that is similar to benzodiazepines or barbiturates, although mechanistically different. In contrast, studies at other synapses and in different neurones have found no change in the decay of miniature IPSP/Cs (or even small IPSP/Cs) with block of GABA uptake, but have found a prolongation of large-amplitude IPSCs [73,74]. Blockade of GABA uptake in large evoked IPSC/Ps affects the late, but not early, decay. The discrepancy between the effects on miniature IPSC/Ps compared with large-amplitude IPSC/Ps can be explained by hypothesizing that the decay of small IPSC/Ps and the initial decay of the IPSC/P are determined by single-channel kinetics and/or diffusion from the cleft [74]. Release of GABA from many sites, however, can result in spillover to GABA receptors beyond the activated synapses, and this spillover is enhanced by a decrease in GABA uptake [73]. Spillover of neurotransmitter can activate not only extrasynaptic $GABA_A$ receptors but also $GABA_B$ receptors, which also lie outside the synaptic cleft [73]. Indeed, despite the presence of postsynaptic $GABA_B$ receptors, GABA released by a single interneurone usually activates postsynaptic $GABA_A$ receptors alone (Fig. 7.8) [58]; spontaneous IPSCs typically lack a $GABA_B$ receptor-mediated component [75]. Synchronous release of GABA from several interneurones, such as occurs with either strong stimulation or synchronous neuronal activity, can, however, activate postsynaptic $GABA_B$ receptors [58,73]. Blocking GABA uptake results in activation of $GABA_B$ receptors by GABA released by even a single interneurone (see Fig. 7.8) [58]. Thus, blocking GABA uptake can result in an enhancement of postsynaptic $GABA_B$ receptor-mediated inhibition. A defect in GABA uptake has been hypothesized to be the substrate for genetic absence epilepsy in one rat model [76]. It is thus not surprising that tiagabine and vigabatrin can worsen absence seizures, and can induce absence status epilepticus in humans [77]. Enhancement of $GABA_B$ receptor activation will have not only a postsynaptic effect, but also a presynaptic effect, and will decrease the release of GABA from GABAergic terminals (decreasing inhibition), and glutamate from glutamatergic terminals (decreasing excitation). The overall effect on the network is thus difficult to predict.

Repetitive stimulation and bursts of neuronal activity such as occur during seizure activity can both cause $GABA_A$ receptor-mediated depolarizing responses (see above), and these could potentiate rather than inhibit epileptic activity. Tiagabine potentiates these depolarizing responses [78], and thus the concern is that, through this mechanism, tiagabine could in some circumstances enhance seizure activity.

Other targets

Glutamate and glutamate receptors

Glutamate is a non-essential amino acid that does not cross the blood–brain barrier but is readily synthesized by various biochemical pathways from different precursors including α-ketoglutarate (an intermediate of the Krebs' cycle), glutamine, ornithine and proline. GABA transaminase contributes to the synthesis of glutamate (see Fig. 7.5). Thus vigabatrin, which inhibits GABA transaminase as well as inhibiting the breakdown of GABA, may also decrease the synthesis of glutamate [79]. Glutamate is present in abundance in brain tissue, and is the major excitatory transmitter in the central nervous system. Glutamate is transported into vesicles by a specific vesicular transporter, and exhaustion of vesicular glutamate has been proposed to be a possible mechanism of seizure termination. Abnormalities of glutamate uptake have been hypothesized to contribute to seizure generation, and thus drugs that modulate glutamate uptake may have an antiepileptic effect. Glutamate is present in the brain in large concentrations (10 mmol), but this is predominantly intracellular glutamate [80]. The extracellular glutamate is maintained at concentrations 5000 times lower than this (approximately 2 μmol) by high-affinity glutamate uptake into predominantly glia. Glutamate acts at three distinct receptor types: NMDA, non-NMDA [consisting of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic (AMPA)- and kainic acid (KA)-sensitive receptors] and metabotropic glutamate receptors. These receptor subtypes have very different properties (Table 7.3).

AMPA and kainate receptors

Non-NMDA receptors are mainly associated with channels that are permeable to sodium ions, and are responsible for fast excit-

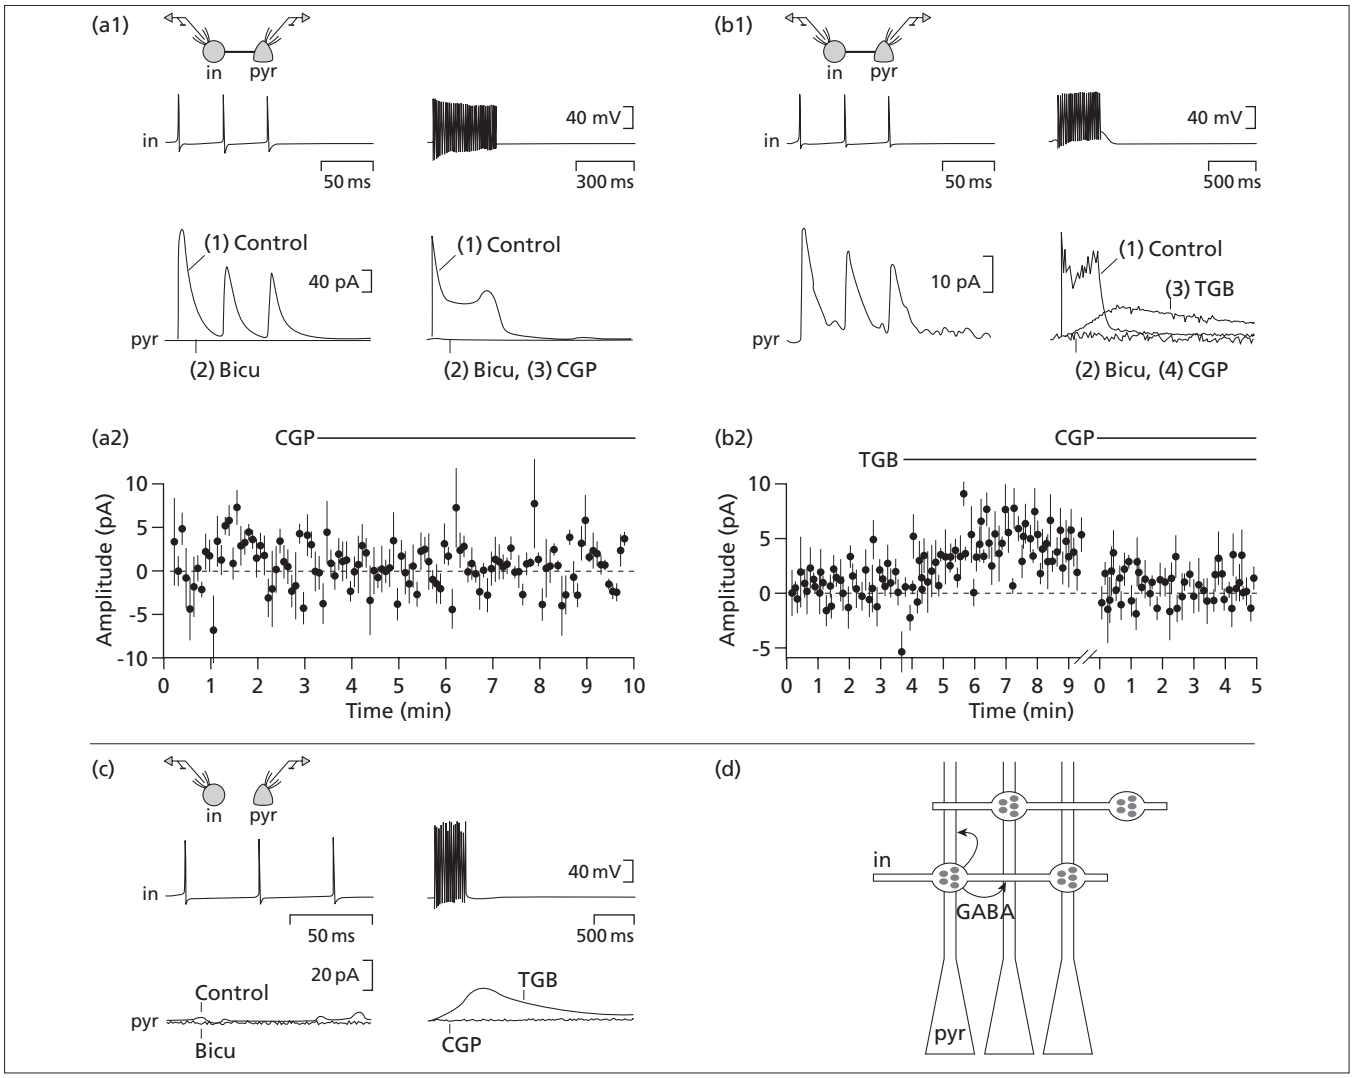

Fig. 7.8 Activation of $GABA_B$Rs by release of GABA from a single interneurone. (a1) Dual recording from a connected interneurone/pyramidal cell (in/pyr) pair. Three action potentials triggered in the interneurone elicit three inhibitory postsynaptic currents in the pyramidal cell. A train of action potentials (100 Hz) from the interneurone elicits an outward current in the pyramidal cell. Both types of responses are completely blocked by the $GABA_A$R antagonist bicuculline. Addition of the $GABA_B$R antagonist CGP62349 (2 μmol) has no further effect. (a2) Summary graph of the time-course of the amplitude of the response, after application of bicuculline, for eight experiments. (b1) Similar experiment to that illustrated in (a1), with the difference that the GABA uptake-blocker tiagabine (TGB; 10 μmol) was applied after perfusion of bicuculline. Under these conditions, the AP train elicits a long-lasting outward current, which is abolished by CGP62349. (b2) Summary graph of the time-course of the amplitude of the response, after application of bicuculline, for six experiments. (c) Dual recording from a non-connected in/pyr cell pair. After application of tiagabine, a train of APs in the interneurone elicits an outward current that can be blocked by CGP62349. (d) Schematic diagram illustrating extrasynaptic $GABA_B$R activation by diffusion of GABA on both postsynaptic and neighbouring pyramidal cells. From ref. 58.

EC_{50} for glutamate	–	500 μmol	2–3 μmol

atory neurotransmission. The receptors consist of four subunits; receptors comprising GluR1–4 subunits are the AMPA receptors, and those comprising GluR5–7 and KA1–2 are the kainate receptors [81]. AMPA receptors lacking the GluR2 component are also permeable to calcium ions. Relatively large concentrations of glutamate result in channel opening and a rapid depolarization. The concentration that gives half the maximum response (EC_{50}) for AMPA receptors is of the order of 500 μmol of glutamate [82]. AMPA receptors are putative targets for antiepileptic drugs. Since AMPA receptors mediate most excitatory transmission in the brain, drugs acting at these receptors are likely to have physiological consequences. Nevertheless, topiramate at high concentrations acts at AMPA/kainate receptors [83]; whether this

is responsible for its antiepileptic effect or dose-related side-effects is unknown. Levetiracetam also inhibits AMPA receptor currents at clinically relevant concentrations, which may partially explain its antiepileptic action [84]. There are other drugs in clinical trials, such as talampanel, that are AMPA receptor antagonists [85]. Kainate receptors, as well as having a postsynaptic role in exciting interneurones and principal cells, are also present presynaptically [86]. These presynaptic receptors can increase or decrease neurotransmitter release depending on subtype and target. In addition, axonal kainate receptors can affect axonal excitability, leading to ectopic action potentials [87]. It is thus difficult to predict whether the effect of kainate receptor activation would be pro- or anti-ictogenic [88]. The agonist KA is, however, a powerful convulsant, thus kainate antagonists would perhaps be expected to have antiseizure effects [88]. Of interest is that interneurones may express a different kainate receptor subtype from that expressed on principal cells, raising the possibility that kainate receptor subtype-specific agonists and antagonists may provide a powerful approach to modulate the excitability of the system [88]. Indeed, there has been a report of a GluR5-specific antagonist with antiepileptic effects in pilocarpine-induced seizures [89], yet there is a separate study demonstrating that GluR5 agonists can be antiepileptic [90]. This dichotomy demonstrates the difficulties in predicting the effects of kainate receptor antagonists and agonists.

NMDA receptors

NMDA receptors are associated with channels that are permeable to calcium and sodium ions. NMDA receptors are composed of multiple NR1 subunits in combination with at least one subtype of NR2 subunit (NR2A, B, C or D) and occasionally NR3 subunit. The receptor has high-affinity sites for both glycine and glutamate as well as sites for polyamines and zinc. Relatively low concentrations of glutamate are necessary to activate the receptor. NMDA receptors typically have an EC_{50} for peak response of the order of 2–3 μmol of glutamate (i.e. orders of magnitude lower than that of AMPA receptors) [82]. NMDA receptors are thus influenced by the ambient glutamate concentration and can be activated extrasynaptically by glutamate spillover during excessive synaptic activity such as occurs during seizures. NMDA receptor responses decay slowly, leading to a persistent depolarization that lasts for hundreds of milliseconds [91] and which can thus contribute to burst firing. NMDA activation by glutamate does not necessarily result in any detectable current flow, because at negative potentials the ionic pore is tonically blocked by magnesium. This block is released by depolarization. During normal synaptic activity, the time-course of the non-NMDA excitatory postsynaptic potential (EPSP) is substantially shorter than the latency for NMDA receptor activation. Even if activation of non-NMDA receptors should result in a sufficient depolarization to release the magnesium block, by the time most NMDA receptors are activated by glutamate, most neurones will have repolarized to such an extent that the magnesium block will be in place and no current will flow through the NMDA receptors [91]. If, however, the NMDA receptor activation coincides with neuronal depolarization, then the resultant depolarization will result in removal of the magnesium block and the channel will open and current will flow. The NMDA receptor thus acts as a coincidence detector. The resultant influx of calcium through NMDA receptors has secondary consequences, affecting the phosphorylation of proteins that can produce long-term synaptic potentiation, modulation of other receptors and, if excessive, even cell death. NMDA receptors would seem an ideal target for antiepileptic drugs, to prevent burst firing, proepileptogenic synaptic plasticity and neuronal death during prolonged epileptic activity (i.e. status epilepticus).

NMDA receptors, however, have numerous physiological roles in learning and motor control. This has meant that many of the NMDA receptor antagonists tried in epilepsy or for neuroprotection have had unacceptable side-effects. Interestingly, the adverse effects associated with NMDA receptor antagonists may be more prevalent in people with epilepsy, perhaps due to receptor modifications that occur with epileptogenesis. Nevertheless, some presently available antiepileptic drugs may have modulatory effects on NMDA receptors. NMDA receptors have binding sites not only for glutamate, but also for zinc, glycine and polyamines. These sites modulate receptor function by affecting rates of desensitization, affinity for glutamate and channel opening. The glycine site has also been proposed to be essential for NMDA receptor activation. Thus, felbamate, a drug that acts at the glycine site of the NMDA receptor, modulates NMDA receptor function [92]. Remacemide and its des-glycine metabolite may have a variety of effects on the NMDA receptor, acting both as channel blockers and as modulators [93]. NMDA receptors can also be modulated by other factors, such as pH, redox state and phosphorylation, that may provide additional drug targets. In addition, drugs that influence glutamate uptake can affect NMDA receptor activation, and so could possess antiepileptic activity [94].

Metabotropic glutamate receptors

Metabotropic glutamate receptors are G-protein-linked receptors that can be classified into three groups. Group I receptors are mainly expressed postsynaptically, where they enhance postsynaptic calcium entry, calcium release from internal stores and depolarization through inhibition of potassium currents. Group I receptors may thus play a part in neurodegeneration. Group I antagonists have neuroprotective and antiepileptic potential [95]. Presynaptic group I receptors can enhance neurotransmitter release. In contrast, presynaptic group II and group III metabotropic glutamate receptors inhibit both GABA and glutamate release. The selectivity of some group II receptors for GABA synapses onto interneurones results in agonists inhibiting the inhibition of interneurones (i.e. decreasing the excitability of the system). Indeed group II and group III agonists have had antiepileptic effects in genetic epilepsy models and kindling [96–99], and may prove useful as antiepileptic drugs.

Potassium channels

Potassium channels form one of the most diverse groups of ion channels. There are persistent potassium currents that determine the resting potential of neurones, but there are, in addition, other voltage-gated potassium channels with varying functions. The voltage-gated potassium channels influence the resting potential and thus the excitability of neurones. They also repolarize neurones following action potentials, and so partly determine action

potential width – a factor that can influence transmitter release. In addition, the rate of inactivation of potassium channels, which are activated during an action potential, influences the propensity for rapid repetitive firing. Voltage-gated potassium channels are thus critical for determining neuronal excitability.

Voltage-gated channels are assembled from four α-subunits, and the diversity of possible α-subunits leads to a multitude of combinations with different properties. The α-subunits vary in size; the largest have six transmembrane segments (similar to a single domain of the sodium and calcium channels). Analogous to sodium channels, the voltage-sensing segment is S4 and the pore is composed of S5 and S6; in contrast to sodium channels, the mechanism of fast inactivation depends on an N-terminal structure that, like a ball and chain, occludes the pore. There is also a slower form of inactivation, which is poorly understood. There are smaller α-subunits, which consist of two transmembrane segments that make up the inward rectifying potassium channels. Auxiliary β-subunits can also combine with the α-subunits and can influence channel kinetics and possibly receptor expression.

Conventionally, the voltage-gated potassium channels in the brain can be divided into channels that rapidly activate and inactivate (A-type channels), and channels that open upon depolarization but do not significantly inactivate (delayed rectifier channels). There are also potassium channels that close upon depolarization but are open at the resting potential (inward rectifying channels); these channels do not inactivate in the same fashion as the other voltage-gated potassium channels, but the channels are rather blocked by internal ions at depolarized potentials. There are a variety of inward rectifying channels: some are G-protein linked and are opened by activation of G-protein-linked receptors (e.g. $GABA_B$ receptors), whilst some are opened by rises in intracellular adenosine triphosphate (ATP). There are other potassium channels that are similar in structure to the voltage-gated potassium channel, but are opened by intracellular calcium (calcium-activated potassium channels that mediate the afterhyperpolarization) or by cyclic nucleotides (mainly present in the retina, where they mediate photoreceptor responses). There are also specific potassium channels that are inactivated by acetylcholine – termed M-type channels.

Although modulation of potassium channels would seem to be an ideal target for antiepileptic drugs, most drugs have no or poorly characterized effects on potassium channels. Phenytoin and levetiracetam may selectively block delayed rectifier potassium channels [100,101]; this inhibition could prolong the action potential duration, thereby prolonging the 'refractory period', resulting in a reduction of sustained repetitive firing. Indeed, at lower firing frequencies, such an effect may be proconvulsant; a longer action potential at the presynaptic terminal could increase the calcium influx, thereby enhancing neurotransmitter release. Drugs that potentiate potassium channels would be expected to have an antiepileptic effect by decreasing the excitability of neurones. Potentiation of specific potassium channels has indeed been proposed to contribute to the action of some presently available antiepileptic drugs. Thus, gabapentin potentiates ATP-activated inward-rectifying potassium channels [102], and topiramate and acetazolamide induce a membrane hyperpolarization that is blocked by the potassium channel blocker, barium [43]. The afterhyperpolarization induced by calcium-dependent potassium channels also reduces neuronal excitability, and ethosuximide may mediate some of its effect by potentiating such channels [33].

Retigabine, a putative antiepileptic drug, has as perhaps its main mode of action potentiation of potassium channels. Retigabine induces a hyperpolarizing shift in the activation curves of KCNQ2/3 channels and probably other potassium channels from the same family that are responsible for the M current in neurones [103]. Interestingly, mutations of KCNQ2/3 are responsible for benign neonatal seizures. The extent to which other antiepileptic drugs affect potassium channels remains unknown, but it is likely that modulation of potassium channels will be a future target for antiepileptic drug development.

Cyclic nucleotide-gated channels

The importance of hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels in epilepsy has only recently been recognized. Their structure resembles those of Shaker K^+ channels: each HCN subunit consists of six transmembrane segments with a positively charged segment S4 serving as voltage sensor and an ion conduction pore between segment S5 and S6. Four subunits are thought to assemble to one homo- or heteromeric channel. There are four separate genes encoding biophysically distinct subunits termed HCN1–4. HCN channels are ubiquitously present in the brain with predominant expression of the HCN1, 2 and 4 subunits. The expression patterns substantially vary in different brain regions, e.g. the thalamus exhibits high expression of the 'slow activating' subunits HCN2 and 4, whereas hippocampal CA1 pyramidal neurones mainly express the 'fast activating' HCN1 subunit together with HCN2. Moreover, HCN channels also display distinct subcellular expression pattern, for example in CA1 pyramidal neurones they are expressed at a higher density in distal dendrites than in the somatodendritic membrane. Their functions depend on their subcellular localization and the HCN subunits expressed.

Cyclic nucleotide-gated channels underlie the H-current, which is different from other voltage-gated ion currents in many features. The H-current is a mixed inward current, carried by Na^+ and K^+ ions, that develops slowly upon hyperpolarization to below –60 mV. Conversely, it slowly deactivates upon depolarization. H-currents are directly enhanced by the second messenger, cAMP, the binding of which shifts the voltage-dependent activation curve to more depolarized potentials, so that more HCN channels are open at a given membrane potential. In the hippocampus and neocortex, H-currents contribute to the resting membrane potential, and to the integration of synaptic and somatic integration by partially setting the neuronal input resistance. The latter determines the neuron's sensitivity to incoming signals, as the H-current shunts the dendritic currents. In the thalamus, H-currents serve as the classical 'pacemaker' currents and generate, together with T-type calcium currents, physiological oscillations [31].

A down-regulation of dendritic H-currents has been suggested to be a proepileptic in animal models of chronic partial epilepsy (pilocarpine model, kainate model), whereas an up-regulation has been considered as a compensatory antiepileptic effect (e.g. in the hippocampal dentate gyrus of pilocarpine model and in patients

with mesial temporal lobe epilepsy) [104]. In absence seizures and the related thalamocortical loop, region-specific changes in HCN expression patterns were observed that may disturb the subtle interactions within this circuit, thereby favouring onset of spike–wave discharges and absences [105].

Cyclic nucleotide-gated channels are considered potential targets for antiepileptic drug therapy. Indeed, H-currents are enhanced by acetazolamide, gabapentin and lamotrigine [106–108]. Lamotrigine shifts the activation curve to more depolarized potentials, whereas gabapentin probably directly increases HCN channel conductance. Acetazolamide indirectly enhances H-currents via intracellular alkalinization. Increasing the H-current may have two potentially antiepileptic effects. In the hippocampus it would inhibit excitatory transmission to the soma and decrease excitability, so perhaps contributing to the efficacy of acetazolamide, gabapentin and lamotrigine in partial epilepsy. In the thalamus, it would depolarize thalamocortical neurones and so inhibit or terminate spike–wave discharges, possibly explaining the efficacy of acetazolamide, and lamotrigine against absence seizures. The role of HCN channels is, however, not clear-cut as pentobarbital has been reported to decrease, while the pro-absence drug gabapentin has been reported to increase, the H-current [109]. These apparent inconsistencies could be explained by the multiple targets of the drugs.

Synaptic vesicle protein SV2A

Synaptic vesicle fusion that precedes neurotransmitter release is a complex process involving a variety of proteins. Levetiracetam binds to one of these, the synaptic vesicle protein SV2A [110]. Binding does not occur to the two isoforms SV2B or SV2C. Importantly, in different animal models of epilepsy, the antiepileptic potency of levetiracetam and its derivatives positively correlated with their SV2A binding affinity (Fig. 7.9) [111]. This, and the fact that SV2A knockout mice strains display a severe seizure phenotype, strongly suggest that levetiracetam binding to SV2A is involved in its antiepileptic effect. SV2A is a glycoprotein with 12 transmembrane regions, a cytosolic N and C terminus, a long cytosolic loop and a long intravesicular loop that is glycosylated. Unfortunately, to date, the specific binding site of levetiracetam on the SV2A protein has not been reported. The function of SV2A is still unclear, and SV2A may regulate presynaptic calcium levels and also supports GABAergic and excitatory neurotransmission. Although SV2A has been identified as a specific binding site for levetiracetam, exactly how the drug exerts its antiepileptic effect and what changes in synaptic transmission occur is unknown.

Monoamines

It has been well established that monoamines play an integral role in epileptic phenomena. Experiments carried out in excised epi-

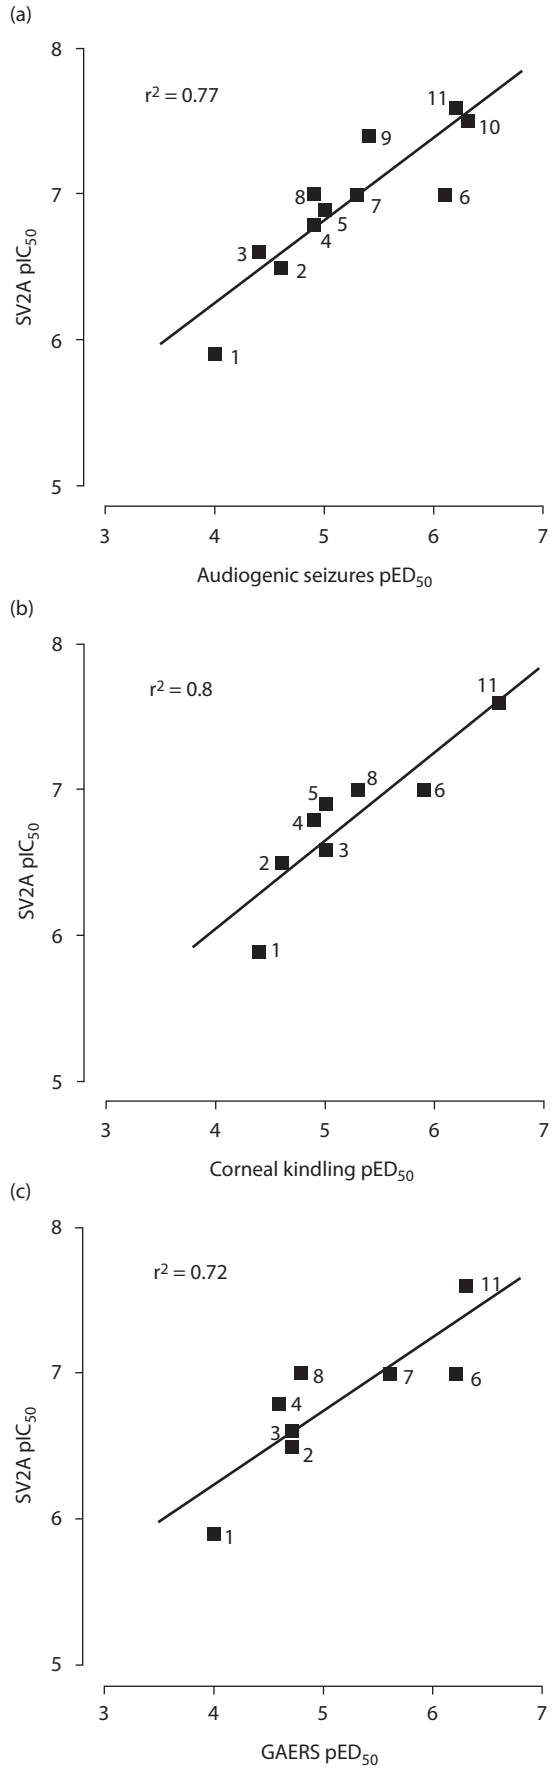

Fig. 7.9 Correlation between binding affinity and anticonvulsant potency of SV2A ligands against audiogenic seizures. (a) Corneal kindling (as a model for partial seizures). (b) Absence seizures (genetic absence epilepsy rats from Strasbourg; GAERS). (c) SV2A binding affinities (expressed as pIC_{50}) were measured in rat brain membranes with the use of [^{3}H]ucb 30889. Anticonvulsant potencies, based on dose–response studies, are shown as pED_{50}. Reprinted from ref. 111 with permission from Elsevier.

leptic brain tissue have shown alterations in both catecholaminergic and indoleaminergic activity when compared with non-epileptic tissue. In addition, monoamine content has been shown to differ in the cerebrospinal fluid of epileptic patients compared with non-epileptic patients [112]. Indeed, experimentally induced attenuation of monoamine content has been directly implicated in the onset and propagation of many seizure disorders [113,114] whereas experimentally induced accretion of monoaminergic activity has been shown to retard the development of epileptiform activity [115,116]. The role of GABA in the epilepsies has been well characterized but little is known of the input that other monoamines have to play in, or following, seizure generation.

Dopamine

It is generally accepted that alterations in central dopamine levels are responsible, in part, for the onset and continuance of many seizure disorders (see ref. 117 for a review). In the midbrain, inhibition of the substantia nigra (SN) has been shown to attenuate seizures in many animal models of seizure disorders. The SN projects dopaminergic neurones to the caudate putamen and, in turn, receives GABAergic afferents from the caudate putamen via one of two pathways. The first pathway, commonly known as the direct pathway, offers a direct monosynaptic GABAergic projection from the caudate putamen to the SN. The second pathway (indirect pathway) involves a GABAergic projection from the caudate putamen to the lateral globus pallidus. The globus pallidus then projects GABAergic efferents to the subthalamic nucleus that finally exerts glutamatergic tone onto the SN.

The SN and the caudate putamen have been thought to play major roles in the interruption and triggering of seizure generation, respectively. Seizure control appears to be partly regulated by the direct pathway and its ability to potentiate GABAergic activity within the SN. The antiepileptic profile of the indirect pathway is exemplified following the attenuation of seizure activity after local administration of NMDA antagonists either in the SN or in the subthalamic nucleus. It would appear that both these pathways act through the SN control of seizure propagation, despite the fact that they exert opposite effects on SN neuronal activity.

As yet, it remains undetermined just how these pathways interact to control seizures or whether or not anatomical subpopulations of striatal efferents have the propensity to control specific types of seizure.

The prefrontal cortex is also served by dopaminergic neurones that have their soma located in the ventral tegmental area (VTA). Innervation of the prefrontal cortex from the VTA has been thought to be responsible for the modulation of cognitive processes in humans in addition to having a role to play in inhibiting spontaneous prefrontal neuronal firing. In the primate cortex, dopamine terminals have been shown to co-localize with glutamate terminals on dendritic spines of pyramidal neurones. Furthermore, dopaminergic terminals have been found to exist in close proximity to the dendrites of inhibitory interneurones. Thus, it appears that dopamine has the potential to provide a regulatory control over the degree of excitatory input into the cortex [118]. Indeed, dopamine has been shown to attenuate the spontaneous firing of rodent prefrontal neurones [119], possibly via an enhancement of the frequency and amplitude of spontaneous IPSCs [120].

Noradrenaline

Noradrenaline (NA) in the central nervous system is formed by the α-hydroxylation of dopamine and is considered to be primarily an inhibitory neurotransmitter. Attenuating synaptic NA levels has been shown to exert proconvulsant effects in models of seizure disorder [121], whereas increasing NA neurotransmission has been shown to reduce seizure activity [122]. Furthermore, synaptic noradrenergic activity has been shown to retard the kindling process (i.e. epileptogenesis) [115]. It has been proposed that the anticonvulsant activity of sodium valproate and carbamazepine can be partly attributed to their ability to heighten noradrenergic activity [123,124].

5-Hydroxytrytamine

5-Hydroxytrytamine (5HT) acts in the mammalian central nervous system through seven classes of receptor ($5HT_{1–7}$). At least four ($5HT_{1–4}$) are thought to modify neuronal excitability and/or neurotransmitter release [125].

In the brain, the prominent 5HT cell bodies are located in the raphe nuclei, which send ascending projections to the hippocampus [126]. 5HT has been shown to either inhibit or excite GABAergic interneurones in the CA1 region of the hippocampus following stimulation of $5HT_{1A}$ and/or $5HT_3$ receptors [127,128] and this has been proposed to modify excitatory responses within this region.

Serotonergic neurotransmission has been shown to influence the generation of certain types of seizure disorder in various experimental models, including hippocampal kindling [129] and systemic administration of proconvulsants [130]. One report comparing monoamines and their metabolites in brain tissue from epileptic patients undergoing temporal lobe resections for seizure control found that the compensatory activation of serotonergic neurotransmission that exists in human epilepsy generated an increase in 5HT turnover as reflected in cerebrospinal fluid 5-hydroxyindoleacetic acid (5HIAA) levels. However, in this study, the increase in 5HT turnover rate was reported to be insufficient for blocking seizure activity [112]. Furthermore, pharmacological agents which enhance and facilitate 5HT neurotransmission have been shown to provide anticonvulsant effects in a wide range of experimental models of seizure disorder, including the genetically epilepsy-prone rat model of generalized tonic–clonic epilepsy (GEPR) [131]. Drugs such as the selective serotonin reuptake inhibitor (SSRI) fluoxetine have been shown to augment the synaptic concentration of 5HT and may be effective against generalized tonic seizures [132]. Antiepileptic drugs such as carbamazepine [116], sodium valproate [133] and zonisamide [134] have all been shown to elevate extracellular hippocampal 5HT levels in rodents. Lamotrigine has also been shown to elevate synaptic 5HT levels by inhibiting its uptake in synaptosomal preparations from rodent cortex [135].

Effects of antiepileptic drugs

Carbamazepine, phenytoin, valproate and zonisamide are four of the most commonly cited antiepileptic drugs associated with alterations in monoaminergic neurotransmission. All of these

antiepileptic drugs are thought to mediate their actions, at least in part, via a blockade of Na^+ channels [12,136–138]. It has been well established that blockade of Na^+ ion channels inhibits neuronal firing. However, at therapeutically relevant concentrations carbamazepine, phenytoin, valproate and zonisamide have been found to enhance monoamine neurotransmission [133,134,139]. Moreover, therapeutically relevant concentrations of carbamazepine and zonisamide have been shown to facilitate basal monoamine release without affecting basal glutamate release, and inhibited the depolarization-induced release of glutamate and monoamines [140]. This effect appears to be biphasic in that at supratherapeutic levels carbamazepine and zonisamide reduced brain monoamine concentrations [141,142]. The finding that carbamazepine produced a concentration-dependent increase in [^{3}H]5HT overspill without affecting Ca^{2+}- [116] or K^+-evoked neurotransmission [143] suggests that carbamazepine-induced 5HT release is not dependent on depolarization or exocytosis.

It is interesting to note that co-administration of zonisamide with either phenytoin or valproate increased brain concentrations of dopamine and 5HT compared with treatment with zonisamide alone [144]. It has previously been shown that zonisamide does not affect the pharmacokinetic properties of valproate [145] and therefore it would be interesting to discover whether polypharmacy involving zonisamide as add-on therapy to existing valproate treatment would yield greater clinical benefit than that seen with valproate monotherapy.

Intracellular signalling pathways

There are numerous intracellular signalling pathways that can be activated or inactivated by activity at membrane receptors (in particular metabotropic receptors described above) and, conversely, can modulate membrane receptors and channels. Such intracellular pathways may provide a powerful means of altering cellular excitability. Identifying the relevance of intracellular drug targets is, however, complex because of the intricate relationships between different intracellular processes and the consequent difficulty in distinguishing direct from indirect effects. Many of the effects on intracellular mechanisms may be important for the action of antiepileptic drugs in other conditions, especially psychiatric disorders, and as neuroprotectants [146]. Perhaps the antiepileptic drug that has been most studied in regards to intracellular targets because of its powerful mood-stabilizing effect is valproate. Valproate has been reported to inhibit histone deacetylase (HDAC) enzymes [147], which would increase gene expression and may contribute to an antitumour effect; inhibit glycogen synthase kinase-3 [148], perhaps contributing to its mood-stabilizing effect; modulate MAPK/ERK signalling [149], perhaps contributing to its neuroprotective effects; and attenuate inositol (1,4,5)-triphosphate (IP3) signalling [150], perhaps contributing to its effects in bipolar mood disorder. Carbamazepine shares some of these intracellular effects [146].

A potentially important intracellular target is the intraneuronal calcium store, which substantially contributes to the regulation of neuronal excitability, neurotransmission and regulation of gene expression and disease-related processes such as epileptogenesis [151,152]. Ca^{2+} release from these stores is mainly regulated by IP3 and ryanodine receptors. Some AEDs, such as levetiracetam [153], topiramate [154], zonisamide [155] and carbamazepine [156], were reported to modulate IP3 and ryanodine receptors. The extent to which these intracellular effects contribute to these drugs' efficacy in epilepsy is unclear. It has, for example, been postulated that many of the effects of topiramate on channels and receptors are mediated through an action of topiramate in inhibiting protein phosphorylation [157].

8 Mechanisms of Tolerance and Drug Resistance

Wolfgang Löscher[1] *and Dieter Schmidt*[2]

[1]University of Veterinary Medicine, Hannover, Germany
[2]Epilepsy Research Group, Berlin, Germany

Introduction

The primary aim of epilepsy therapy by antiepileptic drugs (AEDs) is seizure freedom. However, about one-third of patients with epilepsy have drug-resistant epilepsy. This is associated with an increased risk of death and debilitating psychosocial consequences and thus is one of the major problems in epilepsy therapy [1]. Drug-resistant epilepsy is defined as the persistence of seizures despite treatment with a range of AEDs, using different mechanisms of action singly or in combination at maximum tolerated doses. To overcome this problem, there is a pressing need to develop more effective treatments and strategies. To attain this goal, we need to understand the mechanisms underlying drug resistance. In this chapter, several possible mechanisms of drug resistance will be reviewed (Fig. 8.1). These mechanisms will be assigned to three major categories: (1) disease-related mechanisms; (2) drug-related mechanisms; and (3) pharmacogenetic mechanisms. As will be discussed in this chapter, development of tolerance, i.e. the reduction in response to an AED after repeated administrations, also constitutes an important drug-related mechanism of resistance, and is reviewed in the section on drug-related mechanisms of drug resistance in epilepsy.

Disease-related mechanisms of drug resistance in epilepsy

In this section we will examine the clinical evidence for hypotheses concerning disease-related mechanisms of drug resistance, which are both plausible and based on a reasonable body of evidence (Fig. 8.1). These are:

- epilepsy syndromes including their aetiology;
- progression of disease;
- structural brain alterations and/or network changes as assessed by studies of patients undergoing epilepsy surgery and, if possible, appropriate controls;
- alterations in drug targets; and
- alterations in drug uptake into the brain.

For our discussion it is worthwhile to note that several mechanisms outlined above may act together and possibly even interact. It is probably naïve to think that only one mechanism explains drug resistance in an individual patient. In addition, assessing the clinical evidence for disease mechanisms of drug resistance is fraught with a number of difficulties. There is no universal definition of drug resistance. Many authors define drug resistance as the persistence of seizures despite treatment with a range of AEDs used alone or in combination at maximum tolerated doses [1,2]. However, drug resistance is a graded process, and past treatment history has an effect on response. Although relative drug resistance can be identified after failure of two past drugs (see ref. 3), a significant minority of patients (17%) is rendered seizure free by addition of newly administered AEDs even after failure of two to five past AEDs [4]. Furthermore, the definition of seizure outcome in patients undergoing surgical or non-surgical treatment for drug resistance is often author specific and is thus difficult to compare between studies [5]. There are many clinical reasons why patients may be resistant to AED therapy. An incorrect diagnosis can lead to ineffective treatment. For example, use of carbamazepine in a patient with absence seizures and generalized spike–wave activity can exacerbate seizures. Likewise, treating a patient with complex partial seizures with ethosuximide is unlikely to be efficacious. Certain AEDs, such as gabapentin, pregabalin, vigabatrin and lamotrigine, can exacerbate myoclonic seizures [1,6]. Diagnostic issues, poor choice of AEDs or insufficient doses leading to inadequate drug treatment and failure to become seizure free will not be discussed here [1,6]. We will also not discuss mechanisms of co-morbidity or mortality associated with drug resistance in this chapter. Here, the clinical and experimental evidence for putative disease-related mechanisms of drug resistance will be reviewed.

Epilepsy syndrome associated with drug resistance

The underlying epilepsy syndrome is a significant predictor for drug resistance [1,7–9]. Children with one of the epileptic encephalopathies are most likely to have drug-resistant epilepsy, and those with symptomatic partial epilepsies are more likely to be drug resistant than those with other syndromes including idiopathic partial or generalized, cryptogenic partial, and unclassified epilepsies [8]. Clinical features, such as the epilepsy syndrome or the aetiology, may reasonably predict if temporal lobe epilepsy (TLE) in children will turn out to be drug resistant [9].

However, in some epileptic syndromes, the proportion of patients with drug-resistant epilepsy varies considerably and the determinants of this variation are largely unknown [1].

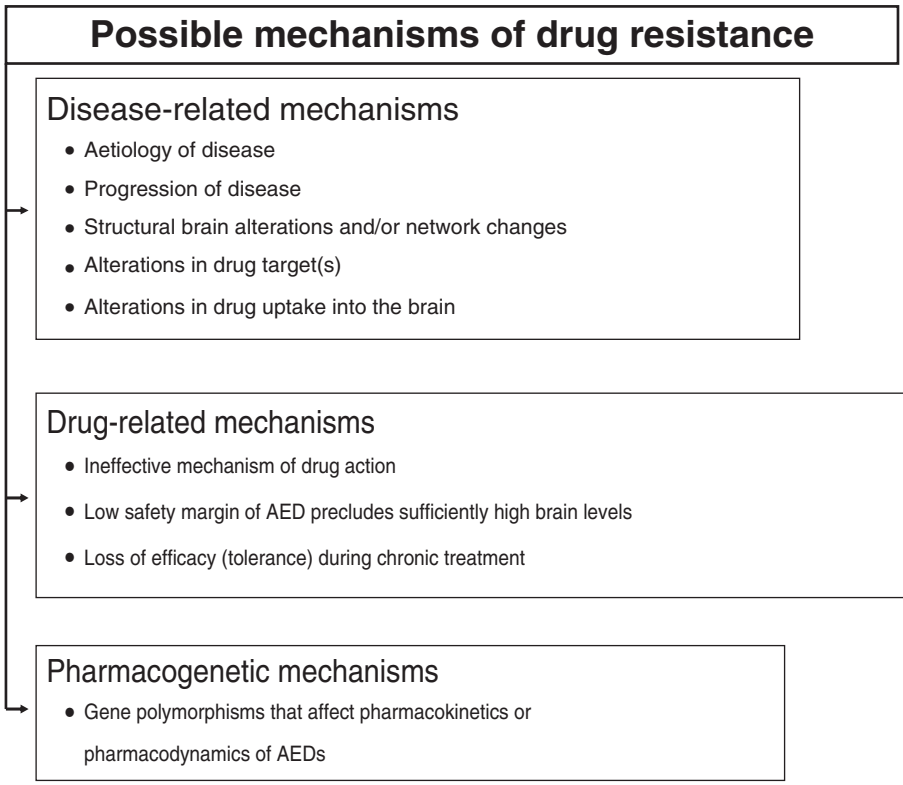

Fig. 8.1 Possible mechanisms of drug resistance. Adapted from ref. 57.

Progression of disease

Disease-related mechanisms of drug resistance may change in the course of the epilepsy. In a study of 613 children, around 70% were seizure free after 2 years, 20% were no longer seizure free having relapsed, and 10% had never been seizure free [8]. In a prospective, long-term population-based study of 144 patients followed for a median of 40 years since their first seizure before the age of 16 years, 19% of patients were drug resistant from the start to the end of follow-up, while a further 14% relapsed after remission and became drug resistant, indicating a worsening course of epilepsy [10]. On the other hand, 32% of patients became seizure free after a median of 9 years of treatment and remained seizure free to the end of follow-up. This longitudinal study provided incontrovertible evidence that the epilepsy may switch in a significant proportion of patients in the course of the disorder from being drug resistant to becoming controlled and vice versa [10]. In these patients, drug resistance and its underlying mechanisms have changed over time. Seizures themselves could, among other non-seizure-related factors, be involved in the generation of drug resistance. This hypothesis is supported by the observation that seizure clusters, defined as three or more seizures per 24 h, occurring often as many as 15 years after starting drug treatment, increased the risk of drug-resistant epilepsy by a factor of 3 compared with those without clusters [11]. In contrast, patients with seizure clustering prior to treatment versus no clustering showed no difference in seizure outcome [11].

Structural brain alterations and/or network changes

Resective surgery is standard care for eligible patients with drug-resistant epilepsy [12]. Long-term studies of clinical experience suggest that following temporal lobe surgery a median of 50–66% of patients with formerly drug-resistant TLE become seizure free with continued medical treatment, including 20–25% of patients who are seizure free without AEDs [14,15]. There is agreement that the best seizure outcome has been reported for patients with mesial TLE, particularly those with a structural lesion in the MRI [5]. Hippocampal sclerosis is a common finding in patients with pharmacoresistant TLE, so that it is often suggested that hippocampal sclerosis plays a causal role in the mechanisms underlying AED resistance [1]. However, as pointed out in a recent critical review on TLE surgery [16], it is quite difficult to be certain which specific structures of the medial temporal lobe need to be resected to eliminate drug resistance and allow a patient to become seizure free. In fact, a review of 53 studies addressing extent of resection in surgery for patients with TLE identified only seven prospective studies, of which four were randomized [16]. Schramm [16] noted that class I evidence concerning seizure outcome related to type and extent of resection of mesial temporal lobe structures is rare. Most studies reviewed found no positive correlation between extent of mesial resection and seizure freedom after surgery; even leaving hippocampus and amygdala untouched can result in seizure freedom rates of around 50% [16].

Another important issue that makes it difficult to determine which structures of the mesial temporal lobe are involved in generating or maintaining drug resistance is that the results of seizure freedom after surgery can be fully attributed to surgery only if no previously drug-resistant patients become seizure free without surgery [15,17]. However, apart from one 12-month randomized trial, the long-term seizure outcome of surgery versus medical treatment in non-operated patients is not well known [5,17,18]. In a study from Bonn, Germany, the seizure outcome of drug-resistant epilepsy, mostly TLE, was compared in patients undergoing surgery and in those who were ineligible for surgery. Both groups received medical treatment. Although 52% of surgical patients were seizure free in the last year of follow-up, as many as 24% of patients became seizure free without undergoing surgery, just with a change of medical regimen [19]. In addition, a number of clinical observations have reported that around 20% of formerly drug-resistant patients with partial epilepsy, including patients ineligible for surgery, become seizure free without surgery only through a change of medical regimen [20–22].

For the search for structural brain alterations associated with drug resistance, these findings have important implications. If AEDs are required to become seizure free, it is not unreasonable to consider that the effect of AEDs outside of the resected area is needed for seizure control after surgery. There is preliminary evidence from functional imaging [23,24] and from transcranial magnetic stimulation for changes in the contralateral hemisphere after successful temporal lobe surgery [25]. Extended changes in excitability and in functional imaging after surgery may be related to widespread functional impairment in patients with partial epilepsy and support the existence of network changes beyond the resected area in patients undergoing temporal lobe surgery. In addition, as noted above, only about half of all seizure-free surgical patients are seizure free when off AEDs. For the other half, it is not unreasonable to consider that AEDs are needed to target areas outside of the resected zone [17]. The network hypothesis of drug resistance after surgery is based on the existence of non-resected limbic or extralimbic seizure generators left behind during surgery. If AEDs protect from effects of non-resected limbic or extralimbic seizure generators, the surgical patient is seizure free on AEDs; if not, surgery has failed to suppress drug resistance. It is not unreasonable to consider that for patients whose limbic seizure generators have been completely removed or affected and who have no other active seizure generators, surgery will achieve seizure freedom when also off AEDs, as in 20–25% of patients undergoing temporal lobe surgery [17].

A further issue is that, in many (but not all [26]) studies, surgical outcome worsens over the years [13,17]. In a series of patients who were initially seizure free after temporal lobe surgery, the proportion that remained seizure free dropped from 76 out of 88 patients (86%) at 3 months after surgery to 9 out of 12 patients (75%) available for review after 9 years or 9 of 88 (10%) of all patients initially seizure free [27]. In a study of surgical patients with mostly TLE, who had been seizure free (allowing for simple partial seizures) 5 years after surgery, the proportion of seizure-free patients dropped from 100% at 5 years to approximately 50% at 15 years after surgery [28]. AED discontinuation in seizure-free patients has been shown to lead to relapse in one in three patients [29]. Although many other causes for early and late relapses exist that may be unrelated to the mechanism of drug resistance, this finding, if confirmed, also has implications for the search for a structure-related mechanism of drug resistance in TLE. If, in fact, patients who were seizure free after surgery return to having seizures despite AED treatment and thus become again drug resistant, mechanisms involving remodelling of brain circuitry outside of the resected area may be involved. This has been called in experimental models of epilepsy ‘rewiring the brain’ [30].

How can hippocampal sclerosis contribute to drug resistance? In the hippocampal formation, the dentate gyrus normally functions as a high-resistance gate or filter, preventing the propagation of synchronized activity from the entorhinal cortex into the seizure-prone hippocampus [31]. In patients with TLE and in animal models of TLE, this filter or ‘gatekeeper’ attribute of the dentate gyrus is compromised in that dentate granule cells form an interconnected synaptic network associated with loss of (GABA-ergic) hilar interneurones [31]. Indeed, loss of neurones in the hilus of the dentate gyrus, which is closely associated with development of granule cell disinhibition and hyperexcitability, has been proposed to be the common pathological denominator and primary network defect underlying development of a hippocampal seizure focus [31,32].

To address directly whether structural changes are causally related to AED resistance, we recently compared hippocampal damage in epileptic rats that either responded or did not respond to AED treatment [33,34]. In this model, spontaneous recurrent seizures develop after a status epilepticus induced by prolonged electrical stimulation of the basolateral amygdala. The response to prolonged daily administration of phenobarbital at maximum tolerable doses in epileptic rats of this model can be divided into two categories: a responder subgroup with control of seizures and a non-responder subgroup without any significant reduction in seizure frequency. The resistance to phenobarbital extends to other AEDs, including phenytoin, thus resembling the multidrug type of AED resistance in patients with intractable TLE. This model thus offers unique approaches to the biological basis of refractoriness, particularly because pathological alterations in such AED-resistant rats can be directly compared with those of rats that do respond to AEDs. In most (>90%) non-responders of this model, we determined a significant loss of neurones in the CA1, CA3c/CA4 and dentate hilus, whereas most (>90%) of the responders did not differ in hippocampal morphology from non-epileptic controls, resulting in a highly significant difference between pharmacoresistant and responsive epileptic rats [33,34]. Based on these observations, it appears that the functional alterations in the dentate gyrus developing as a response to hilar cell loss are critically involved in the mechanisms underlying the refractoriness of seizures to AED treatment. Such structural and functional network changes will also affect AED targets, as will be discussed in the next section.

Alterations in drug targets

The target hypothesis of AED resistance in epilepsy suggests that acquired alterations to the structure and/or functionality of target ion channels and neurotransmitter receptors underlie drug resistance [35]. To exhibit antiepileptic activity, a drug must act on one or more target molecules in the brain. These targets include

voltage-dependent ion channels, neurotransmitter receptors and transporters or metabolic enzymes involved in the release, uptake and metabolism of neurotransmitters [36]. The target hypothesis is primarily based on studies with carbamazepine on voltage-gated sodium channels in hippocampal neurones. Voltage-gated Na^+ channels are ubiquitously expressed in excitable cells and appear to be targets for multiple first-line AEDs, including carbamazepine, phenytoin and lamotrigine.

To our knowledge, Wytse Wadman's group [37] was the first to report a loss of carbamazepine's modulatory effects on sodium channels in hippocampal neurones of patients with intractable epilepsy. The group found that the modulation of sodium current inactivation by carbamazepine in hippocampal CA1 neurones from patients with TLE and mesial temporal sclerosis was only half of that encountered in neocortical neurones from the same patients, and only half of that encountered in CA1 neurones from patients without mesial temporal sclerosis [37]. More recently, Heinz Beck's group [38] substantiated and extended these data by showing that the use-dependent block of voltage-dependent Na^+ channels of dentate granule cells by carbamazepine is completely lost in patients with carbamazepine-resistant TLE in comparison with patients clinically responsive to this AED. In addition to the loss of use-dependent inhibition of Na^+ channels by carbamazepine, the fast recovery from inactivation of the fast Na^+ current was carbamazepine insensitive in pharmacoresistant patients, whereas recovery was markedly slowed in cells from carbamazepine-responsive patients [38]. Consistent with these data from patients with intractable TLE, Remy *et al*. [38] also showed that use-dependent block of Na^+ channels by carbamazepine in dentate granule cells is absent in the pilocarpine rat model of TLE. Based on these data, the authors suggested that a loss of Na^+ channel drug sensitivity may explain the development of drug-resistant epilepsy. In a subsequent study in the rat pilocarpine model in TLE, Remy *et al*. [39] demonstrated that the effects of phenytoin on fast recovery from inactivation of Na^+ channels of hippocampal granule neurones were significantly reduced, though not to the same degree as observed with carbamazepine, substantiating the concept that reduced pharmacosensitivity of Na^+ channels may contribute to the development of drug resistance. In contrast to carbamazepine and phenytoin, lamotrigine slowed the time-course of recovery from fast inactivation in both epileptic and control rats without significant inter-group difference [39]. In the pilocarpine model, a loss of sensitivity of sodium channels to carbamazepine and phenytoin was also found in hippocampal CA1 neurones, although the loss of AED sensitivity was less pronounced in CA1 neurones than in dentate granule neurones [40]. Thus, the results of Beck and colleagues suggested that target mechanisms of drug resistance are cell type and AED specific.

Which mechanisms can account for altered sensitivity of Na^+ channels in CA1 or dentate granule cells in epileptic tissue? One possibility is that the subunit composition of these channels is altered, resulting in channels with lower AED sensitivity [35]. Several changes in Na^+ subunit expression have been observed in both human and experimental epilepsy [35]. For instance, in the pilocarpine model of TLE, the accessory β_1- and β_2-subunits were down-regulated, which was suggested to play a role in the altered pharmacosensitivity of Na^+ channels [41]. This view is supported by a study by Lucas *et al*. [42] showing that a mutation in the β_1-subunit of the voltage-gated sodium channel results in a dramatic loss of channel sensitivity to phenytoin.

A critical question in studying target alterations in epilepsy is the relation of changes at the cellular level to AED sensitivity *in vivo*. While such a correlation has been observed in patients with TLE [38,43], such a correlative analysis has not yet been performed for the pilocarpine model of TLE, which has been used in most studies by Beck's group. We used the kindling model of TLE to study whether AED responders and non-responders differ in pharmacological sensitivity of voltage-dependent sodium channels [44]. Responders and non-responders were selected by repeated testing with phenytoin *in vivo*, followed by evaluation of phenytoin's *in vitro* effects on voltage-gated Na^+ channels of hippocampal CA1 neurones. The *in vivo* resistance to phenytoin was not associated with altered tonic block of Na^+ channels by phenytoin, but recovery from Na^+ channel inactivation and use-dependent blocking effects were not analysed in this study [44].

Apart from voltage-dependent Na^+ channels, other drug targets, such as GABA-mediated inhibition, may be altered in patients with intractable epilepsy. Using the rat pilocarpine model of TLE, Brooks-Kayal *et al*. [45] demonstrated that expression of $GABA_A$ receptor subunit mRNAs is substantially altered in hippocampal dentate granule cells of pilocarpine-treated rats compared with controls. These changes in $GABA_A$ receptor subunit expression correlated with profound alterations in receptor function and pharmacology [45–47]. In normal granule cells, $GABA_A$ receptors of dentate granule cells are insensitive to zinc, which is released from mossy fibres and functions as a negative allosteric modulator of $GABA_A$ receptors. This zinc insensitivity of normal $GABA_A$ receptors is a result of high levels of expression of the α_1-subunit in these cells [46]. In epileptic rats, expression of the α_1- and β_1-subunits decreases and expression of α_4- and δ-subunits increases, leading to an assembly of $GABA_A$ receptors that are strikingly zinc sensitive. In addition to the enhanced zinc sensitivity, $GABA_A$ receptors from the epileptic hippocampus lose their sensitivity to augmentation by the benzodiazepine type site I modulator, zolpidem [48]. Coulter [46,47] has proposed that this temporal and spatial juxtaposition of these pathophysiological alterations may compromise the normal 'gatekeeper' function of the dentate gyrus through dynamic zinc-induced failure of inhibition, predisposing the hippocampal circuit to generate seizures. Of course, assuming that similar alterations in $GABA_A$ receptor function and pharmacology also take place in the epileptogenic human hippocampus, this could lead to reduced efficacy of AEDs acting via GABA-mediated inhibition.

We have recently examined whether AED-resistant rats differ from AED responders in expression and pharmacological sensitivity of $GABA_A$ receptors [33,34]. Phenobarbital-resistant rats differed strikingly from responsive rats in autoradiographic imaging of diazepam-sensitive and -insensitive $GABA_A$ receptor binding in the dentate gyrus with a significant shift to enhanced diazepam-insensitive binding in non-responders [33]. To address the hypothesis that diazepam-insensitive receptors contain the α_4- and δ-subunits that mediate tonic inhibition in the dentate gyrus, the expression of various $GABA_A$ receptor subunits was determined in AED responders and non-responders [34]. In non-

responders, decreased expression of various subunits, including α_1, $\beta_{2/3}$ and γ_2, was observed in CA1, CA2, CA3, and dentate gyrus, whereas much less widespread alterations were determined in responders. Furthermore, up-regulation of the α_4-subunit was observed in CA1 pyramidal cells of non-responders. Phenobarbital's anticonvulsant effect is thought to be primarily related to enhancement of GABA-mediated inhibitory synaptic transmission via modulation of $GABA_A$ receptors [36]. Although the effects of barbiturates on the $GABA_A$ receptor depend largely on the β-subunit, their agonist activity is substantially influenced by the α-subunit subtype. The marked decreases in β- and α-subunits observed in phenobarbital non-responders are likely to reduce the effect of phenobarbital on $GABA_A$ receptors and thus could be involved in the lack of anticonvulsant efficacy of phenobarbital in these animals. Profound alterations in $GABA_A$ receptor subtype expression have also been reported in patients with AED-resistant TLE [49]. The concomitant alterations in $GABA_A$ receptor expression and hippocampal morphology in pharmacoresistant rats of our model of TLE suggest that structural and functional network changes will also affect AED targets [33,34]. A similar association between structural changes and $GABA_A$ receptor expression has also been reported in patients with AED-resistant TLE [49].

Further evidence that changes in $GABA_A$ receptors occur during epileptogenesis that can lead to drug resistance comes from a series of studies of Bob Macdonald's and Claude Wasterlain's groups using the pilocarpine model [50,51]. These groups demonstrated that during a pilocarpine-induced status epilepticus there is a substantial reduction of potency for termination of seizures by AEDs that enhance $GABA_A$-mediated inhibition, such as benzodiazepines and phenobarbital. This progressive development of pharmacoresistance during a sustained status epilepticus is paralleled by alterations in the functional properties of dentate granule cell $GABA_A$ receptors. It was concluded that rapid modulation of $GABA_A$ receptors during status epilepticus may result in pharmacoresistance to AEDs that enhance $GABA_A$ receptor-mediated inhibition [50]. More recently, Goodkin *et al.* [52] and Naylor *et al.* [53] showed that internalization of $GABA_A$ receptors, i.e. trafficking of these receptors from the synaptic membrane to submembranous compartments, causes a decrease in the number of functional postsynaptic $GABA_A$ receptors that is likely to explain the pharmacoresistance to GABA-mimetic AEDs in status epilepticus.

Other than alterations in $GABA_A$ receptor subunit expression and receptor trafficking, there is a third potential mechanism to explain loss of pharmacological sensitivity of these receptors: a shift from adult inhibitory to neonatal excitatory $GABA_A$ receptors [54]. Such a shift in GABAergic response polarity from hyperpolarizing to depolarizing has been described in human epileptic neurones recorded in the subiculum of hippocampal slices obtained from resections in patients suffering from mesial TLE [55]. This shift is thought to be a result of increased intraneuronal Cl^- levels, caused by increased neuronal expression of NKCC1, an inwardly directed Na^+–K^+–$2Cl^-$ cotransporter that facilitates the accumulation of intracellular Cl^-, and down-regulation of KCC2, an outwardly directed K^+–Cl^- cotransporter [56]. Up-regulation of NKCC1 and down-regulation of KCC2 in the hippocampus have been described both in patients with TLE and in the kindling model of TLE. We currently plan to examine whether the brain expression of these chloride transporters differs in phenobarbital-responsive and -resistant epileptic rats.

As a proof-of-principle for the target hypothesis, it will be important to demonstrate that AED-resistant subgroups of patients differ from AED-responsive subgroups in their AED target sensitivity. Such a proof-of-principle is difficult to obtain in patients, because, in contrast to patients with intractable epilepsy, patients responding to AEDs in general do not undergo surgical treatment for their epilepsy. Although Remy *et al.* [38] obtained surgical 'reference' specimens from two patients who responded well to treatment with carbamazepine for comparison with 10 patients with carbamazepine-resistant TLE, differences in age, gender, history of epilepsy and AED treatment and various other variables may form a bias for such a comparison. As illustrated by our recent studies, animal models of TLE allowing selection of age-matched AED responders and non-responders may be useful to further evaluate the target hypothesis. Although the target hypothesis is a novel and biologically plausible theory to explain drug resistance, the fact that most patients resistant to AED treatment are resistant to a broad range of AEDs with different mechanisms of action suggests that other less mechanism-specific factors contribute to drug resistance. The most prominent hypothesis in this respect, the transporter hypothesis, which was first explored in chemotherapy-resistant cancer, currently attracts growing interest as one further putative mechanism to explain drug resistance in epilepsy by reduced penetration of AEDs into the brain.

Multidrug transporter hypothesis

The importance of (multi)drug efflux transporters, such as P-glycoprotein (P-gp), in disease processes and treatment has become increasingly evident in recent years [57,58]. Drug efflux transporters have a major impact on the pharmacological behaviour of most clinically used drugs, critically affecting drug absorption, disposition, and elimination in the body [59]. Furthermore, such transporters are involved in the emergence of multidrug resistance (MDR), which plays an important role in the failure of treatments of tumours, infectious diseases and several brain disorders, including epilepsy [57,58,60]. P-gp, the encoded product of the human multidrug resistance-1 (*MDR1*; *ABCB1*) gene, is of particular clinical relevance in that this transporter has a broad substrate specificity (which led to the term multidrug transporter), including a variety of structurally divergent drugs in clinical use today [61]. Furthermore, P-gp is expressed by tissues with excretory function (small intestine, liver and kidney) and at blood–tissue barriers [blood–brain barrier (BBB), blood–testis barrier and placenta], thus limiting drug entry into the body after oral administration, promoting drug elimination into bile and urine, and limiting drug penetration into sensitive tissues such as the brain [61].

In the BBB, multidrug transporters such as P-gp, members of the multidrug resistance protein (MRP) family and breast cancer-related protein (BCRP) are located in brain capillary endothelial cells that form the BBB and combine to reduce the brain penetration of many drugs [57,58]. This phenomenon of multidrug resistance is a major hurdle when it comes to the delivery of therapeutics to the brain. Therefore, the development of strategies for bypassing the influence of these drug efflux transporters,

for the design of effective drugs that are not substrates, and for the development of inhibitors for the transporters has become an imperative for the pharmaceutical industry [62].

Tishler *et al*. [63] were the first to report that brain expression of *MDR1*, which encodes P-gp in humans, is markedly increased in the majority of patients with medically intractable partial (mostly temporal lobe) epilepsy. Based on their findings, Tishler *et al*. [63] proposed that P-gp may play a clinically significant role by limiting access of AEDs to the brain parenchyma, so that increased P-gp expression may contribute to the refractoriness of seizures in patients with treatment-resistant epilepsy. Following the report by Tishler *et al*. in 1995 [63], the finding of *MDR1*/P-gp overexpression in epileptogenic brain tissue of patients with drug-refractory epilepsy was confirmed by several other groups [1,57,58,64]. Furthermore, it was shown that, in addition to P-gp, several MRPs, but not BCRP, are overexpressed in brain capillary endothelial cells and/or astrocytes of pharmacoresistant patients [1,58,65]. In some of these studies, the overexpression of drug efflux transporters in astrocytes appeared most marked around blood vessels. In view of data indicating that the endothelial barrier function of the BBB is transiently disrupted during seizures [65], overexpression of multidrug transporters in astroglial endfeet covering the blood vessels may represent a 'second barrier' under these conditions. As a consequence, overexpressed multidrug transporters may lower the extracellular concentration of AEDs in the vicinity of the epileptogenic pathology and thereby render the epilepsy caused by these pathologies resistant to AED treatment.

An open question is whether the overexpression of P-gp and MRPs in epileptogenic brain tissue of patients with intractable epilepsy is intrinsic (constitutive) or acquired, i.e. a consequence of epilepsy, of uncontrolled seizures, of chronic treatment with AEDs, or of combinations of these factors. Because treatment-resistant patients have no fewer neurotoxic side-effects under AED treatment than patients who are controlled by AEDs, the overexpression of drug transporters in treatment-resistant patients is most likely restricted to the epileptic focus or circuit. This is substantiated by a previous study of Sisodiya *et al*. [66] in which overexpression of P-gp and MRP1 was found in epileptogenic tissue but not in adjacent normal tissue of the same patients.

In animal models of TLE, such as the kindling and kainate models, a transient overexpression of P-gp was found in brain capillary endothelial cells, astroglia and neurones following seizures [1,58], indicating that seizures themselves can induce overexpression of drug transporters. This could explain why one of the major predictors of drug resistance is high seizure frequency (or density) prior to initiation of treatment [7]. However, constitutive rather than induced or acquired overexpression of multidrug transporters has been reported in patients with malformations of cortical development [67]. In addition to intrinsic or acquired overexpression of multidrug transporters in the BBB of patients with epilepsy, polymorphisms in transporter genes may play a role in drug resistance (see below). Furthermore, alterations in expression and functionality of multidrug transporters in patients with intractable epilepsy need not necessarily be restricted to the brain but could also occur in other tissues, such as the small intestine, where P-gp is thought to form a barrier against entrance of drugs from the intestinal lumen into the bloodstream, thereby limiting their oral bioavailability [61]. In this respect, it is interesting to note that Lazarowski *et al*. [68] have reported persistent subtherapeutic plasma levels of AEDs (including phenytoin and phenobarbital) despite aggressive and continuous AED administration in patients with refractory epilepsy that was associated with overexpression of *MDR1*.

In view of the emerging evidence that multidrug transporters are overexpressed in epileptogenic brain tissue, particularly in capillary endothelial cells and astrocytes, contributing to BBB permeability, it is important obviously to know whether AEDs are substrates for these transporters. The first indication that AEDs are substrates for P-gp came from experiments by Tishler *et al*. [63], who found that intracellular phenytoin levels in an *MDR1*-expressing neuroectodermal cell line were only one-quarter of that in *MDR1*-negative cells, suggesting that P-gp significantly contributes to cell export of phenytoin. Phenytoin transport by P-gp was also demonstrated in a kidney epithelial cell line transfected with the rodent *mdr1a* cDNA, which could be blocked by the P-gp inhibitor PSC833 [69].

More recently, Rizzi *et al*. [70] demonstrated that *mdr1a/b* knockout mice, which lack P-gp, exhibit a significant 50% increase in phenytoin levels in the hippocampus compared with wild-type mice. *Mdr1* knockout mice were also used to demonstrate P-gp transport of carbamazepine [70] and topiramate [71]. By using a rat microdialysis model with microdialysis probes in both brain hemispheres and local (cerebral) inhibition of multidrug transporters in one hemisphere, we have previously demonstrated that several major AEDs are substrates for either P-gp or MRPs, or both [58]. In general, the data from these different experimental approaches indicate that several major AEDs (phenytoin, phenobarbital, oxcarbazepine, lamotrigine, gabapentin, felbamate, topiramate) are substrates for P-gp and some of them (phenytoin, valproate) seem also to be transported by MRPs at the BBB [58].

However, the situation is not straightforward. Recent data from our group demonstrated species differences in the transport of AEDs by P-gp in that significant transport could be demonstrated with rodent but not human P-gp in an *in vitro* transport assay [72]. In this respect, it is important to note that most AEDs are highly lipophilic, a property which could conceal asymmetrical transport in *in vitro* transport assays that are commonly used for identifying P-gp substrates. This prompted us to modify such assays in a way that allows evaluation of active transport independently of the passive permeability component, demonstrating transport of several major AEDs, including phenytoin, phenobarbital and lamotrigine, by human P-gp [73]. Using an *in vitro* BBB model with human capillary endothelial cells from either normal brain or drug-resistant epileptic brain, Cucullo *et al*. [74] recently reported a dramatically reduced permeability of phenytoin across the *in vitro* BBB formed from endothelial cells of patients with refractory epilepsy, which could be partially counteracted by the selective P-gp inhibitor tariquidar, substantiating transport of AEDs by human P-gp.

In view of the overexpressed efflux transporters found in epileptogenic brain tissue of patients with pharmacoresistant epilepsy and animal models of epilepsy, another important question is whether this overexpression lowers brain uptake of AEDs. By

using the kainate model of TLE in mice, Rizzi *et al*. [70] demonstrated that the significant increase in *mdr1* mRNA expression measured by reverse transcriptase polymerase chain reaction (RT-PCR) in the hippocampus after kainate-induced seizures was associated with a 30% decrease in the brain–plasma ratio of phenytoin, thus substantiating the view that P-gp alterations significantly affect concentrations of AEDs in the brain. More recently, van Vliet *et al*. [75] reported decreased brain levels of phenytoin that were restricted to brain regions with increased expression of P-gp in epileptic rats, which could be counteracted by inhibiting P-gp. In patients with oxcarbazepine (OXC)-resistant epilepsy, the brain tissue expression of *ABCB1* mRNA was found to be inversely correlated with brain levels of 10-OHCBZ (10,11-dihydro-10-hydroxy-5H-dibenzo(b,f)azepine-5-carboxamide), the active metabolite of OXC, indicating that P-gp may play a role in the pharmacoresistance to OXC by causing insufficient concentrations of its active metabolite at neuronal targets [76].

A further important step in the evaluation of the multidrug transporter hypothesis of drug-resistant epilepsy was the demonstration that rats that do not respond to AEDs exhibit significantly higher expression levels of P-gp in brain capillary endothelial cells of the BBB than AED-responsive rats [77,78]. This was demonstrated for two different rat models of TLE: phenytoin-resistant kindled rats and phenobarbital-resistant rats with spontaneous recurrent seizures [77,78].

If drug resistance is due to such processes, it should be possible to demonstrate that the inhibition or avoidance of the resistance-mediating mechanism counteracts drug resistance in epilepsy. Some indirect, correlative evidence came from experiments with diverse AEDs in pharmacoresistant kindled rats, selected by repeated testing with phenytoin [79]. As described above, these phenytoin-resistant rats have an increased expression of P-gp in focal epileptogenic brain tissue. All AEDs that were substrates for P-gp showed absent or low anticonvulsant efficacy in phenytoin non-responders [79,80]. The only exception was levetiracetam, which was equally efficacious in responders and non-responders [79] and seems not to be a substrate for rat P-gp [81]. A further important step is to examine whether P-gp inhibitors counteract multidrug resistance. For this purpose, we used epileptic rats that were either responsive or resistant to phenobarbital [82]. In resistant animals, coadministration of the selective P-gp inhibitor, tariquidar, together with phenobarbital reversed resistance, leading to seizure control in animals that were resistant to phenobarbital alone [82]. That such a strategy may be functioning in patients with epilepsy is suggested by a recent anecdotal report by Summers *et al*. [83] on a single patient with intractable epilepsy in whom the P-gp inhibitor verapamil was added to the AED regimen. A similar clinical improvement after verapamil was reported by Iannetti *et al*. [84]. However, such an anecdote is weak evidence. The effects of more selective P-gp inhibitors, such as tariquidar or elacridar, are currently unclear.

Drug-related mechanisms of drug resistance in epilepsy

Antiepileptic drugs themselves may contribute to drug resistance (Fig. 8.1). First, the mechanisms of action of available AEDs is an important consideration. AEDs with novel mechanisms of action can control seizures that other drugs have failed to control. Second, the risk–benefit ratio (safety margin) of AEDs, i.e. the ratio between adverse (or toxic) and antiepileptic effects, may prevent the achievement of sufficiently high AED levels to suppress a specific type of epilepsy or seizures. Thus, development of an AED with better tolerability may allow control of this type of epilepsy. Third, development of tolerance to the antiepileptic activity of an AED can result in resistance.

Development of tolerance, i.e. the reduction in response to a drug after repeated administrations, is an adaptive response of the body to prolonged exposure to the drug, and tolerance to AEDs is no exception (see ref. 85 for a detailed review of this topic). Tolerance develops to some drugs effects much more rapidly than to others. The extent of tolerance depends on the drug and individual genetic factors. Tolerance to adverse effects of AEDs is well known and clinically accepted, but there is increasing evidence that tolerance may also lead to loss of efficacy of AEDs and is reversible after discontinuation of drug treatment. There are two major types of tolerance: pharmacokinetic and pharmacodynamic. Pharmacokinetic (metabolic) tolerance is due to induction of AED-metabolizing enzymes, and has been shown for most first-generation AEDs, but is easy to overcome by increasing dosage. However, in addition to increasing their own metabolism, AEDs may affect their distribution into the brain by increasing the expression of P-gp; this is a new type of pharmacokinetic tolerance that may also affect newer AEDs [85]. The second type of tolerance is pharmacodynamic (functional) tolerance, which is due to 'adaptation' of AED targets, by loss of receptor sensitivity for example, and has been shown experimentally for all AEDs that lose activity during prolonged treatment [85]. Functional tolerance may lead to complete loss of AED activity and cross-tolerance to other AEDs. There is convincing experimental evidence that almost all first-, second- and third-generation AEDs lose their antiepileptic activity during prolonged treatment, although to a different extent [85]. Because of diverse confounding factors, detecting tolerance in patients with epilepsy is more difficult but can be done with careful assessment of decline during long-term individual patient response. After excluding confounding factors, tolerance to antiepileptic effect for most modern and old AEDs can be shown in small subgroups of responders by assessing individual or group response [85]. Development of tolerance to the antiepileptic activity of an AED is likely to be one important reason for failure of drug treatment.

Pharmacogenetic mechanisms of drug resistance in epilepsy

Drug treatment of epilepsy is characterized by unpredictability of efficacy, adverse drug reactions and optimal doses in individual patients, which, at least in part, is thought to be a consequence of genetic variation [86]. It is becoming increasingly clear that genetic variation plays an integral role in variability of both AED pharmacokinetics and pharmacodynamics. Single-nucleotide polymorphisms (SNPs), variations at a single site in the DNA, are the most frequent form of sequence variations in the human genome and can affect the efficacy, tolerability and duration of

action of AEDs. Drug targets and drug transporters can be affected by genetic variation. In terms of AED targets, so far the most interesting data have been accrued for voltage-dependent Na^+ channels [87]. In studies on genetic variation in *SCN1A*, the gene encoding for the α-subunit of the voltage-gated neuronal sodium channel, associations of functional SNPs with clinical response to phenytoin, carbamazepine, lamotrigine and oxcarbazepine were reported [87,88].

Polymorphisms in various candidate drug transporter genes have been evaluated, including variation in the *MDR1* (*ABCB1*) gene, which encodes P-gp, to determine whether these are associated with variation in AED response in patients with epilepsy [86]. A common SNP (C3435T) identified within exon 26 of the *MDR1* gene has been reported to be associated with differential expression and function of P-gp [89]. Siddiqui *et al*. [90] were the first to report that patients with multidrug-resistant epilepsy were significantly more likely to be homozygous for the C allele than the T allele; however, this was not confirmed by several subsequent studies [86]. One major reason for inconsistent data on this polymorphism may be that several of the associated genetics studies involved AEDs that are not transported by human P-gp. Two recent studies on patients undergoing monotherapy with AEDs (phenytoin or phenobarbital) that are transported by human P-gp showed that pharmacoresistance was much more frequent in patients with the CC genotype of the *MDR1* C3435T polymorphism [91,92]. Furthermore, the study by Basic *et al*. [92] indicated that the CC genotype is associated with lower cerebrospinal fluid levels of phenobarbital than the CT or TT genotype. However, causality has not been proven in any of these studies, but all reported findings remain interesting associations. Future ongoing studies with specific P-gp inhibitors may be able to extend the evidence from association to causation.

Conclusions

Although AEDs are very useful in blocking seizures, many patients do not respond adequately to these agents. In order to enhance our understanding about the mechanisms of pharmacoresistance in epilepsy and thereby develop new strategies for more efficacious treatments, studies on brain tissue from drug-resistant patients and suitable experimental models of intractable epilepsy are mandatory. There is increasing evidence from studies on epileptic brain tissue that AED target alterations and overexpression of multidrug transporters may be important mechanisms of pharmacoresistance, and both mechanisms of refractoriness may coexist in the same epileptogenic brain tissue. Target and transporter alterations in patients with epilepsy may be a consequence of the disease, the treatment, genetic factors or combinations of these possibilities. In addition, structural brain alterations in focal epileptogenic tissue, for example hippocampal sclerosis or cortical dysplasia, and beyond may be involved in rendering epilepsy drug resistant. Furthermore, long-term, progressive changes in neural networks during development and progression of epilepsy may lead to reduced pharmacosensitivity. However, much of the evidence is correlative in nature. As outlined in this chapter, there are several other potential mechanisms contributing to pharmacoresistance (including tolerance) that have to be dealt with when thinking about effective therapeutic agents for hitherto intractable types of epilepsy. Thus, development of novel pharmacological and surgical strategies for improved treatment of drug-refractory epilepsy is now, and will be in the future, a complex venture.

9 General Principles of Medical Management

Emilio Perucca
University of Pavia, Pavia, Italy

The medical management of epilepsy requires more than knowledge of the clinical pharmacology of antiepileptic drugs. In fact, many factors need to be considered for rational management decisions. To start with, determining whether treatment is indicated requires assessment of the risk–benefit ratio in the individual patient, which, in turn, is influenced not only by the type and the frequency of the seizures, but also by age, gender, associated medical conditions and the impact of potential adverse effects of available treatment options on the patient's quality of life. A thorough diagnostic evaluation is essential in this process because the type of treatment, its duration and long-term prognosis are dependent upon a correct identification of seizure types and, whenever possible, of the underlying epilepsy syndrome and related aetiological factors.

Although achieving seizure control is a most important objective, seizures are not the only cause for concern in patients with epilepsy. Any associated neurological, psychological, psychiatric and social handicaps need to be equally addressed. Patients and their caregivers need to be informed about the nature of the disease, its prognostic implications, the objectives of therapy, the risks and benefits of drug treatment (including the risks associated with poor compliance and with abrupt drug withdrawal) and the availability of alternative therapeutic strategies, including epilepsy surgery. Medical management should also involve a discussion of factors that could impact negatively on seizure control, without placing undue restrictions on the patient's lifestyle. Counselling about marriage, reproduction, driving regulations and other legal matters may be indicated. Even in affluent societies, epilepsy is still associated with stigma, and affected patients may suffer more from prejudice and discrimination than from the actual manifestations of the disease. As a result, psychological and social support is often required and represents a major component of clinical management in individual cases.

The purpose of this chapter is to review the general principles of medical management. Specific therapeutic strategies in relation to the stage of the disease and to individual characteristics, including age, gender, associated learning disability, other comorbidities and associated drug treatments, are discussed in detail in the following chapters, while the criteria for choosing specific antiepileptic drugs are addressed in Chapter 30.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Aims of treatment

The primary goal of treatment is to ensure the best possible quality of life that is compatible with the nature of the patient's seizure disorder and with any associated mental or physical disabilities [1,2]. To achieve this general goal, various objectives need to be addressed whenever relevant or feasible.

Complete seizure control

If exception is made for the control of ongoing seizures and status epilepticus, the treatment of epilepsy is primarily prophylactic (e.g. aimed at preventing seizure recurrence). Prospective studies have demonstrated that there is a world of difference for some individuals' quality of life between a state of complete seizure freedom and even rare seizures separated by long intervals [3]. In general terms, therefore, the primary objective of treatment should be complete seizure control where this is feasible. This, however, should not be achieved at all costs. Antiepileptic drugs can produce severe adverse effects, particularly when they are administered at high dosages or in combination, and the situation should never arise where a patient is made to suffer more from the adverse effects of treatment than from the symptoms of the disease [4]. Whenever complete seizure freedom proves to be a non-realistic goal, optimal treatment should result from the best compromise between the desire to minimize seizure frequency and the need to maintain adverse effects within acceptable limits.

Reduction of seizure severity

Although most outcome studies in epilepsy have focused on seizure frequency, seizure severity, particularly with respect to occurrence of potentially injurious ictal manifestations, is by itself an important determinant of quality of life [5]. In patients whose seizures cannot be controlled completely, it makes sense to aim at suppressing preferentially those seizures which are most disabling. For example, in patients with Lennox–Gastaut syndrome, controlling drop attacks may produce greater benefit than suppressing associated partial or atypical absence seizures. Likewise, a treatment that will prevent secondary generalization would be expected to have a major impact on the quality of life of a patient with simple sensory partial seizures. Indeed, antiepileptic drugs may have differential effects on the components of ictal events and seizure spread, by suppressing or modifying the type or the duration of auras, convulsive manifestations, associated autonomic features and postictal events [6]. Assessing the most disabling seizure types can require assistance from an external

observer, but the patient's perceptions are more important. A seizure component that may appear trivial or negligible to an observer may be perceived as very distressing by the patient. Unfortunately, the ways in which antiepileptic drugs modify seizure components have been little studied, but in individual patients this aspect may have an important impact on management decisions.

Avoidance of adverse effects

The prescription of antiepileptic medication entails a significant risk of adverse effects. While many patients with recently diagnosed epilepsy can be controlled at low dosages, which produce only modest detectable toxicity [7], patients with severe epilepsies may have to pay a significant price in terms of adverse effects to avoid or minimize seizure recurrence.

It has been shown that, particularly in patients with refractory epilepsies, quality of life may be affected to a greater extent by the adverse effects of medication than by the occurrence of seizures [8]. This should be kept in mind to avoid overtreatment, and a strategy to reduce drug toxicity should be part of routine management (Chapter 22). There is evidence that physicians do not pay sufficient attention to the adverse effects of medications, and that use of simple self-administered questionnaires for the screening of adverse effects can do much to improve clinical outcome [8].

Occasionally, patients in whom available medications do not seem to have any significant effect on their seizures are encountered. These patients are only harmed by antiepileptic drugs, and physicians should be prepared to accept that the best management in such cases is not to prescribe any drug at all. Treatment may also not be indicated in patients with very infrequent seizures, especially when these occur only at night or in relation to predictable and avoidable precipitating events, such as severe sleep deprivation, or have no important impact on the patient's psychological, social or professional conditions.

Suppression of subclinical epileptic activity

Antiepileptic drug therapy should be aimed primarily at suppressing the clinical manifestations of seizures, and normalization of the electroencephalogram (EEG) generally is neither a major nor an attainable objective, nor in some cases even desirable. In certain situations, however, suppression of epileptiform EEG abnormalities is a justifiable therapeutic goal. This is the case when there is a close correlate between clinical seizures and EEG paroxysms, and the seizures are not easily quantifiable clinically, as in childhood absence epilepsy or some photosensitive epilepsies. The EEG may also be important in guiding treatment in infants and children with severe epileptiform EEG abnormalities co-existing with brain dysfunction: in these situations, the extent of EEG-related dysfunction should be determined, and vigorous treatment may be needed to abate its effects (see Chapters 13 and 14). In the syndrome of continuous spike–waves during sleep (CSWS), for example, the occurrence of electrical status epilepticus during sleep plays a key role in causing cognitive regression, and the intellectual development of these children improves dramatically when therapy improves or normalizes the EEG [9]. The same may apply in the Landau–Kleffner syndrome (see Chapter 14).

Intermittent and short-lived epileptiform discharges in the EEG may lead to subtle functional impairment, which is only detectable at careful cognitive testing, especially in children with generalized epilepsies. While monitoring the EEG in these patients can be useful in optimizing treatment, it is important to document that suppression of the EEG discharges does result in functional improvement. In fact, there is a risk that any improvement secondary to suppression of such discharges be overshadowed by direct negative effects of the drugs on cognitive function or behaviour. Furthermore, occasionally normalization of the EEG is associated with behavioural deterioration.

Reduction of seizure-related mortality and morbidity

In some cases where seizures are triggered by a treatable cause, such as a brain tumour, removal of the latter is essential to reduce any related morbidity and mortality. In recent years, however, evidence has accumulated that seizures per se are also associated with an increased mortality, partly in relation to accidents which may occur during a seizure and partly in relation to the risk of sudden unexpected death in epilepsy (SUDEP) [2,10]. In patients with frequent convulsive seizures, the incidence of SUDEP may be as high as 1 per 100 or 200 patient-years. Seizures are also associated with an increased risk of physical injuries, particularly burns, head trauma and bone fractures. An effective treatment would be expected to reduce mortality and morbidity, even though this has not been adequately investigated.

Addressing co-morbidities

Many symptomatic epilepsies are aetiologically related to malformative, vascular, neoplastic, degenerative, inflammatory or metabolic disorders which affect the central nervous system, and appropriate management of these conditions must be part of the comprehensive care of these patients.

Neuropsychiatric disorders are also relatively common in patients with epilepsy [11]. In a recent community-based Canadian study of 36 984 individuals, the lifetime prevalence of anxiety disorder was twice as high in people with epilepsy as in those without epilepsy (22.8% versus 11.2%, respectively) [12]. The lifetime prevalence of major depressive disorder and suicidal ideation was 17.4% and 25.0% in people with epilepsy, compared with 10.7% and 13.3%, respectively, in people without epilepsy. Although these co-morbidities have been traditionally regarded as a consequence of the physical and psychosocial limitations associated with seizures, and the adverse effects of antiepileptic drugs, there is increasing evidence that other factors are also involved. In particular, pre-existing depression or a history of suicide attempt have been identified as separate risk factors for incident unprovoked seizures [13].

Many physicians treating epilepsy do not routinely screen for psychiatric disorders, which is regrettable because these co-morbidities may impact on quality of life more than epilepsy and seizures themselves, and therefore need to be identified and treated as appropriate. In a recent study from the USA, the severity of depressive symptoms and the adverse effects of drugs in patients with epilepsy correlated independently with subjective health status, and these factors explained 72% of the variance [14].

Avoidance of adverse drug interactions

Patients receiving therapy with a combination of drugs are at risk for adverse drug interactions, at either the pharmacokinetic or pharmacodynamic level. Drug interactions are not restricted to those resulting from combinations of antiepileptic drugs, but also involve medications taken for other indications [15]. Physicians should be aware of this, and should take all necessary steps to minimize any adverse consequences.

Many drug interactions can be predicted through knowledge of the influence of different drugs on liver drug-metabolizing isoenzymes (see Chapter 28), and in many cases they can be managed with appropriate dosage adjustments and monitoring of plasma drug concentrations. Some antiepileptic drugs have little or no potential for being either a cause or a target of drug interactions, which makes them particularly advantageous in patients requiring multiple drug therapy.

Avoidance of obstruction to patient's life

Therapeutic outcome may be influenced by the patient's ability to identify and avoid situations which could affect susceptibility to seizures, such as excessive sleep deprivation, or – in some photosensitive epilepsies – exposure to intermittent flashing lights or certain video games. While these risk factors need to be discussed and appropriate counselling given, it is equally important to avoid undue restrictions on the patient's lifestyle. For example, alcohol abuse should be actively discouraged, but there is no reason to prohibit one glass of beer or wine at meal times. In general, patients should be encouraged to live a normal life, while avoiding extreme deviations from what would be considered a regular lifestyle.

Prescription of medication should also be aimed at minimizing interference with daily activities. Antiepileptic drugs which can be given once or twice daily are less likely to obstruct daily routines and to cause psychosocial embarrassment, and they are associated with a better compliance. For drugs which can be given once or twice daily but do not have a long half-life, a twice-daily schedule may be preferable because it minimizes the adverse consequences of missing one dose. In general, once-daily dosing does not entail better compliance than twice-daily dosing, but it may have psychological advantages, particularly in patients who are seizure free and perceive each act of pill-taking as the only unpleasant reminder of their disease.

Prevention of epileptogenesis

Experiments in animal models suggest that some antiepileptic drugs not only exert a symptomatic effect by raising seizure threshold, but might also antagonize epileptogenic processes, i.e. the mechanisms through which an epileptic condition becomes established [16]. The suggestion has been made that recurrent clinical seizures may also lead to irreversible neuroanatomical changes which may render the disease more difficult to control, but evidence for this is controversial [17]. If uncontrolled seizure activity leads to the 'chronicization' of the disorder, a case could be made for early and aggressive treatment, and for preferential use of drugs which putatively antagonize epileptogenic processes. Available studies, however, suggest that in most epilepsy syndromes antiepileptic drugs exert merely a symptomatic effect and do not affect the natural course of the disease [18–21]. Admittedly, special conditions may exist in which early effective treatment may improve the ultimate prognosis, possible examples being West syndrome and other early-childhood myoclonic encephalopathies associated with progressive cognitive decline. In the latter conditions, however, the benefit of early seizure control seems to relate more to cognitive outcome than to the history of epilepsy per se [20].

Although not an option at the current state of knowledge, the prevention of epilepsy by using antiepileptogenic drugs in patients at high risk (e.g. after severe head trauma or prolonged convulsive status) may be the ultimate frontier of pharmacological treatment (see Chapter 19). Development of drugs with antiepileptogenic effects could be made easier by advances in the understanding of the molecular mechanisms involved in epileptogenesis. In some conditions, such as tuberous sclerosis, these advances have been truly impressive [22].

When should treatment be started?

The treatment of newly diagnosed epilepsy is discussed in Chapter 10. As emphasized there, a correct diagnosis should be formulated before treatment can be instituted. Differentiation between epileptic and non-epileptic attacks (e.g. psychogenic seizures or syncopal episodes) is not always obvious, and appropriate investigations are required to establish the nature of the disorder. In addition, every effort should be made to identify as early as possible seizure type and syndromic form, because these are important in determining drug selection and prognosis. Although making a syndromic diagnosis is not always easy at the outset, experienced physicians can identify correctly the vast majority of epilepsy syndromes at the very beginning [23]. This is not the case, however, when epilepsy is managed by non-specialists. For example, a recent UK survey of 275 individuals with epilepsy in a deprived area who had no previous contact with the local epilepsy services found that approximately 55% had never received specialist advice, a situation which clearly resulted in suboptimal management [24].

Antiepileptic drug treatment is indicated whenever the expected benefits outweigh potential risks. The risk to benefit equation, in turn, is determined by many factors, including the type of epilepsy, the frequency and severity of the seizures, the age and the occupation of the patient, associated pathological conditions, the characteristics of the drug(s) being considered and the presumed influence of treatment on the patient's well-being and aspirations [1]. These factors are explored in more detail in Chapter 10.

In many situations, the decision on whether to start treatment or to withhold it will involve no uncertainty, but grey areas exist where the optimal therapeutic strategy is uncertain [21]. In any case, the patient should always be involved in the therapeutic decision, because his or her attitude towards the possibility of recurrence of seizures and towards the risks of drug treatment is an important consideration in establishing the indications for treatment.

The actual decision depends on individual factors. A number of different scenarios will be discussed briefly below, and other aspects are covered in Chapter 10.

Patients with a single seizure

The most common situation where there may be uncertainty on whether chronic treatment is justified is when a patient presents with a single unprovoked tonic–clonic seizure whose nature is considered to be probably epileptic [25]. Because many such patients will not have a recurrence when left untreated [26], and because treatment after a first seizure does not improve long-term prognosis [19,21,27], indiscriminate prescription of antiepileptic drugs after a first tonic–clonic seizure, whilst effective in reducing the risk of relapse [21,28], will unnecessarily expose many patients to adverse effects. Therefore, drug therapy is generally deferred until a second seizure occurs. Treatment after a first seizure, however, may be considered when specific prognostic factors indicate a high risk of recurrence (in particular, when the EEG shows interictal epileptiform abnormalities, and/or there is an identified persisting cause for the seizures, such as an MRI-documented cortical dysplasia), when the first unprovoked seizure presented as status epilepticus (suggesting the possibility of an equally prolonged seizure in case of recurrence), or when it is felt that the physical or psychosocial consequences of a seizure recurrence outweigh the risks associated with drug treatment [19,21,25,29,30]. To this purpose, it is essential to fully inform the patient of the implications of starting or withholding treatment, and the patient (or parents) should be involved in the decision process.

The quality of life outcomes of immediate versus deferred treatment in patients with a single seizure or early epilepsy for whom there was uncertainty about the indication for starting treatment was investigated recently in a subcohort of 331 patients in a randomized trial [31]. After 2 years of follow-up, patients randomized to deferred treatment were no more likely to report impairments in general health, cognitive function, psychological well-being or social function than patients assigned to immediate treatment. One area where a difference was identified was driving, where those randomized to deferred treatment were disadvantaged.

Patients with a history of two or more unprovoked seizures

Provided that the epileptic nature of the seizures has been established, patients with recurrent seizures generally require antiepileptic drug therapy [21]. Exceptions may be patients with very minor seizures or rare seizures, particularly when these are mild, brief or occur only during sleep, and do not interfere with daily activities, occupation, psychological state and social integration. Pharmacological treatment is generally not indicated in some benign childhood epilepsies with a self-remitting course, when the adverse effects of antiepileptic drugs are expected to affect quality of life to a greater extent than the seizures themselves (Chapter 14). The best example is represented by children with benign partial epilepsy with centrotemporal spikes (rolandic epilepsy), in whom treatment is usually indicated only in the few cases in whom seizures are frequent, severe and occur during daytime.

Patients with seizures precipitated by specific triggers

When seizures are precipitated by specific triggers, avoidance of the latter may be sufficient. Some forms of photosensitive epilepsy, for example, can be managed by prescribing appropriate lenses, or by instructing the patient on how to avoid exposure to the offending light frequencies. Continuous pharmacological prophylaxis is also not indicated in most children with febrile seizures who are older than 1 year [32].

Other situations

Occasionally, treatment may be justified without a clear diagnosis of epilepsy. When even intensive monitoring fails to provide differentiation between epileptic seizures and pseudo-seizures, a therapeutic trial may be indicated. Lack of response to treatment suggests a non-epileptic nature of the attacks, but it should not be regarded as a conclusive proof for this. Conversely, improvement or even disappearance of seizures after treatment does not prove that the attacks were epileptic in origin. Apart from the possibility of a placebo response or a spontaneous change in the natural history of the disorder, it should be remembered that antiepileptic drugs are not specific in their actions and may influence a wide array of symptoms and signs, including some originating from psychiatric and cardiac diseases. Interpretation of response to treatment is also complicated by the fact that epileptic seizures and pseudo-seizures may co-exist.

It has been argued that under certain circumstances prophylactic treatment may be justified even in the absence of any previous seizure. For example, it has been suggested that in infants with tuberous sclerosis early antiepileptic drug therapy may prevent the occurrence of infantile spasms and, possibly, associated neurological deterioration [1]. Antiepileptic drugs are at times prescribed in the absence of a history of seizures in patients who had a severe head trauma, or those who underwent supratentorial brain surgery, but this practice is not correct. While phenytoin has been found to reduce the risk of early post-traumatic seizures (i.e. seizures occurring in the first 7 days after head trauma) [33], neither phenytoin nor other drugs have been found to be of value in the long-term management of patients with head trauma or brain surgery [18]. In fact, the vast majority of these patients will not develop seizures in the long term and, more importantly, no antiepileptic drug has been found to be effective in reducing the incidence of late post-traumatic or postoperative epilepsy [18].

Initiation of treatment and dose optimization

Rational therapy requires not only choosing the most appropriate drug, but also identifying the optimal dosage [34]. Indeed, one of the most significant advances in the modern treatment of epilepsy has been the recognition that dose requirements vary greatly across individuals, due to pharmacokinetic and pharmacodynamic differences [34]. Optimizing drug choice and dosage are complex processes, and different aspects need to be addressed.

Choice of the most appropriate drug

As a general rule, treatment should be started with a single drug (Table 9.1). To achieve optimal outcome, drug choice should be tailored to ensure the best match between the properties of the medication and the characteristics of the individual. Critical medication-related features include spectrum of efficacy against differ-

ent seizure types, expected magnitude of therapeutic response in the condition of interest, indications and contraindications, characteristics of available formulations, dose escalation and dosing regimen requirements, adverse effects profile, interaction potential, impact on co-morbid conditions, cost and reimbursability. Patient-related factors to be considered include seizure type and syndromic diagnosis, age, gender, co-morbidities, co-medications, risk factors for potential adverse effects (including genotype) and other characteristics such as personal attitudes in relation to possible recurrence or seizures or appearance of specific adverse drug effects. An extensive discussion on how these factors impact on drug selection is provided in Chapter 30.

Dose escalation

When an immediate therapeutic effect is required, as in the management of status epilepticus or frequently recurring seizures, treatment can be started with a loading dose. In most situations, however, this aggressive approach is neither necessary nor desirable, and treatment should be initiated with a small dose and increased gradually to a target maintenance level. Gradual dose escalation has several advantages:

- With most antiepileptic drugs, adaptation (tolerance) to adverse central nervous system and, sometimes, other effects occurs slowly after initiation of treatment [35], and immediate use of a full maintenance dosage may cause major tolerability problems. Drugs which are most likely to produce adverse central nervous system effects when started at doses close to the maintenance dosage include primidone, benzodiazepines, topiramate, tiagabine, vigabatrin, zonisamide and lacosamide. Primidone may cause a particularly marked transient intolerance reaction in patients not previously exposed to barbiturates, and it should be started at a dose (62.5 mg/day in adults) which is only about one-tenth of the usual maintenance dosage [34].
- Despite common belief, allergic and idiosyncratic reactions are often dependent on starting dose and rate of dose escalation [36]. Skin rashes requiring drug withdrawal when treatment is initiated at too-high doses are especially frequent with carbamazepine, phenytoin and lamotrigine. Because valproic acid increases the plasma levels of lamotrigine, the risk of lamotrigine-induced allergic reactions is greatly increased in patients co-medicated with valproic acid, and in these patients it is essential that lamotrigine dosage is escalated at a very slow rate.
- Some patients can be optimally controlled at doses below the initial target maintenance dosage. When seizure frequency is sufficiently high to permit a meaningful assessment of therapeutic response over a short period, slow dose escalation may allow identification of the lowest dose regimen at which patients respond. Conversely, some patients are unusually sensitive to adverse effects, and slow dose escalation will prevent them from being exposed to dosages higher than those tolerated.

Unfortunately, in the case of most antiepileptic drugs, evidence on the optimal rate of dose escalation is limited. Optimal dose titration rates are seldom established in regulatory clinical trials and, therefore, they are mostly identified through postmarketing experience [1]. As shown in Table 9.2, phenytoin, levetiracetam, gabapentin and pregabalin are among the drugs for which the target maintenance dosage can be achieved rapidly without undue toxicity, which is an advantage when latency to onset of therapeutic effects must be minimized. Phenobarbital may also be started at a 'therapeutic' dosage, but because of its long half-life the time-course of pharmacological action is influenced by the slow accumulation of the drug in plasma, a process which may require several weeks. The escalation schemes given in Table 9.2 are only intended for general orientation, and deviations from these recommendations may be indicated in individual cases, or as a result of newly acquired information. Children, elderly patients and patients with certain co-morbidities or co-medications may require doses and titration rates different from those given in the table [34]. The rate of dose escalation is also partly dependent on the treatment setting: a patient with frequent seizures, for example, may require more rapid dose escalation than a patient with infrequent seizures.

Table 9.1 Advantages of monotherapy.

High efficacy (complete seizure control in the majority of patients)
Better tolerated than multiple drug therapy
Easy management (efficacy and safety of individual drugs can be evaluated separately)
Simple (possibly better compliance)
No adverse drug interactions
Cost-effective

Initial target maintenance dosage

The initial target maintenance dosage can be defined as the dosage at which the patient is stabilized at the end of the initial dose escalation phase [34]. In general, this corresponds to the lowest daily dosage which is expected to produce seizure control in that individual patient. This approach is justified by the desire to minimize the probability of exposing patients to long-term treatment with dosages higher than necessary.

In recent years, evidence has accumulated that most patients with newly diagnosed epilepsy who achieve seizure freedom on the initially prescribed drug do so at relatively low doses, and only a small group necessitates doses in the medium to high range. In a large single-centre study which explored the effectiveness of the first prescribed antiepileptic drug, the majority of patients who became seizure free were controlled at doses of 400–600 mg/day for carbamazepine, 600–1000 mg/day for valproate and 125–200 mg/day for lamotrigine [7]. In a recent randomized trial that compared carbamazepine and levetiracetam in adults with newly diagnosed partial epilepsy, about 90% of seizure-free patients were controlled at doses of 400 mg/day for carbamazepine and 1000 mg/day for levetiracetam [37].

An indication of possible initial target maintenance dosages is provided in Table 9.2. In practice, the target dosage should be individualized based on expectations concerning the patient's responsiveness to the drug. Many idiopathic generalized epilepsies respond well to treatment, and it may be justified in these patients to aim at initial maintenance dosages and plasma drug levels in the low range. For example, the dosage of valproic acid required to control primary generalized tonic–clonic seizures has been found to be about 30% lower than that required to control partial seizures [38]. A high seizure frequency before starting

Table 9.2 Suggested initial target maintenance dosages, frequency of administration and titration rates for the main antiepileptic drugs in adults.

Drug	Usual initial target maintenance dosage (mg/day)	Usual maintenance dosage (mg/day)	Frequency of administration	Suggested titration rate
Carbamazepine	400–600[a]	400–1600	2 to 3 times/day (twice daily with controlled-release formulations)	Start with 100 or 200 mg/day and increase to target dosage over 1–4 weeks
Clobazam	10	10–30	Once or twice daily	Start with 10 mg/day. If indicated, increase to 20 mg/day after 1–2 weeks
Ethosuximide	500–750[a]	500–1500	2 to 3 times/day	Start with 250 mg/day and increase to target dosage over 1–3 weeks
Felbamate	1800–2400	1800–3600	3 or 4 times/day	Start with 600–1200 mg/day and increase to target dosage over 10–21 days
Gabapentin	900–1800	900–3600	2 or 3 times/day	Start with 300–900 mg/day and increase to target dosage over 5–10 days
Lamotrigine	50–150 (monotherapy); 50–100 (patients on valproic acid); 200–300 (patients on enzyme inducers)	50–200 (monotherapy or patients on valproic acid); 200–500 (patients on enzyme inducers)	Twice daily (once daily possible with monotherapy and valproic acid co-medication)	Monotherapy: start with 25 mg/day for 2 weeks, then increase to 50 mg/day for 2 weeks. Further increases by 50 mg/day every 2 weeks Valproic acid co-medication: start with 25 mg on alternate days for 2 weeks, then 25 mg/day for 2 weeks. Further increases by 25–50 mg/day every 2 weeks Enzyme-inducing co-medication: start with 25 or 50 mg/day for 2 weeks, then increase to 50 or 100 mg/day for 2 weeks. Further increases by 50–100 mg/day every 2 weeks
Lacosamide	200–400	200–400	Twice daily	Start with 100 mg/day and increase to target dosage by increments of 100 mg/day every week
Levetiracetam	1000–2000[a]	1000–3000	Twice daily	Start with 500 or 1000 mg/day and increase, if indicated, after 2 weeks
Oxcarbazepine	600–900[a]	600–3000	2 or 3 times/day	Start with 300 mg/day and increase to target dosage over 1–3 weeks
Phenobarbital	50–100[a]	50–200	Once daily	Start with 30–50 mg at bedtime and increase, if indicated, after 10–15 days
Phenytoin	200–300[a]	200–400	Once or twice/day	Start with 100 mg/day and increase to target dosage over 3–7 days
Pregabalin	150–300	150–600	2 or 3 times/day	Start with 75 mg/day for 3 days, then increase to 150 mg/day. If indicated, increase to 300 mg/day after 2 weeks
Primidone	500–750[a]	500–1500	2 or 3 times/day	Start with 62.5 mg/day and increase to target dosage over about 3 weeks. In patients on enzyme-inducing co-medication a faster titration may be used
Rufinamide	1200	1200–3200	Twice daily	Start with 400 mg/day and increase by 400 mg/day increments every 2–4 days
Tiagabine	30 (patients on enzyme inducers); 15 (patients not on enzyme inducers)	30–50 (patients on enzyme inducers); 15–30 (patients not on enzyme inducers)	2 to 4 times/day	Start with 5 mg/day and increase by 5 mg/day increments at weekly intervals
Topiramate	100[a]	100–400	Twice daily	Start with 25 mg/day and increase by 25 or 50 mg/day increments every 2 weeks
Valproic acid	500–1000[a]	500–2500	2 or 3 times/day (once or twice daily with controlled-release formulations)	Start with 500 mg/day and increase, if indicated, after about 1 week
Vigabatrin	1000	1000–3000	Once or twice daily	Start with 250 or 500 mg/day and increase to target dosage over 1–2 weeks
Zonisamide	200	200–500	Twice daily	Start with 50 mg/day, increase to 100 mg/day after 1 week and to 200 mg/day after 1 further week

From ref. 34.

This information reflects the author's assessment of available evidence and may differ from information reported in data sheets in individual countries. Some patients will require dosages, titration rates and dosing regimens different from those given in this table.

[a] Suggested target dosage for initial monotherapy in patients with newly diagnosed epilepsy. For some drugs, larger target dosages may be appropriate in refractory patients.

therapy, symptomatic epilepsy, partial seizures, multiple seizure types, associated neurological handicaps and an unfavourable response to previous antiepileptic drug therapy all influence the prognosis negatively [39,40], and patients with these features are expected to require comparatively higher doses and plasma drug levels. Other factors affecting choice of the initial maintenance dosage include the presence of physiological or pathological conditions leading to altered drug disposition [41–44], and any co-medication expected to interact pharmacokinetically or pharmacodynamically with the drug to be administered [15]. Elderly patients, in particular, generally require dosages in the low range, since they exhibit an increased sensitivity to the effects of antiepileptic drugs [45,46].

The patient's attitude should also be considered. A higher maintenance dosage is justifiable wherever recurrence of seizures is expected to have a particularly severe psychological or social impact on the individual's life. Some neurologists also favour the use of relatively high initial maintenance dosages out of fear that a delay in achieving complete seizure control may increase the probability of the epilepsy becoming intractable. However, as discussed earlier in this chapter, at least for most of the epilepsy syndromes, there is no evidence that this is the case.

Frequency of administration

For most antiepileptic drugs, attainment of an adequate response is dependent on the persistence of efficacious drug concentrations at the site of action in the brain. Because the concentration at the site of action is in equilibrium with the concentration in plasma, a dosing scheme should be used which is adequate to maintain relatively stable plasma drug concentrations throughout a 24-h period [47].

The degree of fluctuation in plasma drug concentration during a dosing interval is dependent on the duration of such interval, the rate of absorption of the drug and its elimination half-life. With rapidly absorbed compounds, it is a good general rule to choose a dosing interval which is no greater than the half-life of the drug. Drugs with a slow elimination rate such as phenobarbital may be given once daily at bedtime, but most other antiepileptic drugs need to be given two or three times daily. The optimal frequency of administration may also vary depending on pharmacokinetic patterns in different patient groups. For example, lamotrigine should be given twice daily in patients taking concomitant enzyme-inducing anticonvulsants (due to its relatively short half-life in these patients), but it may be given once daily in adults receiving no co-medication, and, even more appropriately, in those co-medicated with valproic acid, which prolongs the half-life of lamotrigine.

For short half-life compounds such as carbamazepine and tiagabine, more than two daily administrations may be required to minimize excessive fluctuations in plasma concentration. This is especially important for patients in whom half-lives are at the shorter end of the spectrum, such as children and enzyme-induced individuals [34]. With these drugs, intermittent adverse effects are not uncommon at the time of peak drug concentration, whereas breakthrough seizures may occur when plasma drug levels fall below a critical threshold. More than twice-daily dosing may similarly be required for gabapentin, which also has a short half-life and, additionally, is absorbed from the intestine by a saturable transport mechanism [47]. Particularly in patients receiving high dosages, utilizing multiple daily administrations of gabapentin provides a strategy to improve the oral absorption of the drug. To minimize the inconvenience of multiple daily dosing and to improve compliance, extended-release formulations suitable for twice-, and in some cases, once-daily dosing have been developed for a number of drugs [48]. These are discussed briefly in the next section of this chapter.

In some patients, even drugs with short half-lives such as gabapentin and tiagabine may still produce adequate responses with a twice-daily schedule. This may be explained, at least in part, by pharmacodynamic variability, i.e. the fact that some patients may tolerate well high peak plasma drug levels or, conversely, maintain a good response at low trough concentrations. For some drugs, there is also evidence that a dissociation exists between their concentration profile in plasma and the duration of effect. For example, levetiracetam is recommended for use on a twice-daily schedule despite a plasma half-life of about 7 h. In the case of vigabatrin, which also has a plasma half-life of about 7 h, even once-daily dosing may be appropriate due to the fact that its action involves irreversible inhibition of GABA transaminase, and therefore duration of effect is dependent more on the turnover rate of the enzyme than on the chemical half-life of the drug in plasma [49]. There is some evidence that valproic acid also has a longer duration of action than expected from its half-life [50], and once-daily dosing of valproate is feasible in many patients, particularly when a sustained-release formulation is used. Once-daily valproic acid, however, is not recommended in women of childbearing potential, because animal studies suggest that teratogenic effects may be enhanced at high peak plasma concentrations of the drug [51].

Choosing among different formulations (including generics)

For patients stabilized on chronic treatment, tablets or capsules should be preferred to syrups, whenever possible, because they allow more precise dosing, avoid the effect of tooth-damaging ingredients such as sucrose, and minimize the risk of adverse effects associated with excessively rapid absorption. Nearly all children above the age of 5 years can cope with conventional solid dosage forms. For some drugs, solid dose forms designed especially for infants and younger children (e.g. powders, sprinkles and granules) have also been made available. The type of formulation influences the rate of drug delivery to the bloodstream and, hence, to the site of action. Enteric-coated tablets, such as those utilized in some formulations of valproic acid, can be absorbed only after the tablet reaches the intestine, and therefore absorption shows a lag-time related to the rate of gastric emptying. Typically, the passage of enteric-coated tablets to the intestine is delayed by the concomitant ingestion of food, and, therefore, when enteric-coated formulations are administered with a meal, drug absorption may not take place for up to many hours after the ingestion [47].

In most countries, different formulations of the same drug are available, and some of these may differ in bioavailability. Switching between products with different bioavailability (for example, switching from a regular to a modified-release product, or between other products known not to be bioequivalent) may result in a

change in plasma drug levels and, consequently, in loss of seizure control or clinical toxicity. To minimize risks, switches between these products should be done only when necessary, clinical response should be monitored carefully and, whenever possible, plasma drug concentrations should be measured to determine whether dose adjustments are needed.

In recent years, generic products of antiepileptic drugs have been introduced in most countries. Current regulations concerning the approval of generics are strict, at least in Europe and the USA, and require that the plasma concentrations of the active principle after intake of the generic be equivalent to those measured after intake of the brand [52]. In practice, bioequivalence is established by demonstrating that 90% confidence limits for the ratio of key pharmacokinetic parameters after intake of the generic and brand product fall within the 80–125% range. For those confidence limits to be met, however, mean estimates for ratios of measures of rate and extent of absorption must be relatively close to 100%. There has been considerable debate about benefits and risks associated with generic prescribing [52,53]. Generics bring major cost benefits to individuals and to society, but concern has been expressed that conventional confidence limits for bioequivalence may be too wide for antiepileptic drugs, and that even a modest reduction in plasma drug concentration after switching to/from a generic may be sufficient to cause recurrence of seizures in occasional patients. Moreover, it has been pointed out that while each generic has to be bioequivalent to the corresponding brand, bioequivalence is not guaranteed when switching from a generic to another [52]. In view of these considerations, there is general agreement that any switch between pharmaceutical products of antiepileptic drugs should be approved by the physician, that switches between different generics should be avoided whenever possible, and that there may be special categories of patients (particularly those who are seizure free) in whom switches may be generally undesirable [52,53]. Greater concerns apply to countries in which regulatory control of the quality of pharmaceuticals is less strict, particularly in the underprivileged world [54]. Monitoring plasma concentrations can be useful for rapid detection of potential changes in plasma drug concentration when switching formulations.

Sometimes, it is desirable to modify a drug's rate and extent of absorption in order to obtain a more favourable plasma concentration profile. In particular, for drugs which are absorbed and eliminated rapidly, sustained-release preparations have been developed which are designed to prolong the absorption, produce a smoother drug concentration profile and allow less frequent dosing [48]. Modified-release products are currently available for carbamazepine, valproic acid, phenytoin, lamotrigine, oxcarbazepine and levetiracetam. These formulations can be administered conveniently twice daily, and some are also suitable for once-daily dosing. With once-daily dosing, however, the advantages of improved convenience should be weighed against the risks associated with a prominent decrease in plasma drug levels should the patient forget to take one dose [48]. At least for some drugs, most notably carbamazepine, sustained-release formulations provide clear advantages, particularly in reducing intolerability associated with excessively high peak plasma concentrations [46,48]. It should be noted, however, that some modified-release formulations may differ from conventional formulations not only in rate, but also in extent of absorption. Therefore, an adjustment in total daily dosage may be needed when switching from a conventional to a modified-release formulation or vice versa.

In certain situations, routes of administration other than the oral route may be indicated, and appropriate formulations will then be needed. When an immediate effect is required, such as in the treatment of status epilepticus, the intravenous route is preferred whenever feasible (see Chapter 18). Intramuscular administration of drugs such as phenytoin, phenobarbital and diazepam is generally not recommended, because absorption may be slow and poorly predictable. Midazolam and fosphenytoin, on the other hand, are absorbed efficiently when given intramuscularly. In the case of diazepam, the rectal route provides rapid and efficient absorption when solutions, gels or rectal capsules are used, and can be utilized by non-medical personnel in selected situations, for example to prevent or terminate a seizure in a febrile child. With midazolam, the buccal and the intranasal routes may also ensure rapid absorption, and have been used for rescue therapy in seizure patients [55]. Formulations suitable for alternative routes of administration are also desirable to substitute for oral medication in patients unable to take a medicine orally, for example after abdominal surgery.

Adjusting dosage in patients not responding to the initial target dosage

According to pharmacokinetic principles, about five half-lives are required to reach steady-state plasma concentrations after stabilizing the patient on a given dosage [47]. Response to treatment cannot be fully evaluated before this period, and this should be taken into account in determining the minimum interval which should elapse before assessing the need for dosage adjustments. For drugs such as valproic acid and carbamazepine, which have relatively short half-lives, steady-state conditions are achieved within a few days (Table 9.3), whereas for phenytoin and phenobarbital it may take weeks for the plasma concentration to stabilize following a dose change. There are instances of patients who have been discharged from clinical observation too soon after a dose increment and became subsequently intoxicated as a result of progressive drug accumulation.

In patients who continue to have seizures after stabilization at the initial target dose, dosage should be increased stepwise within the recommended range until seizures are controlled or until intolerable adverse effects appear. The magnitude of dosage increments should be determined by the steepness of the dose–response relationship, which varies between drugs, and by the patient's response at the previously assessed dose. Particular care should be taken when adjusting phenytoin dosage, because small dose increments can result in disproportionate increase in plasma drug levels [56]. Although most physicians are aware of the need for careful individualization of dosage, inadequate dosing remains an important determinant of suboptimal seizure control. In a study of 74 consecutive patients referred for epilepsy surgery to a tertiary level centre in Germany due to 'medical intractability', careful evaluation of medical history revealed that these patients had not been exposed to maximally tolerated doses of carbamazepine, phenytoin or barbiturates [57]. When the same patients were rechallenged with appropriate doses of one or more of these drugs, seven showed such a major improvement in seizure control

Table 9.3 Elimination half-lives of antiepileptic drugs and time to reach steady-state plasma drug concentrations in adults. Half-lives may be longer in newborns and shorter in infants and children.

Drug	Half-life		Time to reach steady state (days)	Comments
	Patients not taking enzyme inducers[a]	Patients taking enzyme inducers[a]		
Carbamazepine	8–25 h	5–15 h	2–7 days	Owing to autoinduction, plasma drug levels may decline after about 14 days of initiation of treatment
Clobazam	10–30 h	8–16 h	2–6 days	Active demethylated metabolite with longer half-life requires about 10 days to reach steady state
Clonazepam	20–60 h	10–35 h	2–10 days	
Ethosuximide	40–60 h	20–40 h	4–10 days	
Felbamate	14–23 h	10–18 h	2–4 days	
Gabapentin	5–7 h	5–7 h	2 days	
Lamotrigine	15–35 h	8–20 h	2–6 days	In patients comedicated with valproic acid, half-life is longer (40–80 h) and steady state may not be reached until 7–15 days
Lacosamide	12–16 h	12–16 h	2–4 days	
Levetiracetam	6–8 h	4–8 h	2 days	
Oxcarbazepine	8–15 h	7–12 h	2–4 days	Data refer to the metabolite monohydroxy-carbazepine, for which oxcarbazepine can be considered a prodrug
Phenobarbital	50–170 h	50–170 h	8–30 days	
Phenytoin	10–100 h	10–100 h	4–20 days	Half-life and time to reach steady state increase with increasing dosage
Pregabalin	5–7 h	5–7 h	2 days	
Primidone	10–20 h	5–10 h	2–4 days	Most of the pharmacological effects are mediated by the metabolite phenobarbital, which may require 8–30 days to reach steady state
Rufinamide	6–10 h	6–8 h	2 days	
Tiagabine	4–13 h	2–4 h	2 days	
Topiramate	20–30 h	10–15 h	2–5 days	
Valproic acid	11–20 h	6–12 h	2–4 days	
Vigabatrin	5–8 h	5–8 h	2 days	
Zonisamide	50–70 h	25–35 h	5–12 days	

[a] Enzyme inducers include carbamazepine, phenytoin, phenobarbital and primidone.

that their surgery programme was cancelled. Admittedly, it may be difficult to reach consensus on what is a maximally tolerated dosage in an individual patient, as this is influenced by both physician's and patient's perceptions. In particular, the acceptability of adverse effects depends on the patient's lifestyle priorities; for example, age and occupation will influence a patient's reaction to the modest cognitive impairment or verbal slowness which can be associated with some treatments. If individual preferences are not addressed adequately, the patient may find it difficult to adhere to the prescribed dosing regimen.

The need to adjust dosage in uncontrolled patients cannot be disputed, and the therapeutic potential of any given drug should be fully explored before switching to alternative treatments. However, there should be no overexpectations of outcomes achievable with high-dose therapy. In fact, only a modest proportion of patients who fail to respond to doses in the low to medium range will achieve seizure freedom at higher doses [7,37], and even subsequent treatments with alternative drugs will not produce high seizure freedom rates in these patients [39,58]. It should also be recognized that the efficacy of antiepileptic drugs does not always increase with increasing dosage. Too-large dosages, or simultaneous prescription of too many drugs, may lead to a paradoxical increase in seizure frequency [59]. The physician should be aware of this possibility, because failure to recognize drug-induced seizure aggravation may lead to further increase in drug load and consequent clinical worsening.

Monitoring plasma drug concentrations can be useful in deciding the need and magnitude of dosage adjustments [60]. However, dose adjustments should be based primarily on clinical response and patients who are seizure free at low plasma drug concentrations should not have their dosage increased. Conversely, since some patients may tolerate and indeed require plasma drug concentrations above the upper limit of the reference range, no patient should be considered drug resistant unless seizures continue at the maximal tolerated dosage (within the clinically used dose range), irrespective of plasma drug concentrations.

Dose optimization in special situations

The strategy concerning dose titration used in children is similar to that described for adults, although some severe conditions, such as West syndrome, may dictate more aggressive dose escalation. Since drug clearance for most antiepileptic drugs is higher in infants and children than in adults [41,42], dosage requirements on a milligram per kilogram basis are usually higher in paediatric patients than in adults (Table 9.4). Conversely, newborns, especially when born prematurely, often have a reduced drug clearance and therefore may require lower dosages. During chronic treatment in children, dosage is rarely modified based on

Table 9.4 Suggested maintenance dosages of AEDs in infants and children.

Drug	Maintenance dosage for infants (mg/kg/day)	Maintenance dosage for children (mg/kg/day)
Carbamazepine	10–40[a]	5–30
Clobazam	0.5–1	0.25–0.75
Clonazepam	0.1–0.2	0.05–0.1
Ethosuximide	20–40	15–45
Felbamate	20–60	15–45
Gabapentin	ND	10–30
Lacosamide	ND	ND
Lamotrigine	ND	1–5 (valproate co-medication) 5–15 (enzyme-inducing co-medication)
Levetiracetam	ND	10–60
Oxcarbazepine	15–60	10–50
Phenobarbital	3–5	2–4
Phenytoin	5–15[a]	5–9
Pregabalin	ND	ND
Primidone	ND	5–25
Rufinamide	ND	[c]
Tiagabine	ND	ND
Topiramate	ND	1–5
Valproic acid	20–40[b]	10–30[b]
Vigabatrin	80–150	40–80
Zonisamide	ND	4–12

Modified from ref. 34.

This information reflects the author's assessment of available evidence and may differ from information reported in data sheets in individual countries. Some patients will require dosages different from those given in this table.

ND, no adequate data available or not approved in this age group.

[a] Bioavailability may be poor in infants.

[b] Higher dosages may be needed in patients comedicated with enzyme inducers.

[c] Rufinamide doses approved in Europe are 200–1000 mg/day for patients without valproate co-medication weighing <30 kg, 200–600 mg/day for patients comedicated with valproate weighing <30 kg, and 400–1800 mg/day for patients weighing 30–50 kg.

body weight changes alone, and assessment of clinical response is essential in determining the need for dose adjustments [34]. Compared with adults, children are more often treated with liquid dosage forms, which show faster rates of absorption than tablets or capsules. Coupled with the shorter half-life of many drugs in children, this results in amplified fluctuations in plasma drug levels, often necessitating more frequent daily dosing to avoid intermittent adverse effects.

At the other extreme of age, in the elderly, dosage may need to be adjusted to compensate for reduced renal and hepatic drug clearances [41]. Binding of drugs to plasma proteins may be altered in elderly people with hypoalbuminaemia, and consequently total plasma drug concentrations may underestimate the levels of unbound, pharmacologically active drug in these patients. In general, epilepsy in the elderly tends to respond to lower dosages than those used in younger patients, but the elderly also show an increased susceptibility to adverse effects [44–46].

Associated diseases, particularly those affecting the liver and the kidney, may alter dosage requirements to a major extent [43,44]. Patients with associated diseases are also more likely to take concomitant medications, with the attendant risk of drug interactions (Chapter 28).

Assessing clinical response

Under usual circumstances, assessment of therapeutic response is based on direct observation of seizures. Patients or their relatives should be provided with a diary and instructed to record seizures carefully, utilizing simple codes which allow differentiation by seizure type. In addition to dates on which seizures occur, it may be useful to include in the diary information on the actual timing of the seizures (e.g. nocturnal, awakening or diurnal seizures) and events potentially affecting seizure susceptibility, i.e. menstrual periods, situations leading to sleep deprivation, and days on which medication was missed or taken incorrectly. When assessing the effect of therapy on seizure frequency, consideration should be given to whether plasma drug levels had reached steady-state conditions after a change in dosage. Baseline seizure frequency also needs to be considered: if at baseline a patient experienced only one seizure every 2 or 3 months, it may take up to 1 year to determine with reasonable confidence whether a change in drug therapy led to seizure freedom. As discussed earlier in this chapter, efficacy should not be established by assessing changes in the EEG: however, EEG recordings may be useful or even required to assess drug response in special situations, e.g. in status epilepticus (particularly when anaesthesia has been applied and there is no other method to determine ongoing electrical activity in the brain), in patients with absence seizures and wherever subclinical EEG paroxysms cause functional impairment.

It is essential that the patient be monitored carefully not only for seizure activity, but also for potential co-morbidities (particularly psychiatric conditions) and adverse drug effects [4,61]. This can be done by interviews and examinations at appropriate intervals. Since important adverse effects are easily overlooked, the use of simple, self-administered questionnaires can be of great value in screening patients for potential toxicity, and have been shown to improve substantially clinical outcome [8]. Likewise, the patient and the family should be informed about adverse effects that may be anticipated and any action that may have to be taken, particularly with respect to early signs of serious toxicity.

Routine haematology and blood chemistry tests should be obtained before starting treatment, and repeated at least once during treatment and when another drug is added or substituted. While more frequent laboratory safety monitoring may be recommended for certain drugs (most notably, felbamate), the most efficient strategy for identifying serious adverse effects is to alert patients about the need to report immediately any warning symptoms and signs [36,62]. In particular, bleeding, bruising and infections may be early manifestations of blood dyscrasias, whereas profound asthenia, marked sedation, vomiting, fever and increased seizure frequency should alert about the possibility of valproic acid-induced liver toxicity. Special safety tests are required in special circumstances: patients started on vigabatrin, for example, must have their visual fields tested regularly by Goldman perimetry. The value of monitoring plasma drug concentrations as an

aid to improve clinical response is discussed later in this chapter.

What next when the initial treatment fails?

The treatment of chronic and active epilepsy is discussed further in Chapter 11, but here a number of general aspects are covered, which apply to epilepsy at all stages in its evolution.

When seizures continue at the maximally tolerated dose of an antiepileptic drug, a care review is indicated. First, it is important to confirm that the diagnosis was correct, that the initial treatment was appropriate and that there are no removable causes of inadequate response (e.g. poor compliance, sleep deprivation or alcohol abuse). After excluding these sources of poor response, the best strategy in most cases is to substitute the first drug with a second, also given as monotherapy. As discussed below, monotherapy with an alternative drug will produce seizure control in an appreciable number of patients, and is likely to be better tolerated than combination therapy [4,39,58]. Early combination therapy, however, may be preferred in selected cases, for example in patients with severe epilepsies who showed a favourable but incomplete response to the initially prescribed drug and are considered unlikely to achieve seizure freedom on an alternative monotherapy. Trials of combination therapy are also justified in patients who failed two or more sequential monotherapies. The probability of achieving sustained seizure freedom after failing to respond at maximally tolerated dosages of three or more antiepileptic drugs is much less than in newly diagnosed patients, but even in chronic established epilepsy, a significant minority of patients will respond at least to some extent (this is discussed further in Chapter 11). Where epilepsy is severe and intractable, early consideration should be given to the feasibility of epilepsy surgery.

Alternative monotherapy

As summarized in the preface of this book, the vogue for antiepileptic drug monotherapy dates from the late 1970s and the advantage of monotherapy over combination therapy has been stressed many times since. The first formal trial comparing alternative monotherapy with combination therapy was conducted by Hakkarainen [63], who randomized 100 patients with newly diagnosed convulsive seizures to either carbamazepine or phenytoin. The 50 patients who continued to have seizures after 1 year on the allocated treatment were switched to monotherapy with the alternative drug and, of these, 17 (34%) became seizure free. On the other hand, of the 33 patients who were refractory to *both* phenytoin and carbamazepine as monotherapy, only five (15%) could be controlled when the two drugs were given together. While the value of combination therapy in this trial may have been underestimated due to the fact that carbamazepine and phenytoin, sharing similar mechanisms of action and adverse effect profiles, are probably not the best drugs to use together, the study clearly showed that alternative monotherapy is a valuable option in patients refractory to initial treatment. This finding has been confirmed repeatedly. In a large observational study in which a variety of drugs were used, 67 of 248 patients (27%) refractory to initial monotherapy were rendered seizure free with a second or third drug used as monotherapy, and only 12 were controlled by combination therapy [39]. In a more recent pragmatic controlled trial, 157 patients with refractory partial epilepsy not controlled after single ($n = 94$) or sequential monotherapies were randomized to monotherapy with an alternative drug or to combination therapy by adding a second drug [64]. The 12-month probability of remaining on the assigned treatment was 55% in patients randomized to alternative monotherapy, and 65% on those randomized to adjunctive therapy, a non-statistically significant difference. The 12-month probability of remaining seizure free in the two groups was 14% and 16% respectively. Although the statistical power of the study was limited by the relatively small sample size, these results reinforce the evidence that success rates on combination therapy are not much greater than those achieved with alternative monotherapy. In the latter trial, adverse effects rates associated with monotherapy were not lower than those reported with combination therapy. However, in other studies where patients refractory to initial treatment were switched to combination therapy, the burden of adverse effects was greater with polytherapy than with monotherapy [65].

Based on the above evidence, switching to an alternative monotherapy seems to be the best strategy in the majority of patients unresponsive to initial treatment. While it could be argued that addition (rather than substitution) of a second drug will allow more rapid achievement of seizure control in those few patients who do require combination therapy, such a policy has the drawback of exposing to a greater burden of adverse effects many patients who can be managed with a single drug. In practice, to minimize the risk of withdrawal seizures, it is preferable to avoid abrupt discontinuation of pre-existing medication when switching to an alternative drug. Many physicians prefer to titrate the dosage of the second agent up to the maintenance level before starting the gradual withdrawal of the initial medication. This procedure offers the advantage of minimizing the risk of seizure worsening during the switch-over phase, although there is a drawback in that the patient may be exposed to a greater risk of adverse drug interactions during the addition or discontinuation phase. An alternative strategy is to decrease gradually the dosage of the initial drug whilst substitution therapy is being introduced, although this may involve a greater risk of seizures during the switch-over phase. Some drugs, particularly benzodiazepines, carbamazepine, barbiturates, phenytoin and vigabatrin, should be withdrawn with special caution, taking into consideration the previous duration of exposure and the pre-existing dosage of these drugs, with at least 2–3 months being usually advisable to complete the withdrawal [34].

A therapeutic strategy which is intermediate between alternative monotherapy and combination therapy involves adding initially a second drug, stabilizing the patient for a period sufficient to assess response to combination therapy at optimized dosages, and then proceeding with gradual removal of the initial drug if a good response has been achieved. If the patient needs the drug combination to remain seizure free, this will become readily apparent and the withdrawal procedure can be rapidly reversed. While apparently attractive, this procedure has drawbacks. It exposes the patient to the risk of adverse drug interactions and to the adverse effects of prolonged polytherapy. Furthermore,

many patients who become seizure free will be unwilling to take any risks associated with a treatment change, and may therefore elect to continue to take a pharmacological load which is possibly greater than necessary.

Combination therapy

As discussed above, combination therapy should be preferably reserved for patients refractory to two or more sequential monotherapies, even though earlier, more aggressive utilization of polypharmacy may be justified in occasional cases, for example in severe and notoriously refractory epilepsy syndromes. The usefulness of adding a second, and sometimes even a third, drug in patients with refractory epilepsy is well documented by long-standing clinical experience and by the results of many placebo-controlled add-on trials [66], even though it cannot be excluded that in some trials an improvement in seizure frequency could have been obtained simply by increasing the dosage of baseline medication or by switching to an alternative monotherapy. In general, between 20% and 50% of patients with chronic refractory epilepsies show at least a 50% reduction in seizure frequency after adding a second or third drug [66,67], but the actual proportion achieving seizure freedom is considerably smaller (less than 20%) [68].

When another drug is added on, pharmacokinetic and/or pharmacodynamic interactions may occur, leading to the need for dosage adjustments (Chapter 28). For example, valproic acid inhibits the metabolism of lamotrigine and phenobarbital, and a reduction in the dosage of the latter drugs is usually indicated when valproic acid is added on [69]. Most pharmacokinetic interactions can be identified and managed by monitoring plasma drug concentrations, but measurement of drug levels is of no value when the interaction is pharmacodynamic. One example of adverse pharmacodynamic interaction is provided by the appearance of symptoms suggestive of carbamazepine toxicity in some carbamazepine-treated patients started on adjunctive treatment with lamotrigine. These symptoms are not usually associated with any change in the plasma concentration of carbamazepine or carbamazepine-10,11-epoxide, though they generally disappear after a reduction in carbamazepine dosage [70].

While the value of combination therapy in selected patients (albeit a minority of all patients) is unquestionable, the risk of overtreatment is significant [4] and a common problem in epilepsy practice. Polytherapy, especially when high dosages are used, involves a greater burden of adverse effects, and the overall impact on the patient's quality of life must be closely scrutinized. It should also be remembered that in patients with chronic refractory epilepsy, any beneficial effects following a change in treatment may be more apparent than real. In fact, these patients typically show wide fluctuations in seizure frequency over time, and it is not uncommon for an antiepileptic drug to be added during a period of spontaneous exacerbation: under these conditions, the subsequent improvement in seizure frequency may be related to spontaneous amelioration (the phenomenon of regression to the mean) rather than to the effect of the added drug [71]. Because of this, the need for maintaining combination therapy should be reassessed at regular intervals, and monotherapy should be re-instituted whenever appropriate. Furthermore, as mentioned above, an excessive drug burden created by drug combinations may also lead to a paradoxical deterioration in seizure control. In many patients who fail to achieve sustained benefit from an added drug, restoration of monotherapy may result not only in relief from adverse effects but also, sometimes, in improved seizure control.

Are some drug combinations more useful than others ('rational polytherapy')?

The possibility exists that two antiepileptic drugs interact pharmacodynamically by enhancing reciprocally their seizure-suppressing effects, without any potentiation of their toxicity. In animal experiments, some drug combinations do show a better therapeutic index than others, but the clinical relevance of these findings is difficult to assess [72]. Although the suggestion has been made that combining antiepileptic drugs with different mechanisms of action should be beneficial [73], current knowledge of the modes of action of the various drugs, most of which have more than one primary action, is insufficient to allow a rational application of this principle [72]. Therefore, drugs are usually combined on empirical grounds. In particular, it is generally desirable, whenever possible, to use combinations of drugs with different (or, possibly, even antagonistic) adverse effects, and to avoid drugs associated with major adverse interactions. The term 'rational polytherapy' has been coined, although there is nothing particularly rational about the choices made, and the term has a greater marketing than scientific value.

In general, there is meagre clinical evidence in favour of any particular combination. The best documented useful combinations are valproic acid plus ethosuximide in the management of refractory absence seizures [74] and valproic acid plus lamotrigine in a variety of refractory seizure types [69,73,75]. The latter combination also has minor pharmaco-economic advantages, because valproic acid inhibits lamotrigine metabolism and reduces the dosage requirements (and associated cost) of the latter. However, because of the risk of pharmacokinetic interactions, the use of the lamotrigine–valproic acid combination requires special caution, and care must be taken that the lamotrigine dosage is escalated slowly in these patients. The dosage of valproic acid may also need to be adjusted to optimize efficacy and tolerability, and further adjustments in lamotrigine dosage are likely to be required should valproic acid be discontinued.

Monitoring plasma drug concentrations as a tool to improve therapeutic outcome

The pharmacokinetics of most antiepileptic drugs exhibits marked inter-individual variation, resulting in large differences in plasma drug concentrations at steady state among patients receiving the same dose. Since the drug concentration in plasma is in equilibrium with that in the brain, this variability affects the degree of pharmacological response, and therapeutic and toxic effects are expected to correlate better with the drug concentration in plasma than with the prescribed daily dose [60]. Based on this background, monitoring plasma drug concentrations ('therapeutic drug monitoring') has been found to provide a useful guide to adjusting dosage of many antiepileptic drugs.

In practice, therapeutic drug monitoring requires considerable interpretative skills [76], and physicians should always adhere to

the principle that therapeutic decisions must be based primarily on evaluation of clinical response rather than drug measurements alone. The use of plasma drug levels in the treatment of epilepsy is discussed comprehensively in a recent position paper of the International League Against Epilepsy (ILAE) [60], and only basic concepts are outlined below.

When should blood samples be taken?

In general, blood samples for drug measurements should be taken at steady state, i.e. when at least five half-lives have elapsed since the last dose change. For drugs with a long half-life, such as phenobarbital, the daily fluctuation in plasma concentration is negligible and the exact time of sampling is not important. With other compounds, it is preferable to collect the sample in the morning before the first daily dose, when the concentration is usually at its trough. For drugs exhibiting significant variation in plasma concentration during the dosing interval, such as carbamazepine and valproic acid, it is at times useful to obtain a second sample at the time of the expected peak concentration, in order to estimate the degree of fluctuation as a potential cause of intermittent adverse effects.

The concept of 'reference range'

Inconsistent use of terminology has created confusion in the therapeutic drug monitoring literature. Terms such as 'reference range', 'therapeutic range', 'optimal range', 'effective range', and 'target range' have all been used, either interchangeably or with different meanings.

The ILAE position paper recommends that the term 'reference range' be used to define 'a range of drug concentration which is quoted by a laboratory and specifies a lower limit below which a therapeutic response is relatively unlikely to occur, and an upper limit above which toxicity is relatively likely to occur' [60]. Indeed, research in therapeutic drug monitoring has been aimed mostly at identifying a reference range which laboratories can quote and which clinicians can use as a guide. Although 'references ranges' of drug concentrations have been described for many antiepileptic drugs (Table 9.5), it would be incorrect to suggest that all patients should have their dosage adjusted in order to produce plasma concentrations within the indicated limits. These ranges are simply representative of the plasma concentrations at which most patients respond. There may be a large variation in the degree of response at any given plasma drug concentration, and many patients achieve control at concentrations which are below or above the reference ranges quoted in the literature. In other words, the 'reference range' is not necessarily a 'therapeutic range'. As explained in greater detail in the section below, the term 'therapeutic range' should be reserved to define 'the range of drug concentrations which are associated with the best achievable response in a given person, and therefore it can only be determined for the individual' [59]. If known, the 'therapeutic range' is clinically more useful than the 'reference

Table 9.5 Reference ranges of plasma concentrations for commonly used antiepileptic drugs.

Drug	Optimal range	Comments
Benzodiazepines	Not applicable	Plasma drug level monitoring not indicated. No consistent relationship between plasma drug concentration and effect
Carbamazepine	4–12 μg/ml (17–51 μmol/l)	Plasma drug level monitoring useful, though often dosage can be adjusted solely on the basis of clinical response
Ethosuximide	40–100 μg/ml (283–708 μmol/l)	Plasma drug level monitoring useful, though often dosage can be adjusted solely on the basis of clinical response
Felbamate	30–60 μg/ml (116–252 μmol/l)	Dosage adjustments are usually based solely on clinical response
Gabapentin	2–20 μg/ml (12–117 μmol/l)	Dosage adjustments are usually based solely on clinical response. Interpretation of plasma drug levels is complicated by marked fluctuations in drug concentrations during a dosing interval
Lamotrigine	2.5–15 μg/ml (10–58 μmol/l)	Plasma drug level monitoring is useful because dosage requirements are markedly affected by intra- and inter-individual pharmacokinetic variability
Levetiracetam	12–46 μg/ml (70–270 μmol/l)	Dosage adjustments are usually based solely on clinical response. Interpretation of plasma drug levels is complicated by marked fluctuations in drug concentrations during a dosing interval
Oxcarbazepine	3–35 μg/ml (12–139 μmol/l)	Reference range refers to the active metabolite monohydroxycarbazepine. Therapeutic drug monitoring may be useful due to significant pharmacokinetic variability
Phenobarbital	10–40 μg/ml (43–172 μmol/l)	Imprecise upper limit due to tolerance to the sedative effects
Phenytoin	10–20 μg/ml (40–80 μmol/l)	Plasma drug level monitoring very useful because of saturation kinetics and narrow therapeutic index
Pregabalin	Insufficient data	Reference range not established. Interpretation of plasma pregabalin levels is complicated by marked fluctuations in drug concentrations during a dosing interval
Primidone	4–12 μg/ml (18–55 μmol/l)	Plasma drug level monitoring of unchanged primidone seldom required. It is more relevant to measure the levels of the metabolite phenobarbital
Rufinamide	Insufficient data	Plasma drug level monitoring expected to be useful because of pharmacokinetic variability related to dose-dependent bioavailability
Tiagabine	0.02–0.2 μg/ml (0.5–5 μmol/l)	Dosage adjustments are usually based solely on clinical response. Measurement of the low concentrations of tiagabine is technically difficult and interpretation of plasma levels is complicated by marked fluctuations in drug concentrations during a dosing interval
Topiramate	5–20 μg/ml (15–59 μmol/l)	Dosage adjustments may be based solely on clinical response
Valproic acid	50–100 μg/ml (346–693 μmol/l)	Usefulness of plasma drug level monitoring limited in most cases
Vigabatrin	Not applicable	Plasma drug level monitoring not indicated, except as a check for compliance. Due to irreversible mode of action, time-course of effect is dissociated from time-course of plasma vigabatrin levels
Zonisamide	10–40 μg/ml (47–188 μmol/l)	Dosage adjustments may be based solely on clinical response

For further information and bibliography, see ref. 60.

range'; for example, if a patient is known to have become seizure free at concentrations below the lower limits of the 'reference range', those concentrations can be regarded as 'therapeutic' for that patient, and there will be no need to increase dosage.

Despite the limitations related to inter-patient variability in concentration–response relationships, 'reference ranges' are clinically useful because they provide a measure of the amount of drug which is present in the circulation and of the probability that the patient is benefiting optimally from the treatment. For example, a drug concentration below the reference range in an individual with uncontrolled seizures will give the clinician greater confidence in increasing dosage, and may help in deciding the magnitude of the dosage increment. Based on knowledge of concentration–response relationships in specific seizure types, physicians may also elect to aim initially at a predefined target drug concentration, rather than at a target maintenance dosage. Decisions must also take into consideration the patient's attitudes; for example, if an individual is likely to be very distressed by occurrence of another seizure, it would make sense to aim initially at a serum drug concentration in the upper portion of the 'reference range'. Conversely, lower concentrations may be targeted whenever tolerability concerns outweigh concerns of seizure recurrence. More examples of the use of therapeutic drug monitoring in clinical management are given in the section 'When should drug concentrations be measured?'.

The use of drug concentrations as an aid to dose adjustments does not exempt the clinician from monitoring clinical response carefully. In fact, achieving a desired drug concentration is no guarantee that an optimal response will be obtained, and many subjects experience therapeutic or toxic effects at concentrations higher or lower than expected.

Why do individuals respond differently to the same drug concentration?

Several factors are responsible for the differences in clinical response at any plasma drug concentration, and many of these are not understood completely. One major source of variability is the variation in pathophysiology of epilepsy. Because the epilepsies are a variety of disorders, heterogeneous in terms of aetiology, underlying mechanisms, type and extent and location of structural abnormalities (if present) and clinical manifestations, it is no surprise that the type and severity of epilepsy greatly affect the response to any given drug concentration. Patients with easily manageable forms of epilepsy tend to be controlled at plasma drug concentrations near or below the lower limit of the 'reference range', whereas patients with epilepsies more difficult to control (e.g. symptomatic partial epilepsies) tend to require higher levels. In a representative study, Schmidt and Haenel [40] assessed the plasma concentration required to achieve optimal seizure control in patients with different seizure types treated with monotherapy. Among 40 well-controlled patients with generalized tonic–clonic seizures, 26 achieved freedom from seizures at plasma drug concentrations below the mid-portion of the 'reference range'. Conversely, among 19 well-controlled patients with both generalized tonic–clonic and complex partial seizures, only three were controlled at plasma drug levels in the lower range. The median number of seizures during the first year of epilepsy was five for the patients who were controlled at lower concentrations compared with 29 for those who required higher concentrations. The fact that for some drugs the 'reference ranges' quoted in Table 9.5 were established mostly in relatively severe forms of epilepsy provides an explanation for the observation that in newly diagnosed patients optimal responses are not infrequently seen at concentrations lower than these. This is an important point, often overlooked by non-specialists. Because of this, it has been suggested that the lower limits of the commonly quoted 'reference ranges' should be disregarded, and that any concentration up to the upper limits of these ranges should be considered as potentially therapeutic [77].

Response at any given drug concentration may vary over time within the same individual. For example, for some drugs, therapeutic and/or toxic effects often decrease over time, due to 'adaptation' mechanisms at the site of action, despite persistence of stable drug concentrations in blood. This phenomenon, known as pharmacodynamic tolerance, is seen most frequently with benzodiazepines and barbiturates. Because of the development of tolerance to the sedative effects of these drugs, patients treated chronically with benzodiazepines or barbiturates may tolerate well plasma drug concentrations which would be very toxic and even cause coma in acutely exposed subjects [77]. With phenobarbital, tolerance to sedative effects usually does not entail a simultaneous loss of anticonvulsant activity. This is not always the case for benzodiazepines, whose therapeutic value during chronic treatment is often limited by full or partial loss of efficacy.

Apart from the heterogeneity of seizure disorders and adaptive changes at the site of drug action, other factors contribute to variability in the relationship between plasma drug concentration and response. These include alterations in the degree of drug binding to plasma proteins (see the section below on monitoring unbound drug concentrations) and the confounding effects of active metabolites and pharmacodynamic interactions with concomitant medications. Plasma concentrations of the active metabolites of some antiepileptic drugs are not routinely measured, and therapeutic errors may arise when the concentrations of the parent drug are interpreted without taking into account the potential contribution of metabolites [60]. For example, addition of valpromide, a valproic acid derivative, to the regimen of patients stabilized on carbamazepine causes a marked increase in the plasma concentration of the active metabolite carbamazepine-10,11-epoxide [78], resulting frequently in signs of intoxication (Fig. 9.1). Since the plasma concentration of the parent drug is not affected by this interaction, monitoring plasma carbamazepine concentration provides no clue to the mechanism underlying the development of adverse effects. A similar situation arises in the presence of drugs which interact at pharmacodynamic levels. Since the adverse central nervous system effects of antiepileptic drugs may be additive, it is not uncommon for patients on multiple drug therapy to develop clinical signs of toxicity at drug concentrations within or even below the 'reference ranges' quoted in the literature [4].

The concept of individual 'therapeutic concentrations'

The marked interindividual variability in response at any drug concentration complicates the interpretation of therapeutic drug

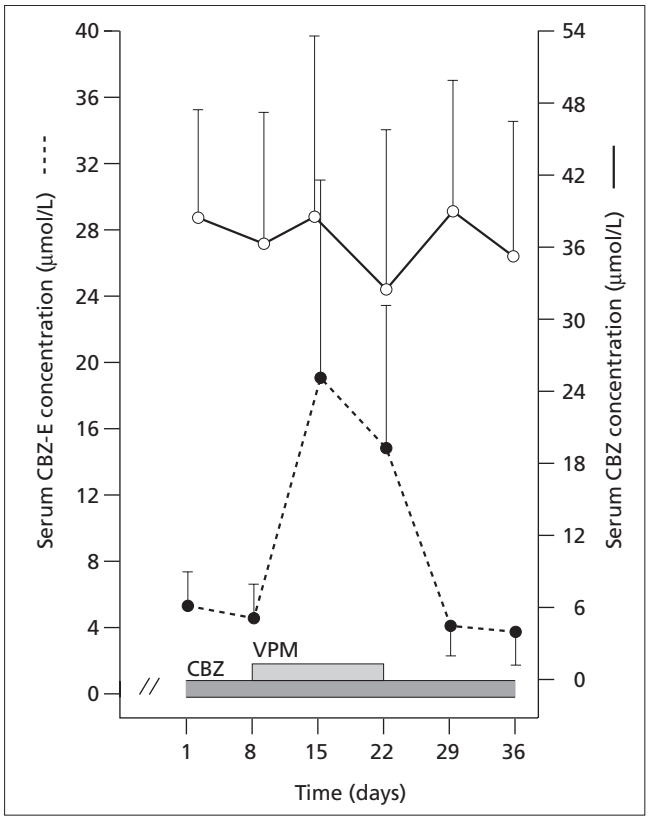

Fig. 9.1 Effect of valpromide (VPM, 1200 mg/day for 2 weeks), the amide derivative of valproic acid, on the serum concentration of carbamazepine (CBZ) and its active 10,11-epoxide metabolite (CBZ-E) in six patients stabilized on a constant dosage of carbamazepine. Values are means ± SEM. Note the marked elevation in the concentration of carbamazepine-10,11-epoxide after addition of valpromide, an inhibitor of the enzyme responsible for the conversion of the epoxide to the corresponding diol. The apparent decrease in the concentration of carbamazepine-10,11-epoxide on day 14 of combined therapy (compared with day 7) is due to exclusion of two patients with very high concentrations of the metabolite, who required discontinuation of valpromide because of side-effects. Data from ref. 78.

monitoring data. However, the fact that the optimal concentration of an antiepileptic drug varies from patient to patient does not eliminate the value of therapeutic drug monitoring. In fact, in clinical practice it is often possible, and even desirable, to establish empirically the plasma concentration at which an individual patient exhibits the best response [60,79]. In other words, once dose has been adjusted on the basis of clinical response and an optimal effect has been achieved, the concentration associated with such an outcome can be measured and considered as an estimate of the 'therapeutic concentration' in that individual. Depending on the characteristics of the individual, an optimal response may be either sustained seizure freedom, or the best compromise between reduction in seizure frequency and adverse effects. Establishing an individual 'therapeutic concentration' (or 'therapeutic range', if repeated concentration measurements are taken in a patient who achieved an optimal response) may require considerable time, particularly in seizure-free patients in whom prolonged observation may be needed to confirm that sustained remission has been obtained.

The 'therapeutic concentration' in an individual, once established, provides useful information for subsequent management. For example, if a few years later the same individual will experience a seizure breakthrough, a second measurement of the plasma drug concentration may provide clues as to the possible causes [80]. In particular, if at the time of the seizure breakthrough the drug concentration is found to be lower than the previously established 'therapeutic concentration', there is a strong indication that the relapse was due, depending on clinical context, to either a change in compliance or a change in drug disposition under the influence of physiological factors, disease states or drug interactions [60]. Knowledge of the plasma concentration at which that individual had responded in the past will also aid in deciding what dosage adjustments will be needed if seizure breakthrough was caused by altered drug disposition.

Whenever a patient is exposed to conditions known or suspected to alter plasma drug levels, information on the 'therapeutic concentration' in that individual may be used to prevent recurrence of seizures or drug toxicity. For example, oral contraceptives are known to cause a marked but variable decrease in plasma lamotrigine concentration [15]. If the individual 'therapeutic concentration' of lamotrigine is known in a woman with well-controlled epilepsy who is starting an oral contraceptive, serial drug level monitoring will enable rapid detection of contraceptive-induced changes in lamotrigine concentration, and appropriate dose adjustments can then be made to restore the 'therapeutic concentration' of the drug and thereby prevent possible seizure recurrence. Another example of the application of the 'therapeutic concentration' concept can be found in a recent study on the consequences of a fall in plasma lamotrigine levels during pregnancy [81].

The determination of individual 'therapeutic concentrations' is a useful tool which can be applied to any antiepileptic drug, including new-generation drugs [79]. To ensure optimum accuracy in establishing 'therapeutic concentrations', sampling time must be standardized carefully, and at least two determinations should be obtained on different dates, in order to assess the variability of the estimate. It is also important to remember that even carefully determined 'therapeutic concentrations' need to be interpreted flexibly, because the patient's sensitivity to a given drug concentration may change over time. This may occur as a result of alterations in the pathophysiology of the seizure disorder (particularly during the period of brain maturation), pharmacodynamic interactions with concomitant medications, or changes in drug binding to plasma proteins due to disease or displacement by interacting drugs [60,79].

Value of therapeutic drug monitoring of individual drugs

The value of therapeutic drug monitoring is greatest for phenytoin, for which the relationship between plasma concentration and effect is relatively consistent (Table 9.5). Since the enzymes responsible for phenytoin metabolism become saturated at clinically occurring concentrations, small changes in phenytoin dosage can produce disproportionately large changes in drug concentration. Under these conditions, knowledge of the plasma concentration is particularly important in deciding the magnitude of dosage adjustments; in particular, when the steady-state phenytoin

concentration approaches the lower limit of the 'reference range', dose increments should be very small to minimize the risk of intoxication [56,60].

A relatively good relationship between plasma concentration and response is also observed with ethosuximide and carbamazepine, but the dosage of these drugs can be individualized relatively easily on the basis of clinical response [77]. In the case of phenobarbital, interpretation of plasma drug concentrations is complicated by the development of tolerance, which causes a large variation in the levels at which toxicity occurs. For valproic acid, the relationship between concentration and response is rather variable, but some adverse effects, such as tremor, certain encephalopathic symptoms and changes in platelet function, may be related to high plasma valproic acid concentrations, and monitoring valproic acid levels may be of particular value when toxicity is suspected or in patients receiving high dosages [77].

Among second-generation antiepileptic drugs, therapeutic drug monitoring is particularly useful for lamotrigine, the plasma concentrations of which exhibit large inter- and intra-individual variability under the influence of age, pregnancy and drug interactions [60]. Topiramate, zonisamide, oxcarbazepine, gabapentin, rufinamide, levetiracetam, pregabalin, tiagabine and felbamate also show marked pharmacokinetic variability, which is likely to contribute to differences in dosage requirements. The concept of 'individual therapeutic drug concentration' may be of special value in optimizing monitoring of some of these medications. For short-half-life drugs such as levetiracetam, gabapentin, pregabalin and tiagabine, interpretation of drug monitoring data is complicated by the variability caused by prominent fluctuations in drug levels during a dosing interval.

Monitoring unbound drug concentrations

Although routine analytical methods measure the total concentration of the drug in plasma, it is only the free, non-protein-bound fraction which is available to equilibrate with receptor sites and to produce pharmacological effects. When the unbound fraction is increased, the total concentration in plasma may underestimate the amount of drug which is pharmacologically active, and this should be taken into account when interpreting the plasma concentration of highly protein-bound drugs such as phenytoin and valproic acid [60]. An increased unbound fraction of these drugs is observed in conditions associated with hypoalbuminaemia (e.g. neonatal age, advanced pregnancy, old age, chronic liver disease, nephrotic syndrome) or accumulation of endogenous displacing agents (e.g. uraemia). An increase in unbound fraction may also be caused by drug interactions: valproic acid, for example, increases the unbound fraction of phenytoin by displacing phenytoin from protein binding sites. In all these conditions, therapeutic and toxic effects may be observed at total drug concentrations lower than usual, and failure to recognize this may mislead the clinician into making inappropriate dosage adjustments. The suggestion has been made that in the presence of altered binding to plasma proteins it would be preferable to monitor directly the unbound drug concentration. In practice, however, this is not always necessary because often the increase in unbound fraction may be predicted on the basis of other parameters such as plasma albumin or, in uraemic patients, plasma creatinine concentration. In addition, unbound plasma drug concentrations are much smaller than total concentrations and not always easy to measure. Results may vary depending on the assay technique, and there is a greater possibility of analytical error than with measurements of total drug concentrations.

With certain drugs such as carbamazepine and phenytoin, the concentration in saliva correlates relatively well with the unbound concentration in plasma [60]. Therefore, salivary concentrations have been proposed for monitoring purposes, particularly in children who find venepunctures distressing. However, the use of salivary samples is not without problems because leakage of exudate (e.g. due to gingivitis) or dose residuals in the mouth may lead to erroneous results. Moreover, as mentioned above, measuring drug concentrations is subject to error, particularly when laboratories do not apply rigorous quality control measures, and such errors are more likely to occur with salivary samples, partly due to the fact that for some drugs the concentration in saliva is much lower than in plasma. Furthermore, it should be stressed that the relationship between unbound drug concentration in plasma and drug concentration in saliva is not the same for all drugs [60]. In the case of phenobarbital, the concentration in saliva is dependent upon salivary pH and cannot be used as a measure of free concentration in plasma unless calculations are made to account for differences in pH. For valproic acid, measuring salivary concentrations is meaningless because the drug concentration in saliva bears no consistent relationship with the concentration in plasma.

When should drug concentrations be measured?

The practice of monitoring plasma drug concentrations, introduced in the 1960s, has played a major role in improving the quality of epilepsy care. It is thanks to therapeutic drug monitoring that many drug interactions have been discovered, and plasma drug level measurements have contributed greatly to stimulating awareness about the need to tailor dosage to the individual patient [60]. As a result of these advances in knowledge, however, physicians have also acquired skills in utilizing antiepileptic drugs correctly even without the aid of plasma drug concentrations. Antiepileptic drug therapy can be optimized on purely clinical grounds, as shown in a trial where no differences in outcome were observed between patients randomized to have their dosage adjusted empirically and those in whom dosage was tailored based on drug concentration measurements [82]. It should be noted, however, that few patients in that trial were treated with phenytoin, the drug for which measurement of plasma concentrations is particularly useful.

If the concept of individualized 'therapeutic drug concentrations' is accepted, a case can be made for determining plasma drug concentrations in any patient who has been stabilized on a satisfactory drug regimen. As discussed in some detail above, the information derived from these measurements can be extremely useful for subsequent management, particularly when a patient shows an unexpected change in clinical response or is exposed to conditions causing pharmacokinetic changes.

In routine clinical practice, there are many other situations in which measuring plasma drug levels may be indicated [60]:

- At the onset of treatment, if the physician elects to stabilize the patient on a desired target concentration, rather than a desired target maintenance dosage.
- When the patient fails to achieve an adequate therapeutic response despite an apparently adequate dosage. In this situation, assessment of the drug concentration will be useful in identifying potential sources of poor response, such as low drug concentrations due to unusual pharmacokinetic patterns or poor compliance.
- In the presence of physiological or pathological conditions known to be associated with pharmacokinetic changes. These include paediatric age, pregnancy, old age and diseases affecting the liver, the kidney and the gastrointestinal tract. If applicable, knowledge of a pre-established individual 'therapeutic concentration' is of particular value in the management of these patients. However, it should be noted that, in some of these conditions, drug binding to plasma proteins and pharmacodynamic sensitivity to the drug may also be altered, and this should be taken into account when interpreting concentration data. For example, if an emergent condition resulted in an increased unbound fraction of the drug, therapeutic and toxic effects will be expected to occur at comparatively lower total drug concentrations.
- In establishing a differential diagnosis of drug toxicity. This is especially important when toxic symptoms (e.g. exacerbation of seizure frequency, incoordination or mental symptoms) may not be differentiated easily from those of underlying or associated diseases, or when the patient is unable to report adverse effects properly (young children or unconscious patients).
- To minimize the difficulties in dosage adjustments caused by dose-dependent pharmacokinetics, particularly with phenytoin.
- In patients receiving multiple drug therapy, in order to identify and to minimize the consequences of adverse drug interactions. When seizure control is unsatisfactory or toxic signs develop in patients on polytherapy, measuring the concentration of individual drugs (or their active metabolites, for instance carbamazepine-10,11-epoxide) may also assist in identifying the agent whose dosage should be preferentially adjusted.
- When a drug formulation has been changed, to assess the possibility of a clinically significant change in bioavailability.
- When poor compliance is suspected. Compliance problems are suggested by unusually low and variable concentrations, which increase following supervision of drug intake.

Use of therapeutic drug monitoring requires a close collaboration between clinicians and their laboratory colleagues. Adequate quality control measures must be in place to ensure the reliability of the analytical determinations, and apparent discrepancies between the patient's status and therapeutic drug monitoring results should be appropriately evaluated and discussed.

While the value of therapeutic drug monitoring cannot be questioned, it should be recognized that drug concentrations are often measured unnecessarily or interpreted incorrectly [76]. These determinations should be requested only when there is a sound indication, and dosage adjustments should be made only when there is a clinical need, irrespective of the drug level in the blood. Physicians must always remember that the primary aim of therapy is to treat a patient and not a laboratory value.

How long should treatment be continued?

Since many epilepsies are prone to undergo spontaneous remission, the possibility of discontinuing antiepileptic medication after an adequate period of seizure freedom should be considered. This is especially important in children, who show a higher prevalence of self-remitting syndromes and in whom the psychosocial consequences of seizure relapse are less severe than in adults. The option of discontinuing treatment should be discussed with the patient and the family, taking into consideration not only the probability of relapse, but also any adverse effects of treatment, the patient's attitude to continuation of treatment and to the possibility of seizure recurrence, and legal implications with special reference to driving regulations.

Because stopping antiepileptic drugs abruptly may cause withdrawal seizures and even status epilepticus, discontinuation of medications should be carried out gradually, to allow assessment of response at each dose level and to minimize risks. The proportion of patients whose seizures recur within 2 years following discontinuation of therapy is on average about 30% [83], but this figure in itself has limited meaning in individual cases because relapse rates range from close to zero to over 90% depending on the characteristics of the population. Predictors associated with an increased risk of relapse include increasing age, partial seizures, symptomatic epilepsy, an abnormal EEG and a longer duration of active disease prior to seizure control. Another important prognostic factor is the epilepsy syndrome, with relapse rates being lowest in rolandic epilepsy and highest in juvenile myoclonic epilepsy [84].

Generally speaking, stopping medication always carries some risk of recurrence, and a decision about drug withdrawal should be based on an assessment of the benefits versus risks. This is an individual and sometimes difficult decision, which should be taken by the patient after full appraisal of the relevant facts. A detailed discussion of clinical management of patients in remission is given in Chapter 12.

10 Management of Newly Diagnosed Epilepsy

Yvonne M. Hart
John Radcliffe Hospital, Oxford, UK

The implications of newly diagnosed epilepsy

The diagnosis of epilepsy has important medical and social implications. The seizures themselves may cause injury and embarrassment, as well as anxiety about the underlying cause (particularly brain tumour). The secondary effects of seizures are likely to affect many aspects of everyday life. Loss of the driving licence is often particularly distressing, causing loss of independence, with consequences for employment, finance and even housing if a mortgage is involved or the patient lives in an isolated area. Leisure activities are likely to be affected and, for children, epilepsy may disrupt education. Medication may cause adverse effects and concerns about teratogenicity and breastfeeding for women with epilepsy. Finally, parents often worry that their children will inherit the epileptic tendency. For all these reasons, it is essential both to ensure that the diagnosis is correct before considering treatment and to provide the patient with adequate education and information about the condition.

The diagnosis of epilepsy

Epilepsy has been defined as 'the tendency to recurrent unprovoked seizures'. Diagnosis involves not only confirmation of the fact that the person is having seizures, but also classification of the seizure type, which guides the choice of antiepileptic treatment, and the epilepsy syndrome, with its implications for long-term prognosis. The International Classification of Epileptic Seizures and International Classification of Epilepsies and Epileptic Syndromes produced by the International League against Epilepsy [1,2] are commonly used for this purpose. An attempt should also be made to identify the underlying cause.

The differential diagnosis of epilepsy is wide (Table 10.1), with syncope and psychogenic non-epileptic seizures being the most frequently encountered (see Chapter 4). Except in the rare situation in which the patient has a seizure while undergoing recording of an electroencephalogram (EEG), the diagnosis of epilepsy is made on the basis of the clinical history, taken both from the patient and from someone who has observed the seizures. It may be impossible to make the diagnosis with certainty in the absence of an eye-witness description, particularly where the seizure involves loss of consciousness. In addition to the description of the attack, information should be sought regarding the presence or absence of precipitating factors, duration and severity of postictal phase, family history of epilepsy, other medical history indicating a possible predisposition towards seizures or other paroxysmal conditions (for example, prolonged febrile seizure, head injury, somatization disorder), drug history and alcohol intake. Diagnosis may be difficult, and in one study [3] it was found that up to 20% of patients admitted to a psychiatric hospital with refractory epilepsy did not have this disorder.

The routine EEG is of low sensitivity in making the diagnosis of epilepsy. Only about 35% of patients with epilepsy consistently show epileptic abnormalities on their EEG [4], although the yield is increased by repeated recordings, particularly with sleep deprivation [5]. In patients presenting with a suspected single seizure, the proportion with epileptic abnormalities may be as low as 21% [6]. However, only 0.5% of people without seizures show epileptic abnormalities in their EEG, which may thus be helpful in confirming a diagnosis of epilepsy in those with a suggestive history [7]. The EEG may be useful in determining whether seizures are generalized or partial.

The epilepsy syndrome has implications for both prognosis and treatment. For example, benign epilepsy of childhood with centrotemporal spikes usually remits by puberty, while juvenile myoclonic epilepsy is associated with a very high risk of relapse without medication [8]. However, it may be difficult to identify the epilepsy syndrome at the time of presentation. King *et al.* [9] studied 300 consecutive adults and children over the age of 5 years presenting with unexplained seizures. Although the intention was to study patients presenting with a first generalized tonic–clonic seizure, 17% were found to have had previous similar events and 28% had experienced other epileptic symptoms, such as absences, myoclonus or temporal lobe auras. An EEG was performed within 24 h of the seizure where possible, and magnetic resonance imaging (MRI) scanning was also performed electively. The authors could diagnose a generalized or partial epilepsy syndrome clinically in 141 patients (47%), with only three of these clinical diagnoses later being proved incorrect: after EEG and MRI, it was possible to diagnose 81% of patients as having a generalized epilepsy (23%) or partial epilepsy (58%). Jallon *et al.* [10] studied 1942 patients presenting with unprovoked seizures, of whom 47.7% had had a single seizure and 52.3% more than one seizure at initial presentation, most of whom underwent EEG and neuroimaging. In the group presenting after a single seizure, 46.2% had partial seizures, 31.9% generalized seizures and 21.9% unclassified seizures. Among those having more than one seizure by the time of presentation, the first seizure type was partial in 48.1%, generalized in 39.9%

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

and unclassified in 12%. An epilepsy syndrome could be assigned in 98.6% of patients having more than one seizure at the time of diagnosis.

Rationale for treatment

As indicated above, the diagnosis of epilepsy has important medical and social implications. The decision whether to start medication depends on the likelihood of recurrence and an evaluation of the risk of harmful consequences from the seizures themselves (including injury, death, psychosocial morbidity and the effect of recurrent seizures on long-term prognosis) weighed against the adverse effects of medication.

Risk of recurrence after a first seizure

Estimates of the risk of recurrence following a first seizure have varied widely from 27% by 3 years [11] to 84% after a variable period of follow-up [12]. The true figure probably lies somewhere in between. In the FIRST seizure study of patients seen within 1 week of their first generalized tonic–clonic seizure [13], the risk of recurrence in untreated patients was 51% by 1 year. In the MESS study [14] of immediate versus deferred antiepileptic drug (AED) treatment for early epilepsy and single seizures, Marson *et al.* found a recurrence rate in untreated patients at 2 years of 39% in those patients randomized after a single seizure, and 61% in those having multiple seizures before randomization.

The differences between the various studies can largely be explained on the basis of variations in study design. The time elapsing between the time of first seizure and entry into the study is particularly important, since the risk of recurrence is greatest in the first few weeks after the first seizure [15] (Fig. 10.1), and any delay in recruiting the patient to the study will exclude those who have already had a second seizure, leading to an artificially low recurrence rate. A further problem in assessing recurrence is the difficulty in making the diagnosis at the outset, particularly if the initial seizure is unwitnessed, or if earlier seizures have been mild (for example, absences, myoclonus or simple partial seizures), a fact illustrated by the Rochester study of Hauser *et al.* [16], which found that the time from the first afebrile seizure to diagnosis was longer than 6 months in 50% of patients, and longer than 2 years in more than 30%. The use of crude recurrence rates may also lead to distortion through incomplete follow-up, as may bias where the study design is retrospective.

The influence of aetiology, seizure type, age of the patient, EEG abnormalities, timing of first seizure (during sleep or while awake) and coexistence of mental retardation or other neurological abnormalities on risk of recurrence is controversial. The First Seizure Trial Group [13] found a 1.7-fold increase in the risk of recurrent seizures in patients with epileptiform abnormalities on their EEG. This study also found age less than 16 years and remote aetiological factors to be predictive of relapse, whereas acute treatment of the initial seizure with benzodiazepines was associated with a lower subsequent relapse rate [17]. Van Donselaar *et al.* [18] similarly found the presence of epileptic discharges on EEG to be strongly predictive of seizure recurrence. Other factors increasing the risk of recurrence in this study were younger age, occurrence of first seizure during sleep or on awakening, and tongue biting. Hauser *et al.* [11] also found the EEG to be helpful in predicting prognosis among patients with idiopathic seizures, those with a generalized spike–wave pattern having a significantly higher rate of recurrence (50% at 24 months, compared with 14% in those with normal or non-specific tracings). However, risk of recurrence was not significantly increased by focal slowing or spikes compared with normal or non-specifically abnormal tracings. Other adverse factors in this study included a known remote aetiology for a first seizure, Todd's paresis following the first seizure, and a history of acute symptomatic seizures. The MESS study found

Table 10.1 Conditions that may be confused with seizures.

Vasovagal syncope
Cardiac dysrhythmias
Non-epileptic seizures (of psychological origin)
Panic attacks
Migraine
Breath-holding attacks (in children)
Sleep terrors and other parasomnias
Other paroxysmal movement disorders (e.g. paroxysmal kinesigenic choreoathetosis)
Narcolepsy/cataplexy
Vertigo
Hypoglycaemia
Other metabolic disorders
Alcohol/substance abuse

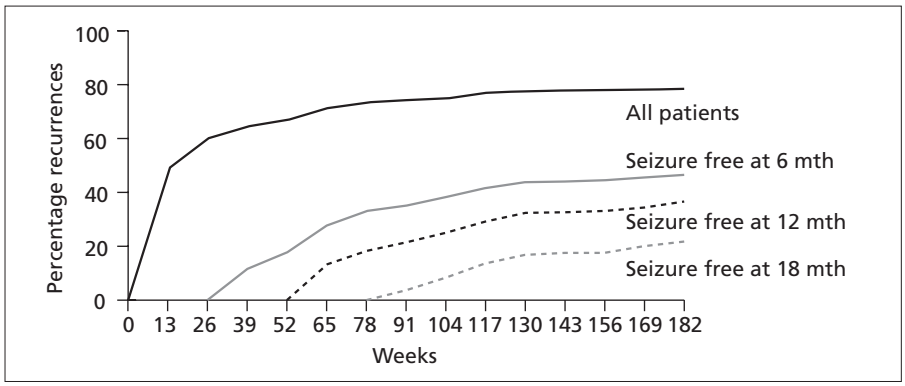

Fig. 10.1 National General Practice Study of Epilepsy: actuarial percentage of recurrence after first seizure. A study of 564 patients followed prospectively from the time of diagnosis. Within 3 years of their first seizure, 78% of patients had a recurrence of their attacks. If attacks had not recurred within 6, 12 or 18 months, the chance of recurrence was substantially reduced, falling to 44%, 32% and 17%, respectively. From ref. 15.

number of seizures of all types at presentation, presence of a neurological abnormality, and an abnormal EEG, to be significant factors in predicting future seizures [19].

Seizure aetiology was of prognostic importance in the National General Practice Study of Epilepsy [15]. Recurrence was lower in patients experiencing acute symptomatic seizures (seizures occurring in the context of an acute insult to the brain, such as stroke, head injury or encephalitis, or as a result of drugs or metabolic disturbance) than in those with idiopathic seizures or seizures due to a remote symptomatic cause. Seizures associated with a neurological deficit presumed present at birth had the highest rate of recurrence (100% by 18 months). Other factors associated with an increased risk of recurrence were age (the highest risk being for patients under the age of 16 or over the age of 59) and seizure type, recurrence being higher in patients with simple or complex partial seizures.

A meta-analysis of 16 studies examining the risk of recurrence after a first seizure was carried out by Berg and Shinnar [20], who concluded that seizure aetiology and the EEG were the strongest predictors of recurrence.

Effect of repeated seizures on risk of recurrence

Several studies suggest that the risk of recurrence is increased in patients who have a second or third seizure. Hauser *et al.* [21] studied 204 patients with a first unprovoked seizure prospectively for 5 years or until the time of the third seizure. The overall recurrence rate was lower than in many other studies, only 33% (95% CI 26–40%) having a second unprovoked seizure within 5 years of the first. Among the 63 patients who had a second seizure, the risk of further unprovoked seizures was 32% by 3 months, and 73% by 4 years. Of note in this study is that 432 patients were excluded through having had multiple seizures before their first medical evaluation, emphasizing the late presentation of many patients with epilepsy: similarly in the National General Practice Study of Epilepsy [15] only 44.7% of patients were registered at the time of their first seizure, and in the CAROLE study (Coordination Active du Réseau Observatoire Longitudinal de l'Epilepsie [10]) 52.3% of patients had already had two or more seizures at the time of presentation. In line with these studies are the observations of MacDonald *et al.* [22], who carried out a population-based study following patients newly presenting with seizures prospectively, and found that the number of seizures in the 6 months following presentation was the single most important predictive factor for both early and long-term remission of seizures.

Effect of treatment after a first seizure on risk of recurrence

In a number of studies, assessment of recurrence rate has been confounded by the fact that some patients are treated following their first seizure. Usually this is not random, with treatment being started in those patients who are considered to be at higher risk of recurrence, and, because of this, such patients are usually retained within the study to avoid bias. The effect of medication on recurrence as determined in these studies has been confusing: in the National General Practice Study of Epilepsy [15] patients starting medication after a first seizure had a lower risk of recurrence [50% (95% CI 40–61%) by 1 year], whereas other trials [11,23] have found no difference in the risk of recurrence between treated and untreated patients.

In four studies in which patients have been randomized to immediate or delayed treatment following a single seizure, however, a clear reduction in the risk of seizure recurrence has been shown. The largest such study was carried out by the MESS Study Group [14]. Overall 722 patients with early epilepsy or single seizures were assigned to immediate treatment with AEDs, and 721 to deferred treatment. The recurrence rate at 2 years was 32% for those assigned immediate treatment following a single seizure compared with 39% for those whose treatment was deferred (difference 11%, 95% CI 6.2–16.7), and 43% for those assigned immediate treatment following multiple seizures at randomization compared with 61% for those assigned deferred treatment.

The First Seizure Trial Group [13] was a multicentre study of 397 patients aged from 2 to 70 years presenting within 7 days of a first generalized tonic–clonic seizure (excluding acute symptomatic seizures and seizures associated with progressive neurological disorders, metabolic disorders or alcohol) and randomized to immediate treatment with carbamazepine, phenytoin, phenobarbital or sodium valproate, according to the preference of the physician. Analysis was on an intention to treat basis. Among the treated group, the probability of recurrence was 4% by 1 month, 7% by 3 months, 9% by 6 months, 17% by 1 year and 25% by 2 years: the corresponding figures for the untreated subjects were 8%, 18%, 41% and 45%. The hazard ratio of relapse for untreated subjects, estimated by the Cox proportional hazard model adjusting simultaneously for the prognostic predictors, was 2.8% (95% CI 1.9–4.2). The effect of treatment was even greater in those compliant with medication: among the 20% allocated to treatment who discontinued it at some time, 27% had a relapse, compared with only 15% in whom compliance was good. However, even among the group not receiving treatment, fewer than 50% had a recurrence within 2 years. A similar difference in recurrence rate was noted in two smaller studies [24,25].

Effect of treatment on long-term prognosis

There has been considerable debate about the effect of treatment on the long-term prognosis of epilepsy [26–28]. Gowers' view was that the occurrence of seizures facilitated the development of further seizures. This standpoint has been endorsed by Reynolds [29], who noted that among patients with newly diagnosed epilepsy treated with AEDs, the most important influence on prognosis was the number of seizures prior to starting treatment, along with a declining interval between seizures in patients with new epilepsy [30], suggesting an accelerating process in the development of epilepsy.

Others have argued that the hypothesis that early AED treatment improves the prognosis of epilepsy has not been proven. Chadwick [28] pointed out that the prognosis for certain epilepsy syndromes is consistent regardless of treatment. Hence benign epilepsy of childhood with centrotemporal spikes almost invariably remits by puberty, while the prognosis for relapse in juvenile myoclonic epilepsy is consistently high after withdrawal of treatment. O'Donoghue and Sander [31] noted the importance of other factors, such as aetiology, on prognosis, with remission rates for those with neurological deficits present since birth being

considerably poorer than those seen in idiopathic or cryptogenic epilepsy.

Several studies have suggested that the latter view may be correct. The FIRST Seizure Trial Group [17] found no significant difference in longer-term outcome between patients randomized to treatment after a first unprovoked seizure and those in whom treatment was delayed, although early recurrences were more common in the latter group. The MESS study similarly found that immediate antiepileptic drug treatment did not affect long-term remission in individuals with single or infrequent seizures [14]. Indirect evidence is provided by a study by Feksi *et al.* [32] of 302 patients with active seizures randomized to treatment with carbamazepine or phenobarbital in rural and semi-urban Kenya. Fifty-three per cent of patients became seizure free in the second 6 months of therapy (the two drugs being equally effective) and a further 26% had a reduction in their seizures of greater than 50% compared with their pretreatment frequency. The effect of therapy was not influenced by the duration of epilepsy (more or less than 5 years) prior to treatment or by the lifetime number of seizures before treatment.

Two surveys of people with epilepsy who remained untreated also indicate that epilepsy may run a benign course in many people. In a community-based survey undertaken in Ecuador [33], 44% of all patients who were identified as having had epilepsy had been free of seizures for at least 12 months, even though nearly two-thirds of these had never received treatment with antiepileptic drugs. Similarly, in a survey of all people living in the Kuopio University Hospital district in Finland who had had at least two unprovoked non-febrile seizures, 50 patients (4.1%) had never had their seizures treated. Of 33 patients who were followed for at least 2 years, the probability of remission was 42% at 10 years and 52% at 20 years after the onset of epilepsy [34]. The balance of evidence from the available studies is thus now firmly against the view that failure to treat early results in a worse outcome.

It has been argued that seizures might cause intellectual deterioration, which could be prevented by antiepileptic drug treatment. On occasion, falls owing to seizures cause significant head injury, which can result in cognitive problems [35]. However, with respect to seizures in general, no significant deterioration was found in the Collaborative Perinatal Project of the National Institute of Neurological and Communicative Disorders and Stroke [36], which compared a cohort of children studied from birth to the age of 7, who developed seizures between the ages of 4 and 7 years, with age- and sex-matched control subjects of the same socioeconomic level and the same IQ score at the age of 4 years. There was no significant difference in IQ from the control group at the age of 7 years. Further studies are required in this area.

Risk of mortality in early epilepsy

Until recently, little research had been carried out into sudden unexpected death in epilepsy (SUDEP) and other causes of increased mortality. Measurement of excess mortality is difficult owing to poor documentation of both epilepsy and cause of death. It is now recognized, however, that the standardized mortality ratio (SMR) in people with epilepsy is of the order of 2–3. It is higher in the first few years after diagnosis and in males, those with learning disabilities, those with symptomatic (rather than idiopathic or cryptogenic) epilepsy, those with convulsive seizures and younger age groups [37]. Causes of this excess mortality include accidental death or drowning due to seizures, death due to the underlying cause, suicide, aspiration, status epilepticus, complications of treatment and sudden unexplained death in epilepsy. The risk of the last has been estimated at between 1 in 500 and 1 in 1000 per year but is higher in those with severe epilepsy, reaching around 1 in 100 per year in those rejected for epilepsy surgery or in whom epilepsy surgery is not successful [38]. Data about death early after the onset of epilepsy are sparse. Loiseau *et al.* [39] examined the short-term mortality of epilepsy after a first epileptic seizure. Overall, 149 out of the 804 patients had died by the end of the first year of follow-up [compared with 16 expected, SMR 9.3 (95% CI 7.9–10.9)]. In nine patients death occurred during a seizure, and in a further 14 the cause of death was unknown; in this group patients died suddenly, sometimes without witnesses and without postmortem, but with a history of other disease. In total, 96 patients died of underlying disease and 30 of causes thought to be unrelated to seizures. Overall, the SMR was 0.0 for patients with idiopathic epilepsy, 1.6 (95% CI 0.4–4.1) for those with cryptogenic epilepsy and 19.8 (95% CI 14.0–27.3) for symptomatic seizures in progressive conditions. Further studies will be required to confirm the incidence of preventable death after a first seizure, which may influence the policy of waiting until a second seizure before starting treatment.

Risk of injury

Accidental injury owing to seizures is common, although studies are few and mainly retrospective. In one community-based study in which an unselected population of patients was mailed questionnaires, 24% of those having at least one seizure during the previous year had had a head injury, 16% a burn or scald, 10% a dental injury and 6% some other fracture [40]. Seizure frequency, seizure severity and sex were predictors of burns or scalds; seizure severity was a predictor of dental injury, and seizure severity and type were predictors of head injury. Another clinic-based survey of 244 patients reported that 25 had had at least one seizure-related burn requiring medical attention, all during seizures involving impairment of consciousness: 12 required hospitalization [41]. Other predictors were the lifetime total number of seizures, the presence of interictal neurological impairment and gender. Such a clinic-based study may be biased in including patients with more severe epilepsy. In a similar retrospective clinic-based survey by Neufeld *et al.* [42], 30% (91 out of 298 patients) reported trauma at some time, with 185 events in total, of which 61 were severe. However, this translated to a rate of only one seizure-related injury every 21 patient-years, with a serious injury every 64 patient-years. Head injury was the most common (55% of events). Those suffering injury had an earlier onset of epilepsy, and were more likely to have tonic–clonic seizures generalized from the onset, complex partial, myoclonic or absence seizures. The risk was less in those with secondary generalization. Even children with typical absence epilepsy are prone to injury, with 16 out of 59 patients (27%) in one study [43] having experienced an accidental injury at some time during an absence seizure (9% per person-year). Eighty-one per cent of these injuries occurred during the course of treatment. This fact, and the relatively low risk of injury per patient-year found by Neufeld

et al. [42], suggests that the risk of injury owing to seizures should play only a minor part in the decision as to when to start antiepileptic drugs.

Psychosocial morbidity

Epilepsy also causes considerable psychosocial morbidity. Patients with newly diagnosed epilepsy recruited into the National General Practice Study of Epilepsy [44] had difficulty accepting the diagnosis and feared future seizures and the effect of stigma on employment. In another study on quality of life involving more than 5000 people with epilepsy from 15 European countries, 48% worried a lot or some about their epilepsy and a similar proportion felt that it affected their plans and ambitions for the future [45]. Their feelings about themselves, and their social life, were also affected. Jacoby *et al.* [46], in a UK community-based study, found that patients with active seizures were more likely to be anxious or depressed, and to feel that their lives were significantly affected by the epilepsy: they were also less likely to be married and more likely to be unemployed or registered 'permanently sick'.

Adverse effects of drugs

Adverse effects of antiepileptic drugs affect a significant minority of patients. They range from mild to life-threatening and often adversely affect adherence to medication. They include symptoms of acute toxicity (such as the ataxia and blurred vision which occur with excess carbamazepine, phenytoin or lamotrigine); chronic toxic symptoms (for example, gingival hyperplasia occurring in about one-third of patients taking phenytoin); idiosyncratic reactions, such as skin rash; and teratogenicity.

The systems mainly affected by adverse antiepileptic drug reactions are the central nervous system, liver, skin and bone marrow [47]. The central nervous system is often affected by dose-related acute toxicity, causing sedation, lethargy and dizziness. Other adverse effects on the central nervous system include psychosis, reported with various drugs, and mood or behavioural changes, such as those seen with phenobarbital. Phenytoin, carbamazepine and phenobarbital induce the hepatic microsomal enzymes, and elevations of alkaline phosphatase and γ-glutamyltransferase, commonly seen in patients taking these drugs, are usually of no clinical significance. Occasionally severe, and sometimes fatal, hepatotoxicity occurs in association with valproate use, mainly in children under the age of 2 years receiving polytherapy [48]. Haematological abnormalities may be clinically unimportant, as is often the case with the mild leucopenia seen in 12% of people receiving carbamazepine therapy [47], but also include such life-threatening conditions as aplastic anaemia. Valproate, not infrequently, causes a dose-related thrombocytopenia, which is usually mild. Dermatological adverse effects are sometimes severe, and include Stevens–Johnson syndrome and exfoliative dermatitis.

Finally, it should be noted that antiepileptic therapy only produces complete seizure control in around 70–80% of patients. In those whose seizures are not fully controlled, antiepileptic drugs are often still beneficial, for example by reducing the severity of seizures (perhaps preventing secondary generalization), or the seizure frequency. Where seizure control is not achieved, however, it is important to minimize adverse effects by reducing the amount of medication to that required to produce the benefit. This is particularly the case where multiple drugs have been introduced and thus when the risk of toxicity is increased considerably.

When to start medication

The adverse effects mentioned above mean that certain criteria should be fulfilled before antiepileptic medication is started (Table 10.2). The diagnosis must be secure, particularly because treatment usually continues for several years. 'Trials of treatment', which rarely clarify the situation and may introduce additional complications, should be avoided. Other factors to be considered include the risk of seizure recurrence (bearing in mind the time elapsing since the last seizure), and the severity and frequency of seizures. The epilepsy syndrome is also important in determining prognosis and, as such, will affect the decision to start or withhold treatment. In the UK, it is usual not to treat after a single seizure, unless a specific factor makes recurrence more likely (for example, the presence of a cerebral tumour or of clear epileptic abnormalities in the interictal EEG). In contrast, in the USA it was, until recently, commonplace for patients to be treated after a first seizure [11], perhaps on account of driving, medicolegal issues or concern that the epilepsy might be progressive. The final decision must depend on an appreciation by the patient of all the risks and benefits of medication. The patient should also be aware of the fact that, once started, antiepileptic drugs are usually continued for at least 2 years, based on the likelihood of recurrence after withdrawal of medication, which has been shown to decrease with increasing length of time since the last seizure [49].

Wishes of the patient

Although most patients would prefer neither to have seizures nor to need medication, for some, the risk of further seizures is paramount (particularly those for whom driving is important or where seizures have caused significant psychosocial morbidity) and for others there is a concern about the concept of long-term medication, such that they would prefer to risk an occasional seizure, particularly if their attacks do not inconvenience them unduly. Although there are some patients (such as those with recurrent injuries due to seizures, or a tendency to status epilepticus) in whom one would strongly recommend treatment and others in whom the benefits of treatment are more doubtful, the co-operation of the patient is essential in all instances to ensure adherence.

Table 10.2 Criteria for starting AEDs.

Diagnosis of epilepsy must be firm
Risk of recurrence and nature of seizures must justify treatment
Good compliance must be likely
The patient should be fully counselled
The patient's wishes should be taken into account

Regardless of their wishes or expectations, it is important to discuss the purpose and limitations of antiepileptic drugs with people developing epilepsy. It is common, for example, for patients to expect that their seizures will be completely controlled as soon as treatment is commenced, or when a 'therapeutic' drug level is reached, whereas in practice, in 20–30% of patients, seizures may be refractory to treatment. In addition, the likely duration of treatment should be explained. Patients should be alerted to common possible adverse effects of medication, particularly skin rash: serious skin reactions can frequently be averted by withdrawing medication at the first sign of their occurrence.

Likelihood of adherence

Antiepileptic drugs must be taken reliably and regularly to maximize their efficacy and minimize the risk of withdrawal seizures. Compliance with antiepileptic medication is often poor [50], but may be improved by providing adequate counselling about the rationale for treatment, the need to take medication regularly, guidance on what to do if a dose is missed and the risk of withdrawal seizures, by the use of drugs with a low incidence of adverse effects and by simplifying the treatment regime. Adverse effects experienced early are especially likely to cause dissatisfaction, and care should be taken to build up the dose of such drugs as carbamazepine sufficiently slowly to avoid this complication. Alcohol may be another reason for poor compliance, either because of patients' concern about 'mixing' it with antiepileptic drugs, or as a result of the effects of alcohol abuse itself.

Type of epilepsy seizures or syndrome

Seizure type (characterized according to the classification of the Commission on Classification and Terminology of the International League against Epilepsy [1]) is important in determining the choice of antiepileptic drug along with the epileptic syndrome, which also affects prognosis [2]. Some types of epilepsy, such as benign childhood epilepsy with centrotemporal spikes, confer a benign prognosis, and treatment may not be required. Although generalized tonic–clonic seizures may occur in this syndrome, the attacks often take the form of simple partial seizures occurring during sleep. In contrast, in such conditions as Lennox–Gastaut syndrome, the chance of complete seizure control is likely to be small. Juvenile myoclonic epilepsy, in which myoclonic jerks, usually accompanied by generalized tonic–clonic seizures, develop during adolescence, commonly responds well to medication (particularly valproate), but carries a high risk of relapse (of the order of 90%) if medication is withdrawn.

The seizure types occurring in a particular syndrome will also guide choice of medication. Thus, while carbamazepine is a useful drug in the treatment of generalized tonic–clonic seizures, it is usually avoided if these form part of a generalized epilepsy syndrome which also includes absence seizures and myoclonic jerks, since these may be exacerbated by this drug (and also by phenytoin). The three seizure types commonly occurring in idiopathic generalized epilepsy (generalized tonic–clonic seizures, myoclonic jerks and absence seizures) are all commonly responsive to sodium valproate, while ethosuximide is effective only against generalized absence seizures. For these reasons, every effort should be made to classify the epilepsy by seizure type and syndrome, if possible.

Which drug to use

Until recently, there was a dearth of randomized controlled trials of antiepileptic drugs, leading to geographical variation in their use. Thus, phenytoin was the most commonly used antiepileptic drug in North America [51], carbamazepine was popular in the UK for seizures of partial onset, and in Italy, the drug most frequently prescribed in the FIRST study [17] following a first generalized tonic–clonic seizure was phenobarbital, which was given to 50% of the treated patients.

Valproate has traditionally been used as the drug of choice in idiopathic generalized epilepsies. In a study of standard and new antiepileptic drugs (SANAD) [52], in which valproate was compared with lamotrigine and topiramate for generalized and unclassifiable epilepsy, valproate was better tolerated than topiramate and more efficacious than lamotrigine, and was recommended as drug of first choice in many patients with these epilepsies. However, although it is often well tolerated in the short term, weight gain, hair loss and dose-related tremor may be problematic in the longer term. The issue of teratogenicity is also of major concern, with the incidence of major malformations in one study in babies of women taking valproate during pregnancy being 6.2% (95% CI 4.6–8.2%) compared with 2.2% (1.4–3.4%) for carbamazepine and 3.2% (2.1–4.9%) for lamotrigine [53]. Lamotrigine may thus be a reasonable alternative as first choice in women of child-bearing age with generalized epilepsy. The SANAD study has been criticized for including unclassifiable epilepsies with generalized epilepsies. In children with absence seizures as their sole seizure type, ethosuximide may be used. Topiramate is also licensed for the treatment of primary generalized tonic–clonic seizures in adults and children over the age of 6 years.

Carbamazepine is commonly used as drug of first choice in the UK and some other European countries for seizures of partial onset, although, as noted above, phenytoin remains popular in the USA. The SANAD study [54] randomized 1721 patients with partial epilepsy to treatment with carbamazepine, gabapentin, lamotrigine, oxcarbazepine or topiramate. The time to treatment failure for any reason (inadequate seizure control or unacceptable adverse events) was better for lamotrigine than for any of the other drugs, largely because it had fewer adverse effects than carbamazepine, which had similar efficacy. However, it has been suggested that the target dose of 600 mg for carbamazepine might have adversely affected its tolerability when compared with lamotrigine. Levetiracetam was not included in the SANAD study, but is licensed in the UK for use as a monotherapy for the treatment of partial-onset seizures with or without secondary generalization in adults and children over 4 years of age.

The effects of carbamazepine, phenobarbital, phenytoin and primidone were compared in a randomized double-blind study of 622 adults with partial and secondarily generalized tonic–clonic seizures carried out by Mattson *et al.* [55]. The retention rate was highest with carbamazepine and phenytoin, with primidone having the worst retention rate, mainly due to adverse effects.

Carbamazepine was reported to provide significantly better total control of partial seizures (43%) than phenobarbital (16%) or primidone (16%), with phenytoin providing intermediate control (26%). A later study by Mattson *et al.* [56] compared valproate with carbamazepine for the treatment of complex partial and secondarily generalized tonic–clonic seizures in adults. The two drugs had similar efficacy in the treatment of tonic–clonic seizures, but carbamazepine gave better results for four of the five outcome measures for complex partial seizures, and was also the preferred drug when adverse effects were included in the analysis. On the other hand, in two prospective randomized studies in patients with newly diagnosed partial or primarily generalized tonic–clonic seizures carried out in the UK, one in adults [57] and one in children [58], valproate and carbamazepine were found to have virtually equivalent efficacy, a finding which applied to both subgroups of patients with partial and with generalized epilepsy, respectively.

Oxcarbazepine has been compared with sodium valproate, carbamazepine and phenytoin in separate studies of adults with newly diagnosed epilepsy. There was no statistically significant difference in efficacy between oxcarbazepine and any of the other three drugs. Comparison with carbamazepine [59] showed that oxcarbazepine caused fewer 'severe' side-effects than carbamazepine, although, again, titration of the latter was carried out relatively quickly. In the comparison of oxcarbazepine with valproate [60], there was no significant difference between the two drugs with regard to either efficacy or adverse effects. The study comparing oxcarbazepine with phenytoin [61] showed no difference between the groups with respect to the total number of premature discontinuations, but with regard to those due to adverse effects, there was a statistically significant difference in favour of oxcarbazepine. Oxcarbazepine also showed superior tolerability when compared with phenytoin in a randomized trial in children and adolescents [62].

Newer drugs are invariably more costly than the older agents available and, where health resources are limited, they must justify their use by clear benefits. It will become easier to define their place in treatment with greater experience in using them and as a result of the trials currently under way. Although the issues of teratogenicity, weight gain and possibly polycystic ovaries may lead to lamotrigine (or another new drug) being used as an alternative to valproate in women of child-bearing age, valproate remains the drug of choice in idiopathic generalized epilepsy in other circumstances, and lamotrigine or carbamazepine are appropriate choices in people with epilepsy of partial onset.

The guidelines issued by the National Institute for Clinical Excellence [63] recommend that the newer AEDs (gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate and vigabatrin), within their licensed indications, be used for the management of epilepsy in people who have not benefited from treatment with the older AEDs, such as carbamazepine or sodium valproate, or for whom the older AEDs are unsuitable because there are contraindications to the drugs, they could interact with other drugs the person is taking (notably oral contraceptives), they are already known to be poorly tolerated by the individual, or the person is a woman of child-bearing potential. In the light of the additional information now available from the SANAD study, it seems reasonable to choose either carbamazepine or lamotrigine as first-line medication for the treatment of partial-onset seizures, and valproate as first-line treatment for generalized seizures, except in women of child-bearing age, in whom lamotrigine may be a more appropriate first choice of treatment.

Women's issues

Epilepsy has specific implications for women, both on account of the effects of epilepsy and AEDs on the reproductive cycle and on the unborn child and because of the effects of pregnancy and hormonal changes on the epilepsy. The issue of teratogenicity has received considerable attention. The risk of major congenital malformations, usually estimated at around 2–3% in the general population, is increased in women taking AEDs during the first trimester of pregnancy. Several pregnancy registers have been established to estimate the relative risk for different AEDs. The UK Pregnancy and Epilepsy Register [53] found that the overall risk of a major congenital malformation was 4.2% (95% CI 3.6–5.0%): it was higher in those on polytherapy [6.0% (95% CI 4.5–8.0%)] than those on monotherapy [3.7% (95% CI 3.0–4.5%)]. The rate of major congenital malformations was significantly greater in the children of women taking valproate [6.2% (95% CI 4.6–8.2%)] than those taking carbamazepine [2.2% (95% CI 1.4–3.4%)]. The risk in babies of women taking lamotrigine was 3.2% (95% CI 2.1–4.9%). Data for other AEDs are awaited.

The possibility has also been raised that certain AEDs taken during pregnancy may adversely affect cognitive function in the unborn child. Adab *et al.* [64] found a significantly lower mean verbal IQ in children of mothers taking valproate than those taking other AEDs. Other studies have produced conflicting results about the effect of AEDs on cognition [65] and further study in this area is required.

The fact that AEDs can reduce the efficacy of the oral contraceptive pill due to induction of the hepatic cytochrome P450 system is also now widely recognized. The drugs involved include carbamazepine, oxcarbazepine, phenytoin, phenobarbital, primidone and, at doses >200 mg/day, also topiramate. The chance of an unwanted pregnancy can be reduced by the use of a combined oral contraceptive pill containing at least 50 μg of oestrogen (a higher dose may be required if breakthrough bleeding occurs).

Some reports have suggested that there may be an increased incidence of polycystic ovaries in women with epilepsy taking sodium valproate [66]. At the time of writing there remains considerable debate about the general applicability of these findings. However, if proven, they may influence the future choice of AEDs in women with epilepsy, as would any difference in rates of teratogenicity between AEDs. In the event of this occurring, it would affect the choice of drug in all women of child-bearing age, including adolescents, as a high proportion of pregnancies are unplanned (56% in the community-based study of Fairgrieve *et al.* [67] of women with epilepsy).

How to start medication

In the majority of people with epilepsy, satisfactory control is achieved with a single AED, with only 10–15% of patients benefiting from polytherapy [68]. A drug appropriate to the seizure type should be chosen (Tables 10.3 and 10.4), giving preference

Table 10.3 Choosing medication for generalized seizures.

First-line drugs (used as monotherapy)
Valproate – all seizure types
Lamotrigine – generalized tonic–clonic seizures, seizures associated with Lennox–Gastaut syndrome (adults and children over 12 years)
Carbamazepine – generalized tonic–clonic seizures only (may exacerbate absence seizures and myoclonic jerks)
Ethosuximide – absence seizures only
Topiramate – generalized tonic–clonic seizures (adults and children over 6 years)
Second-line drugs (used after failure of appropriate first-line drugs)
Clobazam – adjunctive treatment for all seizure types (adults and children over 3 years)
Levetiracetam – adjunctive treatment for generalized tonic–clonic seizures and myoclonus (adults and children over 4 years)
Topiramate – generalized tonic–clonic seizures and seizures associated with Lennox–Gastaut syndrome (adults and children over 2 years if given as adjunctive treatment)
Clonazepam – all seizure types
Phenobarbital – all seizure types except absence seizures
Phenytoin – generalized tonic–clonic seizures (may exacerbate absence seizures and myoclonic jerks)

Table 10.4 Choosing medication for partial-onset seizures.

First-line drugs (used as monotherapy)
Carbamazepine
Lamotrigine
Levetiracetam
Oxcarbazepine
Topiramate
Valproate
Second-line drugs (used after failure of appropriate first-line drugs)
Clobazam – adjunctive treatment (adults and children over 3 years)
Clonazepam
Gabapentin – monotherapy and adjunctive treatment (adults and children over 6 years)
Phenobarbital
Phenytoin
Pregabalin – adjunctive treatment (adults over 18 years)
Primidone
Tiagabine – adjunctive treatment (adults and children over 12 years)
Vigabatrin – initiated and supervised by specialists, adjunctive treatment for partial seizures with or without secondary generalization not controlled by other treatment, also used in infantile spasms as monotherapy
Zonisamide – adjunctive therapy for refractory partial seizures with or without secondary generalization (adults over 18 years)

to an agent whose adverse effect profile is least likely to interfere with the quality of life of the patient. Both the dosage required to obtain a particular level of the drug in the blood and the level required to achieve control of the seizures vary from person to person, as does the level at which symptoms of toxicity are experienced. In order to minimize adverse effects, particularly acute idiosyncratic reactions and symptoms of toxicity, it is recommended that a single first-line drug for the seizure type be given in a small dose, the dose being gradually increased either until complete control of seizures is obtained or until symptoms of toxicity occur (Table 10.5). In practice, if the seizures are infrequent, such a strategy may mean prolonging the titration phase

Table 10.5 How to start AEDs.

Use a first-line drug for the seizure type
Start at a low dose
Gradually increase until seizures stop or adverse effects develop
If seizures remain uncontrolled, review the diagnosis and underlying aetiology
Substitute gradually another first-line drug for the seizure type and increase dosage until seizures stop or adverse effects develop
If necessary, try drug combinations

excessively, and in such circumstances it may be reasonable to increase the dose of medication to an 'average' dose regardless of the occurrence of seizures. For example, most adults with initially diagnosed epilepsy will respond to dosages of 400–600 mg/day carbamazepine or 600–1000 mg/day sodium valproate [69]. Measurement of serum drug levels is helpful as a guide to dosage in the case of phenytoin, which has non-linear pharmacokinetics. Drug level monitoring is occasionally helpful in the case of carbamazepine, phenobarbital and ethosuximide, but is usually unhelpful in the case of valproate and the newer AEDs.

If the patient's seizures fail to be controlled by a single AED, the diagnosis should be reviewed. The possibility of a progressive underlying aetiology should also be considered, and further neuroimaging may be warranted. If the diagnosis is confirmed, a second first-line AED for the seizure type should be added and the original drug should be gradually withdrawn. Many physicians prefer to complete the titration of the new drug before beginning withdrawal of the original medication so that any adverse effects of the drug change can be correctly attributed (although, in some cases, tolerability problems may result from drug interactions) and to avoid the situation in which the patient is receiving two drugs, both at suboptimal doses. Others, however, initiate the tapering off of the original drug whilst the second medication is being gradually introduced. Only if two first-line drugs, given individually, fail should the use of polytherapy be contemplated as a longer-term measure.

Provoking factors for seizures

If seizures are consistently provoked by specific factors, such as excess alcohol or flickering lights, it may be possible to control them without medication by avoiding the relevant stimuli. However, most patients will have some spontaneous seizures in addition to the provoked events, and will therefore require AEDs.

Excess alcohol intake (or its abrupt withdrawal) was thought to be the cause of seizures in 6% of patients registered with the National General Practice Study of Epilepsy [70], and was particularly common in people between the ages of 30 and 39 years, in whom it was responsible for 27% of cases. Drug treatment may be particularly difficult in such patients: adherence is likely to be poor and the adverse effects of alcohol and AEDs on the liver may be additive. Sleep deprivation can also precipitate seizures in susceptible individuals and may be associated with alcohol abuse. Stress, fever or other illness, sleep, heat, flashing lights and, in women, menstruation were identified as seizure

precipitants by patients undertaking a survey at a tertiary care centre [71]. Certain drugs, including most antidepressants and other psychotropic agents, lower the seizure threshold; however, although this may influence choice of drug it is important that mental health disorders are treated appropriately, despite the epilepsy. Withdrawal of benzodiazepines and other sedatives should be undertaken slowly to avoid withdrawal seizures.

Photosensitivity, in which generalized epileptic discharges occur in response to intermittent photic stimulation, occurs in about 5% of people with epilepsy. It is seen particularly in people with idiopathic generalized epilepsy (often developing in childhood or adolescence) but also occurs in some people with occipital epilepsy. The risk of seizures occurring as a result of photosensitivity may be reduced by using a small television screen and increasing the viewing distance, using a remote control to change channels, closing one eye or using polarized spectacles and reducing the screen contrast and brightness.

Other counselling

Education of the person developing epilepsy is an important part of the initial management (Table 10.6 provides an example of a counselling checklist). Epilepsy nurse practitioners, and also epilepsy societies, may be helpful in reinforcing the information provided by the physician and providing written information. The diagnosis of epilepsy carries significant implications for work and leisure, as discussed above, but is also a frightening experience leading to loss of confidence, and often a reluctance to undertake normal daily activities [72].

Information provided to the patient should explain the nature of epilepsy, its causes and the purpose of the various investigations performed (many patients are confused, for example, by the fact that they are diagnosed as having epilepsy despite having a normal EEG). First aid measures for treating seizures should be discussed with the patient and those relatives and friends for whom they deem it appropriate. The risks of seizures (including SUDEP) should be addressed in a sensitive manner, and measures to prevent injury (such as the avoidance of unguarded heights, unguarded fires, swimming alone) in the event of a further seizure discussed. Driving laws vary from country to country, and the patient must be educated about the relevant regulations and of the need to inform the driving authorities, where it is incumbent on them to do so. The need to lead as normal a life as possible within the confines of taking reasonable care, however, should be emphasized: most sports are possible, though some, such as boxing, wrestling, pot-holing and scuba diving, should be avoided.

The issues relating to drugs mentioned above should be discussed. In some countries, patients with epilepsy are eligible to receive free medication. The possibility of interactions with other drugs, especially the oral contraceptive pill, is of particular importance. Patients should be advised to avoid excess alcohol, sleep deprivation and other factors likely to precipitate seizures: on the other hand, they should be reassured in the case that, for example, photosensitivity is *not* an issue. The risk of teratogenicity should be discussed with girls and women of child-bearing age, as should the importance of planning any pregnancy, prior medication review, and the addition of folic acid before pregnancy and for the first trimester.

Some occupations, particularly those requiring a driving licence, or those in which the person with epilepsy has sole responsibility for the safety of another, may not be possible. However, for many, employment can continue to be safely undertaken, particularly with education of the employer. It is important that children with epilepsy be treated in a similar manner to other children, except for simple safety measures to avoid injury; the morbidity attributable to overprotection and underexpectation of such children is often considerably greater than the effect of the seizures themselves. Adequate schooling is also important; it is usually possible for children suffering seizures to rejoin their class after a short recovery period, rather than being sent home on each occasion. On the other hand, teachers and parents should be alert to the possible effects of ongoing epileptic discharges and of AEDs on cognition, with appropriate action being taken if these occur.

Table 10.6 Counselling checklist for people developing epilepsy.

Nature of epilepsy
First aid management of seizures
Avoidance of precipitating factors, including alcohol and sleep deprivation
Purpose of medication, and likely duration
Nature of common adverse effects of medication
Need to take medication regularly
Risks of seizures and advice regarding common hazards
Laws regarding driving
Interaction with other drugs, especially oral contraceptive pill (where relevant)
Possibility of teratogenicity, where relevant

11 Management of Chronic Active Epilepsy in Adults

Simon D. Shorvon

UCL Institute of Neurology, University College London, London, UK

Chronic active epilepsy can be defined as *epilepsy in which seizures are still occurring 5 or more years after the initiation of therapy*. Chronic epilepsy is more difficult to treat than newly diagnosed epilepsy, a fact that has been clearly noted by and interested researchers for at least 150 years. William Aldren Turner, for instance, in 1907 [1], noted in his series of 366 new cases of epilepsy that initial remission occurred in about 50% on therapy (usually with bromide) and long-term remission (effectively a 'cure') in 23.5%. However, by the time epilepsy had persisted and become chronic, he found that the use of bromide was far less successful and indeed 'had relatively little value', and, although drugs often reduced the frequency of seizures, long-term seizure remission was uncommon. Because of this, he emphasized the importance of early diagnosis and early treatment, and indeed went further by recognizing a 'prodromal stage' before seizures actually developed, in which therapy could be preventative. His observations on the relatively good response to therapy in new patients, in contrast to the poorer response in chronic active cases, has been repeatedly confirmed on many occasions since.

In a review of prognosis in epilepsy in 1984 [2], it was pointed out that the most important single predictor of prognosis (in non-syndromic epilepsy) was the temporal stage the epilepsy had reached (i.e. the length of time that epilepsy had been active). It was demonstrated, *inter alia*, that with contemporary therapy: (1) the prognosis in newly diagnosed epilepsy was excellent; (2) the prognosis in chronic established epilepsy was much less good; (3) the longer the epilepsy remained active, the less likely was seizure control to be achieved; and (4) the longer-term prognosis could be, to a large extent, predicted from the course of epilepsy in the few years from the onset of therapy. These points have also been repeatedly confirmed since. In a paper in 1986 [3], it was also shown that the patterns of seizures over time was relatively consistent and that epilepsy tended to run 'true to form'. Whether this is still the case, in an era in which drug therapy has greatly expanded, is questionable and needs to be further researched.

Although it is clear that the response to therapy in new cases is excellent, and better than in chronic cases, this does not mean that the response to therapy in chronic epilepsy or prognosis is necessarily poor [4–7]. A substantial number of patients obtain worthwhile seizure reductions on therapy and a smaller number obtain prolonged remissions, albeit on therapy. In many, quality of life can be greatly improved by appropriate therapy. Furthermore, the term chronic epilepsy encompasses a wide range of different conditions, syndromes and aetiologies. Some syndromes have an almost inevitably poor prognosis, but in others, prolonged remission is to be expected (the treatment of specific syndromes or aetiologies is not covered in this chapter, but is described in other chapters in section 2 of this book). Severity also varies, and patients with mild epilepsy, even if chronic, are not necessarily inconvenienced by the condition and may not require therapy. The response to therapy also depends on age and on aetiology (and these aspects too are described elsewhere in this section). However, the prospect of 'cure' is still, for most adult patients with chronic epilepsy, elusive.

Extent of response to therapy in chronic active epilepsy

In the last 18 years, 14 new antiepileptic drugs have been licensed, all of which have shown unequivocal efficacy in clinical trials (Table 11.1). This greater range of therapies might be expected to have influenced prognosis. Indeed, this seems very likely to be the case, although no recent large-scale long-term studies in unselected populations have been carried out to confirm this. Reduction in seizure numbers or seizure severity is commonly the result of the introduction of previously untried medications (and this has been demonstrated in controlled and randomized clinical trial settings as well as in large-scale clinical studies, including studies of retention of therapy). Furthermore, in several recent hospital-based studies, in selected populations of patients with chronic epilepsy, it has been shown that a substantial number of patients whose epilepsy is not initially controlled can achieve long-term remission on the introduction of newer therapies. In a study of 155 patients with chronic epilepsy (often severe), a change of drug therapy resulted in seizure remission (defined as a 12-month or longer period without seizures) in 28% [7]. It is likely that this encouraging response is, at least in part, due to the greatly increased range of different antiepileptic drugs now available, and indeed, in this group, over an observation period of 5 years or so, even if the first change did not result in seizure response, when a second drug introduction was made, a further 14% of the patients who failed at first change attained seizure freedom, and 15% after a third change in those who failed after a first and second change. The authors concluded that it was incorrect to view intractability as inevitable if seizure control is not obtained with initial medication or within a few years of the onset of therapy. The drug most commonly started in this study was levetiracetam (in 101 patients), but other new drugs also resulted in seizure freedom, as one would expect from the findings of clinical trials. In this study, 25% became seizure free (defined as in remission on the drug at the

[a]Zonisamide was licensed in 1989 in Japan and South Korea as Excegran (manufactured by Dainippon Pharmaceuticals).
From Shorvon SD. A history of the drug treatment of epilepsy in the century of the ILAE: the second 50 years, 1959–2009. *Epilepsia* 2009; **50** (in press).

time of last appointment and follow-up for at least 12 months) [8]. More recently, Callaghan *et al.* [9] reported a series of 246 patients with chronic active epilepsy (having at least one seizure per month and having not responded positively to at least two antiepileptic drugs) and followed the cases prospectively for 3 years in the clinic. Nineteen per cent were in 6-month terminal seizure remission. Similar findings were made by others.

There is a regrettable tendency in many clinics to offer no new therapy when faced with a patient with chronic epilepsy, and this should be resisted. As these studies show, it is important to take an active and explorative approach to drug therapy in these patients (and there are many), in whom the search for seizure freedom is the major priority. The application of a systematic protocol to the treatment of chronic epilepsy will improve seizure control in a substantial proportion of cases.

Intractable (refractory) epilepsy and drug resistance

The term 'intractable' (or refractory) epilepsy is widely used, but difficult to define. It is, of course, a retrospective definition and a 'prediction'. As new therapy is introduced, the seizures in some patients with hitherto refractory epilepsy become controlled, as they do after successful epilepsy surgery. It is arbitrary as there are at least 10 first-line antiepileptic drugs for refractory partial seizures, and far more combinations: with 10 first-line antiepileptic drugs there are 45 different two-drug and 36 different three-drug combinations. All combinations cannot, therefore, be tried. It seems appropriate to use different definitions for different purposes, as suggested by French and colleagues [10,11]. An excellent suggestion is to define intractability by the number of ineffective drugs tried; thus second-level intractability is defined as the failure of two drugs, third-level intractability by the failure of three drugs, and so on [12].

However, whatever definition is used, all are agreed that there are identifiable clinical factors which allow some sort of prediction to be made. In non-syndromic adult epilepsy, the prognosis is generally worse in the presence of frequent seizures, mixed seizure types, additional intellectual impairment, structural pathologies, pathologies with a large extent, cortical pathologies (especially in frontal and temporal regions), additional neurological handicaps or severe psychiatric disorder. To what extent each of these factors worsens prognosis has not been fully established, and there are many patients with chronic epilepsy who present to epilepsy clinics in whom an accurate prediction of prognosis is not possible. Some of the individual childhood syndromes have well-defined and consistent prognoses, both good and bad.

Another simplistic concept is that drug resistance is, at least to an extent, a unitary concept genetically based and related to genetically determined variations in cerebral drug transporters or drug targets (see Chapter 8). In other words, single polymorphisms will be present which if identified could be used to predict response to therapy. Although an initially attractive hypothesis, this theory ignores the variation in other factors. Drug response is clearly affected, for instance, by aetiopathology (i.e. the aetiology, extent or location of lesions), by physiology (type of seizures, physiological basis, syndrome), in the type of medication (different drugs work by different mechanisms) or in other medicinal aspects (dose, serum level, interactions) and by variation over time (brain maturation, time-linked expression of epilepsy, seizure type or syndrome). For these reasons, it seems highly unlikely that a single pharmacogenetic mechanism will be found to account for drug resistance and to be useful in predicting drug response except in exceptional circumstances. Another curious fact about resistance is that it may develop after a long period of remission. In a study by Berg *et al.* [13] 26% of 33 patients presenting for epilepsy surgery reported a previous period of remission (1–28 years). Similarly, as shown above, long remission can occur in previously intractable epilepsy.

Treatment approach for chronic active epilepsy in adult patients

As mentioned above, there are many different types of epilepsy, and the management can vary, especially in children. A detailed description of therapy in childhood epilepsy and in specific epilepsy syndromes and aetiologies can be found in other chapters in Section 2 of this book. Here, the approach to therapy in a typical case of non-syndromic adult chronic epilepsy is outlined, as these cases make up the bulk of those attending specialist epilepsy clinics worldwide. Of course, individuals have different requirements and therapy should be tailored to individual need. Nevertheless, broad principles apply to most cases, and these are the subject of this section. In such cases, the approach to management is divisible into two clearly distinct phases: assessment and treatment (Table 11.2).

Assessment

Faced with a new presentation of chronic epilepsy, the physician should gather and document information which will form the basis of future recommendations for treatment. The following factors should be assessed – this list of factors is not exhaustive but is the minimum required before considering therapy.

Confirming the diagnosis of epilepsy

It may be surprising to know that 20% or more of patients referred to neurology clinics with chronic epilepsy do not in fact

Table 11.2 Principles of treatment in chronic active epilepsy.

Assessment
Review diagnosis and aetiology (history, EEG, imaging)
Classify seizures and syndrome
Review compliance
Review drug history
Which drugs were useful in the past
Which drugs were not useful in the past
Which drugs have not been used in the past
(also dose, length of therapy, reasons for discontinuation)
Review precipitants and non-pharmacological factors
Review co-morbidities
Treatment plan
Decide and document proposed sequence of drug 'trials'
Decide what background medication to continue
Decide upon the sequence of drug additions and withdrawals
Decide the duration of drug 'trials'
Decide when to do serum level monitoring
Consider surgical therapy
Consider non-pharmacological measures (lifestyle, alternative therapy, etc.)
Recognize the limitations of therapy
Counsel and provide information on the above points to patients

suffer from epilepsy at all [14]. Many different conditions may be confused with epilepsy, but the most common are psychogenic seizures, reflex syncope and cardiac arrhythmia. The differential diagnosis of epilepsy is discussed in detail in Chapter 4. As emphasized there, an eye-witness account of the attacks should be obtained and will usually be diagnostic. If there is any doubt, the previous medical records should be inspected and attention paid to previous electroencephalograms (EEGs). A series of normal EEG results should alert one to the possibility that the attacks are non-epileptic, although this is not an infallible rule. A video recording of an attack is extremely helpful in deciding its aetiology – and many patients are able to have their attacks recorded on a camcorder or a mobile phone. Such recordings often obviate the need for video-telemetry and it is surprising how often a short amateur recording is diagnostic.

Establishing the aetiology of the seizures

The cause of the epilepsy must be established. Specific cerebral conditions may require therapy in their own right, and prognosis and response to therapy are strongly influenced by cause. A summary of the causes of epilepsy is given in Chapter 3. A high-quality MRI scan is a mandatory test in an adult patient with chronic epilepsy without a known cause, and not infrequently will reveal a previously undetected cause [15,16]. The therapy of epilepsy is often uninfluenced by the cause but establishing a cause almost always makes the clinical management of a patient with chronic epilepsy easier and allows a more accurate prognosis to be made, which in its turn influences how active the therapeutic approach should be.

Classifying seizure type and syndrome

As is noted repeatedly throughout this book, epilepsy is a highly heterogeneous condition, and varies considerably in form and severity. It is important to classify formally the seizure type and, where appropriate, the epilepsy syndrome, as these classifications will guide the choice of medication. This will often require electroencephalography. The choice of drug for each seizure type is discussed in detail in Chapter 30.

Documenting previous treatment history

The response to an antiepileptic drug is often relatively consistent over time. A knowledge of the previous treatment history, therefore, is vital to the formulation of a rational treatment plan (see Treatment, below). This aspect of assessment is commonly ignored and yet is of the greatest importance. It is important to ascertain what previous drugs have been tried, at what dose (if possible), for how long, in what combinations and with what result. The reasons for discontinuation should be defined.

Reviewing compliance

Poor compliance can also be a reason for poor seizure control, and it is important to ascertain how adequate drug-taking has been. A drug should not be presumed to be ineffective if it was taken erratically. Methods for improving compliance are listed in Table 11.3.

Identifying and treating other factors and co-morbidities

The co-morbidities of epilepsy can influence markedly the response to therapy. The medical and psychiatric co-morbidities are summarized and their effects on therapy are discussed in detail in Chapters 20 and 21.

Treatment

Treatment of chronic epilepsy (as all epilepsy) should be based on balancing the benefits of therapy against the potential risks – and where to strike this balance is a personal decision for each patient. The role of the physician in this regard is to provide estimates of the potential benefits and risks and to discuss these with the patient [17].

The key step is the formulation of an *antiepileptic drug treatment plan*. This plan should be based on the assessment. The plan should take the form of a stepwise series of treatment trials, each to be tried in turn if the previous trial fails to meet the targeted level of seizure control. The plan should be devised to trial suitable antiepileptic drugs in turn, in a reasonable dose, singly or as two-drug (or more rarely three-drug) combinations. The sequence of drugs to be tried should be clearly documented and discussed with the patient.

Such a planned sequence of drug changes can take months to complete and requires patience and tenacity. The procedure should be explained in advance to the patient to maintain

confidence and compliance. Ideally, each antiepileptic drug should be tried in a reasonable dose added to a baseline drug regimen (usually one or two other antiepileptic drugs) which does not change. The duration of the trial will depend largely on seizure frequency, and the higher the frequency the shorter the trial. This topic is discussed further in Chapter 9.

In formulating a plan, decisions have to be made about the therapeutic target (i.e. seizure freedom, seizure reduction, side-effect reduction), which drugs to trial and in what sequence, which drugs to retain as a baseline regime, which drugs to withdraw and the duration of each treatment trial.

Choice of drug to trial

The choice of drugs is discussed in detail in Chapter 30. The drugs should be selected on the basis of seizure type/syndrome (Table 30.2), and other considerations covered in Chapter 30. The drug should usually be one that has not been used before, or not previously used in optimal doses, or which has been used and did prove helpful. Rational choices depend on a well-documented history of previous drug therapy. The initial dose and maximum incremental increases in dose in routine practice are shown in Chapter 9 (Table 9.2).

Drug choice is an individual decision for a patient to make and will depend on potential side-effects and other factors. People differ in their willingness to risk adverse effects, or to try new therapy, and patients' preferences depend on such aspects as age, gender, co-morbidity, co-medication, drug formulation and dosing frequencies, risks in pregnancy and a range of social aspects. Cost is also a consideration in some health-care settings (Table 11.4).

Choice of drug to retain as the baseline regime

It is usual to aim for therapy with either one or two suitable antiepileptic drugs. If drugs are being withdrawn, it is wise to maintain one drug as an 'anchor' to cover the withdrawal period.

Table 11.4 Factors influencing choice of treatment regimen in epilepsy.

Personal patient-related factors
Age and gender
Co-morbidity (physical and mental)
Social circumstances (employment, education, domestic, etc.)
Emotional circumstances
Attitude to risks of seizures and of medication
Factors related to the epilepsy
Syndrome and seizure type
Severity and chronicity
Aetiology (less important in chronic epilepsy)
Factors related to the drug
Mechanism of action
Strength of therapeutic effects
Strength and nature of side-effects
Formulation
Drug interactions and pharmacokinetic properties
Cost

This list illustrates the sort of factors which influence drug choice. It is not comprehensive, and the importance of factors will vary from individual to individual. A more detailed treatment of this topic is covered in Chapter 30.

The advantages and place of monotherapy versus polytherapy are discussed in Chapter 9.

Drug withdrawal

Drug withdrawal needs care. The sudden reduction in dose of an antiepileptic drug can result in a severe worsening of seizures or in status epilepticus – even if the withdrawn drug was apparently not contributing much to seizure control. Why this happens is not clear. Experience from telemetry units suggests that most withdrawal seizures have physiological features similar to the patient's habitual attacks. It is therefore customary, and wise, to withdraw medication slowly. This caution applies particularly to barbiturate drugs (phenobarbital, primidone), benzodiazepine drugs (clobazam, clonazepam, diazepam) and to carbamazepine. The fastest decremental rates that are recommended in normal clinical practice are shown in Chapter 9 (Table 9.2). In many situations, even slower rates of withdrawal are safer and to be preferred. The only advantages to fast withdrawal are better compliance and the faster establishment of a new drug regimen.

Only one drug should be withdrawn at a time. If the withdrawal period is likely to be difficult, the dangers can be reduced by covering the withdrawal period with a benzodiazepine drug (usually clobazam 10 mg/day), given during the phase of active withdrawal. A benzodiazepine can also be given if there is clustering of seizures following withdrawal.

It is sometimes difficult to know whether seizures during withdrawal are a result of the withdrawal or simply the background epilepsy. Whenever possible, a long-term view should be taken and over-reaction in the short-term reaction to seizures should be avoided.

Sometimes the simple withdrawal of a drug will result in improved seizure control by reducing side-effects, assuring better compliance, and reducing drug interactions.

Drug addition

New drugs added to a regimen should also be introduced slowly, at least in the routine clinical situation. This results in better tolerability, and is particularly important when adding benzodiazepines, carbamazepine, lamotrigine, levetiracetam, primidone or topiramate. Too fast an introduction of these drugs will almost invariably result in side-effects. It is usual to aim initially for a low maintenance dose but in severe epilepsy higher doses are often required.

Concomitant medication

Changing the dose of one antiepileptic (either an increment or a decrement) can influence the levels of other drugs, and the changing levels of concomitant medication can contribute to changing side-effects or effectiveness.

Limits on therapy

Drug therapy will fail in about 10–20% of all patients developing epilepsy, and a higher proportion of those with chronic epilepsy. The goal of therapy in these cases is not seizure freedom but the best compromise between inadequate seizure control and drug induced side-effects. Individual patients will take very different views about where to strike this balance.

Table 11.5 Topics for information provision and counselling for all patients with epilepsy.

Nature of epilepsy
First aid management of seizures
Avoidance of precipitating factors, including alcohol and sleep deprivation
Purpose of medication, and likely duration
Nature of common adverse effects of medication
Need to take medication regularly
Risks of seizures (including SUDEP) and advice regarding common hazards
Legal aspects of driving
Interaction with other drugs

Serum level monitoring

For drugs whose effectiveness and/or side-effects are closely linked to serum level – notably phenytoin, carbamazepine and phenobarbital – measurement of the serum level can be helpful in deciding dosage. Monitoring serum level is particularly important in the case of phenytoin, which has a non-linear relationship between dose and serum level.

Drug interactions are another important aspect of therapy with antiepileptic drugs. They are common and important interactions with other antiepileptic and non-antiepileptic drugs [18,19]. These mostly occur in response to inhibition and induction of hepatic enzymes and affect mainly those drugs metabolized by the cytochrome P450 system or uridine diphosphate–glucuronosyltransferase (UGT) enzymes, but increasingly complex interactions at other sites are also recognized. The antiepileptic drugs that are most likely to be involved in drug–drug interactions are carbamazepine, lamotrigine, oxcarbazepine, phenobarbital, phenytoin, primidone, topiramate, tiagabine, valproate and zonisamide.

The usual indications for serum level monitoring are listed in Chapter 9. These are to assess blood levels where there is a poor therapeutic response in spite of adequate dosage; identify the cause of adverse effects where these might be drug induced; measure pharmacokinetic changes in the presence of physiological or pathological conditions known to alter drug disposition (e.g. pregnancy, liver disease, renal failure, gastrointestinal disease, hypoalbulinaemic states); identify and minimize the consequence of adverse drug interactions in patients receiving multiple drug therapy; identify poor compliance; and identify the possibility of level changes owing to change in formulation.

Counselling and information provision

Counselling should be offered for chronic patients, as for all patients, on the topics listed in Table 11.5. Those with chronic active epilepsy, however, have additional problems: fears about the risks of future seizures, anxiety about the stigmatizing effects of epilepsy, and its effects on employment, self-esteem, relationships, schooling and leisure activities. The areas in which the condition impacted were demonstrated in one large survey of 1652 persons on treatment with epilepsy in Britain [20], summarized in Table 11.6. Many of these could be ameliorated by appropriate counselling and these topics should be addressed. The issues depend on age and the severity of epilepsy. A more detailed consideration of counselling is given in Chapter 26.

Table 11.6 The CSAG study of epilepsy (2001): survey of the impact of epilepsy on young adult patients and on elderly patients with epilepsy. In the course of a questionnaire study of their epilepsy, patients were asked to list areas in which epilepsy caused major impacts on their lives.

(a) Patients aged 17–65 years

Patients with mild seizures (568 patients returned a questionnaire; impacts reported = 1140)		Patients with severe seizures (347 patients returned a questionnaire; impacts reported = 842)	
Area	Patients reporting a major impact in this area (%)	Area	Patients reporting a major impact in this area (%)
Driving ban	48	Work	51
Work	36	Psychological	35
Social life	19	Social life	32
Psychological	18	Driving ban	28
Loss of confidence	8	Supervision	10
None	11	Independence	9

(b) Patients > 65 years

Patients with mild seizures (127 patients returned a questionnaire; impacts reported = 191)		Patients with severe seizures (28 patients returned a questionnaire; impacts reported = 57)	
Area	Patients reporting a major impact in this area (%)	Area	Patients reporting a major impact in this area (%)
Driving ban	32	Driving ban	39
Psychological	19	Psychological	29
Work	14	Seizures	21
Bad memory	9	Work	21
None	19	Social life	14
		Loss of self-confidence	11
		Mobility	11
		Supervision	11

Patients' seizures were divided into mild or severe on the basis of frequency and score on the National Hospital Seizure Severity Scale.
CSAG, Clinical Standards Advisory Group.

Epilepsy surgery

Resective or functional surgery for epilepsy should be considered in any patient with epilepsy not responding to drug therapy and if the potential benefits are considered to outweigh the potential risks [21–23]. This assessment is complex and presurgical evaluation should be carried out in an experienced epilepsy surgery unit. The elements of assessment are given in section 4 of this book, and an overview of presurgical assessment in Chapter 60. It is a multidisciplinary process, involving neurologist, neurosurgeon, psychologist, psychiatrist, neurophysiologist and radiologist. Onward referral to a specialized unit should be made for all patients in whom surgery is considered an option.

Drug treatment of chronic active epilepsy in the elderly

About 30% of new cases now occur in people over 65 years and, currently, about 0.7% of the elderly population are treated for epilepsy, making epilepsy the third most common neurological condition in the elderly after dementia and stroke. As the number of elderly people in the population is rising, the numbers of elderly people requiring treatment for epilepsy is also greatly increasing. The chief cause of epilepsy in those over 65 years is cerebrovascular disease. Diagnosis is not always easy, and care must be made to differentiate epilepsy from cardiac arrhythmia, syncope, vascular disease, transient global amnesia, vertigo and non-specific 'funny turns'.

The specific problems of treating epilepsy in the elderly are covered in Chapter 16, but, here, a brief outline will be given of some of the salient points. The general principles of treatment in the elderly are similar to those in other adults, but there are potential differences which deserve special mention.

Pharmacokinetic differences

The pharmacokinetic properties of many AEDs are not only different in the elderly, but the degree of pharmacokinetic variability is greater [24]. There are changes in absorption, protein binding, metabolic metabolism and renal clearance. The last is almost always lower in the elderly than in young adults, and the glomerular filtration rate declines by a mean of over 50% between the age of 30 and 80 years. The volume of distribution for lipid-soluble drugs is increased and the clearance often lowered owing to renal or hepatic disease. The half-life of many drugs is thereby increased.

Reference ranges

The 'reference ranges' of AEDs are somewhat lower in the elderly. The reasons for this are not clear, but presumably reflect pharmacodynamic changes.

Drug interactions

Drug interactions are common [25]. In the USA, persons over the age of 65 constitute 13% of the population yet receive 32% of prescribed medications. In one study of patients with epilepsy over 65 years old in the USA, a mean of 5.6 medications (antiepileptic and non-antiepileptic) per patient were taken [26].

Co-morbidities

Co-morbidities also are common, and most patients over the age of 65 years have other conditions treated by other drugs, with a marked potential for pharmacological and clinical interactions with epilepsy.

Choice of drugs

Choice of drugs is discussed at length in Chapter 16. Suffice to say here that both the antiepileptic effect and particularly the range of side-effects (and the doses and drug levels at which side-effects occur) can be quite different in the elderly. Whatever therapy is chosen, it is usual to start therapy at half the young adult dose and to increment the dose at half the young adult titration speed. Compliance can be poor. Careful clinical and pharmacological monitoring is essential.

For all these reasons, where possible therefore, therapy should be informed by studies conducted specifically in the elderly. Often data are lacking, and this is unsatisfactory.

Drug treatment of chronic active epilepsy in women

There are specific aspects of treatment which apply to women but not to men. These are considered in greater depth in Chapter 25 but will be considered here in outline.

Fertility

Fertility rates have been shown to be lower in women with treated epilepsy than in an age-matched control population. In one study of a general population of 2 052 922 persons in England and Wales, an overall fertility rate was found of 47.1 (95% CI 42.3–52.2) live births/1000 women with epilepsy per year compared with a national rate of 62.6. The difference in rates was found in all age categories between the ages of 25 and 39 years [27]. There are many possible reasons, including social, environmental and genetic factors. However, antiepileptic drug therapy might be a contributing factor and some workers have found an association between valproate therapy and polycystic ovarian syndrome [28]. The findings are controversial and not consistently duplicated.

Contraception

This topic is well reviewed by O'Brien *et al.* [29].

Combined oral contraceptive

There is no reason why women with chronic epilepsy on therapy with antiepileptic drugs should not take the combined oral contraceptive. However, drugs that induce hepatic enzyme activity (particularly CYP3A family enzymes: barbiturate, phenytoin, primidone, oxcarbazepine and carbamazepine) increase the metabolism of the oestrogen and progesterone components of the pill (sometimes by 50%) thereby reducing its efficacy. Topiramate lowers the level of oestrogen by 30% by a different mechanism. Lamotrigine may also affect the efficacy of the combined contraceptive pill and co-medication with the pill also affects lamotrigine levels (by 40–60%). To achieve contraceptive protection, therefore, patients co-medicated with enzyme-inducing antiepileptic drugs usually either need to take a pill with a higher oestrogen content (>60 μg) or double their dose of the lower oestrogen pills or tri-cycle the pill (taking three monthly packets of the contraceptive without a break, followed by an interval of 4 days rather than the usual 7). Despite the well-known risks of drug interaction, the inappropriate prescribing of low-dose contraceptive with enzyme-inducing drugs is widespread. In a large UK general practice survey, 17% (390 out of 2341) of all women with epilepsy were on an oral contraceptive. Of these, 200 were co-medicated with an enzyme-inducing antiepileptic drug, and 44% (87 out of the 200) were taking a contraceptive pill with less than 50 μg of oestradiol.

Other forms of contraception

The progesterone-only pill (the 'mini-pill') is affected in a similar manner to the combined contraceptive. Medroxyprogesterone acetate (Depo-Provera) has no interactions with antiepileptics, as there is virtually 100% clearance on first pass through the liver, and enzyme induction should have no effect. The progestogen implant (Implanon) is affected by enzyme-inducing drugs, and so should not be used. Postcoital contraceptives are also affected by enzyme-inducing antiepileptic drugs, and so the first dose should be doubled and a second single dose given 12 h later. Intrauterine contraceptives are not affected by enzyme-inducing drugs.

Menstruation and catamenial epilepsy

Epilepsy in which the seizure pattern has a strong relationship to the menstrual cycle is referred to as catamenial epilepsy. There have been attempts to devise special treatment approaches to patients with catamenial seizures, but these are generally unsuccessful. Strategies tried include hormonal manipulation and the abolition of the menstrual cycle by hormonal means or even oophorectomy. A widely used approach in chronic active epilepsy is to intensify antiepileptic drug therapy around menstruation. Five to seven days' therapy with diuretics, acetazolamide and clobazam has been tried. In routine clinical practice, these produce a worthwhile effect in only a small number of women.

Drug treatment of chronic active epilepsy during pregnancy

Of all the specific therapeutic issues encountered in an epilepsy clinic, perhaps the most difficult and uncertain relate to therapy in pregnancy. About 3–4 live births per 1000 women of childbearing age with epilepsy occur each year. Therapy in this situation, more than in others, needs to be carefully tailored to the individual – and counselling is imperative.

Teratogenicity and antiepileptic drugs

This topic is covered in depth in Chapter 25. Here, a summary will be given, especially as this relates to chronic active epilepsy. It is the area of greatest concern and also the most difficult in which to give sound advice.

Major malformations associated with antiepileptic drugs

The most common major malformations associated with traditional antiepileptic drug therapy (phenytoin, phenobarbital, primidone, benzodiazepine, valproate, carbamazepine) are cleft palate and cleft lip, cardiac malformations, neural tube defects, hypospadias and skeletal abnormalities. The risk of spina bifida has been particularly well studied. The background population risk of spina bifida is approximately 0.2–0.5% with geographic variation. Valproate is associated with a 1–2% risk of spina bifida aperta, a risk that is strongly dose related. Carbamazepine carries a risk of spina bifida aperta of about 0.5–1%. Both carbamazepine and valproate have been associated also with hypospadias. The overall risk of malformations was thought previously to be particularly high because of phenytoin exposure, although recent studies of phenytoin monotherapy have shown a very low incidence of major defects – and it may be that the previously high rates were attributable to polytherapy and exposure to high levels at a time when blood level control was not available. However, phenytoin therapy has been clearly associated with an increased risk of neuroblastoma in the infant, although the absolute risk is very small. One study purported to demonstrate smaller head circumference in babies of mothers on carbamazepine, but the statistical basis of this observation was not well founded. Small increases in pre- and postnatal growth retardation rates have been found in controlled studies of mothers taking antiepileptic drugs, but the growth differences had disappeared by the time the offspring were 5 years old.

Other developmental abnormalities

In addition to the major malformations, less severe dysmorphic changes ('fetal syndromes') have been postulated, although there is little agreement about their frequency or indeed even their existence. The problem is further complicated by the confounding influences of socioeconomic and genetic factors. The fetal phenytoin syndrome was the first to be described, and is said to comprise a characteristic pattern of facial and limb disturbances (Table 11.7). Most of these features though are minor and

Table 11.7 Some features reported to occur in fetal anticonvulsant syndromes.

Growth
Pre- and postnatal growth deficiencies
Microcephaly
Craniofacial
Short nose, low cranial bridge
Hypertelorism
Epicanthic fold
Strabismus and other ocular abnormalities
Low-set ears and other aural abnormalities
Wide mouth, and prominent lips
Wide fontanelles
Cleft palate and cleft lip
Limbs
Hypoplasia of nails
Transverse palmar crease
Short fingers
Extra digits
Cerebral
Learning disability
Developmental delay
General
Short neck, low hairline
Rib, sternal and spinal anomalies
Widely spaced hypoplastic nipples
Hernias
Undescended testicles
Neuroblastoma and neural ridge tumours
Cardiac and renal abnormalities
Hypospadias
Neural tube defects

This is a list of reported abnormalities, although many are uncontrolled observations and the frequency of the anomalies is unclear (indeed some may be no more frequent in exposed and unexposed infants). The contribution of antiepileptic drugs is also unclear, and genetic, environmental and socioeconomic factors may also play a role in their development.

overlap with the normal variation seen in children born to healthy mothers. Recent prospective and blinded studies have shown that only hypertelorism and distal digital hypoplasia occurred at any greater frequency, and even these associations are weak. Furthermore, the nail hypoplasia tends to disappear during childhood. A carbamazepine syndrome, primidone and phenobarbital syndromes and valproate syndrome are also reported.

Even greater controversy exists in relation to the question of whether maternal drug usage results in developmental delay and learning disability. Although there is no doubt that these occur at a higher frequency among infants born to epileptic mothers (between two- and sevenfold increases), the association could be due to genetic, environmental or socioeconomic factors. A recent study showed that 41 children exposed to valproate monotherapy had significantly lower verbal IQ (VIQ) scores than 52 children exposed to carbamazepine and 21 to phenytoin monotherapy. Low VIQ was also associated with the occurrence of five or more tonic–clonic seizures during pregnancy. There were also higher rates of dysmorphic features in the valproate-exposed children, and these were most common in those with low VIQ scores. Some caution needs to be exercised in interpreting these results: the study was a retrospective survey, the mothers were not randomized to different monotherapies, there was only a 40% response rate, and there are some inconsistencies, for instance, the fact that significant differences in VIQ rates were not found in fetuses that were exposed to valproate polytherapy and there was not a significant dose–response relationship.

When considering the teratogenic potential of the newer antiepileptic drugs, three points from experience with the traditional therapies are worth making. First, even today, the full range of the teratogenicity has not been established. Second, the risk of even major malformations was not noticed until the drugs had been in extensive use for decades. Third, negative animal results are not a reliable indicator of safety. Any claims of safety for newer drugs should be taken in this context. Reported defects in infants born to mothers taking vigabatrin include spina bifida, cleft palate and absent diaphragm; conjoined twins have also been reported. Topiramate, in animal models, causes right-sided ectrodactyly and rib and vertebral abnormalities, a pattern similar to that observed with acetazolamide, also a carbonic anhydrase inhibitor. No similar human abnormalities have been reported on carbonic anhydrase inhibitors, and none in the small number of topiramate pregnancies. Gabapentin causes hydroureter and hydronephrosis in rabbits, but there have been no reported human pregnancy abnormalities. Lamotrigine has not been associated with any consistent animal or human abnormalities, although human experience is limited. Currently, the advice has to be to avoid the use of any of these drugs in pregnancy until more definitive advice can be given.

The effect of seizures on the pregnancy

Epilepsy has been reported, in retrospective (and therefore selected) series, to increase up to threefold the risks of various common complications. The perinatal mortality rate has been found to be twice that of the general population. No large-scale prospective investigation has been carried out, but there seems little doubt that these pregnancies require special consideration. The obstetricians may be more likely to recommend intervention and to manage the case in a distinctive manner. About 1–2% of all women with epilepsy will have tonic–clonic seizures during delivery and this can clearly complicate labour. The fetal heart rate can be dramatically slowed by a seizure, and fetal monitoring is recommended during vaginal delivery. Home birth should not generally be contemplated. Pregnancy has a random effect on seizure frequency. About one-third of women experience increased numbers of seizures, and this is especially likely in severe epilepsy. A similar number of women have fewer seizures during pregnancy.

Antiepileptic drug serum levels

Blood levels of antiepileptic drugs can fall during pregnancy, especially in the last trimester, and the fall is greatest with lamotrigine, the levels of which can change by over 50%. Thus, serum level monitoring is essential and, in patients at risk of seizures, the doses of the antiepileptic drugs – and especially lamotrigine – will often need to be increased in late pregnancy.

The effect of seizures on the fetus

This is a controversial area. Clearly, in the later stages of pregnancy, a convulsion carries the risk of trauma to the placenta or fetus, especially if the women falls. However, most debate has revolved around the postulation that seizures damage the fetus through lactic acidosis or hypoxia. The hypoxia is usually very short-lived and the placenta is a well-buffered system, and these risks seem intuitively likely to be small. Fetal asphyxia manifested by prolonged bradycardia has been recorded after maternal seizures, and one case of postictal fetal intracranial haemorrhage has been recorded. However, these are probably exceptional, and in most situations isolated seizures are harmless. There is one study which has suggested that first-trimester seizures are accompanied by a higher risk of fetal malformation than seizures at other times, although methodological issues cloud the reliability of the conclusions. Stillbirth has been recorded after a single seizure or series of seizures; this though must be very rare. Partial seizures have no known effects upon a fetus. However, status epilepticus during pregnancy results in significant maternal and infant morbidity.

Folic acid supplementation

The fetus of an epileptic women is at a greater than expected risk of a neural tube defect, particularly if the mother is taking valproate, but an association is also noted with exposure during pregnancy to other antiepileptic drugs. A recent Medical Research Council (MRC) trial of folic acid supplementation during pregnancy showed a 72% protective effect against neural tube defects in women who had conceived a fetus previously with neural tube defects, and a positive primary preventative action has also been demonstrated. Although there has been no specific study in epilepsy, it would seem reasonable for all epileptic women to be given folic acid supplementation during pregnancy, especially as many patients with epilepsy have low serum and tissue folate levels due to enhanced drug-induced hepatic metabolism. A dose of 4–5 mg/day is recommended on

an empirical basis, as lower doses may not fully restore folate levels.

The puerperium

There is still an increased risk of seizures in the puerperium, and precautions may be necessary. It is sometimes helpful to continue clobazam for a few days after delivery to cover this period. If antiepileptic drug dosage had been increased in response to falling levels during pregnancy, the dose should be returned during the first week to its previous levels; this is necessary as the pharmacokinetic changes of pregnancy are rapidly reversed in the puerperium. Drugs circulating in the mother's serum cross the placenta. If maternal antiepileptic drug levels were high, the infant may experience withdrawal symptoms (tremor, irritability, agitation, and even seizures) and neonatal serum levels should be measured in cases at risk.

Breast feeding

The concentration of most antiepileptic drugs in breast milk is less than 30% than that of plasma; exceptions are concentrations of ethosuximide, gabapentin, lamotrigine, levetiracetam, phenobarbital and topiramate. Furthermore, even if a drug is present in significant concentrations in breast milk, the amount ingested by the infant is usually much less than would normally be considered needed for clinical effects – and only in the case of ethosuximide, lamotrigine and phenobarbital (and primidone) are significant doses absorbed. Thus, only with these drugs are precautions necessary (and possibly levetiracetam – although data are sparse), at least at normal doses. The problem of lamotrigine is compounded if co-medication with valproate is given, which prolongs the half-life of the drug. Particular caution is advised in the case of maternal phenobarbital ingestion, as in neonates the half-life of phenobarbital is long (up to 300 h) and the free fraction is higher than in adults; neonatal levels can therefore sometimes exceed maternal levels. Neonatal phenytoin and valproate half-lives are also increased (Table 11.8). Neonatal lethargy, irritability and feeding difficulties have also been attributed to maternal antiepileptic drug intake, although evidence is slight and these findings are not correlated with maternal drug dosage or serum level.

Table 11.8 Pharmacokinetic parameters of drugs transmitted to the fetus in breast milk.

	Dose of antiepileptic drugs acquired from breast milk[a] (%)	Breast milk/ plasma concentration ratio	Elimination half-life (h)	
			Adult	Neonate
Carbamazepine	<5	0.3–0.4	5–26	8–28
Ethosuximide	>50	0.9	30–60	40
Lamotrigine	>50	0.6	12–60	Not known
Phenobarbital	>50	0.4–0.6	75–120	45–300
Phenytoin	<5	0.2–0.4	7–42	15–100
Valproate	<5	0.01	12–17	30–60

Personal communication from Dr M. O'Brien.

[a] Amount of drug received in a fully breast-fed infant – expressed as a percentage of the lowest recommended daily therapeutic dose for an infant.

Maternal epilepsy

A mother at risk from seizures with altered consciousness should not be left alone with a small child. There is a danger of dropping the child or leaving the child unattended, and maternal epilepsy probably poses a greater risk to infants and toddlers than to the fetus. Sensible precautions should be taken if seizures pose a risk of dropping a child. These might include avoiding carrying the child unaccompanied, changing and feeding the infant at ground level, and bathing the infant only when someone else is present.

12 Management of Epilepsy in Remission

Patrick Kwan and Howan Leung

The Chinese University of Hong Kong, Prince of Wales Hospital, Hong Kong, China

Introduction

Long-term outcome studies have shown that at least two-thirds of patients with newly diagnosed epilepsy will become seizure free upon antiepileptic drug (AED) treatment [1], and most patients do so immediately or shortly after beginning therapy [2]. For suitable candidates with medically refractory epilepsy, depending on the type of procedures, 50–80% may become seizure free after epilepsy surgery [3–5]. For such patients whose epilepsy is regarded as having entered 'remission', one of the key management issues concerns whether AED therapy should be continued or withdrawn. The practical dilemma arises from our inadequate understanding of the way in which AED treatment may (or may not) interact with the natural history of epilepsy [6]. For instance, it remains unclear to what extent patients with a significant period without seizures are now 'cured' (i.e. their seizure freedom is no longer dependent on treatment) of the condition, or the epilepsy is only controlled by ongoing treatment. If some are indeed 'cured' it is difficult to determine whether this is due to the treatment they received, or simply reflects the natural history of the condition ('spontaneous' remission) [6].

In practice, the decision to continue or withdraw AED therapy in these patients should involve a careful risk–benefit assessment of both seizures and continuing treatment for the individual patients. In particular, the following questions should be considered:

- What is the risk of seizure relapse upon AED withdrawal, and what are the factors associated with increased risk?
- What are the potential harmful consequences of seizure relapse?
- What are the risks in continuing AED treatment (or in other words, the benefits of AED withdrawal)?

This chapter aims to review the evidence base addressing these and other related questions pertinent to deciding whether AED therapy should be continued in a seizure-free patient, as well as to provide practical recommendations for the drug withdrawal process. The discussion will focus on drug withdrawal for patients who have become seizure free on AED treatment. Withdrawal of AEDs in patients entering remission following epilepsy surgery will also be briefly discussed.

Risk of relapse upon AED withdrawal

Medical Research Council Antiepileptic Drug Withdrawal Study

The Medical Research Council (MRC) Antiepileptic Drug Withdrawal Study, conducted in the 1980s in the UK, remains the only large-scale randomized controlled trial that compared the policies of continued versus slow discontinuation (over 6 months) of treatment in patients who had become seizure free while on AED therapy [7]. One thousand and thirteen patients (mainly adults) who had been seizure free for at least 2 years were randomized to one of these policies, and followed up for between 1 and 5 years. Based on actuarial analysis, by 2 years after randomization, 22% of patients in the continued therapy group had relapse of seizure(s), compared with 41% in the withdrawal group. In the slow withdrawal group, 48% seizures occurred during the tapering phase.

The study was limited by its open-label design, and hence full compliance with the randomized policies was not attained and complete discontinuation was achieved in only 73% patients in the slow withdrawal group, and 35% patients randomized to continued therapy nonetheless reduced or withdrew treatment during follow-up. In addition, there was substantial self-selection with 776 eligible subjects refusing to be randomized, the most important reason being possession of a driving licence. Despite these limitations, the study remains the most authoritative trial to date comparing AED withdrawal and discontinuation in seizure-free patients.

Akershus double-blind antiepileptic drug withdrawal study

Lossius and colleagues [8] reported the first double-blind AED withdrawal study. One hundred and sixty adult patients who had been seizure free for at least 2 years on AED monotherapy were randomized to either gradual withdrawal of medication (over 3 months) or non-withdrawal. The reduced medication was replaced by a placebo to keep the study double-blinded. By 1 year, only 15% of patients in whom AED treatment was withdrawn had a seizure relapse, compared with 7% of patients in whom treatment was continued. The difference was not significant statistically. At termination of the 1-year double-blind period, most of the patients in the initial non-withdrawal group decided to taper their AEDs too. Thus, among the combined group of patients who tapered their AEDs with a median follow-up of 41 months off medication, there was a declining monthly risk of seizures from 0.01 immediately after tapering

to 0.009 at 6 and 12 months, 0.006 at 24 months and 0.003 at 36 months.

Such relapse rates were markedly lower than those observed in the MRC AED Withdrawal Study. The authors attributed the differences to inclusion of patients with perhaps 'milder' epilepsy controlled on a single AED, 67% of whom had been seizure free for more than 5 years. Normal neurological examination and use of carbamazepine prior to withdrawal were the only factors found to be associated with seizure freedom after AED withdrawal, but the ability of the study to identify other predictors was limited by its small sample size.

Non-randomized controlled or uncontrolled studies

A number of retrospective and prospective non-randomized studies, including both paediatric and adult patient populations, have examined seizure relapse rate following AED withdrawal. Using specific methodological criteria, Berg and Shinnar [9] systematically reviewed 25 reports and concluded that the typical estimate of risk of relapse was 25% at 1 year after initiating AED withdrawal and 29% at 2 years. Of all recurrences, 80% occur within the first year and 90% within the first 2 years. However, these studies likely suffered from significant selection bias and might have underestimated (or overestimated in some cases) the relapse rates, as many were small scale and retrospective and all but one were uncontrolled.

Subsequent to this review, a further controlled non-randomized study reported relapse rates in 330 patients who were referred to an epilepsy centre seizure free for at least 2 years while on stable AED monotherapy. AED discontinuation was 'proposed' to all eligible patients, of whom 225 opted to continue and 105 opted to withdraw treatment. The regimen of withdrawal was not standardized. Compliance was not reported and the mean follow-up period was nearly 4 years. Overall, 28% of patients in whom treatment was continued had a relapse, compared with 50% of patients in whom AED was withdrawn. Factors influencing the risk of seizure relapse in the multivariate model included drug withdrawal, duration of active disease, number of years of remission at study entry, abnormal psychiatric examination and epilepsy syndrome [10].

In summary, regardless of design, the comparative studies suggest that, among patients who have been seizure free on medical treatment for 2 years or more, slow AED withdrawal is associated with an approximately twofold increase in risk of relapse compared with treatment continuation. The risk is highest within the first 6–12 months of withdrawal (including the tapering phase). The actual relapse rates observed appeared to be heavily influenced by the characteristics of the populations included. It should also be noted that the stipulation of 2 years' seizure freedom before drug withdrawal is, in fact, largely arbitrary.

Early versus late withdrawal in children

Whether AED treatment can be withdrawn in patients with shorter periods of seizure freedom is particularly relevant in children when considering the potential deleterious effects of AEDs on the maturing brain. A Cochrane review in 2001 quantified seizure relapse risk after early (less than two seizure-free years) versus late (more than two seizure-free years) AED withdrawal in paediatric epilepsy patients (the reviewers could not identify any eligible trial performed in adults) [11]. Seven controlled trials, including 924 randomized children, were reviewed. The relative risk for seizure relapse in early versus late AED withdrawal was 1.32. The number needed to harm by early withdrawal was 10, meaning that for every 10 children that are withdrawn later, one seizure relapse is prevented compared with early withdrawal. There was a trend that early withdrawal was associated with greater risk of relapse in children with partial seizures or abnormal electroencephalograms (EEGs) but the association did not reach statistical significance. The systematic reviewers concluded that current evidence supported the recommendation of waiting for two or more seizure-free years before discontinuing AEDs in children, particularly if they have an abnormal EEG and partial seizures.

Rapid versus slow withdrawal

A recent Cochrane review examined the effect of the mode of AED withdrawal (whether rapid or slow tapering) on recurrence [12]. Rapid tapering was defined as withdrawal over 3 months or less and slow tapering as withdrawal over more than 3 months. Only a single study of paediatric patients was identified [13]. The rapid taper group (tapering over 6 weeks) recruited 81 participants and the slow taper group (9 months) included 68 participants. There was no significant difference in risk of relapse between the two groups. However, because of the small sample size, the reviewers felt it not possible to draw a reliable conclusion.

Factors associated with seizure relapse after AED withdrawal

A number of clinical factors have been identified that are associated with the risk of relapse following AED withdrawal in a patient who has become seizure free on AED treatment (Table 12.1). Some of these factors are discussed in detail below.

Table 12.1 Some factors that have been reported to adversely affect the risk of seizure relapse after discontinuation of AED therapy in patients with epilepsy in remission.

Short duration of seizure freedom prior to drug withdrawal
Age above 16 years
Epilepsy with onset in adolescence or adulthood
Juvenile myoclonic epilepsy
Remote symptomatic epilepsy
History of myoclonic seizures
History of multiple seizure types
History of primary or secondarily generalized tonic–clonic seizures
History of atypical febrile seizures (in children)
Prolonged period before achieving seizure control
Seizures while on treatment
Seizure control requiring multiple drug therapy
Abnormal EEG
Learning disability
Associated neurological handicaps
Previous failed attempts to stop medication

AED, antiepileptic drug.

Syndromic classification

The risk of relapsing after treatment withdrawal appears to be strongly influenced by the underlying epilepsy syndrome. Among the idiopathic epilepsy syndromes, benign epilepsy with centrotemporal spikes has an excellent long-term prognosis, and relapse is rare when medications are stopped [14]. Childhood absence epilepsy has a less certain prognosis for remission. Although, in the short term, most of these children become seizure free on treatment, about 25% relapse when medications are withdrawn [15,16]. Juvenile myoclonic epilepsy (JME) has an excellent response to treatment, but relapses are believed to occur in most patients when medications are stopped [17], although this has not been subject to rigorous study.

Remote symptomatic epilepsies are less likely to be controlled than idiopathic epilepsies [1], and are about 50% more likely to relapse if medication is stopped, according to a meta-analysis of non-randomized studies [9]. Learning disability, at least in children, may be a stronger predictor of relapse than motor impairments or other neurological disorders that are not associated with impairment of cognitive function [18]. Among the randomized trials, the impact of a remote symptomatic aetiology on risk of relapse was not clearly defined in the MRC AED Withdrawal Study [7]. This was probably related to the limited availability of sophisticated neuroimaging techniques at the time the study was conducted in the early 1980s. Findings were also conflicting in the more recent Akershus study in which all patients underwent brain MRI at recruitment [8]. Neither partial seizures nor MRI findings were associated with seizure relapse after AED withdrawal, but a normal neurological examination was a significant predictor for remaining seizure free.

Seizure type

Many studies have examined the outcome of particular types of seizures rather than syndromes. This is partly because epilepsy syndromes may be difficult to identify with confidence in patients with mild epilepsies characterized by only a few seizures responding immediately to treatment, as well as the limited neuroimaging techniques available in the older studies. The MRC AED Withdrawal Study found that a history of primary or secondarily generalized tonic–clonic seizures and myoclonic seizures was associated with increased risk of recurrence [7]. However, because a particular seizure type may be a characteristic of very differing syndromes, the results of such analyses could be conflicting. Thus, tonic–clonic seizures may occur in juvenile myoclonic epilepsy, benign epilepsy with centrotemporal spikes, juvenile absence epilepsy and many other syndromes. Similarly, simple partial seizures occur in both benign epilepsy with centrotemporal spikes and the more refractory types of temporal lobe epilepsy. Having multiple as opposed to single seizure types has been associated with a higher risk of relapse in some studies but not in others [19]; however, as severe epilepsy syndromes are often characterized by multiple seizure types, it is likely that the underlying epilepsy syndrome may better account for the likelihood of relapse after stopping AED.

Age at onset

Most studies find a favourable prognosis in epilepsy with onset in childhood, which is probably due to the occurrence of many benign epilepsy syndromes in this age group. Studies including both childhood- and adolescent-onset epilepsy usually find a substantially increased risk of relapse in those with adolescent onset. Childhood onset of epilepsy is usually associated with a risk of relapse of approximately 20% compared with 35–40% for adolescent-onset epilepsy. Adult-onset epilepsy, on the other hand, is about 30% more likely to relapse than childhood-onset epilepsy [9].

EEG findings

The value of the EEG in predicting the prognosis for relapse after stopping treatment remains controversial. Studies varied in the timing of EEG in relation to AED withdrawal and the types of abnormalities examined. Some studies have examined the degree of 'improvement' in the EEG from starting treatment to the time of its withdrawal. Most studies investigated the correlation between EEG findings immediately prior to withdrawal and relapse rate. The appearance or worsening of EEG abnormalities during the AED discontinuation period has also been suggested as a separate prognostic factor. In addition, studies varied in their focus on the types of EEG abnormalities. In one study, children with normal EEGs had an extremely low risk of relapse, those with either epileptiform abnormalities or slowing had a moderate risk and those with both epileptiform abnormalities and slowing had almost a 100% risk of relapse [20]. High rates of relapse have been reported in patients with photoconvulsive responses on EEGs [21]. In the MRC AED Withdrawal Study [7], which included mainly adult patients, an 'abnormal' (not further defined) EEG was associated with a trend towards an increase in risk of relapse. In the Akershus study, in which electroencephalography was performed routinely at baseline and during follow-up, abnormalities were categorized into epileptiform activity, focal epileptiform activity, generalized epileptiform activity and abnormal activity other than epileptiform discharges. None of the various types of abnormal EEG findings at baseline and upon retesting was associated with seizure relapse among both the withdrawal and non-withdrawal groups [8].

Overall, data suggest that electroencephalography is of greater prognostic significance in children than in adults. It is uncertain to what degree EEG abnormalities are independent prognostic variables or are simply more common in individuals already identified as high risk by clinical factors such as having symptomatic epilepsy or other adverse clinical prognostic factors [22].

Severity of epilepsy and duration of seizure freedom

A number of clinical features that may reflect the severity of epilepsy have been studied for their association with relapse after drug withdrawal. They include a history of status epilepticus, the duration of epilepsy, the number of seizures before remission, the duration of treatment, the requirement for two or more AEDs for remission and previously failed attempts to stop medication. Most studies indicate that these surrogate measures of severity all adversely affect the risk of recurrence [19]. However, no single indicator or set of indicators is clearly superior to the others as a marker of prognosis after stopping AED.

In the MRC AED Withdrawal Study, longer periods of seizure freedom (reducing the risk) and taking more than one AED

(increasing the risk) were two of the most important factors predicting relapse [7]. The duration of epilepsy and the duration of treatment are clearly correlated. There is a consensus that patients with fewer seizures, responding more rapidly to treatment, have a better outcome when medication is withdrawn. In the MRC AED Withdrawal Study, having seizures whilst on drug treatment was associated with an increased risk of relapse [7]. In both children [18] and adults [7] a previously failed attempt to stop treatment has not been found to be independently associated with an increased risk of relapse, although the power of these studies to detect an effect is poor, given that many patients might be reluctant to undertake a second attempt of withdrawal.

Although patients with status epilepticus may have poorer response to drug treatment, at least among children [23,24], those who become seizure free do not seem to have a higher risk of relapse. This was the case in both adults [7] and children [18].

Influence of individual drugs

It is often suggested that the risk of seizure recurrence may differ depending on the drug that is to be withdrawn. Withdrawal seizures are particularly said to occur with the discontinuation of benzodiazepines and phenobarbital. This idea has rarely been exposed to systematic study. There were large subgroups of patients receiving monotherapy with carbamazepine, valproate, phenytoin and barbiturate drugs (phenobarbital and primidone) in the MRC AED Withdrawal Study [7]. The temporal pattern of seizure recurrence was similar in the barbiturate group and the other groups. Perhaps surprisingly, the withdrawal of carbamazepine was associated with a lower relative risk of seizure recurrence on withdrawal than were other drugs even after adjustment for other predictors of outcome [25]. This finding has been replicated in the more recent Akershus study, in which withdrawal of carbamazepine was associated with lower risk of relapse compared with withdrawal of other AEDs [8]. The reason for this association is unclear. There is no clinical evidence to suggest that carbamazepine (or any other AED) influences the natural history of epilepsy. Since carbamazepine is the first-line treatment in partial epilepsy, investigators of the Akershus study postulated that patients demonstrating a good response to carbamazepine might have 'easy-to-treat' epilepsy [8].

Models for prediction of relapse

A predictive model for relapse in patients continuing or stopping their medication has been developed based on results of the MRC AED Withdrawal Study [26]. The model gave decreasing weight to the following factors: whether or not treatment was withdrawn, period of time that was seizure free, taking two or more AEDs, being 16 years or older at the time of withdrawal, having myoclonic seizures, having tonic–clonic seizures of any type and an abnormal EEG (Table 12.2). Comparatively simpler models have also been developed to predict relapse in children based on smaller study populations [18,27]. Scores were assigned to various predictive factors such as sex, age at seizure onset, presence of neurological abnormality, seizure types, broad epilepsy types, family history of epilepsy, EEG changes and mental retardation. The clinical usefulness of such models remains uncertain because they have not been prospectively validated in external cohorts. The model based on the MRC AED Withdrawal Study does not include the underlying syndromic classification and aetiologies of epilepsy, which is recognized to be one of the major prognostic factors of treatment outcome [28].

Table 12.2 Factors for the calculation of a prognostic index for seizure recurrence by 1 and 2 years following continued treatment or slow withdrawal of AED, in patients with a minimum remission of seizures lasting for 2 years while on treatment.

Starting score for all patients	**–175**	
Factor to be added to starting score		
Age > 16 years	45	
Taking more than one AED	50	
Seizures occurring after the start of treatment	35	
History of any tonic–clonic seizure (generalized or partial in onset)	35	
History of myoclonic seizures	50	
EEG while in remission		
Not done	15	
Abnormal	20	
Duration of seizure free period (years) = *D*	200/*D*	
Total score	*T*	
Exponentiate T/100 ($Z = e^{T/100}$)	*Z*	
Probability of seizure recurrence	*By 1 year*	*By 2 years*
On continued treatment	$1–0.89^Z$	$1–0.79^Z$
On slow withdrawal of treatment	$1–0.69^Z$	$1–0.60^Z$

D, duration of seizure-free period (years); *T*, total score; *Z*, exponentiate *T*/100 ($Z = e^{T/100}$).

Antiepileptic drug withdrawal after epilepsy surgery

Compared with the large body of literature on treatment withdrawal in patients treated medically, there is a dearth of information about the pharmacological management in postsurgical seizure-free patients. Little is known to guide whether and when AEDs should be withdrawn, or about the risk and predictors of relapse following withdrawal. There has been no randomized controlled trial to examine these issues, and only few studies have reported clinical experience from individual centres in patients undergoing a mixture of surgical procedures.

Schmidt and colleagues [29] reviewed five studies reporting relapse following planned discontinuation of AEDs in patients becoming seizure free after surgery. All were retrospective in nature. In the four adult series including a total of 464 patients with follow-up ranging from 1 to 6 years, 48% of patients discontinued AED treatment: the mean recurrence rate was 33.8%. In comparison, relapse rates were 7% and 17% for patients who continued AEDs at follow-up of 1 and 5 years. Among those who relapsed, more than 90% regained seizure control with reinstitution of AED therapy. Only one paediatric study published in abstract form was included in the review. Among 97 children with temporal and extratemporal epilepsy who became seizure free after surgery, 70% withdrew AEDs and the recurrence rate was 16%. Predictive factors of recurrence were not systematically examined in these studies.

Subsequent to this review, McIntosh *et al.* [30] reported retrospective analysis of seizure outcome in 157 patients who had been

seizure free for at least 2 years post surgery. There was no significant difference in probabilities of remaining seizure free between patients who discontinued ($n = 83$) and continued ($n = 74$) AED treatment. However, interpretation was confounded by the fact that, for those patients who continued AEDs and experienced seizure recurrence, 42% had reduced AED dosage. Another large controlled prospective study (the US Multicenter Study of Epilepsy Surgery) examined recurrence in 301 patients who had been seizure free for 1 year post surgery [31]. AEDs were reduced in 162 patients, but the proportion of patients actually achieving complete AED discontinuation was not specified. After initial reduction of AEDs, the probability of remaining seizure free was 0.84 and 0.74 at 1 and 2 years, respectively. Two-thirds of patients who relapsed after AED reduction had regained remission at the time of analysis. Relapse was significantly associated with delayed rather than immediate remission, but not with AED reduction. Of note, those who chose to continue AED regimens were also more likely to have had delayed remission, indicating selection bias. Other recent retrospective uncontrolled studies in adults [32–34] and children [35] have not shown substantially different findings.

In summary, these observations suggest that relapse upon AED reduction/withdrawal occurs in up to one-third of patients who have been seizure free for 1–2 years post surgery. The majority of these patients can expect to regain seizure control on resumption of AED treatment. There is no evidence to suggest that delaying AED withdrawal beyond 1 to 2 years of complete postoperative seizure freedom would reduce relapse rate. However, firm conclusion cannot be drawn from these mostly retrospective, non-randomized, open and often uncontrolled studies due to likely selection bias, incomplete follow-up, non-standardized AED taper regimen and sometimes confusion between reduction and complete discontinuation of AEDs in reporting.

Consequences of relapse

The potential consequences, including physical, psychological and social, of seizure relapse should be carefully considered and thoroughly discussed with the patient and family when deciding whether AED therapy should be withdrawn. Physical consequences of seizure relapse may entail accidental injuries, burns, fractures or even death. Perhaps surprisingly, these consequences have rarely been documented in the AED withdrawal studies. In the Akershus randomized controlled trial, seizures that relapsed during the 12-month double-blind study period did not cause any serious harm; however, among the 136 patients who eventually withdrew/tapered their AED therapy in the open-label extension phase, two patients apparently died of sudden unexpected death in epilepsy. Of these, one died only a few weeks after withdrawal and one died 4 years after withdrawal [8]. However, it is unknown whether continuation of AED in these two patients would have prevented their death (or indeed seizure recurrence).

Seizure relapse may induce much anxiety and affect self-esteem in the patient who might have considered himself or herself 'cured' after an initial period of seizure freedom while off medication. In addition, patients may be worried about the prognosis on resuming treatment.

Most evidence indicates that the majority of patients who relapse when medication is stopped will regain acceptable control when treatment is reintroduced. However, it is important to bear in mind that, for some patients, regaining remission may require intensive drug manipulation and may take some time, during which seizure recurrence can have serious consequences with negative impact on the patients' quality of life. In the MRC AED Withdrawal Study, 95% of those who relapsed experienced at least a 1-year remission within 3 years of the initial relapse. By 5 years, 90% had experienced a remission of at least 2 years' duration. Factors associated with a poorer outcome after relapse were having a partial seizure at the time of relapse, having a previous history of seizures while on medication and shorter duration of seizure freedom prior to the relapse [36].

Seizure relapse may have social consequences such as impact on employment and driving. In many countries, not having had a daytime seizure for certain length of time will qualify for reinstatement of driving licence, and seizure relapse may lead to loss of this privilege. Indeed in the MRC AED Withdrawal Study, possession of a driving licence was the most important reason for eligible patients to refuse randomization [7]. Therefore, an individualized approach is needed to assess the potential impact of relapse based on the patient's occupation, living conditions and caring issues. Arrangement should be made to ensure the safety of patients during and after the period of AED discontinuation whenever possible.

Risks associated with continuing AEDs (or benefits of withdrawal)

Antiepileptic drugs are associated with a range of adverse effects. Withdrawal may lead to cessation of adverse effects that the patient is experiencing at present, particularly neurocognitive side-effects, as well as avoidance of complications associated with long-term use. In the double-blind Akershus study involving adult patients taking monotherapy, AED withdrawal was associated with significant improvement in the scores of a range of neuropsychological tests, including memory, attention, psychomotor speed and executive functions [8]. Previous studies in children have demonstrated subtle improvement in cognitive symptoms and functions after AED withdrawal [37]. However, quantifying the degree to which AEDs contribute to perceived change in cognition and behaviour is often difficult because other factors, such as seizure burden and the underlying neuropathology, may also have negative effects on neuropsychological functioning [38].

Changes in other aspects of psychosocial functioning and overall quality of life associated with AED withdrawal have not been well studied. For some patients, the responsibility of remembering to take medication on time and obtaining repeat prescriptions is an unwanted source of stress. For many patients, continued therapy, with or without seizures, implies continued epilepsy. Patients who discontinue AEDs successfully are able to think that they are free not only from recurrent seizures, but also from a diagnostic label that many believe to be stigmatizing [39]. However, measuring these improvements may be logistically difficult from a research standpoint. In the MRC AED Withdrawal Study, a self-administered questionnaire covering a range of

psychosocial measures was sent to patients 2 years after randomization. AED withdrawal was associated with non-significant improvements in the sense of well-being, self-esteem, and perceived stigma, although remaining seizure free, whether on or off medication, seemed to be more important [39]. In the Akershus study, there was no significant change in health-related quality of life scores at 4 months after completion of AED withdrawal compared with baseline [8]. The authors suggested that the double-blinded design of the study excluded one known positive effect of being off medication, namely not having to take drugs regularly, and that fear of seizure relapse due to patients being blinded might even have had a negative impact on quality of life.

Successful discontinuation of AEDs means the patient is no longer exposed to the risk of complications associated with long-term treatment. One such long-term complication of increasing concern is AED-induced bone loss and resultant increased risk of fractures. Both enzyme- and non-enzyme-inducing agents are implicated, and their effects may be additive and progressive with duration of treatment [40]. Although evidence is conflicting, long-term treatment with valproate may be associated with various endocrine abnormalities including polycystic ovarian syndrome [41]. For female patients of child-bearing age, an added concern that may tip the balance towards drug withdrawal is the teratogenicity of AEDs. *In utero* exposure to the established AEDs (carbamazepine, phenobarbital, phenytoin, valproate) has been shown to increase the likelihood of fetal malformations. Among the newer drugs, recent evidence from the UK AED pregnancy registry suggests a dose–response effect for the risk of major malformation associated with lamotrigine [42]. There are insufficient data regarding the safety of other newer agents. Therefore, preconception planning is of paramount importance and AED withdrawal, if deemed appropriate, should be carried out well before the planned pregnancy.

Last but not least, since many AEDs are metabolized by and induce/inhibit the hepatic cytochrome P450 enzyme system [43], withdrawal will avoid potentially deleterious interactions with concomitant medications the patient is currently taking, or may need to take in future.

Patient attitudes

As already discussed, the decision to withdraw AED therapy will be influenced both by the risk of further seizures and by a personal view of the impact of further seizures on the individual's expectations. These issues demand careful consideration and discussion, and ultimately the decision can only be made by the patient. Personal circumstances may play a very important role. For example, a 25-year-old man whose job is dependent on holding a driving licence might well feel that a 40% risk of seizure recurrence on drug withdrawal was unacceptable. However, a similar risk in his 25-year-old wife might be acceptable if it allowed a drug-free pregnancy.

The complexity of these issues is further highlighted by studies of patients' views. Jacoby *et al.* [44] found that 43% of subjects with their epilepsy in remission were undecided what to do after a period in remission. This number was considerably reduced (to 9%) by the use of a predictive model, which presented the risk of seizure recurrence for policies of continued treatment and withdrawal. The latter policy consistently predicted greater risks of relapse than did the former. Only 10% of subjects (almost entirely adults) decided to withdraw treatment after reviewing the results of the model. In the case of children, Gordon *et al.* [45] found parents' views of acceptable risk of withdrawal corresponded very poorly with those of their physicians, and in a way that was not easily predicted by clinical factors in the children.

Clinical therapeutics

The decision to stop AED treatment in a seizure-free patient requires a careful assessment of individual risks of both seizure relapse and continuing treatment. The physician's role is to provide all necessary information for the patient and their family to make an informed decision. Generally speaking, in adults we favour continuation of treatment until there has been a remission of between 2 and 5 years, but in children shorter remission periods of 12 months may be adequate for consideration of drug withdrawal. The benefits of stopping medications in children earlier would seem to outweigh their risks in most circumstances. In adults, by contrast, the risks and consequences associated with a relapse are such that the decision to stop medications is more complicated. Overall, the clinical risks of relapse might be largely counterbalanced by the psychosocial benefits of discontinuing treatment.

In terms of the speed of withdrawal, one drug should be tapered at a time, each gradually over a 3- to 6-month period. For patients taking high dosages or multiple drug therapy, and for those taking drugs such as barbiturates and benzodiazepines, many physicians will favour a slower withdrawal. For children in remission, occasional seizures while remaining off treatment may be acceptable under some circumstances but, for many adults, a seizure recurrence will usually require the prompt reinstitution of the AED regimen that was previously successful. A wait-and-see policy might be adopted if the recurrence occurs a long time after AED therapy was withdrawn.

The patient should be counselled on any lifestyle issues that may need to be adjusted during and after drug withdrawal, considering that most relapses occur during and within the first 6–12 months after discontinuation. In the UK, the Driver and Vehicle Licensing Agency recommends that driving should cease during the period of AED withdrawal and for 6 months afterwards. We also advise women of child-bearing age to postpone pregnancy beyond the same period of time.

13 Management of Epilepsy in Infants

Catherine Chiron
Inserm U663, Paris, France

Infancy is defined as the age range that occurs between the neonatal period (the first month of life) and childhood (from 2 years of age). As in the other age ranges, the choice of antiepileptic drugs (AEDs) is highly dependent on the type of epilepsy syndrome and limited by tolerability. However, because of various age-related characteristics, management of epilepsy is quite specific in infancy.

Infancy-specific issues in the management of epilepsy

Age-dependent pharmacokinetics and pharmacodynamics

The pharmacokinetics of AEDs varies according to maturational stage. Specific pharmacokinetic features in infants compared with children and adults may include slower gastrointestinal absorption rates, higher volumes of distribution, higher apparent clearance values and shorter half-lives [1]. As a result, dose requirements need to be higher in infants than in older children and the intervals between doses need to be shortened. Equally important, intra- and interindividual variability in pharmacokinetics and dose requirement are more marked in infants than in older children.

Pharmacokinetic parameters in infants are known for most established AEDs. Valproic acid and phenobarbital exhibit relatively favourable pharmacokinetics, whereas carbamazepine and phenytoin do not. Carbamazepine daily dosages in infants need to be increased up to mean values of 30–50 mg/kg compared with 15–25 mg/kg for older children; in infants, three times daily administration is usually required although, in older age groups, two times daily dosing may be feasible. The use of phenytoin is even more problematic because of non-linear pharmacokinetics, and an adequate dose of phenytoin is particularly difficult to determine in infants [2].

As far as new AEDs are concerned, pharmacokinetic data are accruing progressively in infants. The pharmacologically active *S*(+)-enantiomer of vigabatrin has age-dependent kinetics: its absorption is significantly slower in infants than in children and adults, and its area under the curve and its elimination half-life increase linearly with age [3]. For lamotrigine, apparent clearance also increases during the first year of life from the age of 2 months [4]. An age of less than 4 years and concomitant enzyme inducers significantly increased the clearance of topiramate in children, both factors acting independently [5,6]. By contrast, inducers do not modify the pharmacokinetics of oxcarbazepine so that the concentrations of its metabolite can be predicted in infants using the same linear population-PK model as in older children [7]. Preliminary data with levetiracetam given as single dose also disclose a more rapid clearance in infants than in older ages [8].

Tolerability profiles differ in infants compared with other age groups. The risk of hepatic failure with valproate is an obvious example. Although the overall incidence is very low (1 out of 37 000), the risk is small in adults and is greatly increased below the age of 2 years, especially in infants who have been recently started on the drug and are treated with high doses, with polytherapy and in the presence of an associated psychomotor delay. Some of these patients may suffer from an undiagnosed inherited metabolic disease decompensated by valproate, such as carnitine deficiency or Alpers' disease. The changes in acylcarnitine subspecies associated with valproate treatment in epileptic children were recently identified [9]. By contrast, in infants, phenobarbital very frequently causes behavioural side-effects that limit its use in this age group: about one-third of phenobarbital-treated children develop hyperexcitability and insomnia, and the intelligence quotient (IQ) has been reported to be significantly reduced in children who received 2 years of treatment with phenobarbital as prophylaxis against recurrence of febrile seizures [10]. As far as phenytoin is concerned, overdosing is not an uncommon cause of side-effects in infants [2]. Benzodiazepines induce a paradoxical hyperexcitation, with sleep disorders rather than somnolence, in infants. When infantile spasms are treated with clonazepam, more than half of the infants experience severe side-effects, such as increased secretion of saliva, difficulty in swallowing and mucous obstruction of the bronchi. With nitrazepam, a mortality rate of 25% among infants with spasms has been reported after administration of doses above 0.8 mg/kg/day. Hypotonia and somnolence have been specifically reported in infants treated with vigabatrin. The risk for visual field defects due to vigabatrin is not evaluable at this age, even using electroretinography [11]. A recent study confirms that retinal toxicity is associated with duration and dose of vigabatrin therapy, and is therefore lower in children than in adults [12]. Adverse events were reported to be similar in infants and older children taking lamotrigine or oxcarbazepine as add-on therapy [13,14]. By contrast, metabolic acidosis induced by topiramate may be more frequent in infants than in adults [15].

Available formulations of many AEDs are unsatisfactory for use in infants. For instance, phenytoin and clobazam do not have

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

a formulation suitable for infants. However, the pharmaceutical industry is currently investing in the development of formulations of new AEDs that would be appropriate for use in infants. These include liquid forms of oxcarbazepine and levetiracetam, low-dosage tablets or capsules of lamotrigine, topiramate and gabapentin, and the innovative chronosphere formulation of valproate as controlled-release formulation suitable for low daily dosages.

Characteristics of infantile epilepsies

The distinction between partial and generalized epilepsies, which is considered crucial to determine drug choice in children and adults, is not easily applicable to infants. Generalized epilepsy syndromes may be difficult to identify at onset because their initial manifestations involve partial features. There can also be rapid changes in epilepsy syndromes during infancy, eventually sometimes mixing the characteristics of both partial and generalized epilepsy, as in the case of infantile spasms progressing to partial epilepsy.

The incidence of epilepsy is higher in infancy than in childhood, possibly due to active maturational phenomena, and infancy is therefore a critical period for epileptogenesis. For the same reasons, epilepsy carries major associated risks in this age group, including a risk for altered motor function, as in the hemiplegia–hemiconvulsion syndrome, and a risk for cognitive deterioration, as in epileptic encephalopathies. Epileptic encephalopathies are conditions in which neurological deterioration results mainly from epileptic activity. Cognitive deterioration can be due to very frequent or severe seizures, or to subcontinuous paroxysmal 'interictal' activity. The former situation is seen mainly in severe myoclonic epilepsy in infancy and in migrating partial epilepsy in infancy. Cognitive deterioration related to subcontinuous paroxysmal interictal activity is seen in infants with suppression bursts, as in Ohtahara's syndrome, and in infants with infantile spasms.

Effects of antiepileptic drugs on infantile epilepsies

The efficacy of AEDs is partly determined by the type of epilepsy syndrome. Some syndromes may be improved by certain drugs, whereas others may be worsened. For example, carbamazepine may worsen infantile spasms and myoclonic epilepsies [16], lamotrigine may worsen severe myoclonic epilepsy in infancy [17] and vigabatrin may aggravate myoclonic epilepsies.

The management of infantile epilepsy syndromes

Epileptic encephalopathies

Epileptic encephalopathies comprise a series of age-related generalized epilepsy syndromes that in infancy include, in order of decreasing frequency, infantile spasms, severe myoclonic epilepsy in infancy and myoclonic epilepsy in non-progressive encephalopathy, which mostly occur between 3 and 9 months, infantile epileptic encephalopathy with suppression bursts (Ohtahara's syndrome) and infantile epilepsy with migrating partial seizures, which occur in very young babies, at a mean age of 3 months. The last two conditions are to date so intractable that no therapeutic strategy provides seizure control. The reverse is true for infantile spasms, severe myoclonic epilepsy in infancy and myoclonic epilepsy in non-progressive encephalopathy, which, although often are highly refractory, can be improved by specific treatment algorithms.

Infantile spasms (West syndrome)

Infantile spasms (IS) usually occur between 3 and 8 months, with a peak at 4 months. Diagnosis relies on the classical triad of seizures, epileptic spasms, a specific electroencephalogram (EEG) pattern (hypsarrhythmia), and psychomotor deterioration. In fact, one of the three components may be lacking or be atypical. Spasms may be clinically subtle or even subclinical, particularly at onset of the disease or when they are incompletely controlled, thus making EEG a necessary tool to prove their complete disappearance. The spasms may be symmetrical or asymmetrical. Video recording is often required for detailed analysis because asymmetry of spasms or a focal discharge may reveal a focal cortical lesion. Psychomotor deterioration is usually rapid from the time of onset of the epilepsy. The status of psychomotor development (normal or abnormal) before onset is important to be assessed because it carries prognostic implications, with better outcome for patients without regression of eye tracking.

About 30% of children with IS have normal MRI, so-called cryptogenic/idiopathic IS. A large range of cerebral lesions can be the cause in remaining cases, including cortical malformations (such as agyria–pachygyria, hemimegalencephaly, focal cortical dysplasia or polymicrogyria), sequelae of pre-, per- or postnatal anoxic ischaemia (such as periventricular leucomalacia of premature infants, porencephaly or sequelae of subdural haematoma), infection of central nervous system (such as meningitis or encephalitis), neurocutaneous syndromes (such as tuberous sclerosis or neurofibromatosis), chromosome disorders (such as Down syndrome or mutations in *ARX*, *CDKL5* [18] or *Kir 6.2* genes) or inherited metabolic disorders (such as pyridoxine dependency, Menkes' disease or mitochondrial disease due to *NARP* mutation [19]). As a result, specific aetiological treatment (pyridoxine, surgery) is rarely possible, With advances in neuroimaging techniques, the proportion of cryptogenic cases has progressively decreased. However, subtle cortical dysplasia may still be missed by MRI unless cerebral maturation and myelination is sufficient to allow clear differentiation of the grey and white matter, which is usually after 2 years of age. The availability of functional neuroimaging using positron emission tomography (PET) of glucose utilization allows up to 95% of cases initially thought to be cryptogenic to be correctly classified as symptomatic. The majority of cases with unifocal or multifocal abnormalities on PET are believed to represent dysplastic cerebral lesions. This is of importance as about 20% of infants with these lesions on PET could be candidates for epilepsy surgery if they remain refractory to medical treatment.

The term 'idiopathic West syndrome' has been used to describe the condition in some patients who recover spontaneously following a brief period of infantile spasms. Probably less than 5% of patients with West syndrome have the truly idiopathic form.

West syndrome takes a special place among childhood epilepsies because of the severe prognosis in terms of seizure recurrence and mental development, rapid deterioration of psychomotor status at the time of onset of the epilepsy and usual resistance to

conventional AEDs. The treatment of infantile spasms should therefore have two goals: the control of both the seizures and the hypsarrhythmia. Complete cessation of spasms is a prerequisite. The two major therapeutic approaches consist in hormonal treatment [adrenocorticotropin hormone (ACTH) and steroids] and vigabatrin.

Conventional antiepileptic drugs and new antiepileptic drugs other than vigabatrin

Infantile spasms are one of the most resistant epilepsy syndromes. Conventional AEDs are usually ineffective. Most of them were tested through open trials. Valproate and clonazepam control about one-quarter and one-third of the cases, respectively, but relapse rate is very high. Nitrazepam was as effective as ACTH in a randomized study, but there were life-threatening side-effects [20]. Pyridoxine has been proposed, but was disappointing [21]. A positive response was found in 12 out of 37 infants when adding sulthiame to pyridoxine as primary therapy in a randomized double-blind placebo-controlled trial performed in Germany, a country where sulthiame is extensively used in epileptic children [21]. Initial promising reports with immunoglobulins were not confirmed in later studies. Worsening has been observed with carbamazepine use [16].

Preliminary data suggest some improvement with lamotrigine used as add-on therapy [4]. Prolonged control of spasms was found in 4 out of 11 patients with refractory infantile spasms treated with add-on topiramate at a very high dose, but none of these patients had received vigabatrin before [22]. Felbamate, zonisamide, the ketogenic diet and thyrotropin-releasing hormone may be occasionally helpful in refractory cases. The two major therapeutic approaches are hormonal treatment (ACTH or corticosteroids) and vigabatrin.

Adrenocorticotropin hormone and corticosteroids

The first and most extensively studied hormonal therapy in infantile spasms is ACTH. In the review by Dulac and Schlumberger [23], the often recommended daily dose of 40 international units (IU) (3–6 IU/kg) controlled seizures initially in about 75% of the patients. A lower dose (20 IU) was less efficacious and, because of relapse long-term response rates, higher doses of ACTH (150 IU), even though they were more efficacious initially, did not show significant differences between the 40 IU and 150 IU dosage regimens. A long duration of treatment (more than 5 months) at 40 IU/day in one series seemed to be more efficient than a duration of less than 1 month in another. Relapse rates ranged from 33% to 56%. Although relapse rates according to treatment duration were not reported, the lowest relapse rates were observed in patients receiving prolonged high-dose treatment. After a first relapse, a second course of therapy produced a 74% response rate. The incidence of cushinghoid adverse events approaches 100%. Other common adverse effects include infections, increased arterial blood pressure, gastritis and hyperexcitability. These are often reported as severe, with a mortality rate between 2% and 5%.

Oral steroids are less extensively prescribed, although they seem to be better tolerated than ACTH. For hydrocortisone, reported adverse effects rates are in the order of 17%. In a prospective, randomized, blinded study, the efficacy of prednisone (2 mg/kg/day) was inferior to that of ACTH (150 IU/day) given for 2 weeks, but no differences were found when ACTH was administered at lower doses [24,25]. There are no controlled studies comparing hydrocortisone with ACTH but a prospective study including 94 infants, treated for 2 weeks with 15 mg/kg/day hydrocortisone and given tetracosactrin for another 2 weeks if spasms persisted, showed that 74% of patients benefited from low doses of oral steroids, with a relapse rate of 18%. Among the 10 infants treated secondarily with tetracosactrin, nine ceased having spasms [23]. The superiority of ACTH over oral steroids in the management of infantile spasms could be explained by its stronger feedback inhibition of corticotrophin-releasing hormone (CRH) secretion (a factor causing spasms) than that of oral steroids [26].

Rates for favourable cognitive outcome range from 14% to 58% and are higher in cryptogenic than in symptomatic cases. In a large series of 214 Finnish children with symptomatic infantile spasms, about 90 had normal intelligence and socioeconomic status at 20–35 years' follow-up [27]. They represented 64% of the surviving patients (one-third died before 3 years of age, mostly because of infection). All patients in this report had received ACTH. This argues strongly in favour of the prescription of this form of treatment, even in symptomatic cases.

Vigabatrin

The development of vigabatrin has totally modified the approach to the treatment of infantile spasms in the last 15 years. Shortly after an initial add-on open study had shown a complete control of spasms in 43% of 70 patients with refractory West syndrome [28], vigabatrin was advocated for first-line monotherapy. Because it provided an improvement over steroids or ACTH in terms of tolerability and rapidity of the effect, it rapidly became the drug of first choice for infantile spasms in most countries in which this drug was approved, and extensive experience in routine clinical practice appeared to confirm its efficacy as first-line treatment [29,30]. However, the discovery of the risk of retinal toxicity has limited enthusiasm for the use of vigabatrin.

Overall, five randomized studies have been reported of vigabatrin as first-line monotherapy in infantile spasms. In cases of spasms owing to tuberous sclerosis, vigabatrin has proved to be more efficacious, to act more rapidly and to produce less side-effects than oral hydrocortisone. In one study, a small sample of 22 patients was enough to demonstrate a difference ($P < 0.01$) between the two arms, with 100% responders on vigabatrin versus 45% on hydrocortisone at 1-month therapy [31]. In contrast, hormonal treatment was superior to vigabatrin when patients with all aetiologies of spasms were considered [32] or those with tuberous sclerosis were excluded. In a study of 107 patients, there were more responders at 2 weeks on prednisolone or tetracosactrin (73%) than on vigabatrin (54%) ($P < 0.04$) [33]. Similarly, a study of 40 infants with infantile spasms not due to tuberous sclerosis just failed to demonstrate a significant superiority of vigabatrin over placebo, with 35% and 10% responders, respectively ($P < 0.06$) [34]. Finally, a dose-ranging study confirmed the rapid effect and the significantly higher response in tuberous sclerosis than in other aetiologies, and proved that high doses (100–150 mg/kg/day) produced the best results [35].

In the long term, the efficacy of vigabatrin is maintained in about 75% of cases, a proportion similar to that of hormonal treatment, despite the short-term superiority of the latter in non-tuberous sclerosis patients [36]. The most serious side-effect of vigabatrin is its retinal toxicity, which causes constriction of the peripheral visual field. Although this condition has always been asymptomatic in children, it seems to be relatively frequent and irreversible even after stopping the drug. Prevalence of vigabatrin-induced visual field defects is now established to be lower in children than in adults (about 20% in children compared with over 30% in adults), and this is probably because of the lower cumulative drug exposure in children [12]. No case has been found in a child who has had less than 15 months of vigabatrin exposure [37]. However, it is important to caution that it is very difficult to assess the visual field by perimetry in a child below a developmental age of 8 years, although a specific method based on visual-evoked potentials seems to be promising in infants and young children [38].

Proposals for the management of infantile spasms

Vigabatrin and hormonal therapy have a similar efficacy at 1-year follow-up, whereas the former is more effective in tuberous sclerosis and the latter in other causes in the short term. They both have side-effects, although different in potential severity. Vigabatrin induces peripheral visual field in around 20% of cases, and hormonal therapy carries a mortality rate up to 5%. There are local variations in the choice of first-line therapy for infantile spasms, and the choice depends, to an extent, on the influence of local experts [39]. The following questions need to be addressed in devising a management strategy. Does early control of spasms impact on further outcome? What should be the criteria of early control? How long should treatment with vigabatrin be continued?

The early control of spasms seems to improve psychomotor development. In infants with tuberous sclerosis, early control of seizures was found to lead to a significant improvement of cognitive functions in the following 7 years, despite the possible emergence of partial seizures [40]. Developmental quotient (DQ) significantly rose in six of the seven spasm-free patients by 10 to over 45 DQ points, and autistic behaviour disappeared in five out of the six patients who manifested such behaviour. In infants with no identified underlying aetiology, the Vineland score at 1 year was higher in those allocated hormone treatment than in those allocated vigabatrin [36]. The aetiology of infantile spasms may therefore be the major factor for the choice of first-line therapy. Although data still remain limited, there is some evidence that vigabatrin should be preferred in focal cortical dysplasia but hormonal treatment should be preferred in cryptogenic or anoxic ischaemia because of prematurity.

Although individual response to treatment is unpredictable because a sizeable proportion of spasms are difficult to treat, with some responding easily, a graded therapeutic strategy should be considered, provided this is complete within less than 1 month. The endpoint in treating this syndrome is the cessation of spasms and the disappearance of spikes on EEG. Whether vigabatrin or hormonal treatment is initiated, we recommend switching to alternative therapy no later than within 4 weeks where response has been incomplete (i.e. persisting clinical or infraclinical spasms and/or persisting multifocal spikes) at adequate dosages (i.e. at least 100 mg/kg/day for vigabatrin and 40 IU/day for ACTH). Further data are needed to determine the benefit of switching or adding such alternative therapy.

The duration of vigabatrin treatment in controlled patients should be determined by balancing the risk of visual field defects and the risk of relapse of intractable spasms [41]. No case of visual field defect has been reported in children after less than 15 months of vigabatrin exposure [37]. On the other hand, the persistence of spikes on the EEG seems to be the best predictor of relapse of spasms, particularly in infants and in the case of cerebral lesions [42]. Five infants with infantile spasms associated with Down syndrome were reported in whom vigabatrin could be stopped at the age of 15 months without relapse [43]. It seems, therefore, reasonable to stop vigabatrin monotherapy at around 2 years of age if the EEG is normal. A decision to stop therapy is less easy in children with tuberous sclerosis or focal malformations of cortical development, in whom there is a substantial risk of precipitating refractory partial epilepsy when vigabatrin is discontinued [44].

Severe myoclonic epilepsy in infancy (Dravet's syndrome)

Dravet's syndrome is a rare disease affecting 1 in 30 000 to 1 in 40 000 children. Among the severe childhood epilepsies listed in the classification of the International League Against Epilepsy (1989), it is one of the most deleterious. The first seizures occur between 2 and 9 months of age. They are tonic–clonic or clonic seizures, either generalized or affecting alternatively one side of the body, often prolonged, resulting in recurrent status epilepticus and often provoked by fever. Children typically have a normal perinatal history and initially present with normal psychomotor development, normal neurological examination and normal EEG between seizures. The pattern changes from the second year, and tonic–clonic or clonic seizures persist with the same characteristics but additional myoclonia, atypical absences, and partial seizures occur, and patients develop ataxia, hyperactivity and mental retardation. The EEG shows generalized spike–waves during sleep, and spontaneous generalized spike–waves and poly-spike–waves as well as a slowing down of the background activity.

Borderline forms were identified by Japanese authors with potential later onset, no later myoclonia, better cognitive outcome, and less pharmacoresistance [45]. These forms are relatively rare and do not differ from typical Dravet's syndrome at onset. Dravet's syndrome is thus a quite homogeneous syndrome that is relatively easily identifiable, based on electroclinical features, from 1 year of age. A score of earlier diagnosis is currently under validation in Japan [46].

Nonsense mutations (or less commonly microdeletions or duplications) of the *SCN1A* gene, which codes for the α_1-subunit of the voltage-dependent sodium channel, have been identified in up to 70% of patients with Dravet's syndrome [47]. Although identifying an *SCN1A* mutation is helpful in the diagnosis of atypical forms, the diagnosis still relies on electroclinical criteria, as no mutations are found in a quite significant proportion of patients with confirmed Dravet's syndrome, and occasional patients with other types of epilepsy can also exhibit *SCN1A* mutations [48].

Severe myoclonic epilepsy in infancy is one of the few epilepsy syndromes in which the epilepsy is refractory from its onset.

Mental prognosis is poor, with a cognitive decline from normal to severe retardation as soon as the second year of life. The age of onset of mental deterioration and its magnitude seem to be related to the frequency of seizures [49]. AEDs that impact positively on seizure activity would also be expected to affect favourably cognitive prognosis.

Most authors agree that the response to conventional AEDs is generally disappointing. Valproate and benzodiazepines may decrease the frequency and duration of afebrile convulsive seizures but their effect is modest. Some investigators associate phenobarbital, phenytoin or ethosuximide with poor outcome. Japanese authors recently reported bromide as the best compound to prevent status epilepticus in a retrospective review of 99 children with Dravet's syndrome [50]. Paradoxically, some AEDs can aggravate the seizures and should be avoided. In one study, lamotrigine induced worsening of seizures in 80% of 20 patients recruited at three epilepsy centres [17]. In a personal series of 46 patients, 67% of those who received lamotrigine experienced a worsening of seizures, as did 64% of those who received vigabatrin and 61% of those who received carbamazepine [51].

Two new drugs, stiripentol and topiramate, can be helpful in some patients. The main action of the stiripentol compound, when given as add-on therapy, is to inhibit the hepatic cytochrome P450 system, resulting in increased plasma concentration of concomitant AEDs, particularly clobazam. The efficacy and tolerability of stiripentol as add-on therapy in children with refractory epilepsy were first assessed in more than 200 patients in an open trial [52]. Of the 20 children with Dravet's syndrome included in this trial, 10 experienced a more than 50% decrease in seizure frequency when stiripentol was used in combination with valproate and clobazam. These results were confirmed in 41 children with Dravet's syndrome included in a randomized placebo-controlled trial of stiripentol at a mean dosage of 50 mg/kg/day added to valproate and clobazam [53]. Fifteen (71%) patients on stiripentol were responders for tonic–clonic seizures (including nine who became seizure free), whereas there was only one partial responder (5%) on placebo. The percentage change in seizure frequency from baseline was higher on stiripentol (–69%) than on placebo (7%) ($P < 0.0001$). Twenty-one patients had moderate side-effects (drowsiness, loss of appetite) on stiripentol compared with eight on placebo. Most of these side-effects were related to a significant increase in the plasma concentration of valproic acid, clobazam and norclobazam after adding stiripentol, and disappeared when the dose of co-medication was decreased. A comparable superiority of stiripentol on placebo as adjunctive therapy in the short term was independently replicated in a second trial using the same design. To study the long-term usefulness of stiripentol, we assessed retrospectively our cohort of 46 patients with severe myoclonic epilepsy in infancy treated with stiripentol in combination with valproate and clobazam [51]. None of the patients remained seizure free after a median follow-up of 3 years; however, the frequency and the duration of seizures was significantly reduced, as was the number of episodes of convulsive status epilepticus. Response appeared to be better in younger patients. The most frequent adverse effects were loss of appetite and loss of weight. Overall, these results suggest that stiripentol maintains its long-term efficacy, and that it should be introduced in polypharmacy as early as possible in order to prevent convulsive status epilepticus.

Topiramate has not been as extensively studied. In two open studies conducted each in 18 patients, add-on topiramate was given at maximum dosages of 6–8 mg/kg/day and 12 mg/kg/day [54,55]. After a mean 1-year follow-up, 55% of the patients from both studies experienced a more than 50% seizure decrease and three were seizure free. In no patient were seizures aggravated, and side-effects were observed in nine and four patients respectively. These were generally mild and transient and related to rapid dosage titration. Adverse effects usually attributed to valproate, such as apathy and elevated blood ammonia levels, have been recently reported in patients receiving a combination of topiramate and valproate, possibly due to an interaction between these drugs. In a retrospective study of 36 patients with Dravet's syndrome retrospectively considered unsatisfactorily controlled using stiripentol, 78% showed more than 50% reduction in the frequency of generalized tonic–clonic seizures and status epilepticus after the introduction of topiramate and 17% remained seizure free for at least 4 months. The association of stiripentol and topiramate did not induce additional side-effects and did not need any particular adaptation of dosages [56].

In conclusion, because of the remarkably stereotyped clinical manifestations at onset, diagnosing severe myoclonic epilepsy in infancy is usually feasible early in the course of the disorder. The diagnosis should be suspected in any infant experiencing recurrent prolonged seizures with only moderate fever (so-called 'complex febrile seizures') and can usually be confirmed as soon as afebrile seizures occur. We suggest the use of AED treatment as soon as a first complex febrile seizure occurs in a young infant, as well as intermittent prophylaxis with diazepam in case of fever. Because of the risk of exacerbating seizures with phenobarbital in young children, we recommend valproate as the first-choice drug in this context. The combination of clobazam and stiripentol clearly adds benefit after the first prolonged seizure or repeated seizures, by decreasing seizure duration significantly. Topiramate may also be helpful in combination with valproate and benzodiazepines. We also recommend the avoidance of carbamazepine, vigabatrin and lamotrigine, which may exacerbate the epilepsy. In some countries, notably Germany and Japan, topiramate and even bromide are used as second-line therapy.

Differential responses to AEDs in patients with severe myoclonic epilepsy in infancy could be related to the existence, in this condition, of defects affecting a sodium channel gene. This could explain why AEDs which act mainly by blocking sodium channels (carbamazepine, phenytoin and lamotrigine) do not appear to be effective and may even worsen seizures, whereas broad-spectrum AEDs like valproate, benzodiazepines and topiramate may confer some benefit [57].

Myoclonic epilepsy in non-progressive encephalopathy

Non-progressive encephalopathies are a group of conditions with various aetiologies including pre- and perinatal anoxia–ischaemia, fetopathies and chromosome abnormality syndromes such as Angelman's syndrome. Myoclonic seizures are experienced by these patients during infancy, usually very early in life. In addition to massive myoclonic manifestations, erratic myoclonic manifestations are frequent and often misdiagnosed [58]. They can be

associated with non-convulsive status epilepticus, and they may be prolonged for weeks or months before being diagnosed by EEG. As a result, patients experience psychomotor and neurological deterioration, which simulates the deterioration typical of a progressive encephalopathy. Because of the myoclonic components, carbamazepine, phenytoin and vigabatrin frequently worsen the epilepsy. Valproate is usually the first-choice agent, followed by benzodiazepines. Lamotrigine has unpredictable effects: it may be very useful in some cases and precipitate myoclonus in others. Piracetam provides benefit in Angelman's syndrome, due to its antimyoclonic effects, but the high doses required are difficult to administer to infants [58].

Symptomatic and cryptogenic partial epilepsies

Diagnosing focal seizures and focal lesions is more difficult in infants than in later life. Because of the lack of subjective feedback from the patient, focal ictal symptoms are usually missed when they do not include any motor component. Because of myelinic immaturity, focal cortical dysplasia may be undetectable on MRI. As a result, pure focal epilepsies are likely to be overlooked in infancy. Moreover, a large proportion of infants with partial seizures develop infantile spasms during the first year of life. Choice of AED should therefore take into account the potential risk of generalized spasms being facilitated by the administration of carbamazepine. Carbamazepine therapy should be avoided unless there are facilities for close follow-up of clinical signs and EEG changes, especially in the first 6 months of life when spasms frequently develop. Valproate is preferred as a first-line agent, although it is often ineffective in infants with symptomatic partial epilepsy. Phenytoin and benzodiazepines are not recommended because of unfavourable pharmacokinetic and/or safety profiles in infants [2]. Among the new AEDs, only vigabatrin is currently approved for this age range, but four others have been recently studied in randomized controlled trials as adjunctive therapy in infants with partial-onset seizures. Gabapentin was found not to demonstrate any efficacy. High doses of oxcarbazepine (60 mg/kg/day) proved to be more efficient than low doses (10 mg/kg/day) [13], and lamotrigine to be more efficient than placebo using a randomized withdrawal design [14]. Studies of levetiracetam are currently under way.

Sturge–Weber syndrome has a particular place among symptomatic partial epilepsies in infancy. The diagnosis can be made before the occurrence of the first seizure, from the facial angioma located in the first division of the trigeminal nerve and by neuroimaging. More than 75% of patients develop epilepsy, 50% of them during the first year of life. These infantile seizures often result in convulsive status epilepticus and carry great risks for motor and mental development. Therefore, preventative treatment could be started before the first seizure occurs. We compared 37 children with Sturge–Weber disease, of whom 16 were treated with phenobarbital before the occurrence of the first seizure and 21 were treated after the first seizures [59]. Although prophylactic treatment did not significantly prevent the incidence of seizures and motor deficits, it decreased the number of episodes of status epilepticus, and mental development was found to be better in the group given prophylactic treatment (44% were mentally delayed in the latter group, compared with 76% in patients started on treatment after the appearance of seizures). Although a randomized prospective study is necessary to confirm these results, Sturge–Weber disease constitutes a possible model for the study of disease modification in severe epilepsy.

Idiopathic epilepsies

Compared with catastrophic epilepsies, idiopathic (i.e. 'benign') epilepsies are rare in infants. They include benign infantile convulsions, either sporadic or familial, and benign myoclonic epilepsy in infancy. In these conditions, there is normal development prior to the onset of the seizures, there are no underlying disorders, no neurological abnormalities and the interictal EEG is normal. Seizures are easily and completely controlled by treatment, usually with valproate given in monotherapy. These patients usually show a normal developmental outcome, although some learning difficulties have been reported occasionally on long-term follow-up of patients with benign myoclonic epilepsy in infancy [60].

Initiation of treatment in infantile epilepsies

The decision to start treatment in infantile epilepsies depends to a large extent on whether the syndrome is identified, because drug choice varies depending on the syndromic form. Thus, vigabatrin is usually preferred in infantile spasms or symptomatic focal epilepsies before 6 months of age, valproate is often the first choice in generalized or focal convulsive epilepsies (including severe myoclonic epilepsy in infancy) and carbamazepine can be given in symptomatic partial epilepsies after the age of 6 months to minimize the risk of the occurrence of spasms (which is considerable in younger age groups). If the syndrome is not identified, treatment with valproate is preferred. If there is any suspicion of an inborn error of metabolism, which represents a contraindication to the use of valproate (e.g. Alpers' disease), clobazam should be considered.

The prognosis of infantile epilepsies partly depends on a timely and appropriate AED choice. Diagnosis of the epilepsy syndrome is crucial in this process, since inappropriate medication can worsen the condition. There is place for the use of some new compounds as agents of first choice in this age range.

14 Management of Childhood Epilepsy Syndromes

Colin D. Ferrie
Leeds General Infirmary, Leeds, UK

Introduction

The syndromic approach to the epilepsies has proved very useful in children. A syndrome diagnosis at presentation may be possible in as many as 77% of children [1] and it usually offers the best guide to appropriate clinical management, including antiepileptic drug (AED) treatment. The International League Against Epilepsy (ILAE) currently recognizes well over 30 epilepsy syndromes, most of which occur in children. This chapter covers treatment of epilepsy syndromes encountered after 2 years of age, including adolescence. It concentrates on syndromes that characteristically only start in this age group. It is sometimes difficult to draw boundaries. Febrile seizures often start in infancy and juvenile myoclonic epilepsy and only epilepsy with generalized tonic–clonic seizures are often not diagnosed until adult life. All three are considered here. On the other hand, some idiopathic and familial focal epilepsies, such as autosomal dominant familial frontal lobe epilepsy and symptomatic focal epilepsies, including mesial temporal lobe epilepsy, are not included, despite being common in children. This is because they are not characteristically childhood as opposed to adult conditions.

Epilepsy syndromes are traditionally classified according to whether the seizure types encountered are generalized (generalized epilepsy syndromes) or focal (focal epilepsy syndromes) and whether the cause of the epilepsy is known (symptomatic epilepsy syndromes), unknown but an underlying cause suspected (probably symptomatic epilepsy syndromes) or unknown with no underlying structural brain lesion or other neurological signs or symptoms – only epilepsy (idiopathic epilepsy syndromes). However, this classification has largely outlived its usefulness. Not all seizures can be classified as focal or generalized; some epilepsies are characterized by both focal and generalized seizures and some epilepsy syndromes exist in idiopathic, symptomatic and probably symptomatic forms. In this chapter, a pragmatic approach will be followed. Treatment of febrile seizures (the most common epileptic seizure disorder, but not usually considered a type of epilepsy) will be considered first, followed by idiopathic generalized epilepsies (IGEs) (Table 14.1), idiopathic focal epilepsies (Table 14.2) and epileptic encephalopathies (Table 14.3). For each, the evidence from randomized controlled studies will be reviewed, followed by a review of important information from open studies, case series and case studies.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Treatment recommendations from the ILAE [2], the American Academy of Neurology (AAN) and the American Epilepsy Society [3,4] and the National Institute for Health and Clinical Excellence (NICE) [5] will be summarized. Recently surveys of the prescribing choices of expert US [6] and European physicians [7] who regularly treat children with epilepsy have been published and the findings from these are also summarized. Finally, practical advice will be given, based upon the various sources of evidence and personal experience.

Treatment of childhood epilepsy: the evidence base

The randomized controlled trial is considered the 'gold standard' when determining the effectiveness of a medical therapy. However, to be meaningful, at least two conditions must be met: the disorder being studied must be well defined with clear-cut diagnostic criteria, and the therapeutic outcome must be measurable and clinically relevant [8]. Many drug trials undertaken in childhood epilepsy fail one or both of these [9]. They often group together disparate disorders, such as focal seizures, generalized seizures or new-onset seizures, on the basis that this is necessary to achieve sufficient power. However, the STICLO study in Dravet's syndrome demonstrated that this is not always the case [10]. Many randomized controlled trials are of short duration, compare the study drug with placebo rather than with a comparator used in clinical practice and have as their principal outcome measure the proportion of children who have at least a 50% reduction in seizures compared with baseline. These studies are designed to achieve a market licence but are of little clinical relevance. The need for trials to be clinically relevant is emphasized in the ILAE's treatment guidelines [2]. The guidelines define class I evidence as that obtained from a randomized double-blind controlled trial with treatment duration of at least 48 weeks and with information on at least 24 weeks' seizure freedom data or at least 48 weeks' retention data. Moreover, there has to be demonstration of superiority or 80% power to detect at least a 20% difference in efficacy/effectiveness against a suitable comparator. No such study has been reported in any of the syndromes considered here.

Treatment of febrile seizures

Febrile seizures are the commonest epileptic disorder with a cumulative incidence of 2–5%. However, because the seizures

Table 14.1 Summary of the electroclinical features of the IGE of childhood.

Syndrome	Age at onset (years)	Seizure type(s)	Clinical notes	Principal EEG features	Prognosis
CAE	2–10 years (peaks at 5–7)	TAS: these usually last 4–20 s, are frequent (usually tens per day) with abrupt and severe impairment of consciousness (and hence frequent automatisms)	There is an important debate regarding the limits of CAE. Many authorities now favour excluding children with the following: other seizure types (except febrile) prior to onset of TAS; marked myoclonic phenomena during TAS; TAS (prior to AED treatment) with mild impairment of consciousness; irregular spike–wave discharges; photosensitivity	Regular generalized 3-Hz spike–wave discharges easily provoked by hyperventilation	Applying strict diagnostic criteria (see clinical notes), probably around 90% become seizure free by 12 years. Occasional patients develop GTCS in childhood, adolescence or adult life
JAE	5–20 years (peaks at 9–13)	TAS (all patients): these are similar to those in JAE but are not as frequent (a few per day maximum) GTCS (approx. 80% patients or more) MS (around 1 out of 5 patients) Absence status epilepticus (probably fairly common)	As for CAE there is debate as to the limits of this syndrome: Similar exclusion criteria have been proposed except that other seizure types, such as GTCS and MS, may precede TAS. GTCS often become the main problem in adolescence and adult life. MS tend to be infrequent and random rather than showing the characteristics of JME	Similar to CAE. Focal epileptiform abnormalities and abortive asymmetrical bursts of spikes/poly-spikes are common	Probably a life-long disorder, although seizures can be controlled in most patients. With time TAS usually become less frequent, shorter and associated with less severe impairment of consciousness. GTCS may become more troublesome
JME	TAS can begin as early as 5 years: more usually the syndrome begins in late childhood, adolescence or early adult life	TAS (about 1 out of 3 patients): usually brief with mild impairment of consciousness MS (all patients): characteristically occur shortly after awakening or towards the end of the day when tired. May be single or multiple, inconspicuous or violent GTCS (nearly all patients): usually start after GTCS. Often preceded by showers of MS Myoclonic and absence status epilepticus both described	Sleep deprivation, fatigue and alcohol are powerful seizure precipitants in IGE, but particularly JME. Clinical photosensitivity is less frequent than on EEG	Irregular generalized 3- to 6-Hz spike–wave discharges (poly-spikes common). Focal abnormalities with single spikes, spike–wave complexes or slow waves common Photosensitivity in 1 out of 3 patients	Probably a life-long disorder, although seizures can be controlled in most patients
EGTCS	From 6 until adult life (peak in mid-late adolescence)	GTCS	Seizures often occur shortly after awakening	Generalized spike–wave discharges. Up to 1 out of 4 of patients are photosensitive	Probably a life-long disorder, although seizures can be controlled in most patients
Jeavon's syndrome	2–14 years (peak 6–8)	Eyelid myoclonia with or without absences (all patients) GTCS (probably in all patients in the long-term) Absence status epilepticus relatively common	Seizures are provoked by eye closure (voluntary, involuntary or reflex) in light and by other photic factors. There is a controversy about the role of self-induction in the provocation of seizures	Generalized 3- to 6-Hz spike–wave discharges (mainly poly-spikes) which are brief and characteristically provoked by eye-closure in an illuminated recording room and by intermittent photic stimulation	Probably a life-long disorder and seizures (particularly eyelid myoclonia) are often very resistant to medication. However, photosensitivity often disappears in middle age
PMA	2–13 years (median 10)	TAS with rhythmic contractions of the perioral and/or jaw muscles accompanied by variable impairment of consciousness GTCS (probably all patients) Absence status epilepticus common		Generalized spike–wave discharges. Focal abnormalities common. No photosensitivity	Unclear, but may be life-long

CAE, childhood absence epilepsy; EEG, electroencephalogram; EGTCS, epilepsy with generalized tonic–clonic seizures only; GTCS, generalized tonic–clonic seizures; JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy; MS, myoclonic seizures; PMA, perioral myoclonia with absences; TAS, typical absence seizure.
Doose syndrome and epilepsy with myoclonic absences (EMA) are also now considered IGE. Their electroclinical features are summarized in Table 14.3.

Table 14.2 Summary of the electroclinical features of the idiopathic focal epilepsies of childhood.

Syndrome	Age at onset	Seizure types	Clinical notes	Principal EEG features	Prognosis
BECTS	1–14 years (peak 8–9 years)	Focal seizures with hemifacial sensorimotor symptoms, oro-pharyngo-laryngo manifestations, speech arrest and hypersalivation. Secondary generalized seizures are common in sleep	One of the most common epilepsy syndromes with a prevalence of 15% in children aged 1–15 years with seizures. Three out of four seizures occur in sleep, mainly at sleep onset or just before awakening. Most are short (1–3 min) and the total seizure count is usually low	The EEG hallmark is centrotemporal spikes which are high-amplitude sharp- and slow-wave complexes, localized in the C3–C4 or C5–C6 electrodes. They may be unilateral or bilateral, independently right or left. They are activated by sleep. Background EEG is normal	Remission is usually within 2–4 yeas of onset and expected before age 16 years. Some children develop cognitive, linguistic and/or behavioural abnormalities, although these are usually mild. A very small number have atypical evolutions associated with continuous spikes and waves during slow-wave sleep
PS	1–14 years (peak 4–5 years)	Autonomic seizures, particularly with emetic symptoms (nausea, retching ± vomiting). Syncopal-like episodes are also common. Consciousness is usually retained initially but becomes impaired. Secondary generalization may occur	The second most common idiopathic focal epilepsy of childhood. Two out of three of seizures start in sleep. Seizures are characteristically long, often constituting autonomic status epilepticus. The total seizure count is usually low	The interictal EEG shows great variability. Multifocal, high-amplitude, sharp- and slow-wave complexes are common. These are most often seen in the occipital regions but often affect other brain regions as well. Background EEG is normal	Remission usually occurs within 1–2 years of onset. The risk of epilepsy in adult life appears to be no higher than in the general population. As for BECTS, atypical evolutions have been described
IOLE (including IPOLE)	3–15 years. The photosensitive form may begin in childhood or adult life	Focal (occipital) seizures mainly with elementary visual hallucinations, blindness or both. Ictal or, more usually, postictal headache is common. Spread with other focal seizure symptoms or secondarily generalization occurs but relatively infrequently	A relatively rare syndrome. Seizures are usually frequent, diurnal and short (from a few seconds to 1–3 min). In the photosensitive form of the syndrome seizures are sometimes or always precipitated by photic factors	The characteristic interictal EEG abnormality is high-amplitude sharp- and slow-wave complexes occurring in long runs in the posterior head regions (occipital paroxysms). In the photosensitive form of the syndrome there is occipital and/or generalized photosensitivity	Remission occurs in 50–60% of patients within 2–4 years of onset. Persistence into adult life is not uncommon. The prognosis of the photosensitive form depends on the severity and persistence of the photosensitivity and the degree of exposure to provocative factors

BECTS: benign childhood epilepsy with centrotemporal spikes (benign rolandic epilepsy); EEG, electroencephalogram; PS: Panayiotopoulos' syndrome (early-onset benign childhood occipital epilepsy – Panayiotopoulos type); IOLE: idiopathic occipital lobe epilepsy (late-onset childhood occipital epilepsy – Gastaut type); IPOLE: idiopathic photosensitive occipital lobe epilepsy.

occur in the context of a reversible disturbance in homeostasis, even if recurrent, they are not considered a manifestation of epilepsy. Onset usually occurs between 6 months and 3 years and they are recurrent in one-third of affected children. Most febrile seizures are convulsive and, if short (<15 min), generalized and not repeated in the same illness, they are classified as simple; otherwise, they are classified as complex. Complex features increase the risk of subsequent epilepsy, which overall has an incidence of 7% by 25 years. Febrile seizures are considered benign, although they are very occasionally the first manifestation of a severe epilepsy, such as Dravet's syndrome. Prolonged febrile seizures are implicated in the pathogenesis of mesial temporal sclerosis, although the nature of this relationship remains controversial.

Findings from double-blind randomized controlled studies

An influential meta-analysis found nine placebo-controlled studies reviewing the effect of prophylactic treatment with antiepileptic drugs on the recurrence rate of febrile seizures [11]. The risk was significantly lower in children receiving continuous phenobarbital or sodium valproate than in those receiving placebo. However, four patients needed to be treated with valproate and eight with phenobarbital to prevent one recurrence. Compared with placebo, regular pyridoxine and regular phenytoin were not found to prevent recurrences.

An alternative approach to prevent recurrences has been the intermittent but regular use of antiepileptic or antipyretic drugs at the time of fever. The aforementioned meta-analysis found that

Table 14.3 Summary of the electroclinical features of the epileptic encephalopathies of childhood.

Syndrome	Aetiology	Principal clinical features	Principal EEG features	Prognosis
LGS	Two out of three cases are symptomatic of a variety of diffuse, multifocal and even focal brain insults, including some metabolic disorders. Also exists in a probably symptomatic form. A true idiopathic form recognized by some authorities	Onset is from infancy to late childhood, but peaks age 3–5 years. It may develop from West syndrome. Consists of a triad of multiple seizures, characteristic EEG and learning problems. The most characteristic seizures are tonic (especially nocturnal), atonic and atypical absence seizures. Other seizures, including GTCS and focal seizures, may occur. Myoclonic seizures are not prominent. Non-convulsive status epilepticus is common	The background EEG is usually slow. Paroxysms of slow (<2.5 Hz) generalized spike–wave discharges are characteristic and may be ictal or interictal. Sleep recordings often have paroxysms of fast rhythms which may be accompanied by tonic seizures	Overall, 80–90% continue to have seizures into adult life. Severely impaired cognition, often with significant behavioural disturbances, is the rule. A good prognosis, with normal cognitive functioning is reported in around 10–15% of cases
Doose syndrome	Considered an IGE. Similar symptomatic cases occur	Onset is in early to mid-childhood and peaks at 2–4 years. Febrile and afebrile GTCS usually precede the onset of myoclonic–astatic seizures, often with atonic, myoclonic and absence seizures. Myoclonic–astatic status epilepticus is common and is associated with a poorer prognosis. Associated neuropsychological deficits vary greatly in their occurrence and severity	EEG background is usually normal at start but may deteriorate. Paroxysms of 2- to 3-Hz generalized spike–wave and/or irregular spikes or poly-spikes are characteristic. There may be photosensitivity	Variable. Around one-half eventually become seizure free with normal or near-normal development
LKS	Characteristically develops in children with no structural brain problems who were previously neurodevelopmentaly normal	Onset is usually in early/mid-childhood, peaking at 5–7 years. Consists of a triad of acquired language problems (initially a verbal auditory agnosia which may progress to a global aphasia), cognitive and behavioural abnormalities (often severe), and seizures. Seizures can be of many different types and are often infrequent	EEG is mainly characterized by posterior temporal lobe sharp- and slow-wave complexes. These are highly activated by sleep. CSWS occurs at some stage in most, but not all cases	Seizures and EEG abnormalities often remit in childhood/adolescence and this is often accompanied by improvement in the language and neuropsychological disturbances. Around one-half of those affected function reasonably normally in adult life
CSWS	Around one-half of cases are symptomatic of pre-existing brain insults. May develop in children with idiopathic focal epilepsies, including BECTS	Occurs throughout childhood. Peak age of onset is 4–5 years of age. The first stage consists of a rather non-specific epilepsy (although seizures are most often nocturnal and often consist of prolonged hemiconvulsions). Usually after 1–2 years there is a deterioration in seizure control with neuropsychological decline. An opercular syndrome is seen in some. Eventually seizures and EEG abnormalities remit with some improvement in neuropsychological functioning	Continuous spike–waves during non-REM sleep is characteristic of the second stage of the condition	After seizures remit, most patients are left with significant neuropsychological deficits, often severe
EMA	Now classified as an IGE. However, similar symptomatic cases occur	Occurs throughout childhood. Peaks at about 7 years. The characteristic clinical features are myoclonic absences which are similar to typical absences but are accompanied by rhythmic myoclonic jerks, mainly of the shoulders, arms and legs. These may be accompanied by other generalized seizure types. Cognitive and behavioural decline is seen in at least half of patients, even if development was normal prior to the onset of the myoclonic absences	EEG background usually normal at start but may deteriorate or be abnormal in symptomatic cases. Discharges similar to those in CAE accompany myoclonic absences with myoclonic jerks occurring with the spike component of spike–wave complexes	Variable, a minority of children eventually become seizure free with normal or near-normal development

BECTS, benign childhood epilepsy with centrotemporal spikes (benign rolandic epilepsy); CAE, childhood absence epilepsy; CSWS, continuous spikes and waves during slow sleep; EEG, electroencephalogram; EMA, epilepsy with myoclonic absences; GTCS, generalized tonic–clonic seizures; IGE, idiopathic generalized epilepsy; LGS, Lennox–Gastaut syndrome; LKS, Landau–Kleffner syndrome; REM, rapid eye movement.

diazepam was not effective in preventing recurrences [11]. However, a later meta-analysis found that such treatment was effective, with 11.2% of children treated with diazepam during febrile episodes having one or more recurrences compared with 17.2% treated with placebo [12]. Later studies [13,14] showed that intermittent diazepam is particularly effective in those at high risk of recurrences. Intermittent paracetamol or ibuprofen administered during febrile episodes does not prevent further febrile seizures in those at risk [15,16].

Recommendations from expert committees and concluding remarks

Despite the demonstration that prophylactic treatment, whether regularly with phenobarbital or sodium valproate or intermittently with benzodiazepines, reduces the recurrence risk of febrile seizures, clinical practice has switched decisively away from such treatment. This partly reflects the adverse effect profiles of the available agents but is also heavily influenced by the benign nature of febrile seizures. The long-term outcome, including scholastic abilities, was found to be no different in a cohort of 289 children with febrile seizures randomized to either intermittent prophylaxis during fever with diazepam or no prophylaxis [17].

The American Academy of Pediatrics concluded that neither continuous nor intermittent prophylaxis with antiepileptic drugs could be recommended and that neither could the administration of antipyretic drugs during febrile illnesses in order to prevent recurrent febrile seizures [18]. The recommendations of the US and European expert committees are shown in Table 14.4.

Febrile status, usually defined as a febrile seizure lasting at least 30 min or a series of febrile seizures over a period of at least 30 min without full recovery of consciousness between seizures, is still considered an emergency with a risk of both morbidity and mortality. Termination of prolonged febrile seizures using standard protocols for the treatment of status epilepticus is appropriate. Many paediatricians provide the carers of children judged to be at high risk of prolonged febrile seizures with 'rescue medication', particularly rectal diazepam and more recently nasal or buccal midazolam [19]. Given that most febrile seizures last less than 2 min, it is usual to advise administration of rescue medication for seizures lasting longer than this. However, provision of such medication to all children who have had febrile seizures is probably not justified.

Treatment of idiopathic generalized epilepsies

Idiopathic generalized epilepsies (IGEs) are common, particularly in mid and late childhood and adolescence. In these epilepsies, three seizure types are recognized: typical absence seizures (TAS), myoclonic seizures (MS) and generalized tonic–clonic seizures (GTCS). IGE is usually subdivided, and the best-characterized subdivisions are childhood absence epilepsy (CAE), juvenile absence epilepsy (JAE) and juvenile myoclonic epilepsy (JME). The ILAE also recognizes benign myoclonic epilepsy of infancy (BMEI), epilepsy with generalized tonic–clonic seizures only (EGTCS), epilepsy with myoclonic absences (EMAs) and epilepsy with myoclonic–astatic seizures (Doose syndrome). BMEI usually begins under the age of 2 years and is considered in Chapter 14. EMA and Doose syndrome were, until recently, considered as probably symptomatic or symptomatic epilepsies. Both often behave as epileptic encephalopathies and are considered later in this chapter. Finally, there are other proposed syndromes of IGE that characteristically start in childhood and adolescence but are not yet recognized by the ILAE. These include eyelid myoclonia with absences (also known as Jeavon's syndrome) and perioral myoclonia with absences (PMA). Clinical and electroencephalogram (EEG) features of all these syndromes are summarized in Table 14.1.

Findings from double-blind randomized controlled trials

The evidence base from double-blind randomized controlled trials for the treatment of IGE in children is extremely poor. A recent Cochrane review of TASs in children and adolescents found four studies that met its inclusion criteria. However, serious methodological problems were identified in all studies, and a meta-analysis was not considered appropriate. The Cochrane review concluded that these studies did not reliably inform clinical practice [20]. There are no Cochrane reviews to guide management of the other IGEs.

Ethosuximide and sodium valproate have been used for many years to treat IGE. Suzuki *et al.* [21] compared ethosuximide with sodium valproate in 35 children with 'pure petit mal seizures' in a double-blind trial and found no significant difference in response. Sato *et al.* [22] also compared ethosuximide and sodium valproate in a complicated double-blind study that included assessment of efficacy in treatment-naive patients and in patients refractory to ethosuximide. There was a good response to both drugs in the treatment-naive patients but no overall evidence of the superiority of either drug either in treatment-naive patients or in refractory patients. Sato *et al.* [23] compared ethosuximide and clonazepam in 79 children with absences. The retention rate at the end of the trial was better with ethosuximide (92%) than with clonazepam (69.8%).

Frank *et al.* [24] used a complicated trial design in which children with TAS first received lamotrigine in an open-label phase. Responders were then randomized in a double-blind manner to treatment with either lamotrigine or placebo. In the open-label phase 71% of patients became seizure free. In the randomized phase 64% were seizure free on lamotrigine compared with 21% on placebo ($P = 0.02$). Beran *et al.* [25] used a cross-over design to compare lamotrigine and placebo in 22 patients with various IGE who had failed on sodium valproate. Fifty per cent of those with GTCS and 33% with absences had at least a 50% reduction in seizures with lamotrigine.

A double-blind placebo-controlled trials of the use of topiramate in children and adults with primary generalized tonic–clonic seizures was reported by Biton *et al.* [26]. Many, but not all, of the patients had IGE and a post hoc analysis of the 22 patients with JME found that topiramate reduced GTCS by 73% compared with 18% in the placebo group [27].

The efficacy of levetiracetam for the treatment of MS and GTCS in IGE in adolescents and adults has been evaluated. Verdru *et al.* reported that 58% of adolescents and adults treated with levetiracetam in a double-blind, placebo-controlled trial of 122 patients had at least a 50% reduction in seizures compared with 23% treated with placebo [28]. Berkovic *et al.* found that 72% of children and adolescents with an IGE treated with

The treatment recommendations shown have all been published since 2004.
BECTS, benign childhood epilepsy with centrotemporal spikes (benign rolandic epilepsy); CAE, childhood absence epilepsy; CSWS, continuous spikes and waves during slow sleep; IGE, idiopathic generalized epilepsy; IOLE, idiopathic occipital lobe epilepsy (late-onset childhood occipital epilepsy – Gastaut type); JAE, juvenile absence epilepsy; JME, juvenile myoclonic epilepsy; LGS, Lennox–Gastaut syndrome; LKS, Landau–Kleffner syndrome; PS, Panayiotopoulos' syndrome (early-onset benign childhood occipital epilepsy – Panayiotopoulos type).
[a]The guidelines refer to treatment of TAS rather than CAE.

levetiracetam in a double-blind, placebo-controlled trial of 229 patients had at least a 50% reduction in GTCS compared with 45% treated with placebo [29].

Findings from other studies

There are numerous open studies, case series and case reports of the treatment of children with IGE, many of which are very small. Recent detailed reviews have been published by Hitiris and Brodie [30] and Bergery [31]. What follows is a summary of important clinical points from these reports.

Ethosuximide was the first of the 'modern' AEDs reported to be efficacious in 'petit mal'. A number of open, add-on, non-comparative studies were reported [30]. Overall these showed a seizure-free rate of just over 50% but the poor study designs make it difficult to determine what proportion of patients with absence epilepsy responded to the drug. Nevertheless,

ethosuximide is established as a first-line AED for TAS and therefore is similarly associated with CAE. It is not generally considered effective for GTCS and, therefore, neither is it considered effective for JAE and JME. However, Schmitt *et al.* [32], in a retrospective review of 238 patients with absences and 3-Hz spike–wave discharges, found that GTCS were no more likely to develop in those patients treated with ethosuximide than in those treated with other AEDs.

Sodium valproate has been assessed both in open non-comparative studies and in single-blind, placebo-controlled trials in both children and adults with TAS (with or without other seizure types) [31]. These suggest that valproate is efficacious for TAS with seizure-free rates of between 88% and 95%. Case series have also demonstrated good responses to sodium valproate in JME, with seizure freedom rates of 54–93%. The recently reported SANAD B trial compared treatment with sodium valproate, lamotrigine and topiramate (prescribed randomly but unblinded) in 716 children and adults in whom the treating physician considered sodium valproate to be the drug of first choice. Over 60% of patients with TAS had IGE. Sodium valproate was superior to both lamotrigine and topiramate in terms of time to treatment failure and to lamotrigine but not topiramate in terms of time to 12 months' remission. The authors concluded that sodium valproate was more efficacious than lamotrigine and better tolerated than topiramate [33].

Old reports of the use of acetazolamide suggested efficacy both as monotherapy and as add-on therapy for absence seizures and for GTCS in JME [34–36]. It has never been considered a first-line therapy but continues to be used occasionally as an adjunctive treatment in patients with drug-resistant IGE. Similarly, benzodiazepines, particularly clonazepam and clobazam, have been reported as effective in the treatment of both absences and JME [37,38]. Particular efficacy for clonazepam against MS is claimed [39].

Open studies suggest that lamotrigine is an effective treatment for childhood absence epilepsy [40–42], including for initial treatment. However, the slow titration recommended means that control is likely to be achieved more quickly with sodium valproate. Open studies also suggest efficacy of lamotrigine in JME. Morris *et al.* [43] reported its use in 63 patients who had failed on treatment with sodium valproate and found good response rates for GTCS, TAS and MS. However, some patients had an increase in MS, a problem which has also been reported by others [44,45].

Cross *et al.* [46] reported a small open study of topiramate for childhood absences. One child became seizure free, two improved at low dose and two showed no improvement. An open study has suggested efficacy of topiramate in JME [47].

A number of open studies of levetiracetam add to the evidence from controlled studies of its efficacy in IGE. Cavitt *et al.* [48] found it to be effective against typical absences and Verrotti as efficacious as initial monotherapy in JME [49].

Reports of the use of zonisamide in IGE in children are scant. However, a retrospective notes review of using it to treat teenagers and young adults with JME found evidence of efficacy [50].

For many years carbamazepine and phenytoin were considered less effective or ineffective in IGE and, more recently, evidence from case series has demonstrated aggravation of seizures in IGE by these drugs and other newer 'narrow spectrum' AEDs, including vigabatrin, gabapentin, oxcarbazepine, tiagabine and pregabalin. All of these drugs should generally be avoided in children with IGE [51,52]. However, it is possible that refractory GTCS may respond. Phenobarbital is sometimes useful against GTCS in the IGE but may exacerbate TAS. In such cases in which cost considerations are paramount, it may be an appropriate choice.

Recommendations from expert committees

According to the criteria of the ILAE treatment guidelines, the highest level of evidence available is level C for treatment of children with TAS and D for treatment of JME (Table 14.4) [3]. The AAN appraisal of the new AED found evidence of the effectiveness of lamotrigine for the treatment of newly diagnosed TAS and limited evidence of the effectiveness of lamotrigine and topiramate as adjunctive therapy for refractory seizures in IGE [4]. The recommendations of NICE and the US and European expert committees are summarized in Table 14.4.

Concluding remarks

Treating children and teenagers with IGE is usually very rewarding as the success rate is high and many, notably those with CAE, can often successfully discontinue medication. Given that these syndromes are quite common, the lack of robust evidence to guide therapy is surprising. In managing children with IGE, avoiding drugs with the potential to exacerbate seizures is extremely important. Failure to appreciate this leads to apparent refractory epilepsy. Although AEDs such as carbamazepine may successfully control GTCS in patients with IGE (this is not well researched), such drugs should certainly initially be avoided in treating IGE and then be used only with extreme caution.

There is a reasonable evidence base that sodium valproate, lamotrigine, topiramate, levetiracetam and to a lesser extent zonisamide are active against seizures in all IGEs. However, lamotrigine is not a good anti-myoclonic agent and will exacerbate myoclonic seizures in a minority of subjects. Ethosuximide is usually reserved for childhood absence epilepsy, given its narrow spectrum of activity. The choice of AED in any individual is likely to be determined by an evaluation of possible adverse effects and the physician's familiarity with the individual drugs. The most common dilemma is what drug to choose in females of childbearing potential. Fears over the teratogenicity of sodium valproate cause many physicians to choose alternatives, although it must be stressed that lamotrigine (which is often chosen) is not without teratogenic risks and the other newer agents have not been sufficiently evaluated. Overall, sodium valproate remains the most widely prescribed AED for the IGE. Levetiracetam is also efficacious, especially in JME. Levetiracetam, like sodium valproate, is active against photosensitive seizures. The adverse effect profiles of both topiramate and zonisamide mean, in the author's opinion, that neither is likely to become a first-line agent for treating IGE.

Monotherapy is usually effective. In those patients who fail to achieve remission with first-line monotherapy, a trial of a second (and even a third) monotherapy agent is usually appropriate. Beyond that, combinations of AEDs may be needed. A therapeutic interaction between sodium valproate and lamotrigine has been reported [40]. In JME, the addition of a benzodiazepine (clonaz-

epam is probably the best) may be helpful in abolishing troublesome myoclonic seizures in patients in whom GTCS and absences have already been controlled. A similar approach may be helpful in eyelid myoclonus with absences. However, this syndrome often proves very resistant to drug treatment.

Non-drug treatments, such as the vagal nerve stimulator and the ketogenic diet, are rarely needed or contemplated for IGE. There are no published trial data on their effectiveness.

Remission, although not guaranteed, is expected in CAE. Therefore, it is nearly always appropriate to attempt AED withdrawal after two seizure-free years. Indeed, earlier withdrawal may sometimes be reasonable. If relapse occurs, treatment can be restarted and a further attempt at withdrawal made after a suitable interval. For those syndromes in which the prognosis for eventual seizure remission is less certain, notably JAE, it is still nevertheless usually appropriate to attempt withdrawal after suitable discussions with the patient and family. It is often less disruptive if relapse occurs before reaching adulthood. For JME, in which relapse is expected, AED withdrawal should be attempted only if it is clear that the patient understands the risk of recurrence.

Treatment of idiopathic focal epilepsy syndromes of childhood

The ILAE currently recognizes benign childhood epilepsy with centrotemporal spikes (BECTS); early-onset benign childhood occipital epilepsy (Panayiotopoulos type); late-onset childhood occipital epilepsy (Gastaut type); and idiopathic photosensitive occipital lobe epilepsy (IPOLE). BECTS is more commonly called benign rolandic epilepsy. Early-onset benign childhood occipital epilepsy (Panayiotopoulos type) is manifested with autonomic symptoms (and is probably not an occipital epilepsy). It is increasingly referred to as Panayiotopoulos' syndrome (PS). Late-onset childhood occipital epilepsy (Gastaut type) can more conveniently be called idiopathic occipital lobe epilepsy (IOLE). Patients with IPOLE are photosensitive but, otherwise, its clinical features are similar to those of IOLE, thus IPOLE can be considered a subgroup of IOLE. The features of these syndromes are shown in Table 14.2. Although there are a number of other proposed idiopathic focal epilepsies occurring in childhood, these are not well characterized and will not be considered further here.

Findings from double-blind randomized controlled studies

Given how common BECTS and PS are, the lack of high-quality evidence regarding their treatment is surprising. There are no double-blind placebo-controlled studies of PS or IOLE.

There are two double-blind randomized controlled studies in BECTS. Both used a forced exit strategy. Rating *et al.* [53] studied 66 children with BECTS randomized to receive sulthiame (5 mg/kg/day) or placebo for 6 months. The primary outcome measure was the rate of treatment failure events (TFEs). TFEs were seizures 7 days or more into treatment, intolerable adverse events, development of another epilepsy syndrome or termination by parent or patient. Twenty-five out of 31 patients treated with sulthiame had no TFEs compared with 10 out of 35 treated with placebo ($P = 0.0002$). TFEs were mainly seizures (four in the sulthiame group and 21 in the placebo group). Approximately 40% of patients who remained on sulthiame had normal EEGs at the end of the study period. On further analysis, it was concluded that sulthiame led to normalization of the EEG in the majority of subjects treated and that this persisted in over one-half of patients [54]. Effects on quality of life and on cognition and language were not studied. Bourgeois *et al.* [55] reported (in abstract form) a double-blind study of 225 children with BECTS randomized to receive either gabapentin (30 mg/kg/day) or placebo. Treatment was for 36 weeks or until a TFE event occurred. This was defined as a secondary generalized tonic–clonic seizure, three partial seizures, status epilepticus or worsening of seizure activity. Time to TFE was longer for those given gabapentin but this was not statistically significant using the log-rank test but was significant using Wilcoxon's test. The Kaplan–Meier estimate of those completing the 36-week treatment phase was 57% and 44% for gabapentin and placebo respectively. Withdrawals for adverse effects were 3.5% for gabapentin compared with 0% with placebo.

Findings from other studies

Peters *et al.* [56] reported an important population-based study comparing the effects of treatment (44 children) with non-treatment (36 children) in BECTS. Patients were not randomized but physician advice was a major determinant of treatment choice. Treatment was with carbamazepine in 82% of patients. After treatment, 44% of patients became seizure free compared with 11% of untreated patients. There was evidence that treatment prevented secondarily generalized seizures but not focal seizures. All patients eventually became seizure free 4–14 years after diagnosis and there was no evidence of improvement in educational achievement, school satisfaction or social adjustment in the treated group. The authors concluded that a non-AED treatment strategy could be offered.

In recent years, a number of non-randomized, uncontrolled studies have reported the use of the newer AEDs in BECTS. These have suggested that topiramate, levetiracetam and oxcarbazepine may be efficacious [57–60]. However, the small numbers treated and/or the lack of controls limits their usefulness when deciding on AED treatment for a syndrome characterized by a low seizure count and spontaneous remission. Kang *et al.* [57] compared 45 patients with BECTS randomized to open treatment with topiramate monotherapy (mean dose 3.5 mg/kg/day) with 43 randomized to open treatment with carbamazepine monotherapy (mean dose 21.6 mg/kg/day). After 28 weeks' treatment, approximately 70% of patients were seizure free on both treatments but there was evidence of adverse cognitive function and behavioural problems in those treated with topiramate. Kossof *et al.* [61] reported a pilot study of six children with BECTS with impaired auditory comprehension and verbal memory. Significant improvements were seen following switching from existing AED treatment to levetiracetam. Tzitiridou *et al.* [60] reported evidence that treatment of BECTS with oxcarbazepine is effective not only in controlling seizures, but in normalizing the EEG and preserving cognitive and behavioural abilities.

Reports suggest that some children with BECTS treated with carbamazepine or lamotrigine develop learning problems or aggravation of seizures and/or induction of new seizure types [52]. However, a causal link is not firmly established. In the

author's opinion it is likely that some reported cases are coincidental.

There have been over 1000 children with PS reported in a number of large case series. These have included details of how children with the syndrome were managed. A variety of drugs has been used but there has been no detailed analysis of the effectiveness of individual agents. In the most recent report, 172 patients received AED treatment and 20 received no AED treatment [62]. Treatment was mainly with carbamazepine (112 patients), with smaller numbers receiving sodium valproate, phenobarbital, oxcarbazepine and clobazam. One hundred and fifty-two of those treated became seizure free after treatment, although 71 had had only a single seizure before treatment. In all patients seizures remitted within 1–6 years of onset.

Far fewer patients with IOLE have been reported. The largest series to date was of 33 patients with the syndrome, including five who were photosensitive on electroencephalography (four of whom had light-induced seizures) [63]. All were treated with antiepileptic drugs, with sodium valproate and carbamazepine being the most commonly used agents. About 80% of the patients were reported to be seizure free (on or off medication) within 2–7 years of seizure onset.

Atypical evolutions of PS and IOLE with the development of other seizure types and continuous spikes and waves during slow-wave sleep have been reported [64]. However, the relationship of this to AED treatment remains unclear.

Recommendations from expert committees

The recommendations of the ILAE and NICE, and the results of surveys of US and European physicians for the treatment of BECTS, PS and IOLE are summarized in Table 14.4. The lack of consensus is striking.

Concluding remarks

Both BECTS and Panayiotopoulos' syndrome are exceptionally benign syndromes, and there is no evidence that AED treatment alters their long-term prognosis. Many clinicians advocate managing most children with these syndromes without regular AED medication, drug treatment being reserved for those children whose seizures are particularly unpleasant because of their symptomatology or frequency or both [65]. Parental attitudes often play a significant role in determining which children receive regular treatment. An alternative to regular AED treatment is the provision of rescue medication such as rectal diazepam and oral midazolam to terminate prolonged seizures. There are no studies comparing the risk–benefit ratio of such a strategy.

Two justifications are sometimes advanced in favour of treating children with BECTS and/or PS with regular AEDs. First, some children with BECTS develop linguistic, cognitive and behavioural problems. In part, this may be a consequence of transient cognitive impairment during interictal discharges. However, to date there is no convincing evidence that AED treatment can prevent this: indeed, it may cause it [66]. Second, PS is reported occasionally to result in cardiorespiratory arrest [67]. However, it is reassuring that the risk of SUDEP is not increased in children with idiopathic epilepsies.

If regular AED treatment is used, the excellent prognosis of BECTS and Panayiotopoulos' syndrome means that AED drug withdrawal after a suitable seizure-free interval (usually 2 years) is appropriate. Some children will relapse and a further course of treatment may be appropriate. However, given the natural history of these epilepsies, it should be possible to achieve AED withdrawal prior to the age of 16 years. The EEG is not helpful in planning when to withdraw AEDs as persistence of EEG abnormalities long after clinical seizure remission is common.

Treatment considerations in IOLE are different, both because seizures are usually frequent and because remission is less certain. Regular AED treatment is nearly always indicated and, although it is appropriate to try to withdraw AED medication after a suitable seizure-free interval, withdrawal may not be possible in childhood. In a minority of those with the photosensitive form of the syndrome, in whom all seizures are precipitated by photic factors, avoidance of such factors may be sufficient. For the rest, regular AED treatment is indicated. For those on medication, persistence of photosensitivity is a useful indicator of the likelihood of relapse if medication is discontinued.

Treatment of epileptic encephalopathies

An epileptic encephalopathy is defined by the ILAE as: 'A condition in which the epileptiform abnormalities themselves are believed to contribute to the progressive disturbance in cerebral function'. These are epileptic disorders in which, in contrast to non-encephalopathic epilepsies, on-going seizure activity is considered to be the cause of progressive neurological decline with cognitive impairment, behavioural disturbances and, in some cases, the appearance of ataxia and pyramidal signs. The mechanism(s) underlying the neurological decline is unknown. The epileptic encephalopathies must be distinguished from neurodegenerative disorders. In the epileptic encephalopathies the occurrence and severity of the associated neurological deficits vary greatly between individuals and, to a considerable degree, unpredictably. The deficits can fluctuate according to seizure control and, if seizure remission is eventually achieved, further decline is not expected. It follows that effective treatment may be expected to improve the ultimate prognosis. However, proof that this is so is lacking.

The core epileptic encephalopathies encountered beyond infancy are the Lennox–Gastaut syndrome (LGS), the Landau–Kleffner syndrome (LKS) and the related epilepsy with continuous spikes and waves during slow-wave sleep (CSWS). Epilepsy with myoastatic seizures (Doose syndrome) and epilepsy with myoclonic absences (EMAs) behave as epileptic encephalopathies in some but not all affected children.

Myoclonic encephalopathy in non-progressive disorders is increasingly recognized as being a distinct epileptic encephalopathy but has its peak age of onset in infancy and will not be considered here. Important features of the epileptic encephalopathies are given in Table 14.3.

With the possible exception of LKS, it is rare for an epileptic encephalopathy to be diagnosed when the child first presents. Much more usually, the diagnosis becomes apparent after a period during which the clinician considered he was dealing with a more straightforward epilepsy. Consequently most children will already be on AED treatment. It is important to review this as drugs such as carbamazepine, which can exacerbate seizures in IGE, anecdotally may also do so in the epileptic encephalopathies.

Managing a child with epilepsy should never be just about AED treatment. However, this is particularly the case in the epileptic encephalopathies. Drug treatment will only be one aspect, and often not the most important aspect. Management should be undertaken by a multidisciplinary team which may need to include psychology, psychiatry, education, speech and language therapy, physiotherapy and occupational therapy. Joint neuropsychological and speech and language therapy assessment is particularly important in the diagnosis of LKS and its subsequent management. All children with epileptic encephalopathies will have special educational needs. Many will be appropriately educated in the mainstream sector but, for some, placement in a special school may be more appropriate.

Because of the intractable nature of seizures in the epileptic encephalopathies, most children are eventually treated with combination AED therapy. Although improved seizure control may be achieved using two or even three AEDs rather than monotherapy, there is no place for using more than three regular AEDs in any of the epileptic encephalopathies. In some children with LGS, seizures are exacerbated by drug-induced somnolence.

Non-AED treatments, including the ketogenic diet and vagal nerve stimulation, are used in the epileptic encephalopathies more than in other epilepsies. Steroid and immunoglobulins may also have a role in management. Resective surgery is very rarely an option but functional neurosurgery, principally callosotomy and multiple subpial transection, can be useful.

The EEG often plays a significant role in monitoring the effectiveness of treatment in the epileptic encephalopathies. Sleep recordings are essential for the detection of continuous spikes and waves in slow sleep, whether part of LGS or CSWS, and for determining whether a particular therapy has abolished it. It is often useful to determine how 'active' the EEG is in order to help decide whether further treatment is appropriate and to confirm the clinical suspicion of non-convulsive status epilepticus.

Seizure remission occurs in a few patients with epileptic encephalopathies but is expected to occur in LKS. Usually, AED therapy will be continued for some years in those seizure free, but eventual discontinuation of AEDs should be considered. Although not systematically studied, it is probable that the EEG is also helpful in this regard.

Lennox–Gastaut syndrome

Of all paediatric epilepsy syndromes LGS is probably the one whose definition is the most disputed and yet it is also the one that has attracted the most interest from pharmaceutical companies. In North America a broader definition is often used than in Europe. In particular, patients with prominent myoclonic seizures are included and nocturnal fast rhythms on EEG are rarely insisted upon. This is important when assessing the relevance of published drug trials.

Findings from double-blind randomized controlled studies

There have been five double-blind placebo-controlled trials in LGS. All involved the addition of the study drug to existing AEDs [68–72]. The populations studied included children and adults, used broad definitions of the syndrome and had maintenance phases of, at most, only a few months. Cinromide was not shown to be superior to placebo [68]. The other drugs – felbamate, lamotrigine, topiramate and rufinamide – all showed superior efficacy to placebo as summarized in Table 14.5. Open-label extension phases to the double-blind placebo-controlled trials of felbamate, topiramate and rufinamide all suggested that the effi-

Table 14.5 Summary of the results of double-blind, placebo-controlled randomized trials of the treatment of Lennox–Gastaut syndrome.

Drug	Population	Intervention	Key outcomes
Felbamate	73 subjects aged 4–36 years having at least 180 atonic or atypical absences in 8 weeks prior to baseline	*Felbamate versus placebo* (maximum of 45 mg/kg/day or 3600 mg/day, whichever lower) for 70 days	Mean change in total seizure frequency: 19% decrease versus 4% increase[a] Responder rate for total seizures: 50% versus 11%[a] Mean change in atonic seizure frequency: 34% decrease versus 9% decrease[a] Responder rate for atonic seizures: 57% versus 9%[a] Discontinuations due to adverse events: 1 versus 1
Lamotrigine	169 subjects aged 3–25 years with at least one seizure every 2 days	*Lamotrigine versus placebo* (dose dependent on concomitant valproate therapy and body weight) for 16 weeks	Median change in major seizure frequency: 32% decrease versus 9% decrease[a] Responder rate for major seizures: 33% versus 16%[a] Median change in drop attack frequency: 34% decrease versus 9% decrease[*] Responder rate for drop attacks: 37% versus 22%[a] Discontinuations due to adverse events: 3 versus 7
Topiramate	98 subjects aged 1–30 years with at least 60 seizures in month prior to baseline	*Topiramate versus placebo* (target dose approx 6 mg/kg/day) for 11 weeks	Median change in major seizure frequency: 26% decrease versus 5% decrease[a] Responder rate for major seizures: 33% versus 8%[a] Median change in drop attack frequency: 15% decrease versus 5% decrease[a] Responder rate for drop attacks: 28% versus 14% Discontinuations due to adverse events: none
Rufinamide	138 subjects aged 4–37 years with at least 90 seizures (including drop attacks and atypical absences) in month prior to baseline	*Rufinamide versus placebo* (target dose 45 mg/kg/day) for 84 days	Median change in total seizure frequency: 33% decrease versus 12% decrease[a] Median change in tonic–atonic seizure frequency: 43% decrease versus 1% increase[a] Responder rate for tonic–atonic seizures: 43% versus 17%[a] Discontinuations due to adverse events: 6 versus 0

The drug doses shown in the intervention column are those of the active test agent.
[a] $P < 0.05$.

cacy shown in the blinded studies was maintained [73–75]. However, a Cochrane Review concluded that the optimal treatment of LGS remains uncertain with no one drug shown to be highly efficacious [76].

Findings from other studies

There are very few reports of open uncontrolled studies of older AEDs used specifically to treat LGS. Conflicting results have been reported with bromides [77,78]. It has been reported that 1,5-benzodiazepines (such as clonazepam) are efficacious, particularly for myoclonic seizures, although tonic status may be precipitated [79–81]. Clobazam (a 1,5-benzodiazepine) was evaluated as add-on therapy in 31 children, 14 of whom had LGS. Twenty-five experienced a >50% reduction in seizures [82].

There are more reports of open uncontrolled studies and case series of the use of the newer AEDs in LGS. The following summarizes the more pertinent of these, concentrating on AEDs for which there are no data from randomized, double-blind controlled trials and on studies that give additional useful information over and above that obtained from randomized, double-blind controlled trials.

Livingston *et al.* [83] reported a reduction in seizures in one-half of 26 subjects with LGS treated with vigabatrin. Feucht *et al.* [84], in an open dose-ranging study of vigabatrin in 20 subjects with LGS, found that, at 12 months, eight became seizure free and nine had at least a 50% reduction in seizures. In contrast, Luna *et al.* [85] reported a single-blind study of vigabatrin in which only two out of seven subjects with LGS had at least a 50% reduction in seizures and four had a greater than 50% increase in seizures.

In an open-label pilot study of levetiracetam, which included four patients with LGS, two had a long-term seizure reduction, one had an increase in seizures and one withdrew from treatment [86]. In a case series, four out of six patients with LGS treated with levetiracetam had a 100% reduction in myoclonic and tonic–clonic seizures [87].

A postmarketing survey of zonisamide from Japan reported that 28% of those with West syndrome or LGS improved after treatment [88].

Donaldson *et al.* [89] reported a chart review of 16 patients with LGS treated with lamotrigine and found that although tonic, atonic, tonic–clonic and atypical absence seizures appeared to respond, myoclonic seizures did not.

Given the frequent poor response in LGS to conventional AEDs, less conventional therapies are often used. Several small, uncontrolled studies have suggested efficacy of both ACTH and prednisolone. Twenty-three out of 45 children with LGS treated with ACTH became seizure free for more than 10 days, although 10 subsequently relapsed within 6 months [90]. Seven of 10 patients with LGS treated with prednisolone for 12 weeks achieved seizure freedom [91]. However, a Cochrane review [92] found no evidence to support the use of steroids in the treatment of childhood epilepsy, other than West syndrome. Initial encouraging reports suggested efficacy of intravenous immunoglobulin in LGS. However, a subsequent single-blind placebo study in LGS failed to confirm this, as did a double-blind placebo-controlled study of its use in a group of mixed epilepsies which included children with LGS [93,94].

Lennox–Gastaut syndrome is one of the most frequent indications for the ketogenic diet. Neal *et al.* [95] reported a trial of the diet in 145 children who had at least daily seizures. The most common syndrome diagnosis (n = 14) was LGS. Patients were randomized to receive the diet immediately or after 3 months. After 3 months, the mean percentage of baseline seizures was significantly lower in those on the diet. Thirty-eight per cent on the diet had a >50% reduction in seizures compared with 6% not on the diet. Numbers were too small to analyse by syndrome but there was no significant difference in efficacy between symptomatic generalized or symptomatic focal syndromes.

Resective surgery has an extremely limited role in the LGS. Subjects with focal or unihemispheric disease may develop LGS and case reports suggest that they may be exceptionally amenable to surgical treatment. Corpus callosotomy can be used for the treatment of atonic and tonic drop attacks, seizure types which characteristically occur in the LGS. A recent study from Taiwan reported that 68% of patients (children and adults) had at least a 50% reduction in seizures following anterior callosotomy and that this was not dependent on whether or not West syndrome had preceded LGS [96], although the duration of the follow-up period and the effect on different seizure types was not reported. Other studies have shown that, although the initial effect is often good, relapse is common. Callosotomy is, therefore, now only rarely used. In several small studies, which included patients with LGS, the vagal nerve stimulator is reported to have led to a >50% decrease in seizures in 37–73% of patients. A retrospective database analysis of 552 patients with LGS evaluated the response to the vagal nerve stimulator in patients with LGS naive to surgery versus those with a previous callosotomy. In those with no prior surgery, 50% had >50% reduction in seizure at 3 months and 55% at 18 months [97]. Results were similar in those with a prior callosotomy.

Recommendations from expert committees and concluding remarks

Recommendations for the treatment of LGS made by NICE, along with the results of surveys of US and European physicians, are shown in Table 14.4. LGS is best treated using broad-spectrum AEDs and sodium valproate is the usual initial choice. If, as is usually the case, seizure control remains poor, other AEDs such as lamotrigine, topiramate, felbamate and rufinamide have been shown to be efficacious in randomized controlled studies. However, given its potential for serious side-effects, felbamate is not an appropriate early choice. Similarly, lamotrigine should probably be avoided if myoclonic seizures are prominent. Although regular benzodiazepines may be helpful, their usefulness for treatment of episodes of non-convulsive status epilepticus means that they may be best kept in reserve. Carbamazepine, phenytoin, oxcarbazepine, pregabalin, tiagabine and gabapentin are best avoided in LGS as these drugs can exacerbate seizures.

There is, as yet, no consensus as to when less conventional therapies should be tried. The ketogenic diet and vagal nerve stimulator should probably be considered earlier than is often the case – possibly after two or three AEDs have been tried. Realistic goal setting, with quality of life, rather than seizure freedom, is paramount. There are some children with LGS in whom AED treatment appears to achieve nothing, and in a few cases, it is appropriate to wean them off all AEDs.

Doose syndrome

There are no randomized controlled studies of any treatment for Doose syndrome and the best evidence available is from case series. As it is classified as an IGE, the general principles outlined above for management of IGE apply. In particular, drugs which may exacerbate IGE should be avoided.

Sodium valproate is generally considered the first-line AED for Doose syndrome, although the evidence base for this is poor. Other older drugs that are reported to be efficacious include ACTH, ethosuximide and benzodiazepines. Of the newer antiepileptic drugs, lamotrigine, sometimes combined with sodium valproate, is often used. In a series of eight patients with the Doose syndrome, seven became seizure free on lamotrigine and there are no reports of lamotrigine exacerbating seizures in Doose syndrome [98]. In a retrospective review of six patients with Doose syndrome treated with add-on topiramate, all but one improved, with three having a greater than 80% reduction in seizures [99].

Particular efficacy of the ketogenic diet is claimed in Doose syndrome [100]. Caraballo [101] reported 30 patients with Doose syndrome, 11 of whom were treated with the ketogenic diet. At 18 months, six remained on the diet, two were seizure free, two had a 75–99% reduction in seizures and two experienced a 50–74% reduction in seizures. A chart review of 33 patients with Doose syndrome is reported which was carried out to assess which treatments were associated with the patient becoming seizure free for more than 6 months. Seizure freedom was achieved in 30% of those treated with the ketogenic diet, 25% of those treated with ethosuximide, 23% of those treated with topiramate, 18% of those treated with lamotrigine and 10% of those treated with sodium valproate. Treatment with no other drug (including levetiracetam, carbamazepine and benzodiazepines, among others) led to seizure freedom [102]. There is one report of myoclonic status epilepticus in Doose syndrome apparently provoked by levetiracetam [103].

The recommendations of NICE for the treatment of Doose syndrome are shown in Table 14.4.

Landau–Kleffner syndrome and the syndrome of continuous spikes and waves in slow sleep

The Landau–Kleffner syndrome (LKS) and the syndrome of continuous spikes and waves during slow sleep (CSWS) were described as separate syndromes but they share a number of common features. Continuous spikes and waves in slow sleep is a prerequisite for CSWS but, although common in LKS, is not a prerequisite for its diagnosis. Both are rare and there are no randomized controlled trials which help guide their management. In CSWS the epileptic seizures are often frequent and difficult to treat. In LKS, seizures are often infrequent and the language deficits and behavioural problems are usually of more concern than the seizures.

There are anecdotal reports that certain AEDs usually active in focal epilepsies, notably carbamazepine, may exacerbate LKS and CSWS. This and other drugs, such as oxcarbazepine, vigabatrin, tiagabine and gabapentin, are probably best avoided. It is sometimes said that 'conventional AEDs' have little, if any, role in these syndromes. However, most clinicians probably treat with at least one or two of them before trying other treatment modalities. Sodium valproate is probably initially used by most clinicians, although other conventional AEDs with broad spectrums of activity may also be worth trying. Anecdotally good results have been claimed for ethosuximide, benzodiazepines (administered rectally) and sulthiame [104,105].

Steroid medication, including oral prednisolone, intravenous methylprednisolone and ACTH are reported in relatively small case series to be beneficial in both LKS and CSWS [106–108]. It is usually advocated that they should be tried early on the clinical course. There is no consensus as to the most appropriate regimen. Relapses are common and some children require repeated courses, increasing the risk of adverse effects. The latter can be minimized by using the smallest dose possible (often alternate-day treatment). Success is also claimed for the use of intravenous immunoglobulins [109] and vagal nerve stimulation [110].

Eventual remission of seizures is usual in LKS. Therefore, although drug treatment is often required for many years, eventual withdrawal of such treatment can usually be achieved. For cases in which CSWS has been demonstrated, the EEG is likely to be useful during follow-up and in determining how long to continue drug treatment.

In LKS the epileptogenic focus is usually in one or other of the superior temporal gyri. Because this is an area of eloquent cortex, resective surgery is not an option. However, the technique of multiple subpial transections has been pioneered by Morrell for treatment of the syndrome and good results have been obtained in other centres as well [111,112]. However, even in those children who respond quickly, age-appropriate language appears to be only occasionally achieved. Reports suggest that earlier surgery is associated with a better functional impact. The management of the cognitive, language and behavioural co-morbidities in LKS and CSWS requires the input of other professionals, including speech and language therapists and child psychiatrists. The recommendations of NICE for treatment of LKS and CSWS can be seen in Table 14.4.

Myoclonic absence epilepsy

Treatment of this rare syndrome is guided by information from case series. Sodium valproate and ethosuximide, particularly in combination, are the AEDs most frequently mentioned. Achieving good seizure control is said to be associated with a better long-term cognitive outcome, although the evidence for this is not particularly robust. Lamotrigine, benzodiazepines and acetazolamide have also been recommended. The syndrome is listed by the ILAE as an IGE, and other AEDs such as topiramate and levetiracetam may also be appropriate, although narrow-spectrum agents, including carbamazepine, should be avoided. The effect of other therapies, such as steroids, immunoglobulins and the vagal nerve stimulator, is not reported.

15 Management of Epilepsies Associated with Specific Diseases in Children

John H. Livingston
Leeds General Infirmary, Leeds, UK

Despite the great advances in medical knowledge there remains a tension between a purely empirical approach to treatment in epilepsy and treatment guided by a knowledge of the underlying aetiology. Much of therapeutic medicine remains empirical, but there is nonetheless general, if not universal, agreement that an understanding of the aetiology informs therapeutic decisions in a useful way. The multiple axes diagnostic scheme proposed by the ILAE in 2001 [1] encourages this approach. This chapter will consider the management of epilepsies in which there is a specific known aetiology. For most of the conditions considered, the level of evidence on which to base treatment is low and based on expert opinion and case reports.

The biggest impact on treatment in recent years has been as a result of the great improvements in neuroimaging. This has enabled the recognition of an increasing number of malformative, neoplastic or destructive causes of epilepsy that previously were difficult to diagnose in life. This in turn has improved the understanding of the natural history of many symptomatic epilepsies and the identification of good candidates for epilepsy surgery. Medical advances have been slow; however, alongside (and sometimes aided by) the improvements in imaging have been the rapid developments in molecular genetics. The gene mutations responsible for a growing number of conditions that cause, or are associated with, epilepsy have been identified. The next stage is to understand the functional effects of these mutations and devise interventions that may modify or reverse them.

For all of the conditions considered below, the basic principles of good epilepsy management should be followed. In particular the following questions should be considered:

1 Are the events that treatment is being considered for epileptic?
2 Is treatment necessary?
3 Could this treatment aggravate the seizures?

An awareness that non-epileptic paroxysmal disorders occur in many of these disorders is important. For some of the disorders considered below surgery may have a role. As most of these disorders are rare, early referral to a paediatric epilepsy surgery centre is important. If surgery is going to be of benefit, in general the earlier in the natural history of the epilepsy, the better will be the neurodevelopmental outcome.

Important co-morbid conditions in which epilepsy is common will be considered before discussing specific aetiologies.

Epilepsy in cerebral palsy

Epilepsy is common in cerebral palsy (CP), with reported prevalence rates ranging from 10% to 80%. The frequency is different depending on the type of CP: 50–80% for spastic quadriplegia, 50% for hemiplegia and 10–20% for diplegia [2,3].

Children with both epilepsy and cerebral palsy are much more likely to be mentally retarded than those with cerebral palsy without epilepsy. Any seizure type can occur, and common idiopathic epilepsies may also be present by coincidence. In the severely brain-damaged child with quadriplegic CP, many types of non-epileptic events may co-exist, such as myoclonus, startle, dystonia and gastro-oesophageal reflux or other pain-related behaviours. The EEG in some children with severe brain injury may always show multifocal paroxysmal abnormalities and thus diagnosis of which events are seizures may be very difficult. Avoidance of overtreatment is important.

No one antiepileptic drug (AED) has been shown to be superior to another in CP. However, drugs that may aggravate myoclonic seizures in IGEs may also have this effect in children with CP. Refractory epilepsy in hemiplegic CP may benefit from surgery [4,5].

Epilepsy in intellectual disability

The prevalence of epilepsy in children with severe intellectual disability is high (23–45%) [6]. Such children often have multiple co-morbidities that may impact on the diagnosis and management of epileptic seizures. Specific factors relating to the intellectual disability need to be considered:

- Behavioural problems are common but sometimes have an epileptic basis.
- Communication difficulties limit reporting of experiential aspects of seizures and adverse effects of AEDs.
- Adverse behavioural or cognitive effects of AEDs are probably more common.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

- Non-epileptic paroxysmal events are common and often coexist with epilepsy.
- Sleep disturbance is common and may in turn aggravate epileptic seizures.
- Sedative AEDs should be avoided as they may aggravate both cognitive problems and seizures [7].
- There may be a higher risk of accidents and injuries, and avoidable risk factors should be identified and minimized.

Most of the published studies of AED use in children include a high proportion of children with intellectual disabilities and severe epilepsy syndromes, thus the findings of these studies are generally applicable to this population. However, there are few specific research data on AED use in those with intellectual disabilities.

In general, broad-spectrum AEDs should be used and monotherapy should be the aim where possible. The presence of intellectual disability should not preclude consideration of surgical treatment.

Epilepsy in autism

The prevalence of epilepsy in autism is around 30–40% [8–10].

There is a complex inter-relationship between epilepsy and autism. In disorders such as Landau–Kleffner syndrome the autistic features are one of the primary manifestations of the epileptic disorder. In tuberous sclerosis the severity of the epilepsy correlates closely with the autism but is not the sole determinant.

Paroxysmal EEG abnormalities are seen in up to 60% of patients, many of whom do not have clinically apparent epileptic seizures [11,12]. Some children with autism appear particularly susceptible to adverse effects of AEDs. On the other hand, there have been many, largely anecdotal, reports of improvement in the affect on children with autism when they are started on AEDs [13]. Double-blind placebo-controlled trials of lamotrigine or levetiracetam, however, demonstrated no benefit [14,15].

If the epileptic seizures are not overt and there is uncertainty as to the contribution a paroxysmal EEG is making to autistic features, the decision to start an AED needs careful consideration. Assessing the outcome of treatment may require serial behavioural or neuropsychological evaluations, speech and language assessment and/or prolonged EEG recordings.

Epilepsies due to specific aetiologies

Chromosomal disorders

An increasing number of chromosomal disorders have been identified in children with epilepsies [16,17]. The epilepsy phenotypes are in some cases highly characteristic. The chromosomal abnormalities often cause dysmorphic features, brain malformations and other clinical features that may be independent of the epilepsy. It is beyond the scope of this chapter to consider all the chromosome disorders associated with epilepsy. In some disorders epilepsy is almost invariable, whereas in others it is only an occasional occurrence. In some, such as ring chromosome 20, the epilepsy is usually drug resistant.

Down syndrome

Epilepsy in Down syndrome may be secondary to an acquired brain insult (for example perinatal hypoxic ischaemic encephalopathy related to congenital heart disease or CNS infection) or due to the chromosomal abnormality itself. In general, the prognosis for seizure control is good where the seizures are of unknown cause, and for epileptic spasms, which are probably the most common seizure type in Down syndrome [18–20]. Spasms may respond to steroid or conventional AED treatment. There is some evidence that early treatment of spasms results in an improved neurodevelopmental outcome [21]. Late-onset epilepsies, however, may be drug resistant.

Angelman's syndrome

Epilepsy occurs in up to 90% children with Angelman's syndrome [22,23]. The onset is usually in infancy and it is often drug resistant. The common seizure types are atypical absences, myoclonic and generalized tonic–clonic. Status epilepticus (variously called non-convulsive or myoclonic) occurs in up to 50% [23,24]. Non-epileptic myoclonus is also common.

The combination of valproate and clobazam has been reported as particularly effective in case review series [22,25]. Long-term follow-up data, however, are not available. Benzodiazepines may be effective for episodes of status but not always. There are case reports of good responses to levetiracetam, lamotrigine and the ketogenic diet. Vigabatrin or carbamazepine may aggravate myoclonus [23,26].

Rett's syndrome

Epilepsy is common in Rett's syndrome, with a reported prevalence of 70%. Seizures may be drug resistant. However, it is important to recognize that non-epileptic attacks, such as hyperventilation, Valsalva manoeuvres, syncopes and stereotypes, are common and may be misdiagnosed as epileptic phenomena. Epileptic seizures may also be precipitated by hyperventilation in some children. Avoidance of overtreatment is therefore important.

CDKL5 mutation and epilepsy

The epilepsy phenotype associated with *CDKL5* mutations has recently been described in some detail. In the early stages most patients achieved seizure control on one or two first-line AEDs. Thereafter, an epileptic encephalopathy with epileptic spasms that was resistant to corticosteroids developed in just under one-half of patients. Interestingly, on long-term follow-up 7 out of 12 patients reported that they no longer had epilepsy [27].

Malformations of cortical development

Advances in neuroimaging have led to the identification of cortical malformations as the cause of epilepsy in many patients and to the recognition of malformation syndromes, which in many cases have a genetic basis.

The more severe malformations tend to be associated with refractory epilepsies in which, with a few exceptions, there are few data to recommend one treatment over another. On the other hand, in refractory focal epilepsies, identification of a focal malformation may lead to successful surgical treatment.

Shortly after its introduction vigabatrin was recognized as having particular efficacy in epilepsies caused by cortical malformations and particularly in tuberous sclerosis (TS) (see below). The concerns about visual field defects have greatly restricted its use outside patients with TS. In the author's view, the adverse consequences of refractory epilepsy greatly outweigh the potential adverse effects of a visual field constriction and vigabatrin should be more frequently used.

In TS, on the other hand, there is considerable evidence of the value of vigabatrin, particularly in the treatment of epileptic spasms. This includes data from several randomized controlled trials (RCTs). Cessation of epileptic spasms occurred in 90–100% of patients [28,29]. Most of these studies are short term, but long-term benefit has been described [30]. Other seizure types may also respond well to VGB. There are few data on the relevance of other AEDs in TS; however, topiramate, levetiracetam and zonisamide have been reported to be of benefit [31]. The ketogenic diet appears as effective in TS as in other resistant epilepsies [32]. With the exception of TS, no single AED has shown superiority in treating epileptic seizures caused by cortical malformations. Anecdotal reports suggest that ethosuximide has been of particular value in some epilepsies due to polymicrogyria.

Surgical resection of epileptogenic tubers has a growing place in the management of epilepsy due to TS. The best outcomes are following resection of a single tuber from which the majority of seizures have been shown to arise, with up to 90% seizure freedom reported and significant improvements in quality of life [33–35]. However, multifocal resections guided by invasive and/or intraoperative EEG monitoring may have benefit [36]. Longer-term follow-up data will be necessary before the role of surgery is fully established.

The particular efficacy of vigabatrin in TS and the possibility of antenatal detection, or detection in early life before seizures have started, has led to a discussion about 'prophylactic' treatment with vigabatrin (or other AEDs) and the proposal for a trial to study this [37,38].

Hypothalamic hamartoma and intractable epilepsy

Hypothalamic hamartoma (HH) with intractable (often gelastic) seizures is a rare but important syndrome that nearly always presents in childhood and may present with neonatal-onset seizures. The classical seizure type is gelastic (or dacrystic), but seizures often progress into a severe epileptic encephalopathy with frequent mixed seizure types, often with focal features. Antiepileptic drugs are generally ineffective. The importance of diagnosing this syndrome is that surgical treatment is effective in many patients. Different surgical approaches have been advocated including endoscopic resection, thermocoagulation and Gamma Knife® surgery. Follow-up studies have shown up to 66% achieving seizure freedom or only rare seizures with open craniotomy or endoscopic approaches [39,40] (see Chapter 75).

Vascular malformations

Sturge–Weber syndrome

Epilepsy occurs in 80% of children with Sturge–Weber syndrome (SWS) and is intractable in 60–75%. Seizures may respond well to AEDs [41]. There is a significant risk of status epilepticus and prolonged seizures should be treated aggressively because of the risk of postictal hemiplegia. When seizures are refractory, hemispherectomy (or multilobar resections) to remove all of the pial angiomatosis offers the only prospect of seizure control (see Chapter 73). The decision to proceed to surgery depends on several factors, such as the neurodevelopmental stagnation, a progressive hemiplegia and evidence of progressive shrinkage of the affected hemisphere. The seizure outcome from resective surgery is excellent [42].

Other vascular malformations

Arteriovenous malformations (AVMs) present with epileptic seizures as the first clinical feature in around 20% of cases. In general, because of the cumulative life-long risk of bleeding, once an AVM has been identified treatment is recommended. This may take the form of resective surgery, embolization or Gamma Knife surgery. The place of surgery depends on the site and size of the malformation and its vascular anatomy. Surgical resection of AVMs carries significant risks. Surgical resection of cortical AVMs abolishes seizures in up to 50% of patients [43]. No single AED has shown superiority over another in the long-term management.

Cavernomas

Cavernous angiomas or cavernomas are a rare cause of epilepsy but present with epileptic seizures in up to 80% of cases. Multiple cavernomas may be present and are commonly familial, and new lesions may develop with time. Seizures are often difficult to treat and, if refractory, surgical resection results in seizure freedom in up to 85% patients. Gamma Knife surgery may also be effective for lesions in functionally important areas. The surgical resection of individual cavernomas in patients with multiple lesions can be carried out, but the presence of other lesions limits the prophylactic value of surgery.

Mesial temporal lobe epilepsy

Mesial temporal lobe epilepsy (MTLE) is recognized as a syndrome in the ILAE 2001 diagnostic scheme. Many patients with MTLE have hippocampal sclerosis on MRI and this can be regarded as the probable cause of the epilepsy. However, in familial MTLE, hippocampal sclerosis is not present in all affected individuals, suggesting that other factors (genetic or environmental) contribute to the epilepsy [44]. The combination of MTLE and hippocampal sclerosis is a well-characterized syndrome. A recent prospective study of children with TLE demonstrated that long-term remission on medical treatment for children with TLE does not occur in the presence of an imaging abnormality and that early surgery has a high success rate [45].

Epilepsy due to brain tumours

Brain tumours are a rare cause of epilepsy in children. Epileptic seizures, however, are common in children with supratentorial tumours and are often the presenting feature. Low-grade cortical tumours, such as ganglioglioma and dysembryoplastic neuroepithelial tumours (DNETs), are important causes of intractable focal epilepsies that may be surgically treatable. There are two aspects

of management that need to be considered when a possible tumour is demonstrated on a scan in a child with a focal epilepsy: tumour management and epilepsy management.

Tumour management

The choice of therapy depends on various individual factors. In general, though, if the signs and symptoms are rapidly evolving, or there is evidence of radiological progression on sequential scans, then a tissue diagnosis and/or primary resection becomes the priority. Surgical planning should consider the epilepsy management even if the primary reason for surgery is oncological. For example, it may be appropriate to plan total resection rather than a biopsy if the tumour is in a site where this can be achieved with low risk of new damage. Chemotherapy and/or radiotherapy alone is unlikely to cure the epilepsy.

Epilepsy management

If the epilepsy is the primary clinical feature and sequential scans are stable, then the decision to proceed to surgery can be guided by similar criteria as for other lesional focal epilepsies (see Chapter 77). The outcome from complete resection of a neoplastic lesion causing refractory epilepsy is excellent, with up to 80% of patients becoming seizure free [46–48]. Although incomplete resection may produce a significant benefit, the long-term outcome is less favourable and seizures will recur in many patients [49].

No one AED has proven superior in the management of epilepsy due to brain tumours. A recent report suggests that levetiracetam is well tolerated and effective in adults with brain tumours, although the majority of these were high-grade gliomas [50], and there is no convincing evidence that levetiracetam is any better or worse than other AEDs in this situation.

Epilepsy caused by CNS infection

Central nervous system infection is an important cause of epilepsies worldwide. Prevention of the initial infection through public health programmes and early management of infections have the potential to reduce the incidence of epilepsy significantly. In general, the development of an epilepsy correlates with the degree of CNS damage sustained during the acute illness. However, for some infections that do not have distinct acute and chronic phases this is less clear cut. In these situations, as well as AEDs, treatment of the cause of the infection may improve seizure control, for example in neurocysticercosis or tuberculoma. Refractory focal epilepsy following meningitis or encephalitis may benefit from epilepsy surgery. The best outcome can bee seen in those with MTLE with unilateral hippocampal sclerosis [51].

Rasmussen's encephalitis (chronic focal encephalitis)

Rasmussen's encephalitis (RE) is a rare cause of intractable epilepsy in children associated with a progressive hemiparesis, cognitive decline and hemispheric atrophy. AED therapy is usually ineffective, although temporary response may occur and some seizure types in an individual may respond well while others remain refractory. No AED has been proven to be better than another. Because of the severe and frequent seizures, including epilepsia partialis continua, there is a risk of overtreatment with resulting adverse effects. The natural history of RE is for it to burn itself out after many years (usually but not always), with severe cognitive and motor deficits but not necessarily seizure freedom. Because the aetiology is thought to be an inflammatory process with an immunological basis, various immune therapy approaches have been tried. These include steroids, immunoglobulins, plasmapheresis and other immune suppressive therapy. There is evidence that there may be an initial response to treatment with either intravenous steroids or immunoglobulins [52,53]. However, long-term response is disappointing.

The only treatment that has been shown to be of lasting benefit is hemispherectomy (or hemispheric disconnection) [5,54,55]. Limited resections or callosotomy are not of benefit. In theory, early surgery is the optimal treatment; however, time is often needed both to establish the diagnosis and to prepare the child and family for the procedure. In particular, it may be difficult for the family to agree to surgery before a hemiplegia or hemianopia is severe or permanent or if the seizures are temporarily improved with medical treatment. A further consideration is that if the dominant hemisphere is involved, shift of language to the non-dominant hemisphere is unlikely to occur following hemispheric surgery after the age of 10 years.

Hemiconvulsion, hemiplegia, epilepsy syndrome

The hemiconvulsion, hemiplegia, epilepsy syndrome (HHE) syndrome has become rarer in recent years, presumably because of better emergency treatment of prolonged convulsive seizures [56]. The epilepsy in this syndrome is often refractory to AEDs and no single AED has been shown to be superior to another. Surgery may be of benefit, particularly if mesial temporal lobe seizures predominate and there is hippocampal sclerosis [57]. Extratemporal resections including hemispherectomy may also be of some benefit. Determining the extent of resection planned may require invasive electroencephalographic monitoring [56].

Metabolic disorders

Epilepsy is a feature of a large number of neurometabolic disorders – sometimes an occasional feature and sometimes the most prominent feature [58]. In a small number of metabolic disorders, a specific treatment directed at the underlying biochemical defect will control the seizures and greatly improve the neurodevelopmental outcome, even if this is not always returned to normal. Identifying these disorders is therefore a priority in the investigation of children (particularly infants) with epilepsies (Table 15.1) [59–93].

In general, when a metabolic disorder has been diagnosed, the aim of treatment should be to treat the underlying metabolic problem where possible. If seizures are associated with hypoglycaemia, then this should be corrected and the cause treated, for example with dietary measures in fatty acid oxidation disorders. In disorders such as phenylketonuria, there is good evidence that this approach is effective both in preventing the development of seizures and in controlling them if they have occurred.

Table 15.1 Disorders presenting in infancy with epileptic seizures for which there is a specific non-AED treatment.

Disorder	Diagnostic test	Treatment
Glucose transporter deficiency type 1 (Glut–1) [59]	CSF/plasma glucose ratio less than 0.5 Mutation in *Glut1* gene	Ketogenic diet
Biotinidase deficiency	Biotinidase assay – blood	Biotin
Pyridoxine deficiency [60]	Trial of treatment Urinary–α-aminoadipic semialdehyde dehydrogenase (a-AASA) Mutation in antiquitin gene	Pyridoxine
Pyridoxal 5′-phosphate deficiency [61]	Trial of treatment CSF neurotransmitters	Pyridoxal phosphate
Serine biosynthesis disorders [62]	Low CSF serine levels Enzyme activity in fibroblasts	Serine
Fatty acid oxidation disorders	Urine organic acids Blood acyl carnitines	Diet
Creatine synthesis disorders [63]	MRS Urine guanidinoacetic acid	Creatine

AED, antiepileptic drug; CSF, cerebrospinal fluid; MRS, magnetic resonance spectroscopy.

Having excluded the disorders shown in Table 15.1, and assuming that the underlying metabolic disorder is being treated (when possible), then the general approach to the management of epilepsies caused by neurometabolic disorders is the same as for epilepsies of other aetiologies. If a diagnosis of Alpers' disease is possible then the use of valproate may precipitate fatal hepatic failure and is contraindicated. Although there are theoretical reasons for avoiding valproate in other mitochondrial diseases, there is no evidence that this is necessary. On the other hand, valproate is less well tolerated in fatty acid oxidation disorders. Phenobarbital should be avoided in GLUT1 deficiency as it may interfere with transport of glucose into the CNS.

The ketogenic diet is beneficial in pyruvate dehydrogenase deficiency but is contraindicated in pyruvate carboxylase deficiency.

Progressive myoclonus epilepsy syndromes

Progressive myoclonus epilepsies are neurodegenerative disorders in which myoclonus (epileptic and non-epileptic) is particularly prominent. Progressive neurological deterioration, particularly ataxia, is common and other epileptic seizures are prominent. In children the ceroid lipofuscinoses are probably the most common aetiological group. The management of these disorders is challenging and as the disease progresses becomes increasingly palliative. There are, however, some treatments that may be beneficial.

Drugs to avoid in progressive myoclonic epilepsies

It is now well documented that phenytoin severely exacerbates both the epileptic seizures and the cognitive function of patients with Unverrict–Lundborg disease (synonym: Baltic myoclonus) [64]. The reasons for this are not clear. Other AEDs that commonly aggravate myoclonic seizures, such as carbamazepine, oxcarbazepine, tiagabine and vigabatrin, are relatively contraindicated [65].

Antiepileptic drugs that may be of benefit in progressive myoclonus epilepsies

The common seizure types in progressive myoclonic epilepsies (PMEs) are myoclonic, focal and generalized tonic–clonic and reflex seizures, especially light induced. The most useful AEDs, therefore, are those with a broad spectrum and efficacy in photosensitivity. Valproate is probably the most useful AED and there is an increasing number of reports on the efficacy of levetiracetam [66,67].

Benzodiazepines may be of benefit but have the well-recognized problems of tolerance, cognitive adverse effects and difficulty in withdrawal, which can limit their value. The combination of valproate with clobazam or clonazepam may provide considerable benefit [68]. Recent reports have shown that topiramate or zonisamide may also be of benefit [69,70].

Several studies have demonstrated efficacy of piracetam for the myoclonus [71].

As with many of the disorders considered in this chapter, awareness of the risks of overtreatment is crucial. Escalating doses of AEDs may aggravate both epileptic and non-epileptic seizures. On the other hand, worsening irritability accompanied by myoclonus may be better treated with sedative agents, such as opiates or intermittent chloral, than inappropriate AEDs.

Epilepsies caused by specific gene mutations

In recent years, an increasing number of gene mutations, almost all coding for ion channel proteins, have been identified as causing or associated with various 'idiopathic' epilepsy syndromes. The most clinically relevant epilepsy gene identified so far is the *SCN1A* gene, coding for the α_1-subunit of the neuronal sodium channel. Mutations in this gene are present in up to 80% of children with Dravet's syndrome (see Chapter 13). Stiripentol has been shown in a randomized, placebo-controlled study to be effective in treating seizures in children with Dravet's syndrome [72]. In this study it was not known which children had the *SCN1A* mutation, and it is not known how the response to stiripentol relates to the functional abnormalities caused by the mutation. However, this may be the first example of an AED choice that can be targeted to a specific genetic abnormality. There is also evidence that AEDs which block sodium channels, such as phenytoin, lamotrigine or carbamazepine, may aggravate seizures in Dravet's syndrome and should be avoided [73].

The functional effects of most identified mutations are not fully understood; however, it is to be hoped that a fuller

understanding of these effects will lead to the development of rational treatments directed at reversing or attenuating the functional abnormality.

Summary

In this chapter, the influence of the aetiology of an epilepsy on its management has been considered. Many of the disorders considered are individually rare, and robust RCTs of therapies will prove very difficult to perform. However, a small number of such studies have been achieved. The impact of epilepsy surgery illustrates that if a very effective treatment is available, an RCT is not always necessary.

Most of the evidence on AED treatment for the conditions considered above is therefore based on expert opinion and anecdotal reports. The management of an epilepsy is not simply a question of which AED to use: understanding the aetiology has wider implications than this. A knowledge of the natural history enables realistic therapeutic goals to be set and an appropriate prognosis to be given. Early recognition and management of associated medical complications and co-morbidities is possible and this may prevent longer-term problems (both medical and non-medical). In many of the disorders discussed above, non-epileptic paroxysmal events occur, some of which are quite specific to a given disorder. Recognition of this prevents inappropriate and excessive AED use and allows appropriate treatment strategies.

Appropriate genetic counselling can be given to families, and antenatal detection or early diagnosis is possible for an increasing number of diseases. Therapeutic research trials will be most meaningful if patients with the same aetiology can be compared. For many parents and families, understanding the cause of their child's epilepsy helps them to adjust and adapt to it, even if treatment remains difficult.

In most of the conditions considered here, the epilepsy is difficult to treat and often associated with structural brain abnormalities. Thus, in tuberous sclerosis, for instance, identification of the causative genes and a growing understanding of their functions is beginning to suggest therapeutic approaches. Unravelling the causes of idiopathic epilepsies remains an enormous challenge. However, as an increasing number of epilepsy genes are identified, it is not unrealistic to predict that specific treatments will be developed targeting the functional abnormality caused by the abnormal genes.

16 Management of Epilepsy in the Elderly

Hiba Arif, Anil Mendiratta and Lawrence J. Hirsch

Comprehensive Epilepsy Center, Columbia University, New York, NY, USA

Introduction

Seizures and epilepsy are the third most common neurological disorder affecting older adults, after stroke and dementia. As many factors can complicate treatment decisions in elderly patients, management of seizures and epilepsy in this age group warrants special consideration. Age-related physiological changes, both systemic and neurological, require care in the selection of anticonvulsant medication, as well as in dosing regimens. Co-morbid conditions and co-medications, which are commonly present, increase the likelihood of drug interactions. Age-related changes in drug handling and central nervous system (CNS) pharmacodynamics can all reduce efficacy or increase the risk of intolerable side-effects in this age group. Although the primary goals of treatment, including freedom from seizures, absence of adverse effects and the maintenance of a high quality of life, are the same for all patients with epilepsy, the aforementioned issues are significant considerations when making management decisions in the elderly population. Dealing with these challenging issues will assume even more importance in the coming years, since demographic trends are likely to result in greater numbers of the aged, and a greater relative proportion, in the populations of the developed nations. In the USA, the Department of Health and Human Services predicts that by 2030 there will be 71.5 million adults over the age of 65 in the USA, accounting for roughly 20% of the population, in comparison with 36.8 million in 2005 [1].

Epidemiology

Of all age groups, the incidence of both acute symptomatic seizures and unprovoked seizures/epilepsy is highest in people over the age of 65 (Fig. 16.1) [2–4]. The incidence continues to rise with increasing age, and is greatest in the group older than 75 years of age, in which the incidence is five times that of younger adults. Based upon these incidence studies, there are approximately 50 000 new cases of epilepsy in this age group in the USA every year [5].

The overall prevalence of unprovoked seizures is at least 1% in the population over 60 (1.2–1.5% in the population over 75 years), roughly twice the prevalence in younger adults [6,7]. In a study of over one million US veterans at least 65 years of age, 1.8% were found to have epilepsy [8,9]. In specific at-risk populations, such as elderly patients with stroke or dementia, the risk of unprovoked seizures is higher. Overall, stroke patients have an 11.5% probability of experiencing one or more seizures within 5 years of their initial stroke [10]. An elderly patient's risk of an unprovoked seizure increases 6-fold with a diagnosis of Alzheimer's disease and 8-fold with a diagnosis of non-Alzheimer's dementia [11].

Diagnosis

The diagnosis of epilepsy in the elderly is often a challenging process that may be significantly prolonged in many cases. In the Veterans Affairs (VA) cooperative study of seizures in seniors (>60 years old), epilepsy was an initial diagnostic consideration in only 73% of the patients, all of whom were eventually diagnosed with epilepsy [12]. In a subset of this study, looking at 151 veterans, Spitz and colleagues [13] found a significant delay in diagnosis of elderly patients, with a mean time to correct diagnosis of 2.3 years, and a median time of 1 year. Only 37% of patients were correctly diagnosed upon initial evaluation. Of patients with generalized tonic–clonic (GTC) seizures, only two-thirds were diagnosed immediately, and of patients with complex partial seizures, only one-quarter were diagnosed immediately.

The key steps in managing a patient with episodic loss of consciousness (LOC) are:

- determining that the events are in fact seizures and not, for instance, syncope or other causes of episodic LOC;

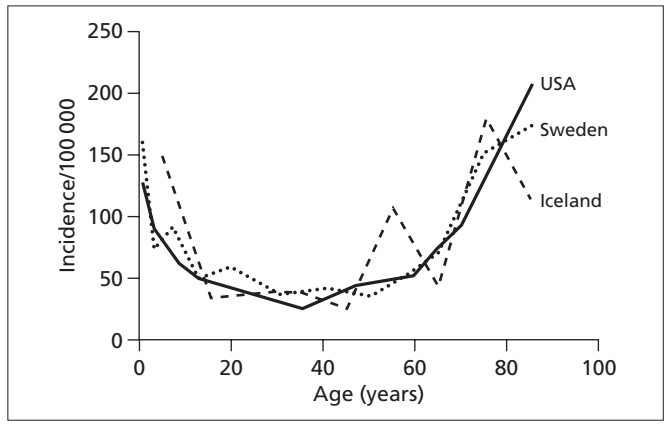

Fig. 16.1 Graph of incidence of unprovoked seizures through lifespan. Reproduced with permission from ref. 4.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

- identifying the aetiology and precipitants for the event, if any;
- determining whether or not the aetiology is amenable to treatment;
- determining the risk of seizure recurrence, and whether or not antiepileptic drug (AED) treatment is needed (acutely and chronically).

There are numerous possible causes of episodic events resembling epileptic seizures (see Chapter 4). These include syncope, transient ischaemic attacks, metabolic disturbances, migraine, transient global amnesia, panic attacks, cataplexy, psychogenic spells, non-specific confusion or amnesia related to dementia, non-epileptic seizures, episodic vertigo and non-specific episodes of dizziness, which may affect up to 10% of older populations [14]. As in younger patients, the most powerful diagnostic tool is an accurate history of the onset, evolution of and recovery from the episode. However, adequate descriptions and eye-witness accounts are often lacking because many older patients may be living alone. In 2006, the US Department of Health and Human Services found that 30% of non-institutionalized people older than 65, totalling more than 10 million people, lived alone [1]. Elderly patients are often brought to the hospital by emergency medical services without anybody to provide a direct description of the episodes. Table 16.1 provides a list of conditions that may commonly mimic seizures and useful clinical features for diagnosis.

In elderly patients, the greatest challenge to a correct diagnosis is the differentiation of seizures from syncopal attacks, as the latter may have multiple causes in older patients, most notably cardiac arrhythmias, carotid sinus syncope and postural hypotension, often due to drugs [15]. Of all the discriminating features, the rapidity of recovery after syncope compared with a seizure is often thought to be the most useful. However, a seizure may be brief (or be reported as brief) whereas syncope associated with an arrhythmia or with prolonged vertical posture may be prolonged. Post-event confusional states are typically prolonged in epileptic seizures and brief with syncope, but may also be prolonged in cerebral anoxia due to syncope associated with a serious cardiac arrhythmia. Cardiogenic or neurocardiogenic (vasovagal) syncope is often accompanied by brief myoclonic jerks, posturing, head turning, automatisms (lip smacking, chewing) or upward deviation of the eyes, and vocalizations may occur [16]. If the anoxic episode itself triggers a full-blown epileptic seizure (a very rare phenomenon, and very difficult to distinguish from an arrhythmia induced by a partial seizure), the situation becomes even more complicated. Typically, syncopal spells are seen infrequently, but in an elderly patient with postural hypotension, this may not be the case. It should be noted that incontinence is not uncommon in syncope, and does not help differentiate syncope from seizures. The most useful features for differentiating seizure from syncope are shown in Table 16.2 [17].

Postictal states are often prolonged in older adults; in one series, 14% of elderly subjects suffered a confusional state lasting more than 24 h, and in some cases it persisted as long as 1 week [18]. When prolonged, the possibility of ongoing seizure activity underlying the 'postictal' states should be suspected, even if the scalp electroencephalogram (EEG) is negative [19]. Postictal hemiparesis (Todd's paresis) is a common occurrence. This may lead to misdiagnosis of stroke; indeed, in one series, this was the most common non-stroke cause of referral to a stroke unit [20]. This is particularly likely to happen when seizures occur against a background of known cerebrovascular disease, and a seizure may be incorrectly diagnosed as a recurrent stroke. In the era of thrombolysis for acute stroke, it is more important than ever to consider the possibility of a seizure rather than stroke, particularly if there is a rapidly improving deficit or if the clinical examination does not fit a known vascular syndrome. One stroke-like presentation that should particularly raise the suspicion of seizures is the occurrence of global aphasia without hemiparesis that resolves (which we have referred to as 'transient global aphasia'), particularly if MRI with diffusion-weighted imaging does not show infarct.

Transient global amnesia (TGA) is a clinical syndrome of the middle-aged or elderly characterized by sudden-onset memory loss without other signs of cognitive impairment or concomitant focal neurological features. During the attack, patients are conscious and alert but show a severe anterograde (and sometimes some retrograde) amnesia. The aetiology of TGA remains debated, and there are proponents of migrainous, epileptic and vascular theories. A report of a 65-year-old woman with recurrent TGA described multiple episodes of amnesia [21]; imaging was normal but an EEG obtained during one of these episodes showed bitemporal asynchronous epileptiform discharges. The episodes were completely controlled by carbamazepine. Thus, TGA (especially if recurrent) can occasionally be a manifestation of a complex partial seizure, although a period with impaired responsiveness is usually present with complex partial seizures (and not in TGA).

Falls, a leading cause for admissions to hospitals, can also be the result of seizures, although these are not usually considered early in the diagnostic evaluation. Often, falls are quickly attributed to cardiovascular causes, gait disturbances, or cerebrovascular events. Even when patients appear encephalopathic, which may be ictal or postictal in nature, the confusional state may be attributed to the associated head trauma and/or associated metabolic disturbances, such as dehydration.

Dementia is a frequent cause of memory loss in the ageing patient. In elderly patients, memory dysfunction may be caused by complex partial seizures and may present either as an insidious fluctuating course of memory loss and confusion that simulates dementia or as discrete episodes of amnesia (and therefore more likely to go unrecognized and unreported). The occurrence of such serial complex partial seizures masquerading as dementia is also known as 'epileptic pseudodementia' and represents a potentially treatable cause of memory dysfunction. When interictal epileptiform discharges (IEDs) are present in patients with epileptic pseudodementia, they have most often been suggestive of a left temporal seizure focus. Tatum *et al.* [22] reported five patients aged 56–79 years who presented to a memory disorders clinic with a prolonged history (1–25 years) of increasingly frequent episodes of memory loss and confusion. Initial EEGs were non-diagnostic in all patients; however, upon repeat EEG (24-h ambulatory in two patients, two video-EEGs and one routine EEG), electrographic seizures (clinically appearing as prominent amnesia), suggesting left temporal origin were

Table 16.1 Common seizure mimics in older adults and useful clinical features for diagnosis.

Diagnosis	Clinical features suggestive of diagnosis rather than seizures
Syncope	Trigger usually identifiable Abrupt onset of autonomic symptoms/pallor No aura or unilateral symptoms LOC < 20 s with rapid return to normal Jerking/posturing, if present, is brief and occurs after the LOC (see also Table 16.2)
Transient ischaemic attack	Variable presentation depending upon area involved Consider focal seizures with any neurological deficit if symptoms are recurrent and stereotyped with no signs of infarct on brain imaging
Migraine (especilally basilar)	Slow march of neurological symptoms over >5 min Prolonged duration (usually 20–60 min) Posterior circulation symptoms; scintillating scotomata; subsequent headache (may be absent)
Transient global amnesia	Prolonged spell (hours) with normal behaviour except for amnesia Personal identity always intact (if not, suspect psychogenic aetiology)
Psychogenic non-epileptic seizures	Psychiatric history (e.g. somatization); history of physical or sexual abuse Eyes closed and normal vitals during spell Recurrent spells not responding to treatment Precipitated by hyperventilation or other suggestive techniques
Panic attack, hyperventilation	Often with environmental trigger; severe fear; hyperventilation with perioral cyanosis, bilateral hand paraesthesias, carpopedal spasm; loss of consciousness absent or incomplete; dyspnoea; palpitations >5 min in duration (seizures are shorter) Associated depression and phobias (95%), esp. agoraphobia; onset in young adulthood
Cataplexy	No loss of consciousness; other features of narcolepsy usually present (daytime somnolence, hypnogogic hallucinations, sleep paralysis) Triggered by emotion, especially laughter
Sleep disorders (paroxysmal nocturnal dystonia, sleep myoclonus, obstructive sleep apnoea, REM behaviour disorder, somnambulism)	Usually difficult to distinguish these from seizures without video-electroencephalographic monitoring, polysomnography, or both, especially if no reliable witness Paroxysmal nocturnal dystonia is probably a CPS/epilepsy in many cases REM behaviour disorder commonly seen in the elderly intermittent loss of REM-related atonia or hypotonia, with abnormal motor activities 'acting out' dreams (often violent) associated with neurodegenerative disease, especially multiple system atrophy and Parkinson's (synucleinopathies) polysomnography for definitive diagnosis treat with clonazepam Somnambulism uncommon in elderly
Staring/behavioural spells in patients with static encephalopathy or dementia	Difficult to distinguish from seizures without video-electroencephalographic monitoring
Metabolic disturbances	Hypoglycaemia Long prodrome; on treatment for diabetes – or insulinoma (rare) Hypo- and hyperglycaemia-related seizures are resistant to AED therapy; treat cause Thyroid storm Typically a history of hyperthyroidism Precipitating event, e.g. infection, surgery, non-compliance with thyroid meds, emotional stress Hypercapnia Subtle personality changes, headache, sedation, confusion More likely to be seen in elderly as ventilatory response to hypercapnia decreases with age Porphyria, acute intermittent Likely precipitant: alcohol, drugs, infection, menstruation Family history is an essential clue for diagnosis
'Drop attacks'	Can be due to cataplexy, cervical spine disease, basilar ischaemia, vertigo attack (Ménière's), seizures (myoclonic, tonic, atonic; rarely complex partial), or syncope (especially cardiac)
Drug intoxication	Prescription medications (antidepressants, antipsychotics, analgesics, anaesthetics, antimicrobials, bronchodilators) Sedative withdrawal (benzodiazepines, barbiturates) may provoke seizures Careful history is important since patients may not have measurable amounts of these drugs in their system at time of seizure occurrence Also consider alcohol withdrawal and substance abuse (cocaine, amphetamines) Low threshold for EEG to different possible NCSE from encephalopathic fluctuations
Infection	Encephalitis HIV (direct infection as well as mass lesions caused by opportunistic infections) Prion diseases (CJD is most common; characterized by rapidly progressive dementia, ataxia and myoclonus (82–100%); periodic discharges on EEG are characteristic)
Epileptic pseudodementia	Serial complex partial seizures mimicking dementia Insidious onset of memory dysfunction and confusion Epileptiform discharges from a left temporal focus may be seen on EEG Treat with AEDs

Adapted and expanded with permission from ref. 17.

AED, antiepileptic drug; CJD, Creutzfeldt–Jakob disease; CPS, complex partial seizure; EEG, electroencephalogram; HIV, human immunodeficiency virus; LOC, loss of consciousness; NCSE, nonconvulsive status epilepticus; REM, rapid eye movement.

Table 16.2 Syncope versus seizure: useful distinguishing features.

	Syncope	Seizure
Before spell		
Trigger (position, emotion, Valsalva)	Common	Rare
Sweating and nausea	Common	Rare
Aura (e.g. smell, déjà vu)	Rare	Common
Unilateral symptoms	Rare	Common
During spell (from eyewitness)		
Pallor	Common	Rare
Cyanosis	Rare	Common
Duration of loss of consciousness	<20 s	>60 s
Movements	A few clonic or myoclonic jerks; brief tonic posturing (a few seconds); duration <15 s; always begin after loss of consciousness	Prolonged tonic phase (~30 s), then prolonged rhythmic clonic movements (~30–60 s); duration >1 min; may begin at onset of loss of consciousness or before; unilateral jerking (partial seizure)
Automatisms	Occasional	Common (in complex partial and secondarily generalized seizures)
Tongue biting, lateral	Rare	Occasional
Frothing/hypersalivation	Rare	Common
Electroencephalography (during event)	Non-specific slowing	Ictal EEG pattern
After spell		
Confusion/disorientation	Rare; <30 s	Common; several minutes or longer
Diffuse myalgias	Rare, brief, usually upper body	Common (hours to days)
CK elevation	Rare	Common (especially after 12–24 h)
Electroencephalography (between events)	Normal	Epileptiform discharges common
Features that are not helpful for differentiating	Incontinence, prolactin level, dizziness, fear, injury other than lateral tongue biting, eye movements (rolling back), brief automatisms, vocalizations, visual or auditory hallucinations	

Adapted with permission from ref. 17.
CK, creatine kinase; EEG, electroencephalogram; GTC, generalized tonic–clonic.

captured in four patients. Four patients improved with AED treatment.

A considerable proportion of patients with seizure-like episodes will actually have non-epileptic events, both physiological and psychogenic. In a study of 94 patients at least 60 years of age (mean 70), referred for video-EEG monitoring for evaluation of paroxysmal episodes, 27 patients were found to have non-epileptic seizures, including 13 with psychogenic non-epileptic seizures (PNESs) [23]. Notably, the majority of those patients diagnosed with non-epileptic episodes had been taking anticonvulsant medications for presumed epileptic seizures. These findings emphasize the need for video-EEG monitoring in patients with atypical events and those whose events have not responded to treatment with AEDs.

Diagnosis becomes increasingly difficult in the presence of co-existing conditions that predispose to syncope. In elderly patients with features suggestive of cerebrovascular disease or of cardiac disease, it may become impossible to ascertain whether or not transient symptoms are cardiac or cerebral in origin. Non-specific abnormalities on an EEG or electrocardiogram (EKG) unrelated to the symptoms may add to the confusion. It has been suggested that head-up tilt testing may be useful in differentiating convulsive syncope from epilepsy [24], and Kenny and Dey [25] extended this to include a carotid sinus massage before and after atropine in prolonged head-up tilt, as cardioneurogenic syncope secondary to carotid sinus hypersensitivity is not uncommon in older people [15]. However, it is crucial to make sure the symptoms precipitated during a tilt table test are typical of habitual spells to avoid false-positive results.

Clinical presentation of epilepsy in the elderly

As would be expected from the range of aetiologies for epilepsy in the elderly, more than 70% of seizures are of partial onset [12,26]. As it is extremely unusual for idiopathic generalized epilepsy syndromes to present in this age group, even apparently generalized tonic–clonic seizures without obvious focal features should be presumed to be partial in onset unless proven otherwise. Seizures in elderly patients may manifest with sensory symptoms, visual phenomena or language disturbances, which may be more difficult to recognize as epileptic in nature. Although it is generally stated that elderly patients have fewer auras and longer durations of postictal confusion, there is little objective evidence to support or refute this. Auras, however, may be very non-specific, for example simply consisting of dizziness. It has been suggested that the variable clinical presentation of seizures in elderly patients is probably because cerebrovascular disease is the most common identifiable cause of new-onset seizures in the elderly, and this tends to most commonly involve the frontal lobe [12]. However, a recent video-EEG monitoring study in elderly patients reported 75% of epileptic events (in 12 patients) as originating from the temporal lobe, similar to young adults [27].

Even after a careful history, examination and appropriate investigations, a firm diagnosis may remain elusive, and in some cases it may be prudent simply to wait and see. A 'therapeutic trial' of anticonvulsants as a diagnostic test is to be recommended even less frequently than in younger patients: unless events are happening very frequently for a therapeutic response to be assessed

quickly, it will rarely produce a decisive answer and only add the burden of unnecessary drug treatment to the patient's problems. Furthermore, if events are occurring frequently, recording them with video-EEGs/EKGs (and ancillary testing as needed, such as blood glucose testing, blood pressure, neurological examination) can provide a definitive diagnosis in almost all cases.

Investigations

Although the importance of a thorough history and comprehensive examination cannot be emphasized enough, routine biochemical and haematological testing may yield helpful clues. Other investigations including electrocardiographic recording, carotid and basilar artery ultrasonography, and orthostatic blood pressure measurement will be directed towards ruling out non-epileptic causes of loss of consciousness; potentially dangerous aetiologies, such as cardiac arrhythmia, should receive first priority, particularly with 'drop attacks' or unwitnessed and unexplained falls. Often, even after extensive cerebral and cardiovascular investigation, the clinician will remain uncertain whether the patient's episodes are cerebral or cardiac in origin, unless a typical spell is recorded with simultaneous video-EEG and electrocardiographic monitoring.

Electroencephalography

The value of special investigations, in particular electroencephalography and neuroimaging, is sometimes overestimated. Misinterpretation of EEG findings or over-reliance on the EEG frequently contributes to misdiagnosis [28]. The presence or absence of interictal epileptiform discharges (IEDs) on EEGs is not definitive and may be misleading [29]. Interictal EEG findings typically change with age [30]. It is commonly stated that epileptiform discharges are less frequently seen in elderly patients with seizures [31,32]. However, the results of at least two monitoring studies using video-electroencephalography in elderly patients appear to suggest otherwise. Kawai *et al*. reviewed the video-EEG records of 71 geriatric veterans (average age of 68 years). Twelve patients had epileptic seizures recorded. Ten of those 12 patients with definite seizures had focal interictal epileptiform discharges, including nine out of nine with temporal lobe seizures. Similarly, in a series of 94 patients (≥60 years) who underwent monitoring using video-EEG [23], 76% of the 46 patients with epileptic events captured on video-EEGs had IEDs, and 26% of the patients with non-epileptic events had 'interictal' discharges as well. These findings reinforce the importance of recording typical spells with video-EEG monitoring, as interictal recordings alone appear to be inadequate for diagnosis in this age group.

When EEGs are interpreted by physicians without specialized training, a number of benign or normal patterns can be commonly misinterpreted as epileptiform. One study identified 46 patients referred to an epilepsy centre with a previous diagnosis of epilepsy; a prior EEG available for all these patients showed wicket patterns. Upon 'blinded' re-interpretation by electroencephalographers at the epilepsy centre, it was found that 46% (21 out of 46) of the patients with wicket patterns also had epileptogenic patterns on the previously performed EEGs or had seizures confirmed with prolonged video-EEG monitoring, while the remaining 54% (25 out of 46) of patients had only wicket rhythms (but no true spikes or sharp waves) that were erroneously diagnosed as epilepsy [33]. Benbadis *et al*. [34] reported 15 patients who were eventually diagnosed with psychogenic non-epileptic seizures, but had previously carried a diagnosis of epilepsy based on EEGs misinterpreted as epileptiform [34]. Of the 15 records reviewed, the patterns that were incorrectly considered epileptiform were wicket spikes ($n = 1$), hypnogogic hypersynchrony ($n = 1$) and hyperventilation-induced slowing ($n = 1$). In the other 12 records, simple fluctuations of sharply contoured baseline background activity and fragmented alpha activity, not identifiable specific variants, were misinterpreted as epileptiform. Repeating the EEG or having it re-interpreted at a tertiary epilepsy centre by a certified electroencephalographer can be helpful in problematic cases. A routine EEG may *support* the diagnosis of epilepsy, especially if clear-cut epileptogenic or ictal discharges are observed, but it is important to remember that a normal EEG is perfectly consistent with epilepsy and can never rule it out. The range of 'normal' increases with age, so that discriminating normal from abnormal becomes more difficult and non-specific or unrelated abnormalities are commonly seen in older patients [35].

Neuroimaging

The mainstay of neuroimaging in epilepsy is MRI (magnetic resonance imaging), and its value in people with epilepsy has been amply demonstrated [36]. This particularly holds true for patients with medically refractory partial seizures, for whom appropriate surgical treatment results in complete resolution of seizures in the majority of patients with unilateral mesial temporal lobe epilepsy [37] or tumours [38], and even dual pathology [39].

Given the lack of prospective data regarding the diagnostic yield of neuroimaging in elderly patients with seizures, as a general rule all patients with new-onset seizures regardless of age at onset need to undergo appropriate imaging to rule out stroke, neoplasms, and subdural haematomas among other causes, and proceed with management accordingly.

Risk of recurrence

In all patients presenting with a first unprovoked seizure, the long-term (at least 2 years' follow-up) risk of recurrence is about 38%, ranging from 25% to 52% [40–43]. Prognostic factors which clearly increase the risk of seizure recurrence include abnormal EEG findings (particularly epileptiform) and the presence of an underlying recognized aetiology (i.e. remote symptomatic seizure).

Data on risk of recurrence after the first unprovoked seizure in older patients are largely inconclusive, as large-scale studies are lacking. However, in the presence of a recognized underlying neurological condition to which the seizure can be attributed, the risk of recurrence is roughly double that of a cryptogenic first seizure [41]. In selected populations, the recurrence rate may be very high, as Luhdorf and colleagues [32] found that seizures recurred in more than 80% of a small series of patients with a remote history of stroke. In many or most cases, a careful history will reveal that the presenting seizure is not actually the first seizure [44].

As many newly diagnosed unprovoked seizures in the elderly have an antecedent cause, most often cerebrovascular disease, it

is likely that most newly diagnosed seizures in the elderly population are likely to recur. In the elderly population, it is reasonable to begin anticonvulsant medication after the first unprovoked seizure, even in the absence of underlying demonstrable pathology. However, useful prospective data are lacking to confirm or refute the clinical value of this approach. In making the decision to begin pharmacological treatment, seizure severity, the risk of recurrence, personal preference and the need to drive must be weighed against the potential for adverse effects of AEDs, which, as discussed, may be more of a concern in elderly patients.

Treatment of epilepsy in the elderly

Although it has been frequently stated that epilepsy is more easily controlled in the elderly population [45,46], there is a dearth of large studies specifically addressing this issue. Data from the two recent studies addressing tolerability of anticonvulsants in the elderly showed seizure-free rates that were not very different from those of the general adult population. Brodie and colleagues compared carbamazepine and lamotrigine in a randomized trial of 150 elderly patients, in whom only 33% remained seizure free during the final 16 weeks of the study [47]. Although a high rate of medication withdrawal probably contributed to the relatively low rate of seizure freedom, these findings suggest that seizures are not so easily controlled in this population. Similarly, in the VA cooperative study #428, which randomized elderly patients with new or recent-onset epilepsy to treatment with gabapentin, lamotrigine or carbamazepine, 53% of patients who remained on treatment were seizure free at 12 months [48]. These data are not substantially different from seizure control rates in the general population; for instance, in a study of 470 previously untreated patients with epilepsy, aged 9–93, Kwan and Brodie [49] found that 47% became seizure free on the first drug, and a total of 67% became seizure free with the second or third monotherapy agent.

Pharmacokinetic changes

When choosing an AED, and when determining the dosing regimen for an elderly patient, one must be cognizant of the high risk of age-related physiological changes. This does not imply that elderly people with epilepsy are a homogeneous group characterized by similar specific physiological changes that will predictably affect the choice of drug and dosage. It should also be noted that the degree and rates of 'age-related' change are not reliably predictable across this age group; a great degree of variability is seen even within normal healthy individuals, and even more variability occurs in elderly patients, who often have multiple co-morbid conditions [8]. Other factors that will contribute in varying degrees to pharmacokinetic variability include physical frailty, dietary influences, compliance and drug interactions resulting from multiple co-medications [50,51]. Nevertheless, the major goal of seizure management in old age is the same as in younger patients: seizure control with minimal side-effects.

A description of pharmacokinetic properties and known age-related changes follows below. See Table 16.3 for a summary of the pharmacokinetic properties of the AEDs.

Absorption

Absorption of medications depends upon the dissolution of drug formulation, largely dependent upon gastric acid secretion, which often declines in the elderly [52]. In addition, gastric emptying may slow, intestinal transit time may increase, mesenteric blood flow may decrease, and the intestinal absorptive surface may decrease, all contributing in varying degrees to variable absorption of different drugs. Overall, this combination of factors typically results in the diminished ability to absorb AEDs, thus reducing bioavailability. This may be compounded by the frequent use of antacids in the elderly, which can specifically impair the absorption of phenytoin [53]. In addition, gabapentin, which is absorbed via a saturable L-amino acid transmitter system in the small intestine [54], may be particularly susceptible to physiological changes in gastrointestinal absorption.

Protein binding

Elderly patients are at significant risk for acute systemic and neurological illnesses, many of which may cause a significant decline in serum albumin levels. Suboptimal nutrition may also contribute to lower albumin levels. A reduction in serum albumin concentrations will cause the free fraction of highly protein-bound medications to increase substantially, and may result in prominent adverse effects despite little or no change in the total serum level. AEDS that are highly protein bound include tiagabine, phenytoin, valproate, diazepam, clonazepam, clobazam and, to a lesser extent, carbamazepine [55].

Hepatic clearance

Hepatic mass and blood flow both decline with age, such that liver volume is about 25% lower in people age 65 than in young adults [56]. The majority of drugs metabolized in the liver are metabolized by the cytochrome P450 system, and with increasing age this system declines in efficiency, although to a variable, unpredictable degree [57].

The AEDs that are metabolized primarily by the cytochrome P450 system include carbamazepine, ethosuximide, oxcarbazepine, phenytoin, phenobarbital, primidone, tiagabine and zonisamide. Felbamate, topiramate and valproate are also partially metabolized via this pathway [8].

The hepatic glucuronidation conjugation process is believed to decline much less with age. AEDs primarily undergoing conjugation include lamotrigine, valproate and the active metabolite of oxcarbazepine [8].

Renal clearance

The most consistent change with age is an age-related decline in renal function, associated with reduction in renal mass, loss of glomeruli, resulting in reduced glomerular filtration rate (GFR) and a reduced ability to handle renally excreted medications and toxins. GFR declines on average by about 50% between the third and eighth decades of life [58], but the degree of change is highly variable, with about one-third of patients not experiencing significant decline [59]. Because muscle mass, the source of serum

Table 16.3 Pharmacokinetic properties of commonly used AEDs in adults.

AED	Oral bioavailability (%)	Plasma protein binding (%)	Half-life (h): patients not on EIAEDs	Half-life (h): patients on EIAEDs	Main route of elimination
Carbamazepine	≤85	~80%	10–25	5–12	Hepatic epoxidation, then conjugation (the 10,11-epoxide metabolite may contribute to efficacy)
Felbamate	~90	~30	14–23	10–20	Hepatic hydroxylation and then conjugation; 40% renal excretion
Gabapentin	≤60 (decreases with increasing dose)	0	5–7	5–7	Renal excretion
Lamotrigine	100	~55	15–30 (30–90 when co-medication is valproate)	8–20 (15–60 when valproate is also present)	Hepatic glucuronidation
Levetiracetam	~100	0	6–8	5–8	Partially hydrolysed to inactive compound; mostly renal excretion
Oxcarbazepine	>95 (active metabolite is MHD)	~40 (MHD)	8–15 (MHD)	7–12 (MHD)	Ketoreduction to MHD, which is eliminated via hydroxylation and then glucuronide conjugation
Phenobarbital	100	45–60	75–125	75–125	Oxidation, conjugation and renal excretion
Phenytoin	~95	85–95	7–42 (increases with increasing dosage)	7–42 (increases with increasing dosage)	Hepatic oxidation and hydroxylation then conjugation
Pregabalin	~90	0	5–7	5–7	Renal excretion
Tiagabine	~100	96	4–13	4–5	Hepatic oxidation then conjugation
Topiramate	>80	~20	20–30	10–15	Mainly hepatic oxidation, and renal excretion
Valproic acid	~100	85–95	10–20	6–12	Hepatic glucuronidation and oxidation then conjugation
Vigabatrin	60–70	0	5–8	5–8	Renal excretion
Zonisamide	≥65	50	50–70	25–35	Hepatic acetylation, isoxazole ring cleavage (via CYP3A) then glucuronide conjugation and renal excretion

AED, antiepileptic drug; CYP3A, cytochrome P450, family 3, subfamily A; EIAED, enzyme-inducing antiepileptic drug (these include carbamazepine, phenytoin, phenobarbital and primidone); MHD, 10-monohydroxy metabolite.

Table 16.4 Average changes in apparent oral clearance of older and newer AEDs in elderly patients.

AED	Decrease in drug clearance in elderly compared with young adults (%)	Reference
Carbamazepine	25–40	Battino *et al*. (2003)
Felbamate	10–20	Richens *et al*. (1997)
Gabapentin	~30–50	Boyd *et al*. (1999)
Lamotrigine	~35	Posner *et al*. (1991)
Levetiracetam	~20–40	Patsalos (2004), Hirsch *et al*. (2007)
Oxcarbazepine	~25–35[a]	van Heiningen *et al*. (1991)
Phenobarbital	~20	Messina *et al*. (2005)
Phenytoin	~25[b]	Bachmann and Belloto (1999)
Tiagabine	~30	Snel *et al*. (1997)
Topiramate	~20	Doose *et al*. (1998)
Valproic acid	~40[c]	Perucca *et al*. (1984)
Vigabatrin	~50–85[d]	Haegele *et al*. (1988)
Zonisamide	No data	–

Modified with permission from ref. 8.
Interindividual variation may be considerable in relation to age and other factors.
[a] Data refer to the active metabolite monohydroxycarbazepine.
[b] Decrease in clearance of unbound drug may be greater.
[c] Decrease in unbound drug clearance. Clearance of total (unbound + protein bound drug) may not change.
[d] These patients, who had various pathologies, were preselected to cover a wide range of impaired renal function.

creatinine, declines with age, the serum creatinine level often does not decline in parallel with declining GFR.

The AEDs that are primarily renally excreted include gabapentin, levetiracetam, vigabatrin and pregabalin. Felbamate, zonisamide, and topiramate are also partially renally excreted [55]. Table 16.4 summarizes the literature on age-related changes in the clearance of the commonly used AEDs [8].

Pharmacodynamic changes

In addition to the pharmacokinetic effects potentially altering levels of medication in the serum, it is also likely that pharmacodynamic alterations in the effects of the drugs at the cellular level are important in the elderly. In particular, adverse central nervous system effects often occur at serum free levels that do not typically produce adverse effects in younger adults. As a result, the therapeutic window, between efficacy and toxicity, is often narrower for AEDs in the elderly population (Fig. 16.2) [60].

Antiepileptic drug choice

As virtually all of the currently used AEDs have been shown to be of approximately equal efficacy in the treatment of partial-onset seizures, considerations of tolerability and safety, including

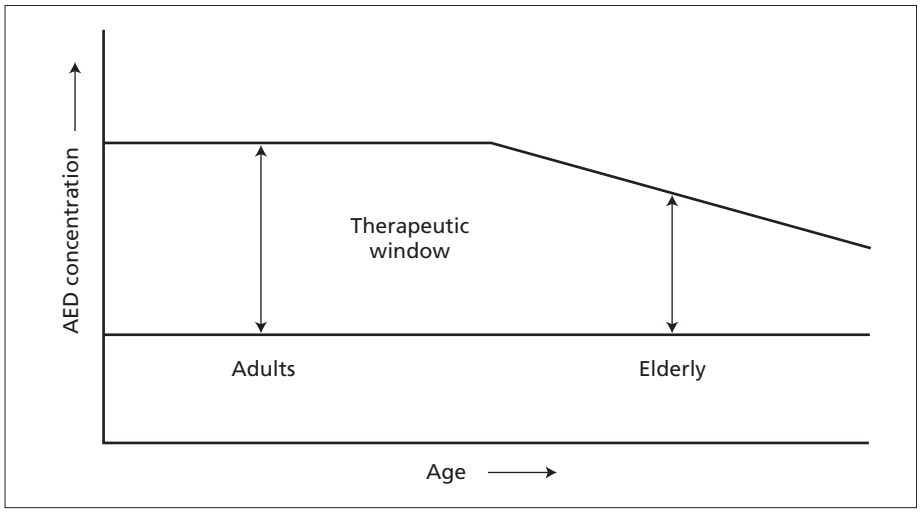

Fig. 16.2 Effect of age on therapeutic ranges. The elderly typically have a narrow therapeutic window, the range between the lowest effective concentration and the maximal tolerated concentration. Reproduced with permission from ref. 61.

Table 16.5 Desirable features of an antiepileptic drug for use in the elderly.

No interactions with other medications
No interactions with other AEDs
Can be introduced at therapeutic doses
No metabolism
No protein binding
Once- or twice-daily dosing
Laboratory monitoring not necessary
Excellent safety record
Good side-effect profile
High therapeutic index
Little effect on cognitive function
Psychoactive benefits

pharmacokinetics and the potential for drug interactions, are at least as important as efficacy in the selection of an AED (Table 16.5) [60].

Older antiepileptic drugs

Although the older AEDs (including phenytoin, phenobarbital, primidone, valproate and carbamazepine) are effective in partial epilepsy [61,62], several features make them less than ideal choices. Phenobarbital and primidone are particularly sedating and may significantly depress cognition, and were shown to be significantly less well tolerated than carbamazepine and phenytoin in the first VA cooperative trial (including all ages) [62]. In addition, these medications are potent hepatic enzyme inducers, reducing the efficacy of many commonly used medications, and are also likely to contribute to bone loss. With these effects in mind, these AEDs should not be considered first-line (and probably not second-line) medication choices in this population.

Phenytoin, despite being the most widely prescribed AED in the USA, has many troublesome features. In particular, the transition from first- to zero-order kinetics at modest doses often leads to widely variable serum levels with small changes in dosing, resulting in a high risk of toxicity. It has adverse effects, including imbalance and ataxic gait, at modest levels and can result in an increased risk of falls and consequent fractures. Because of its potent hepatic enzyme-inducing properties and high degree of protein binding, medication interactions are prominent. It has been clearly demonstrated that even 1 year of use in monotherapy leads to measurable loss of bone density [63]. Although we believe that phenytoin should no longer be used as a first-line (nor probably second-line) agent in the elderly, prescribing patterns are not likely to change markedly in the near future. When phenytoin must be used, dosage adjustments should be made in small increments of 30 mg in order to minimize risks of toxicity. We also recommend not changing formulations of phenytoin (e.g. not changing from brand to generic, or from one generic to another) without close monitoring of serum levels.

Valproate is a potent inhibitor of hepatic enzymes, is highly protein bound and can be involved in numerous drug interactions. Valproate encephalopathy can rarely result from hyperammonaemia in the absence of hepatic enzyme abnormalities [64], and this should be considered in any patient on valproate with unexplained encephalopathy. In addition, it is not rare for valproate to exacerbate or cause parkinsonism [65]. Nonetheless, valproate is often well tolerated and effective in older adults.

In a retrospective analysis of 417 older adults (≥55 years old) from the Columbia AED Database, we compared 12-month retention (a composite measure of efficacy and tolerability) in 247 older adults newly started on any AED at our centre over a 4-year period. The average 12-month retention rate was 65%. Without controlling for severity, lamotrigine had the highest 12-month retention rate (78.6%; n=126), which was higher ($P < 0.05$) than the 12-month retention rates seen with carbamazepine (48.4%; n=31), gabapentin (59%; n=39), oxcarbazepine (23.5%; n=34), phenytoin (59.3%; n=27) and topiramate (55.6%, n=18). The second highest retention rate was seen with levetiracetam (72.5%; n=102), which was statistically higher than with carbamazepine (48.4%) and oxcarbazepine (23.5%). Oxcarbazepine had the worst retention rate (23.5%; n=34), which was significantly lower than with all other AEDs. When the results were stratified into non-refractory and refractory patients, relative rates remained comparable. The 12-month retention rate for valproate in the refractory group was 90% (n=10). In the same analysis, the 12-month seizure freedom rate for valproate in the overall group was only 27.8%, so it may be likely that the high retention rate seen with valproate is attributable, at least in part, to good tolerability of valproate [66].

Carbamazepine, also widely prescribed, has a less than favourable pharmacokinetic profile. As an inducer of hepatic enzymes, numerous drug interactions can occur. Hyponatraemia occurs more commonly in elderly patients taking carbamazepine [67]. Carbamazepine has been shown to be less well tolerated than many of the newer AEDs (see below).

Newer antiepileptic drugs

Two prospective trials in the elderly have shown that lamotrigine and gabapentin are better tolerated and thereby more effective than carbamazepine.

In the VA cooperative study #428, patients 60 years of age or older with newly diagnosed epilepsy were randomized to treatment with gabapentin 1500 mg per day, lamotrigine 150 mg per day or carbamazepine 600 mg per day; dose adjustments were permitted [48]. The primary outcome measure of the study was early termination, which occurred in 64.5% of patients taking carbamazepine, a rate that was significantly higher than the 51% of patients taking gabapentin ($P = 0.008$) and 44% of patients taking lamotrigine ($P < 0.0001$). Fewer lamotrigine patients terminated the study because of adverse reactions than either carbamazepine ($P < 0.0001$) or gabapentin ($P = 0.015$) patients. There were no significant differences in seizure-free rates or time to first seizure. For all three AEDs, the primary factor resulting in early termination was the occurrence of adverse effects: there were significantly more early terminators on carbamazepine (31%) compared with lamotrigine (12.1%; $P < 0.0001$) and on gabapentin (21.6%) compared with lamotrigine (12.1%; $P = 0.015$). The most common neurotoxic side-effects in all three treatment groups included sedation, cognitive disturbances, dizziness, gait problems and changes in mood/affect. More patients on gabapentin experienced large weight gain (>18 pounds) than on carbamazepine ($P = 0.005$) or lamotrigine ($P = 0.014$). Water retention was significantly more likely with gabapentin than with carbamazepine ($P = 0.004$) or lamotrigine ($P = 0.02$). More patients lost weight with lamotrigine than with gabapentin ($P = 0.002$). Hypersensitivity (rash of any degree) occurred more frequently with carbamazepine than with lamotrigine ($P = 0.007$). Of seven patients hospitalized for hypersensitivity reaction, six were in the carbamazepine group and one was treated with lamotrigine. Hyponatraemia (sodium less than 130 mg) occurred more frequently in patients on carbamazepine than on gabapentin.

A similar earlier study by Brodie and colleagues [47], randomizing 150 newly diagnosed elderly subjects (mean age 77 years) with epilepsy to lamotrigine (median dose 100 mg/day) or carbamazepine (400 mg/day), found that 42% of patients on carbamazepine dropped out because of adverse events as opposed to only 18% of patients on lamotrigine [47]. Notably, 29% of patients on carbamazepine complained of somnolence in contrast with only 12% of patients on lamotrigine. Also of interest, only 3% of patients on lamotrigine developed allergic rash, as opposed to 19% on carbamazepine.

The newer AEDs have been reviewed extensively in the 2004 American Academy of Neurology (AAN) guidelines on the efficacy and tolerability of the new antiepileptic drugs [68,69]. Overall, lamotrigine has been shown to have a favourable adverse effect profile. It is non-sedating, and does not produce significant cognitive dysfunction. It is not an inducer of hepatic enzymes and is not highly protein bound, resulting in minimal drug interactions. It should be noted that enzyme-inducing medications and hormone replacement may significantly reduce its level. The interaction between lamotrigine and valproate is a complicating factor, and co-medication with valproate may increase lamotrigine levels by two- to threefold. One potential negative aspect of therapy with lamotrigine is the need for slow titration because of the risk of a potentially severe allergic reaction if titration is too rapid. With gradual dosage titration according to the guidelines, this risk is no greater than (and potentially less than) the risk with most of the older AEDs.

Levetiracetam, approved by the US Food and Drug Administration (FDA) after the VA study began, also has favourable features. It does not produce significant cognitive dysfunction, is renally excreted, is not highly protein bound, and does not undergo oxidative metabolism in the liver; thus it is not associated with any major pharmacokinetic interactions [70]. Enzyme-inducing AEDs, however, can moderately decrease serum levetiracetam concentrations [71–73] but the clinical significance of this decrease is still unclear. A small but significant percentage of patients experience irritability, depression or other behavioural side-effects. A great benefit of levetiracetam is that it has therapeutic efficacy at starting doses; the odds of becoming seizure free increase over twofold as early as the first day of adjunctive treatment with levetiracetam at doses of 1000 mg/day, in patients with refractory epilepsy [74].

Gabapentin and pregabalin also have favourable profiles. Both are renally excreted, have minimal cognitive effects, are not hepatic inducers, and are not protein bound. In addition, both probably have therapeutic efficacy at starting doses.

Oxcarbazepine, although hepatically metabolized, is a weak inducer of hepatic enzymes, and has minimal drug interactions. As is the case with carbamazepine, hyponatraemia is seen more often in elderly patients, and is even more frequent with oxcarbazepine than carbamazepine. Hyponatraemia is particularly common in older adults on diuretics or selective serotonin reuptake inhibitors (SSRIs) [75].

Zonisamide and topiramate are often well tolerated, but both seem to be associated with a relatively high incidence of sedative and cognitive adverse effects. Each is partially excreted unchanged via renal mechanisms and partially metabolized in the liver. Neither is a hepatic enzyme inducer, nor are they highly protein bound, and there are few drug interactions. Each should be titrated slowly. It should also be noted that both are weak carbonic anhydrase inhibitors and carry a small risk of renal stones.

In a recent study of 20 558 veterans with epilepsy aged 65 or older, 70% were found to be on phenytoin [8,76]. An additional 17% were on phenobarbital, 10% on carbamazepine, and notably, gabapentin and lamotrigine were used in less than 10% of newly diagnosed cases.

In a survey of experts, 'opinion leaders in the field of epilepsy' in 2005, for treatment of localization-related epilepsy (LRE) in the healthy elderly, lamotrigine was selected to be the treatment of choice in 66%, recognized as first line by 98%. Levetiracetam was also selected as first line by 95%. Gabapentin, carbamazepine and oxcarbazepine were also recognized as first-line agents by 71%, 59% and 61%, respectively. Other agents were selected

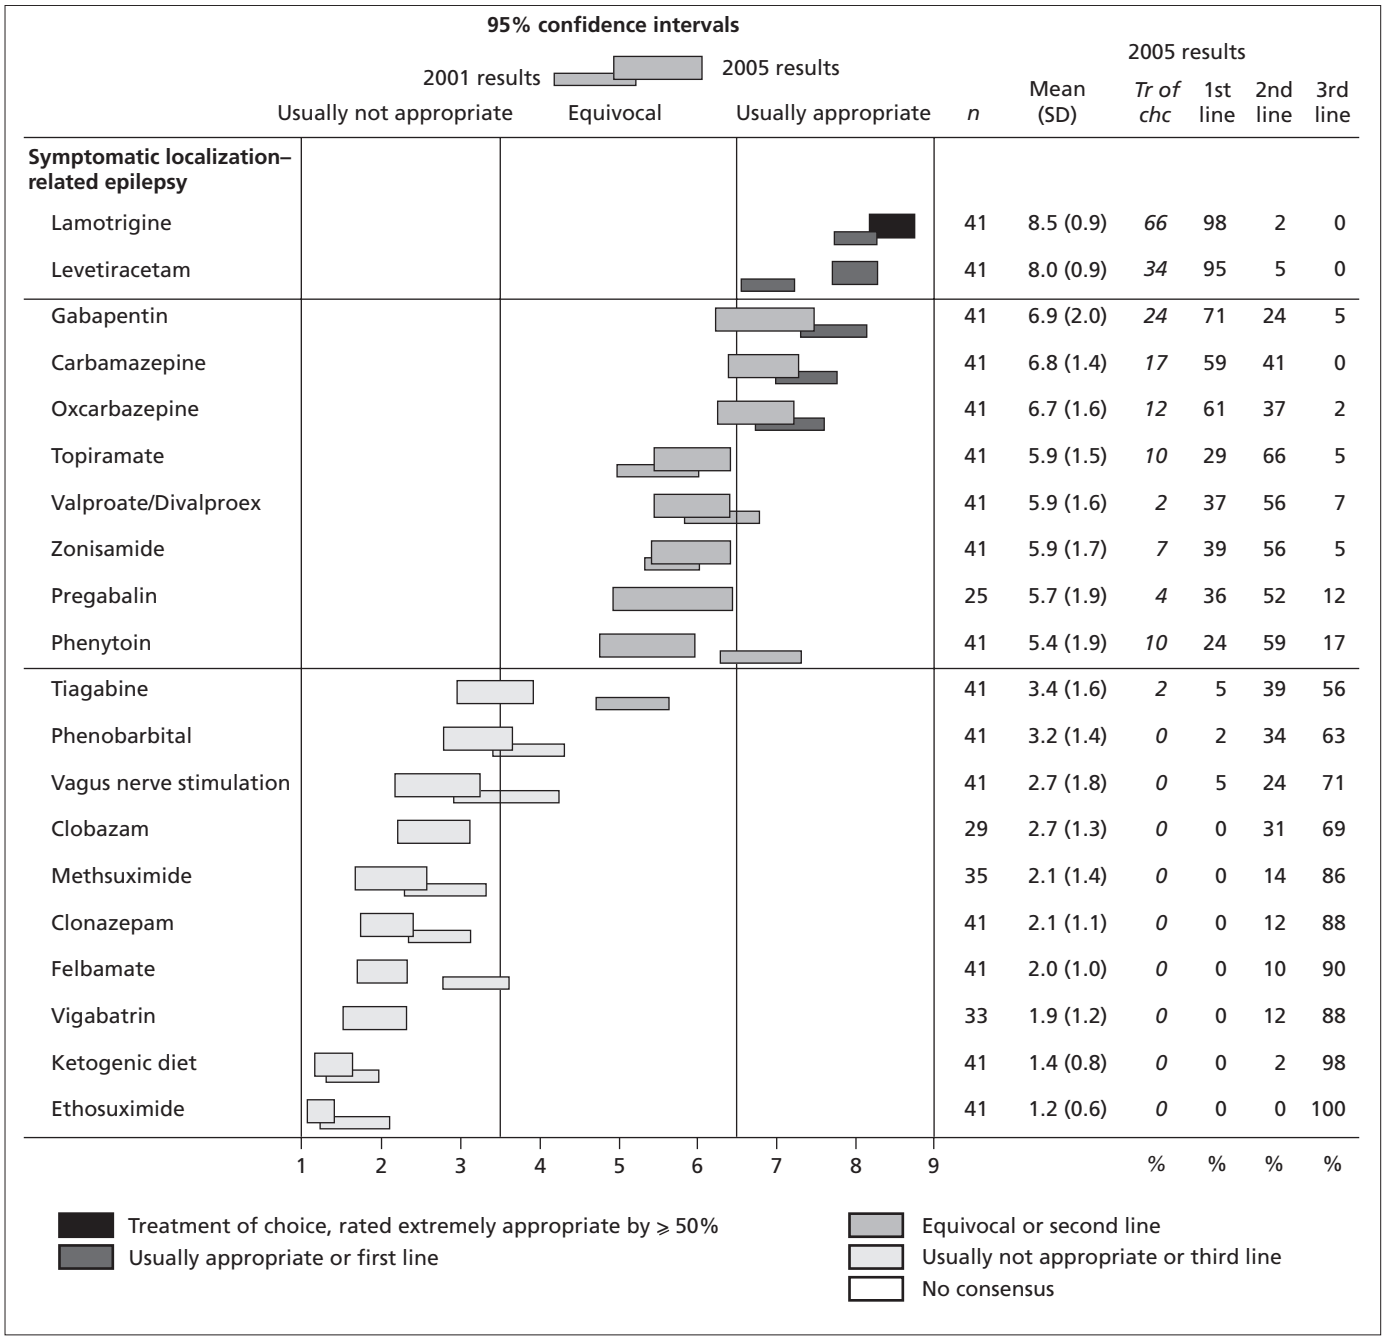

Fig. 16.3 Antiepileptic drug therapy for elderly patients with symptomatic localization-related epilepsy. In this scenario, assume that the patient is a medically stable elderly man or woman. Please rate the appropriateness of each of the following therapies as they might be used in monotherapy in this population. Keep in mind the epilepsy syndrome diagnosis. Reproduced with permission from ref. 77.

by far fewer experts. Phenytoin was selected as first line by only 24% and phenobarbital by only 2% (Fig. 16.3) [77].

Co-morbid conditions and medication interactions

Given the frequency of co-morbid conditions in the elderly, and the myriad of medications used to treat these, these issues must be at the forefront when selecting an AED. Nearly 90% of elderly patients in the community take at least one prescription medication [78], and nursing home residents take an average of approximately five routine medications [53]. An attempt should be made to tailor the expected side-effect profile of the AED to the characteristics of the individual: for example, a drug causing weight loss may be a good choice for the obese patient. Table 16.6 compares AEDs that may be more or less appropriate based on specific co-morbid conditions.

Table 16.6 Selection of AEDs based on common co-morbid conditions: examples.

Co-morbid condition	Potentially beneficial for co-morbid condition	Potentially harmful for co-morbid condition
Osteoporosis	–	Phenobarbital, phenytoin
Obesity	Topiramate, zonisamide	Valproate > gabapentin, pregabalin
Depression	Lamotrigine	Levetiracetam, phenobarbital
Anxiety	Gabapentin, pregabalin	Levetiracetam
Bipolar disorder	Carbamazepine, lamotrigine, valproate	–
Cognitive problems/ dementia		Topiramate
Headache/migraine	Topiramate, valproate	–
RLS/PLMS	Gabapentin	–
Renal stones	–	Topiramate, zonisamide
Hyponatraemia	–	Oxcarbazepine > carbamazepine
Multiple or severe prior allergy/rash	–	Carbamazepine, lamotrigine, phenytoin > oxcarbazepine, phenobarbital, zonisamide

PLMS, periodic limb movements in sleep; RLS, restless legs syndrome.

The major interactions are based upon the cytochrome P450 enzyme-inducing or -inhibiting effects of the AEDs. Potent hepatic inducers include phenobarbital, phenytoin, carbamazepine and phenytoin. Felbamate, oxcarbazepine and topiramate are mild hepatic inducers. Valproate is a potent hepatic enzymatic inhibitor. Ethosuximide, gabapentin, lamotrigine, levetiracetam, tiagabine, zonisamide and pregabalin are neither inducers nor inhibitors of hepatic enzymes. Patsalos and Perucca have published an extensive review on the topic, and readers are referred here for further detail [79]. In summary, lamotrigine, levetiracetam, gabapentin, pregabalin, zonisamide and topiramate have the lowest potential for interaction with medications used to treat co-morbid conditions in the elderly.

In addition, commonly used medications in the elderly may also affect the levels of certain AEDs, and these have also been summarized in the Patsalos and Perucca review. Several commonly used medications inhibit the cytochrome P450 enzymes, and consequently may increase the levels of AEDs metabolized via this pathway. These include H2-blockers (cimetidine), macrolide antibiotics (erythromycin, clarithromycin), antifungal agents (ketoconazole, fluconazole) and isoniazid. Ticlopidine has also been found to increase levels of carbamazepine and phenytoin. Rifampin is an enzyme inducer and can lead to loss of efficacy of many AEDs.

Epilepsy surgery

Given the challenges associated with AED selection and treatment of epilepsy in the elderly, resective surgery must be considered in suitable cases. However, few studies have assessed the efficacy of surgery for temporal lobe epilepsy (TLE) in the elderly [80–83]. In a retrospective study [84], 52 patients >50 years old were studied who underwent surgical treatment for refractory mesial TLE (mean duration of epilepsy, 33 years; mean age at surgery, 55 years). Forty selective amygdalohippocampectomies (33 for hippocampal sclerosis, seven for removal of a mesiotemporal lesion), five lateral temporal lesionectomies plus amygdalohippocampectomy and seven anterior temporal lobectomies were performed. The outcomes were compared with a control group of 321 patients who were younger than 50 years of age at surgery. In the older group, 37 patients attained complete seizure control (71% Engel class I compared with 72% class I in younger patients) and 10 patients had only rare postoperative seizures (19% class II). Four patients improved more than 75% (8% class III), and one patient did not improve (2% class IV). A subgroup analysis of 11 patients older than 60 years at surgery showed a similar rate of seizure control. A trend towards better seizure control was noted in 16 patients with an epilepsy duration of <30 years (all class I or II), and in 20 patients with a seizure frequency of fewer than five seizures per month (all class I or II). A 3.8% rate of permanent neurological morbidity (dysphasia and hemiparesis) was noted. Neuropsychological testing revealed low preoperative performances and some gradual further deterioration after surgery. In the older group, postoperative attentional performance improved significantly in 11 patients (32.4%), remained unchanged in 14 patients (41.2%), and deteriorated significantly in nine patients (26.5%). Younger patients showed significantly stronger benefits after surgery regarding postoperative attentional performance ($P = 0.016$). These results suggest that many elderly patients may benefit significantly from epilepsy surgery, despite a prolonged history of seizures.

The impact of seizures in old age

Seizures in an elderly person can have profound physical and psychological consequences. The physical disability is caused, at least partly, by the increased incidence of falls and diminished bone health in the elderly population, with the consequential increased risk for serious fractures in this age group. The additional risk of falls conferred by seizures, along with the potential deleterious effects of AEDs on bone health, creates a dangerous potential for fractures in elderly patients with epilepsy. Although no adequate prospective studies have been undertaken, there are data to suggest (as reviewed by Downton *et al.* [85]) that a fall may mark a watershed in an older patient's life, after which there is a sharp decline in functional independence that can be attributed not only to the disease underlying the fall but also to a loss of self-confidence.

In a study of more than 8000 community-dwelling women older than 65 years, those taking AEDs were 75% more likely to experience a fall than those not taking AEDs [86]. This increase is likely to be partly related to seizures but also to an increased sensitivity to the CNS effects of AEDs in older patients resulting in a greater tendency to imbalance and consequent falls. Patients with epilepsy have been shown to have approximately double the fracture risk of control subjects [87].

In adults, bone mineral density (BMD) peaks between the ages of 20 and 30 years. Thereafter, BMD steadily and gradually continues to decline, and this is more pronounced in women

following the onset of menopause. Some commonly used older AEDs that are potent inducers of the cytochrome P450 enzyme system are associated with altered bone metabolism and decreased bone density; these include phenytoin, carbamazepine, primidone and phenobarbital [88]. A recent longitudinal study of 93 premenopausal women (age 18–40 years) receiving a single AED (either carbamazepine, lamotrigine, phenytoin or valproate) showed that young women treated with phenytoin monotherapy had significantly more bone loss at the femoral neck (2.6%) over 1 year of treatment than women treated with the other AEDs [63].

Valproate, an inhibitor of the P450 system, was initially believed not to affect bone health, but was recently found to be associated with reductions in BMD [89,90]. Polytherapy has been shown to be associated with a higher risk of bone metabolism abnormalities than monotherapy [91]. Multiple mechanisms have been postulated to support the association; however, no single mechanism explains all the findings.

Data regarding lamotrigine's effects on bone health are mixed. One study linked exposure to lamotrigine to short stature in children, which the investigators speculated as having been possibly related to less physical activity in this group [92]. Another prospective study found elevated osteocalcin, a marker of bone formation, in association with lamotrigine treatment [93]. In contrast, premenopausal women treated with lamotrigine did not have significant reductions in BMD or changes in bone turnover markers [94].

The effects of topiramate and zonisamide on bone have received limited study. The carbonic anhydrase inhibitor action of these AEDs, resulting in renal acidosis, may have secondary negative effects on bone. Interestingly though, carbonic anhydrase also potentiates the action of osteoclasts and so, theoretically, inhibitors may have a bone-sparing effect. The findings of a study in women with glaucoma treated with acetazolamide (another carbonic anhydrase inhibitor) appear to support this hypothesis [95]. Another randomized preliminary study of topiramate as treatment for obesity did not find significant changes in bone turnover markers compared with placebo-treated control subjects [96]. There are limited data about levetiracetam's effects on bone: a preliminary study with a limited sample size found no effects [97].

A number of neuropsychological and neuroimaging studies have linked the deterioration of specific cognitive functions (e.g. memory) and general intellectual ability (IQ) to both temporal and extratemporal epilepsy and to disease variables such as early age at onset and seizure frequency [98,99]. Patients with chronic epilepsy have up-regulation of amyloid precursor protein, increased rates of senile plaque formation and premature accumulation of corpora amylacea; there is increasing evidence that the presence of the *apoE-e4* allele in patients with chronic TLE is linked to age-accelerated memory impairment [100,101]. This literature has been recently reviewed by Hermann and colleagues [100]. Two population-based studies of medical co-morbidities (from the UK and Canada) showed a significant association between Alzheimer's disease and other dementias in persons with epilepsy compared with control subjects [103,104]. Breteler *et al.* [105] demonstrated an age-accelerated risk of dementia in 4505 patients (aged 50–75 years) with epilepsy, compared with age-matched subjects with other medical disorders, over an 8-year observation period [105].

Lifestyle factors, such as decreased physical and mental activity and lack of a social network, are also risk factors for cognitive decline in later life [106]. Many of these risk factors are more common in patients with epilepsy. It is therefore important not only to study causality of these individual risk factors and subsequent cognitive decline but also to ascertain whether cumulative exposure to these risk factors in younger years increases the risk of adverse cognitive outcomes in later life. For many patients, cognitive decline is as important a factor in determining quality of life as seizure control.

Falls in seizures can have a marked psychological impact. Falls can create a greater degree of stigmatization, affect interactions with others, including friends, relatives and caregivers, and restrict activity, mobility and independence (for example by losing a driver's licence), limit participation in decision-making processes and increase dependency. In summary, older patients may experience considerable marginalization and disempowerment, and although seizures will not affect employment or education as in younger persons, the impact on interpersonal relationships and interaction may be no less important [107].

Areas for future research

It is evident from the foregoing that, despite recent interest, geriatric epileptology is a relatively underdeveloped and under-researched field. A number of areas urgently require investigation.

Although it is now clear that cerebrovascular disease is the most common cause of seizures in old age, the relation may be overestimated because of the frequency of vascular disease in the general elderly population. More studies are needed to determine the frequency and types of other causes and, as a corollary, which of these patients are amenable to surgical intervention. Seizure-related fractures and other significant physical injuries are common in elderly patients, and may considerably impact mobility and increase dependence. Similarly, the psychosocial aspects of living with a chronic, stigmatized illness must be studied further. With regard to treatment, many questions remain to be answered. Studies are required to determine whether, and when, one should treat a single unprovoked seizure in old age. The place of newer AEDs such as levetiracetam and pregabalin in the treatment of elderly-onset seizures needs to be assessed prospectively. These studies should focus not simply on the traditional endpoints such as seizure control, but also on the feasibility of reducing subtle adverse effects on, for example, gait and mobility.

Summary and recommendations

Although the goals of treatment are the same in all patients – controlling seizures while minimizing side-effects and their effect on quality of life – there are various issues that make seizure management in elderly patients particularly challenging. These are in large part based upon both physiological changes with age, as well as the high frequency of co-morbid conditions in the elderly. Co-morbidities not only make diagnosis difficult,

but the many co-medications and potential drug interactions can result in suboptimal seizure control and a higher risk of toxicity.

In their approach to the elderly patient with episodic loss of consciousness, clinicians must quickly rule out life-threatening non-seizure diagnoses (usually cardiac causes such as ventricular arrhythmias). Thereafter, the clinician must maintain a high suspicion for seizures, as seizures are not only common in this age group, but frequently present atypically and are mistakenly interpreted as a manifestations of a co-morbid condition (for instance vascular disease). Whenever a diagnosis is in question, video-electroencephalography can help rapidly to confirm or exclude a diagnosis of seizures. The choice of drugs should be based upon adverse effect profile, lack of drug–drug interactions and co-morbid conditions. The newer AEDs should be first-line therapy, assuming no financial barriers. It is also imperative for the clinician to understand age-related pharmacokinetic changes, underlying medical co-morbidities and concomitant medication regimens while starting an AED. It is recommended to start therapy at a low dose and to titrate upwards slowly. In general, we recommend using half the dose and half the titration speed as would be used in a young adult. Finally, close follow-up is essential and compliance is a risk in elderly patients owing to a higher incidence of adverse events, complicated medication regimens and a general lack of social support. Knowledge of an elderly patient's values and expectations is essential in providing high-quality clinical care.

17 Management of Epilepsy in People with Learning Disabilities

Eylert Brodtkorb

St Olav's Hospital, Trondheim University Hospital, Trondheim, Norway

The same disorder that causes seizures has also, in many patients, the potential to limit intellectual development. Mental retardation is present in more than 20% of adult individuals with epilepsy [1]. The risk of developing a seizure disorder increases with the severity of cognitive deficit. People with learning disabilities represent an important subgroup within the population of patients with epilepsy. Here we are faced with many of the most refractory patients. The general principles in the management of epilepsy are no different than for any other patients [2]; nevertheless, the co-existence of intellectual deficits and behavioural abnormalities can substantially interfere with the medical assessment and treatment of seizures. Adverse drug reactions can remain unrecognized and may be more harmful than the seizures themselves. Particular care should be taken to avoid overmedication in this group. During a lifetime, these patients are among the most drug-exposed groups in society. The treatment objective must not necessarily be a seizure-free state, but improvements in seizure control, alertness, mood and behaviour.

Previously, textbooks often conveyed the impression that the combined occurrence of epilepsy and learning disability is predominantly confined to the younger age groups, but, numerically, adult patients far outnumber children (Fig. 17.1) [3], and comprehensive medical follow-up of this patient category must continue beyond the end of adolescence. This chapter will highlight some particular medical problems and complications which accumulate in patients with learning disabilities and associated handicaps.

Comprehensive epilepsy service

Multidisciplinary approach

The cognitive deficits expressed via intelligent quotient (IQ) level are certainly not the only factor for disability in the large and complex group of patients with learning disabilities. The total social handicap largely depends on concomitant neurological handicaps, such as epilepsy, various motor deficits, sensory impairments and behaviour abnormalities, including autistic features. Many problems are particularly prominent in the paediatric age group, but several continue and some arise in adulthood. Patients with learning disabilities represent a particular challenge to the epileptologist. Investigation and treatment are often hampered by contact problems. These people usually have reduced abilities to express their own wishes and requests. Carers have to be relied upon, and a multidisciplinary and comprehensive approach is often needed. Attention should be focused on several factors other than just the seizures, such as behaviour, alertness, mood, communication, co-operation, appetite and sleep pattern. Comprehensive epilepsy service may be divided into three overlapping fields: the medical, the psychological and the social and educational (Table 17.1). A strong awareness of the need for these different approaches is mandatory for an optimal management of patients with learning disabilities. However, in the global assessment of these patients, care should be taken that the pure medical needs are not overshadowed by other aspects.

Medical aspects

There has been an increasing appreciation of the fact that individuals with learning disabilities are very heterogeneous regarding the pathogenic mechanisms and the clinical manifestations of their brain dysfunction. Because of their special needs, these patients are often excluded from the general epilepsy service, especially in adult practice. EEG recordings may be impossible to perform. The presented history is often inaccurate. The key to a precise evaluation is the detailed observation and description of seizures and behaviour by carers and family members. The fundamental importance of detailed anamnestic data, including those from good informants, must be emphasized. The seizure semiology may be atypical. Seizure clustering and transitions between various seizure types are common. In patients with limited understanding and verbal ability, the attacks may be coloured by emotional responses and behavioural reactions. Non-epileptic, seizure-like behaviour is common. A range of paroxysmal events other than epileptic seizures may occur in these patients (Table 17.2) and misinterpretations by caregivers are common. To improve diagnostic accuracy, home video recordings may be helpful. These patients may be more prone to inadequate, long-term antiepileptic drug (AED) treatment than other patients. Inappropriate epilepsy treatment often starts with an insufficient history, particularly in adult patients who are accompanied by caregivers with a limited knowledge of their clients. Information about the individual's past and current health status is the basis of clinical decision-making. Optimal medical management of these patients is often very time-consuming. A specialist epilepsy nurse may play a key role in the service to them, providing supervision of the carers and warranting availability and continuity of high-quality medical care.

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

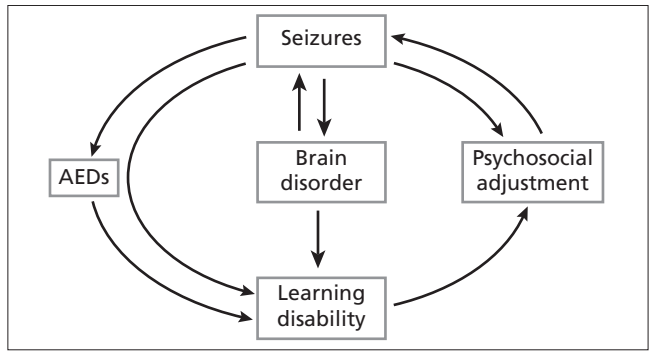

Fig. 17.2 In people with learning disability, overtreatment with antiepileptic drugs may enhance cognitive dysfunction, impair psychosocial adjustment and increase behavioural problems. The various factors may be difficult to identify and may interact in different ways in different patients. Redrawn with permission from Wrightson Biomedical Publishing.

Table 17.1 The three overlapping fields of comprehensive epilepsy service to people with learning disabilities.

Medical	The need for continuous access to current developments in diagnosis and treatment throughout all age groups
Psychological	The need to consider the symptoms and the treatment in relation to psychological and intellectual functioning
Social	The need for social and educational support, and for information and supervision not only for the sufferer, but also for the family and the carers

Table 17.2 Paroxysmal non-epileptic events in patients with learning disability.

Spasms and dyskinesias in co-morbid cerebral palsy
Stereotypes and self-stimulation in patients with autistic features
Activity pauses
Acute dystonia and tardive dyskinesias in patients receiving psychopharmacological treatment
Episodic dyscontrol and attention seeking in patients with behavioural problems
Gastro-oesphageal reflux

Psychological and cognitive aspects

Seizure effects and adverse AED reactions may be masked by the intellectual handicaps. Drowsiness, mood change and behavioural problems may be signs of drug toxicity. Side-effects, neurodeficits, seizure activity and social, educational and behavioural problems often merge. The various factors are sometimes difficult to identify and they may interact in different ways in different patients (Fig. 17.2). In particular, it is important to distinguish between permanent learning disability on the one hand and state-dependent learning disability (pseudo-retardation) on the other [4]. Both forms often occur together. State-dependent learning disability is reversible and potentially treatable, but unfortunately often goes unrecognized. In patients with epilepsy, it may be of two kinds: either drug induced or seizure related, due to epileptiform discharges, subtle or 'subclinical' seizures or postictal effects. When treating patients with learning disabilities, it is imperative to bear in mind the complex inter-relationship between cognitive function and epilepsy-related factors (Fig. 17.2).

Social and educational aspects

Myths and prejudices still persist about patients with learning disability which should be countered by all members of the care team. There is often a long-term and continuing need for social and educational support, not only for the sufferer but also for the family and other persons in the patient's environment. The transfer of competence to the community caregivers should be given high priority. Specialist epilepsy nurses should be assigned the responsibility for providing counselling and relevant information under the supervision of an epileptologist, and for ensuring that each patient has the possibility of taking full advantage of all available services. Close co-operation and co-ordination between the various professions at all levels of health care are essential parts of a well-organized comprehensive treatment programme. The quality of these services should be equally distributed without regard to age, intellectual level or geography. Meaningful occupation and activities improve well-being, enhance psychosocial adjustment and contribute to improved seizure control. Epilepsy management needs to be integrated into the larger context of comprehensive quality care, in which services to the mentally retarded and patients with acquired cognitive deficits form an essential part.

Antiepileptic drug treatment

Compliance

A prerequisite for the successful therapy of epilepsy is good drug compliance that ensures a stable medication effect. People with intellectual disability do not always accept taking tablets, especially large tablets. In multiply handicapped individuals, additional impairments in the form of swallowing problems and/or behavioural abnormalities may interfere with the oral intake of solid formulations. Drugs that are available as liquid, soluble, powder or granular formulations for children may be useful in the mentally retarded adult (Table 17.3). To maintain adequate prophylactic treatment, the rectal route may sometimes be necessary. Suppositories of carbamazepine and valproate are available. When intravenous administration is impossible or inconvenient, the liquid peroral form may, in exceptional situations, be given

Table 17.3 Measures supporting drug compliance in handicapped patients with swallowing difficulties or co-operation problems.

Severe multiple handicaps	Mild cognitive deficits
Alternative drug formulations: *Liquid* (carbamazepine, valproate, levetiracetam); *Soluble tablets* (carbamazepine, lamotrigine); *Powder* (vigabatrin); *Sprinkle* (topiramate, valproate)	Drug dispenser Alarm wristwatch Simple dosing tailored to individual habits and daily routines Social support with regular nurse visits

Table 17.4 Adverse reactions of traditional AEDs causing particular concern in patients with learning disabilities.

Phenobarbital	Somnolence, mood disturbances, behaviour disorders, including hyperactivity
Phenytoin	Cognitive impairment and cerebellar symptoms (phenytoin encephalopathy) after long-term use Gingival hyperplasia, particularly in patients with poor oral hygiene
Carbamazepine	Seizure aggravation in symptomatic generalized epilepsies
Valproate	Severe hepatotoxicity, particularly in mitochondrial disorders Tremor Weight gain

rectally. Patients with severe nutritional problems who require tube feeding and percutaneous gastrostomy also need drugs in fluid or soluble forms. The caregivers are extremely important partners in the treatment of this patient category. The need for education and guidance concerning the goals of therapy and the importance of adherence to the prescribed regimen is obvious.

Patients with only mild intellectual deficits who live partly independently but have an irregular behaviour may need various other measures to enhance drug compliance, including drug dispensers, alarm wristwatches and a social support system which may include regular nurse visits at medication times. Dosing should be kept as simple as possible and the drug intake tailored to their individual habits and activity programmes (Table 17.3). In training for autonomy and independent living, self-medication should not be given early priority. When memory is reduced and the understanding of the need for prophylactic medication inadequate, close supervision is necessary to maintain sufficient treatment. Non-compliance is a significant problem in intractable epilepsy, and may be prevalent particularly in people who have an impaired ability to comprehend information or express views and discuss feelings about the drugs and their effects.

Old drugs

The traditional medications, including phenobarbital, phenytoin, carbamazepine and valproate, are all effective in controlling seizures, but their utility is hampered by their adverse effect profiles and unwanted drug interactions. In patients with intellectual disabilities, some specific issues concerning these drugs need to be taken into account (Table 17.4).

Phenobarbital

Phenobarbital is not considered a first-line agent due to its association with somnolence, irritability and mood disturbances. The most consistent problems in patients with learning disability are the tendencies to exacerbate behaviour disorders, cause hyperactivity, and also to cause sleepiness and depression [5].

Phenytoin

Phenytoin is also not recommended as a first-choice drug due to its potential adverse effects. Patients with severe brain damage who are receiving multiple AEDs are particularly susceptible to the toxic effects of phenytoin, even at low plasma concentrations. Phenytoin encephalopathy is a rare complication, manifested as cognitive impairment and cerebellar symptoms, which may be partly related to the dose-dependent kinetics of the drug, individual differences in drug metabolism and polytherapy. The long-term use of phenytoin is not recommended for patients with loss of locomotion, marked cognitive impairment, or symptoms and signs of cerebellar disease. Phenytoin encephalopathy can progress if exposure to the drug continues. In progressive myoclonic epilepsy of Baltic type, phenytoin has been said to accelerate the disease process, an effect which, in part, has been reversible after switching to valproate [6].

Carbamazepine

Carbamazepine remains one of the most commonly prescribed drugs for partial epilepsy. It is also indicated in the treatment of neuralgias and manic–depressive disorders. Because of its minimal unwanted effects on cognition and behaviour, carbamazepine is an excellent drug for the treatment of people with learning disability and epilepsy. Nevertheless, one should bear in mind that patients with cognitive impairment may have a particularly low threshold for neurotoxicity and that carbamazepine may sometimes have a seizure-inducing effect in these patients, especially in those with symptomatic generalized epilepsies [7].

Valproate

Valproate is a first-line drug in the treatment of primary generalized seizures, but also has effect in other seizure types. It remains the backbone in the treatment of Lennox–Gastaut syndrome because it is effective against multiple seizure types [8]. Particularly in the area of intellectual disability, severe liver toxicity is an important but rare idiosyncratic adverse reaction. Developmental delay and inborn errors of metabolism, particularly mitochondrial disorders, represent risk factors for valproate hepatotoxicity. Particular care should be taken with this drug when such conditions can be suspected, and it should be avoided when a known mitochondrial dysfunction is present. Other predisposing factors are young age, polytherapy and stressful conditions, such as infections and underlying liver disease [9].

New drugs

The newer AEDs broaden the therapeutic options in patients with refractory epilepsy. Several of these drugs have obtained a particular place in the treatment of patients with learning disabilities [10–12]. All of them may have strengths as well as drawbacks in this large and heterogeneous patient group (Table 17.5). Most studies on the treatment of these patients are postmarketing

Table 17.5 Strengths and drawbacks of commonly used new AEDs in treatment of patients with learning disabilities.

Drug	Strengths	Drawbacks
Vigabatrin	Effective in infantile spasms	Visual field defects Psychiatric side-effects Weight gain
Lamotrigine	Broad spectrum Effective in Lennox–Gastaut syndrome Non-sedating Increased attention and alertness	Behaviour problems in some Sometimes exacerbation of myoclonia Skin rashes
Felbamate	Broad spectrum Effective in Lennox–Gastaut syndrome Non-sedating Increased alertness	Bone marrow and liver toxicity Regular laboratory monitoring Insomnia Behaviour problems Anorexia, weight loss
Topiramate	Broad spectrum Effective in Lennox–Gastaut syndrome	Potential cognitive side-effects Anorexia, weight loss
Gabapentin	Effect in pain and anxiety Psychotropic effects	Narrow spectrum (partial epilepsy) Behaviour problems in some Weight gain
Oxcarbazepine	Less interactions and improved tolerability compared with carbamazepine	Hyponatraemia Potential seizure aggravation in symptomatic generalized epilepsies
Tiagabine	Antispastic effect?	Narrow spectrum (partial epilepsy) Dizziness, asthenia, tremor, depression
Levetiracetam	Broad spectrum	Behaviour problems in some Irritability, aggression
Zonisamide	Broad spectrum	Central nervous system side-effects
Pregabalin	Effect in pain and anxiety	Narrow spectrum (partial epilepsy) Weight gain Limited experience
Rufinamide	Efficacy in Lennox–Gastaut syndrome	Limited experience

surveillances, but two epilepsy syndromes which are strongly associated with learning disabilities have recently been the subject of several drug trials: infantile spasms (Chapter 13) and Lennox–Gastaut syndrome (Chapter 14). In Lennox–Gastaut syndrome, double-blind controlled studies have demonstrated efficacy for felbamate, lamotrigine, topiramate and rufinamide [8,13].

Vigabatrin

Vigabatrin has a specific role in the treatment of infantile spasms, particularly when due to tuberous sclerosis. However, the risk of constricted visual fields is difficult to assess in this group [14,15]. Perimetric follow-up is recommended, but standard visual field examinations require a mental level corresponding to at least 9 years. Psychiatric (depression, psychosis) and behavioural side-effects can also be difficult to identify in patients with learning disabilities.

Lamotrigine

Lamotrigine is effective in partial seizures and a wide range of generalized seizures. Tolerability is usually excellent. Synergistic effect with valproate has been reported [16]. Lamotrigine has shown efficacy in patients with symptomatic generalized epilepsies, including Lennox–Gastaut syndrome [8]. It has mood-stabilizing effects, and benefits on behaviour have been demonstrated in patients with learning disabilities. It is usually not sedative and may increase attention and alertness, particularly in children with developmental problems. Improved social engagement has been reported [17,18]. On the other hand, aggravated hyperactivity and irritability have occasionally also been attributed to lamotrigine [19]. The exacerbation of myoclonic seizures has been noted, as well as the emergence of various dyskinesias including blepharospasm, tics and Tourette-like symptoms, particularly in patients with pre-existing central nervous system (CNS) dysfunction [20].

Felbamate

Felbamate is a potent drug with efficacy across a range of seizure types. It has a documented beneficial effect in Lennox–Gastaut syndrome, particularly in atonic seizures, but the use of felbamate is restricted due to potential toxicity in the bone marrow and liver. Blood tests are recommended at least every 2 weeks during the first 3 months of treatment, a practice which may be continued for 6–12 months [21]. This can be difficult to perform in some patients with learning disabilities. Education of caregivers regarding early clinical symptoms and signs of aplastic anaemia and liver failure is important. Insomnia, anorexia and weight loss are common side-effects. Of particular concern is the effect of felbamate on behaviour in the developmentally delayed population. Anxiety and irritability have been noted [18]. However, as with other non-sedating AEDs, brightening and improvement of alertness may also occur, an effect which may be related to improved seizure control. Pharmacokinetic interactions complicate its use in combination therapy. Nevertheless, felbamate has a risk–benefit ratio that allows its use in selected patients with refractory epilepsy [21].

Topiramate

Topiramate is a potent broad-spectrum drug which is also effective in primary generalized seizures. It has documented effect in Lennox–Gastaut syndrome and may be of benefit in myoclonic seizures [8]. Surprisingly, in one double-blind placebo-controlled study in a broad category of patients with learning disability and uncontrolled seizures, efficacy was not confirmed, probably due to insufficient dosing, underpowered design and problems with exact seizure recording [22]. Treatment has been associated with cognitive complaints such as mental slowing, mostly in the form of reduced verbal fluency and particularly when the drug is used in polytherapy. A subgroup of patients seem to experience a reversible worsening of pre-existing neurodeficits, such as speech difficulties and even hemiparesis. Behavioural disturbances can also occur. Nevertheless, many patients with learning disabilities tolerate the drug well [22,23] and it has also been reported to reduce aggression and agitation in some with developmental disability [12].

Gabapentin
Gabapentin is indicated for partial and secondary generalized seizures. It has a favourable side-effect profile and may reduce anxiety and also give relief of painful spasms in patients with cerebral spasticity. The drug has been shown to improve rating scales on a range of behavioural parameters, including co-operation, restlessness and challenging behaviour [17]. However, adverse reactions in the form of aggression, hyperexcitability and tantrums have also been reported. This is more common in patients with pre-existing behavioural difficulties and developmental delay. Even rare cases of involuntary choreiform movements and myoclonus have been reported in neurologically impaired patients [24], an unusual reaction that gabapentin shares with several other AEDs, such as phenytoin and lamotrigine. Unfortunately, gabapentin often has very limited antiepileptic efficacy in the severe therapy-resistant epilepsies of learning-disabled patients [25,26].

Oxcarbazepine
Oxcarbazepine is similar to carbamazepine in its mechanism of action. It exerts its antiepileptic effect through its monohydroxy derivative and is not metabolized into an epoxide. Compared with carbamazepine, it has fewer pharmacokinetic interactions and improved tolerability. It can, however, aggravate or induce generalized seizure types and worsen EEG features in some patients [27]. It can also reduce impulsive aggression [12]. Hyponatraemia may be more common than with carbamazepine, an effect which may be particularly pronounced in patients with central nervous dysfunction with altered fluid intake patterns and central nervous dysregulation of water balance.

Tiagabine
Tiagabine is also effective in partial seizures and has little impact on cognition. Dizziness, asthenia, tremor and depression are amongst its side-effects. In contrast to vigabatrin, which increases γ-aminobutyric acid (GABA) by inhibiting GABA transaminase intracellularly, tiagabine increases GABA in the synaptic cleft by reuptake inhibition. This compartment difference probably explains why tiagabine does not seem to share the serious retinotoxic effects with vigabatrin [15]. There is little experience with this drug in the learning-disabled population [26]. In spite of a mechanism of action similar to vigabatrin, tiagabine has not been trialled in West syndrome.

Levetiracetam
Levetiracetam is a broad-spectrum AED. It generally causes few side-effects and may be a good option in patients with encephalopathies and multiple seizure types. A beneficial effect has been reported in patients with progressive myoclonic epilepsy [28]. However, in a minority of patients severe behavioural side-effects do occur, usually in the form of irritability and aggression. This is a particular problem in people with learning disability [29] and in patients with a previous history of aggression [30]. This effect seems in part to be dose related. In other patients, alertness and behaviour may improve.

Zonisamide
Zonisamide is also effective in partial as well as in generalized seizure types, but has a potential for problematic side-effects. Of particular interest are the reports of efficacy against myoclonic seizures, and it has been reported to be of specific benefit in progressive myoclonic epilepsies [31].

Pregabalin
Pregabalin has a similar narrow-spectrum antiepileptic profile to gabapentin, but is considered a more potent drug. Evidence-based efficacy is also demonstrated in various anxiety and pain disorders [32]. Experience in the learning-disabled population is as yet quite limited.

Rufinamide
Rufinamide modulates the activity of sodium channels. Efficacy in partial seizures and in Lennox–Gastaut syndrome has been demonstrated. In Lennox–Gastaut syndrome, tonic and atonic seizures appear to respond particularly well [13]. However, in patients with multiple seizure types, the frequency of one seizure type can sometimes decrease while another increases.

Further prospective studies comparing efficacy and tolerability, including rating scales on behaviour parameters and other measures adapted for people with intellectual deficits, should be performed to collect more systematic clinical experience in these patients [2,22]. However, trial methodology is difficult due to the heterogeneity of aetiologies and of underlying mechanisms, various co-morbidities, as well as the frequently limited number of patients within one specific subgroup. There are also complex and difficult ethical issues.

Mechanistic considerations

The neurobiology of specific disorders can influence drug choice in certain situations. Several of the adverse reactions of valproate are caused by its effects on mitochondrial function and other enzymes. Valproate inhibits mitochondrial oxidation and facilitates the formation of hepatotoxic metabolites [9]. Hence, this drug should be avoided in mitochondrial disorders. Valproate can also have a negative impact on the underlying biochemical disturbance of Rett's syndrome. This phenomenon may be related to the inhibition of histone deacetylase, which increases the effect of a defective methyl-CpG-binding protein 2 (MeCP2) on the hyperacetylation of histones. Sodium channel blockers may be a better choice in many patients with Rett's syndrome [33]. In contrast, in Angelman's syndrome, carbamazepine and oxcarbazepine are typically not effective and may result in worsening of seizures. In this disorder, the pathophysiological mechanism involves a defect in the DNA coding for subunits of the $GABA_A$ receptor. Accordingly, drugs with GABAergic mechanisms, such as valproate and clonazepam, as well as topiramate, have been reported to be effective [11]. A paradoxical effect of vigabatrin in generalized epilepsies may be caused by an excessive stimulation of $GABA_B$ receptors by a diffuse increase of GABA in the brain. Nevertheless, vigabatrin is now the treatment of choice for infantile spasms in tuberous sclerosis and cortical dysplasia. A reduction in GABAergic interneurone density and a decreased release of GABA have been demonstrated within the cytoarchitectural abnormalities of developmental lesions [14]. The identification of mutations in the sodium channel α_1-subunit (SCNA1) in patients with severe myoclonic epilepsy of infancy and other early-onset epileptic encephalopathies has been an important

advance in the understanding of these disorders [34]. It is to be hoped that we will soon be able to specifically target these genetic defects therapeutically and that future translational research will be able to uncover other pathophysiological mechanisms which lead to more targeted and rational treatments of both the epilepsy syndromes and the neurocognitive deficits.

Central nervous system side-effects

In people with learning disability, it can often be difficult to achieve a satisfactory balance between seizure control and adverse drug effects. These patients may not be able to report the early symptoms of toxicity, such as sedation, blurred vision and ataxia. Subtle cognitive adverse reactions may occur unnoticed by the carers. Side-effects may also sometimes manifest themselves indirectly as behavioural problems [18,35] (Fig. 17.2). Sedation may manifest as hyperactivity. Stress and restlessness may be converted from somatic side-effects (e.g. diplopia).

The four traditional front-line AEDs – phenobarbital, phenytoin, carbamazepine and valproate – have all been reported to be associated with dose-related cognitive side-effects, foremost in the form of slowing of central information processing. These may be considerable for phenobarbital and possibly larger for phenytoin than for carbamazepine and valproate. A chronic phenytoin encephalopathy may occur, particularly in patients with pre-existing neurodeficits, even with plasma levels within the acceptable range [6]. Some of the new drugs are claimed to have favourable cognitive profiles [35], but reliable data are sparse. As mentioned, topiramate can cause cognitive impairment, but this can often be avoided by gradual initial titration. Some pharmacodynamic interactions may be of particular relevance in this patient group. The combination of lamotrigine and carbamazepine can enhance central nervous side-effects. A person unable to express these problems verbally may instead react with disturbed behaviour [18]. Valproate-induced tremor may be aggravated by lamotrigine, particularly in neurologically impaired individuals.

Clinical experience suggests that patients with learning disabilities are often more vulnerable to cognitive side-effects than other patients. However, the subgroup of patients with severe intellectual handicaps is excluded from the ordinary 'pencil and paper' tests of cognitive functions and mood. In lesional epilepsy, specific cognitive abilities are affected (depending on the site of the lesion, e.g. language functions). In monotherapy with carbamazepine and valproate, a subgroup of patients with brain lesions and pre-existing cognitive deficits shaved a significant decrease in memory performance during medication [36]. The existence and extent of underlying brain damage both seem to influence the adverse cognitive effects of a particular drug. Furthermore, mood effects can occur with some AEDs, particularly with barbiturates, vigabatrin and topiramate [37], which indirectly affect cognitive performance.

Many patients with learning disabilities have an inappropriate and excessive medication load that impairs their quality of life. Reduction of undue polytherapy should always be aimed at [38]. A pitfall in the evaluation of more effective and better tolerated treatments in the severely retarded patient lies in the fact that increased alertness and self-assertion may be misinterpreted as behavioural side-effects, the so-called release phenomenon [18]. A more demanding behaviour should not be invariably considered as a sign of toxicity. Such symptoms should be analysed carefully before a new treatment is abandoned. Environmental support and activity programme adjustments may be needed to meet new requirements of more attentive patients. It has been emphasized repeatedly that AED therapy should not exclusively focus on seizure freedom. Patients who, for reasons other than their epilepsy, cannot achieve independent living may tolerate incomplete seizure control better than others.

Table 17.6 Factors predisposing to paradoxical AED-induced aggravation of seizures.

Young age
Multiple seizure types
Prominent epileptiform EEG activity
Learning disabilities and behavioural disorders
Polytherapy
Drug-induced drowsiness

Paradoxical effects

Some AEDs occasionally aggravate epilepsy, and cause increased frequency and severity of seizures. This can be mediated by the non-specific effects of sedation and overtreatment, or can occur as a more specific effect in some seizure types or epilepsy syndromes [7]. Factors predisposing to such effects are listed in Table 17.6. More frequent seizures may be a part of the clinical picture of the insidious phenytoin encephalopathy [6]. There is evidence that carbamazepine and oxcarbazepine may aggravate seizures, particularly 'minor' generalized seizures, and in some patients even generalized tonic–clonic seizures [27]. In symptomatic generalized epilepsies, several seizure types that respond differently to treatment may co-exist. In the Lennox–Gastaut syndrome, carbamazepine may be effective for tonic seizures, but can aggravate atypical absences and myoclonic or atonic seizures. Benzodiazepines can cause an increase in tonic seizures in the same disorder. Vigabatrin and other GABAergic drugs can aggravate generalized seizures (particularly absence, tonic and myoclonic seizures, and even generalized tonic–clonic seizures). Lamotrigine, as well as levetiracetam, can also increase seizure frequency. Lamotrigine has a negative effect in severe myoclonic epilepsy of infancy [7]. In one report, a paradoxical effect of levetiracetam, including the emergence of *de novo* generalized tonic–clonic seizures, appeared most often in patients with learning disabilities [39]. Tiagabine may precipitate non-convulsive status. The clinician should not forget that seizure aggravation may occur as part of the rare valproate hepatotoxicity, which may occur particularly in young children with metabolic disorders [9]. Increased seizure frequency can also occur within the context of a toxic valproate encephalopathy, not necessarily associated with high drug plasma levels, often accompanied by confusion, lethargy, ataxia and hyperammonaemia. Drug-induced drowsiness and inactivity alone may probably contribute to seizure induction in some multiply handicapped patients. Not surprisingly, in patients receiving excessive polytherapy, an improved seizure control may occur when their drug load is reduced [38].

Paradoxical drug reactions are probably widely underestimated in patients with intractable epilepsy, particularly in patients with

intellectual deficits who cannot themselves express their opinions about the prescribed treatment. It is often overlooked by the non-specialist, and even by the carers, as the history is often insufficient due to a lack in the continuity of information sharing. Appropriate follow-up is imperative when prescribing new drugs to these patients.

Can the disease process be influenced?

There is little scientific evidence to suggest that AEDs improve the prognosis of the underlying disorders, beyond their ability to control seizures. However, in some epileptic encephalopathies in childhood, the antiseizure effects appear to be of paramount importance for cognitive development. The so-called catastrophic epilepsies of childhood have their onset in patients younger than 5–6 years of age [31] during the critical period for brain maturation and developmental plasticity. Frequent seizures and/or abundant epileptiform activity may disrupt pathways necessary for cognitive maturation, leading to long-term cognitive deficits [40]. Harmful neuronal reorganization in the form of abnormal synaptic connections may be generated. In these epilepsies of childhood, it has been suggested that controlling seizures does alter the outcome of intellectual functioning. In patients with a history of infantile spasms, the patients who quickly become spasm free are those who are developmentally normal. In children with tuberous sclerosis, the occurrence of autistic regression is often clearly linked to the onset and presence of seizures [41]. Follow-up indicates that controlling secondary generalization induced by infantile spasms represents a key factor for mental and behavioural development. Hence, prompt and effective prophylactic antiepileptic treatment is crucial for these patients.

In prolonged and serial seizures, early and successful acute treatment can improve outcome. After severe status epilepticus, persistent neurocognitive impairment varies with the type and aetiology of epilepsy, the severity of the status, and the age of the patient. In severe and complicated febrile seizures, excitotoxic cell death in the hippocampus may be responsible for the progression of future uncontrolled spontaneous seizures and sometimes for permanent neurological deficits, as in the hemiconvulsion hemiplegia epilepsy (HHE) syndrome [42].

Non-pharmacological treatment

Epilepsy surgery

Patients with learning disabilities can benefit from epilepsy surgery, and cognitive deficits should not be considered a contraindication to resective epilepsy surgery. However, there is a lower probability of a good seizure outcome in patients with low IQs because of the association with diffuse or widespread brain damage. This was shown in a recent national survey from Sweden, where IQ level was an independent predictor of seizure freedom. Nevertheless, many of the low-IQ patients did have a beneficial effect of surgery, especially those with lesions [43]. Patients with neurodeficits and uncontrolled mesial temporal lobe seizures due to the HHE syndrome are good candidates for surgical treatment [42]. Studies have generally not supported the fear that further deterioration of cognitive function and social adjustment will occur after resective treatment [44]. On the contrary, seizure control from surgery at an early age can lead to a catch-up development [45]. Disconnective surgery, such as corpus callosotomy, can occasionally be beneficial in symptomatic and cryptogenic generalized seizures, for instance in Lennox–Gastaut syndrome (Chapter 74), where the operation can reduce the number of generalized tonic–clonic seizures by preventing their generalization from partial onset, and also lower the number of drop attacks, including atonic seizures [46]. Other options include hemispherectomy and multiple subpial transections (Chapters 73 and 75).

Vagus nerve stimulation

Vagus nerve stimulation (Chapter 81) is said to benefit patients with refractory partial epilepsy and learning disabilities. Promising results have been reported in children and adults with symptomatic generalized epilepsy, including Lennox–Gastaut syndrome [46]. Open studies purport to show improved seizure frequency and severity and to reduce clustering and the duration of the postictal period. Unfortunately, the antiepileptic effect is modest in most patients. Nevertheless, this method is free from cognitive adverse effects and may reduce the drug burden. Vagus nerve stimulation has been reported to improve alertness, mood and verbal ability in this category of patients [47] and also has a potential as an antidepressant therapy. In some patients with cognitive deficits, the full compliance ensured by the automatic delivery of this form of therapy can be a particular advantage. On the other hand, severely multi-handicapped individuals might be at an increased risk for certain rare complications, such as vagus-mediated worsening of motor bulbar impairments and aspiration pneumonia.

Ketogenic diet

The enthusiasm for this therapeutic option has fluctuated over the last 50 years. The diet is high in fat and low in carbohydrate and protein and has been employed mainly in children with significant neurological handicaps, particularly in Lennox–Gastaut syndrome. The diet can be very unpalatable. It requires strict supervision and has serious limitations and potential adverse effects. In patients with cognitive or behavioural problems implementation may be difficult. A modified Atkins diet might be better tolerated. The diet is discussed in more detail in Chapter 23.

Acute seizure treatment with benzodiazepines

Clusters of seizures, prolonged seizures and status epilepticus are common complications in the developmentally delayed population. Impending status epilepticus needs swift and effective action. The rectal administration of diazepam has long been widely employed in the emergency treatment of all kinds of epileptic seizures. It is given by parents, teachers and care staff without medical or nursing training. This route may provide therapeutic levels within a few minutes.

The rectal administration of diazepam has definitely resulted in a safer existence to many patients with refractory epilepsy and learning disabilities. However, in individuals with poor seizure control, problems from excessive and too-frequent administration can occur, particularly when the carers are insecure and insufficiently trained. Tolerance and dependence may develop during long-term treatment. Withdrawal symptoms,

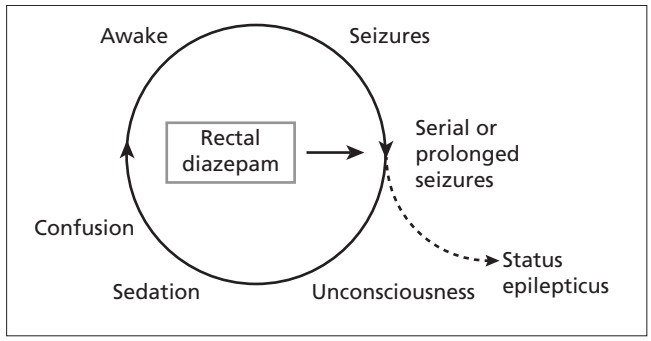

Fig. 17.3 The vicious circle of excessive rectal diazepam treatment in refractory epilepsy. A pattern of cyclic reappearance of prolonged seizures every 3–5 days, interrupted by diazepam and followed by sedation and gradual awakening may be characteristic for this complication. Redrawn with permission from Wrightson Biomedical Publishing.

including seizures, occur if the treatment is stopped after regular administration. Intermittent, large and frequent rectal diazepam doses administered at will cause fluctuations in the plasma drug levels which in themselves can be seizure inducing. Toxic effects, withdrawal and seizure activity can be difficult to manage. Some patients, after long-term use of rectal diazepam, enter a vicious circle, which cannot be broken before the use of the drug is restricted. A cyclic reappearance of prolonged seizures every 3–5 days, interrupted by diazepam, and followed by sedation and gradual awakening, is a characteristic pattern [48] (Fig. 17.3). Non-convulsive status epilepticus may sometimes occur. When restricting intermittent diazepam intake, seizures, wakefulness and behavioural problems can improve. If this strategy proves difficult, oral benzodiazepines in low doses is another option.

Adequate counselling and medically appropriate written directions for the rectal administration of diazepam are mandatory both for patient security and for the legal position of caregivers. The correct and successful use of rectal diazepam depends to a great extent on the competence of the caregiver. The frequency of rectal administration of diazepam should not approach twice weekly for prolonged periods, and it should not be routinely used in short, non-life-threatening seizures lasting less than 2–4 min.

Buccal (or nasal) delivery of midazolam may now be a more convenient and socially acceptable acute treatment of seizures (see Chapters 18 and 34). As with rectal administration, this route also has the advantage of bypassing the portal circulation to avoid first-pass hepatic inactivation.

Concomitant psychopharmacological treatment

Maladaptive, violent or self-injurious behaviour is not unusual in individuals with severe intellectual disabilities. Autistic behaviour is particularly common in children with developmental delay and epilepsy. An exact psychiatric diagnosis is usually difficult to obtain in the severely retarded, but patients with severe learning disabilities or brain lesions often need concomitant antiepileptic and antipsychotic treatment. A range of pharmacodynamic or pharmacokinetic interactions can occur [49]. High doses of antipsychotic drugs can provoke seizures, particularly in patients with organic brain dysfunction [50]. AEDs can induce or aggravate behavioural problems [18,35], which may lead to the prescription of antipsychotic drugs. These drugs can also have cognitive side-effects that compound the effects of the AED. Conversely, enzyme-inducing AEDs, such as carbamazepine, phenytoin and phenobarbital, can profoundly lower the plasma levels of antipsychotic drugs.

Table 17.7 Seizure-inducing properties of some antipsychotic drugs.

High	Clozapine Chlorpromazine
Moderate	Perphenazine and olanzapine Quetiapine Risperidone
Low	Haloperidol

Clozapine and chlorpromazine are among the most proconvulsant antipsychotics. The tendency to provoke seizures is less pronounced with agents that have prominent extrapyramidal side-effects. The seizure-aggravating effects of most atypical antipsychotics are usually modest. Risperidone and quetiapine appear to be less likely to have proconvulsant effects than olanzapine. However, there is, as yet, limited experience with many of these newer drugs in patients with epilepsy. The ranking of the tendencies to precipitate seizures of these drugs in Table 17.7 is not based on accurate data, as doses, co-medication and risk factors for seizures vary among patients. Tricyclic antidepressants may also induce seizures, whereas serotonin reuptake inhibitors have been reported to have antiepileptic effects in open-label studies [49,51]. Polypharmacy with various drugs having the potential to influence the seizure threshold is common in patients with learning disabilities or encephalopathies.

The cause of acute seizure exacerbation in the presence of psychiatric co-morbidity is often complex. Drug toxicity is only one of several subthreshold factors among a cascade of other events, including emotional factors, lack of sleep, stress and possibly the psychiatric disorder in itself. Concomitant withdrawal from benzodiazepines and initiation of antipsychotics carries a risk of seizure breakthrough. A detailed account of all current and recently discontinued medications, even as-needed prescriptions, is of major importance in the evaluation of seizure exacerbation in this population.

The seizure-inducing properties of antipsychotic drugs at small to standard doses should not be overestimated. In some patients, low doses may probably improve seizure control, possibly by suppressing emotional seizure-inducing factors. However, high doses, or an abrupt large dose increase, should be used with caution, especially with antipsychotic drugs with a high potential to lower the seizure threshold [50]. When treating patients with psychiatric co-morbidity, it is essential to be aware of the fact that AEDs themselves possess psychotropic properties, negative as well as positive (Tables 17.4 and 17.5). Atypical behavioural responses are more likely to occur in children and individuals with cognitive deficits. Several AEDs have a role in the treatment of psychiatric conditions [49], including

agitation and aggression in patients with dementia and learning disability [12].

Prognosis of epilepsy in learning disabled patients

Overall prognosis

In about 25% of patients with newly diagnosed epilepsy, seizure control is not possible with the present AEDs. However, in studies of prevalence of epilepsy, the proportion of uncontrolled epilepsy is larger. In a large Swedish study, 57% of patients had experienced seizures during the previous year, and the mean yearly seizure frequency was higher in subjects with mental retardation than in others [1]. Severe epilepsy is significantly related to early onset [52]. In prospective studies, associated neurological or cognitive handicaps have consistently been reported to have an adverse effect on the outcome of epilepsy. Malformations of cortical development are often associated with refractory seizures. These conditions range from the extreme example of lissencephaly, with a smooth cortex and severely affected brain function, to less distinct syndromes with nodular heterotopias and localized cortical dysgenesis with mild clinical symptomatology. In studies correlating aetiology and treatment response in partial epilepsy, cortical dysgenesis had the second worst prognosis after mesial temporal sclerosis [53]. In the catastrophic epilepsies of childhood, the long-term prognosis is generally very poor. A high seizure activity is associated with developmental stagnation or regression in these conditions [4,31].

Nevertheless, the spectrum of seizure disorders in individuals with learning disability is wide, ranging from the most severe and intractable epilepsies to disorders with only isolated attacks, an important fact to bear in mind [11,16,52]. Some patients with severe intellectual deficits may develop generalized tonic–clonic seizures in adult life, even in the absence of prior epilepsy or a diagnosis of Down syndrome. When late-onset epilepsy occurs in such patients without the presence of overt recent or current brain damage, the outlook is usually good [52].

Specific diagnoses are relevant for the prognosis of seizure disorders, even in adulthood. Some examples are detailed below.

Down syndrome

With advancing age, an increased incidence of epilepsy has been demonstrated in Down syndrome, in one study reaching 46% in those over 50 years [54]. Late-onset myoclonic epilepsy in Down syndrome is associated with massive myoclonic jerks, tonic–clonic seizures and progressive dementia [55]. The generalized tonic–clonic seizures seem to respond well to AED treatment in the early stages, but the tendency to seizures usually progresses. The myoclonus may be intractable. AEDs often cause marked side-effects even at plasma levels well within the 'therapeutic' range.

Rett's syndrome

Most girls (80–90%) with Rett's syndrome have epilepsy starting somewhere between 3 and 5 years. The seizures are of various types; many are partial. The seizure frequency appears to peak in the age group of 7–12 years. In adulthood, the epilepsy often improves considerably and can occasionally remit [56]. Many of these profoundly retarded females tend to react adversely to standard antiepileptic regimens, particularly to valproate [33]. Withdrawal of AEDs should always be considered in seizure-free women with Rett's syndrome.

Angelman's syndrome

Epileptic seizures occur in over 90% of patients with Angelman's syndrome, often with onset before 3 years of age. Multiple seizure types can be seen, generalized tonic–clonic seizures, atypical absences, myoclonic seizures and tonic seizures. Epilepsy predominates in childhood, but can persist or reappear in adulthood. The prognosis may be related to the type of 15q11–q13 abnormality. Sustained seizure freedom has been found in four of five patients with deletions [57].

Fragile X syndrome

Epilepsy is present in about 20% of mentally retarded patients with this chromosomal abnormality, usually with onset in childhood. The most common seizure type is complex partial. The characteristic EEG pattern may sometimes resemble centrotemporal spikes characteristic for benign epilepsy of childhood [58]. Seizures are often easy to control and may remit. However, the course of the epilepsy is variable and continuous AED treatment in adult life is not unusual.

Prognosis after withdrawal of AEDs

Many physicians assume that epilepsy in those with learning disability never remits. This is incorrect. In fact, many patients with intellectual deficits have a self-limiting seizure disorder. One important study showed that almost half of adult, mentally retarded patients who had been seizure free for at least 2 years had no recurrences when AEDs were withdrawn [59]. This study refers to patients with a 'diagnosis of epilepsy' rather than 'patients with epilepsy', and epilepsy is often overdiagnosed in severely retarded patients (Table 17.2). Other studies of patients with learning disability and controlled epilepsy confirm the possibility of successful discontinuation of AED treatment in adults, as well as in children. In a large, multicentre AED withdrawal study in patients in remission, the risk of seizure recurrence in patients with delayed development/special schooling was not significantly increased compared with other patients [60]. Specchio and Beghi reviewed 28 studies of discontinuation of AEDs in patients who had been seizure free for 2 years or longer. Intellectual deficits were reported to be present in 19 studies and were found to increase the risk of relapse in eight studies, but not in the remaining. Withdrawal of treatment can also be attempted in patients with cerebral palsy. By multivariate analyses, mental retardation was found to be more important than motor impairment in predicting seizure recurrence [61]. Spastic hemiparesis has been found to be more likely to be associated with seizure recurrence than other forms of cerebral palsy, which predominantly affect white matter [62,63].

Drug withdrawal should be considered in patients with learning disability, as in other patients who attain long-standing seizures remission. Recurrence of seizures in the severely retarded and multiply handicapped group usually carries fewer hazards

and social consequences as these patients are usually accompanied by caregivers at all times.

18 Emergency Treatment of Seizures and Status Epilepticus

Matthew C. Walker and Simon D. Shorvon

UCL Institute of Neurology, University College London, London, UK

Epilepsy is, for the most part, self-terminating. On occasions, however, seizures of any type can continue unabated and the seizure disorder is then best considered as a separate entity – status epilepticus. One of the earliest references to status epilepticus can be found in a Babylonian treatise on epilepsy from the middle of the first millennium BC, in which the grave prognosis of this condition was described: 'If the possessing demon possesses him many times during the middle watch of the night, and at the time of his possession his hands and feet are cold, he is much darkened, keeps opening and closing his mouth, is brown and yellow as to the eyes. It may go on for some time, but he will die' [1,2]. There were, however, few references to status epilepticus in the ensuing years. Why this may be so is a matter of speculation; Hunter [3] noted that status epilepticus was rare before the advent of powerful antiepileptic drugs (AEDs), and the consequent risk of drug withdrawal. This is undoubtedly an important cause of status epilepticus, but cannot account for the large number of drug-naive patients presenting with status epilepticus in present times. In the nineteenth century, the entity of status epilepticus was first clearly distinguished among the epilepsies. Calmeil [4] used the term 'etat de mal' and later the term status epilepticus appeared in Bazire's translation of Trousseau's lectures on clinical medicine [5]. From that time status epilepticus was, on the whole, a term used to describe mostly convulsive status epilepticus. It was not until the Marseilles conference in 1962 that status epilepticus was generally recognized to include all seizure types and that the definition was based solely on the persistence of the seizure rather than its form [5]. This is of great importance as it is now apparent that many forms of status epilepticus can result in neuronal damage, although such damage remains most commonly the consequence of tonic–clonic status epilepticus. Although the length of time that a seizure or series of seizures have to continue before being classified as status epilepticus has been a matter of debate and is to an extent arbitrary, most would accept a limit of 30 min [1]. Treatment, however, should begin before this period (see below). The necessity of differentiating status epilepticus from other seizure conditions relates to its high morbidity and mortality.

The term status epilepticus, as used by Gastaut and colleagues, included three entities: generalized status epilepticus, partial status epilepticus and unilateral status epilepticus [7]. This classification is, however, both incomplete and too broad to be clinically useful, and recently more detailed classifications have been proposed [8] (Table 18.1).

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Estimates of the overall incidence of status epilepticus have varied from 10 to 60 per 100 000 person-years, depending on the population studied and the definitions used [1,9–11]. Some studies are likely to have underestimated incidence due to incomplete case ascertainment. The incidence also varies in different ethnic groups; status epilepticus is more common in Afro-Americans than in whites, and it is not clear to what extent this difference is due to genetic or socioeconomic factors. Status epilepticus is also more frequently associated with mental handicap, and with structural cerebral pathology (especially in the frontal areas). In established epilepsy, status epilepticus can be precipitated by drug withdrawal, intercurrent illness or metabolic disturbance, or the progression of the underlying disease, and is more common in symptomatic than in idiopathic epilepsy. About 5% of all epileptic adult clinic patients will have at least one episode of status epilepticus in the course of their epilepsy [1,12], and in children the proportion is higher (10–25%) [1,12,13]. Most status epilepticus episodes, however, do not develop in patients with a previous diagnosis of epilepsy, and are often due to an acute cerebral disturbance, emphasizing the importance of identifying and treating the acute precipitant. Infections with fever are a common cause of status epilepticus in children, whilst in adults cerebrovascular accidents (CVAs), hypoxia, metabolic causes and alcohol are the main acute causes [10]. Although the prognosis of status epilepticus is related to aetiology, the prognosis of certain conditions such as stroke may be worse if associated with status epilepticus [14]. The overall mortality for status epilepticus is about 20%, most patients dying of the underlying condition, rather than the status epilepticus itself [1,10]. The mortality is age related, and is much lower in children and higher in the elderly [10]. Permanent neurological and mental deterioration can result from status epilepticus, particularly in young children; the risks of morbidity are greatly increased the longer the duration of the status epilepticus episode [15,16]. Furthermore, status epilepticus can result in chronic epilepsy and, indeed, 43% of those with acute symptomatic status epilepticus have a subsequent unprovoked seizure compared with 13% of those with acute symptomatic seizures [17].

Before describing the particular treatment of the various forms of status epilepticus, it is necessary to have an understanding of status-induced neuronal damage, and drug pharmacokinetics and pharmacodynamics during status epilepticus.

Status epilepticus and neuronal damage

The association of neuronal damage with status epilepticus had been noted in the nineteenth century. In more recent times, postmortem studies of individuals who died during status epilepticus

Table 18.1 Classification of status epilepticus (SE).

SE occurring in the neonatal and infantile epilepsy syndromes
West syndrome
Ohtahara's syndrome
Severe myoclonic encephalopathy of infancy (SMEI; Dravet's syndrome)
SE in other forms of neonatal or infantile epilepsy
SE occurring only in childhood
SE in early-onset benign childhood occipital epilepsy (Panayiotopoulos' syndrome)
SE in other forms of childhood epileptic encephalopathies, syndromes and aetiologies (e.g. ring chromosome X and other karyotype abnormalities, Angelman's syndrome, Rett's syndrome, myoclonic–astatic epilepsy), other childhood myoclonic encephalopathies
Electrical status epilepticus in slow-wave sleep (ESES)
Landau–Kleffner syndrome
SE occurring in both childhood and adult life
Convulsive SE
Tonic–clonic SE
Epilepsia partialis continua
Myoclonic SE in coma (after severe brain injury)
Myoclonic SE
NCSE with epileptic encephalopathy
NCSE in Lennox–Gastaut syndrome
Atypical absence status epilepticus
Tonic status epilepticus
Other forms of NCSE in patients with learning disability or disturbed cerebral development (cryptogenic or symptomatic)
NCSE without epileptic encephalopathy
Typical absence status epilepticus in idiopathic generalized epilepsy
Complex partial status epilepticus
Limbic
Non-limbic
NCSE in the aftermath of tonic–clonic seizures
Subtle status epilepticus (myoclonic SE occurring in the late stage of convulsive SE)
Aura continua with sensory, special sensory, autonomic or cognitive symptoms
SE occurring in late adult life
De novo absence status epilepticus of late onset
Boundary syndromes[a]
Some cases of epileptic encephalopathy
Some cases of coma due to acute brain injury with epileptiform EEG changes
Some cases of epileptic behavioural disturbance or psychosis
Some cases of drug-induced or metabolic confusional state with epileptiform EEG changes

[a] Boundary syndromes are defined as cases in which it is not clear to what extent the continuous epileptiform electrographic abnormalities are contributing to the clinical impairment.
NCSE, non-convulsive status epilepticus.
From ref. 1.

have revealed extensive neuronal damage in the temporal lobes [18]. Furthermore, levels of neurone-specific enolase, a marker of neuronal injury, are elevated immediately following status epilepticus [16], and there have been case reports describing the development of hippocampal atrophy in patients followed with neuroimaging after an episode of status epilepticus [e.g. 19,20]. The interpretation of the human data is, however, confounded by other factors such as aetiology, metabolic compromise and treatment. Animal experiments have thus provided a greater insight into neuronal damage associated with status epilepticus [22]. Initial experiments demonstrated that convulsive status epilepticus resulted in neuronal damage, and that neuronal damage occurred even if the systemic and metabolic compromise that occurs in convulsive status epilepticus was controlled. This led to the concept that it was the presence of ongoing electrographic seizure activity that itself resulted in neuronal damage (excitotoxic neuronal damage) [22,23]. Animal studies of non-convulsive status have shown similar changes [24]. Importantly, this neuronal damage is time dependent, and as such stopping the status epilepticus as soon as possible will prevent much of the damage from occurring.

Tonic–clonic status epilepticus can undoubtedly cause neuronal damage, although the damage is more likely to depend on the site of cerebral origin of the epilepsy, its severity and clinical context. Damage is certainly not invariable, and one encounters some patients who have had severe attacks, prolonged attacks or repeated attacks and who make complete recoveries without noticeable damage. It is important to realize that the animal models were developed to explore excitotoxicity, and caution is needed in extrapolating these findings to the human condition. The animal models used generally involve induction of status epilepticus in a non-epileptic animal with either powerful chemoconvulsants or prolonged high-frequency repetitive stimulation [24–26]. There are rare occurrences of comparable precipitants in humans, such as domoic acid poisoning from mussels, in which pathological changes occurr that are similar to the animal models [18], but these are exceptional. Complex partial status epilepticus (CPSE) in humans, in particular, is very different from that in animal models. CPSE in humans tends to have lower-frequency discharges, which, if reproduced in animal models, produces substantially less neuronal damage [27–30]. In general, it seems that human CPSE is more benign than the experimentally produced CPSE. Most patients recover without any sequelae. There have been reports of prolonged memory problems, hemiparesis and death occurring following CPSE, although, in many of these cases, the outcome relates to the underlying aetiology [31–33]. In one study, only 10 patients were identified with significant morbidity from CPSE over a 10-year period (this almost certainly represents a small fraction of all patients with CPSE during this period) [34]. Furthermore, in seven of these patients, coincident conditions undoubtedly contributed significantly to this morbidity. In many reported cases, aggressive treatment with intravenous therapy and, on occasions, barbiturate anaesthesia could also contribute to the consequent morbidity. Importantly, there have also been large case series of prolonged CPSE with no neurological sequelae [35,36]. Ceiling effects (damage only in the early episodes) in patients with repeated episodes of status also complicate assessment.

One postmortem study has reported substantial neuronal damage following partial status epilepticus in three patients [19]. The aetiology of the status epilepticus is unclear in two cases and the aetiology in the third case was related to carcinomatous meningitis. It is thus difficult to know if the damage is due to the status epilepticus or some unknown pathogenic process (in the two cryptogenic cases, for instance, viral or autoimmune encephalitis).

There are many measurable changes following an episode of status epilepticus, for instance changes in gene expression, recep-

tor trafficking, neurochemical changes, neurophysiological and neuropathological changes (see ref. 37). Rises in serum neurone-specific enolase have also been used as an argument that CPSE results in neuronal damage [38]. These rises could be partially the result of a breakdown in the blood–brain barrier rather than an increase in neuronal death, and cerebrospinal fluid neurone-specific enolase would be a more accurate predictor [39]. The degree to which serum neurone-specific enolase correlates with neurological and cognitive disability in CPSE is especially unclear, since some patients with very high serum neuronal enolase have a good outcome. Neuroimaging in complex partial status has largely also been inconclusive; reversible changes do occur and in some selected patients mild atrophy can be associated with CPSE [40].

Animal evidence also suggests that there may be certain groups who are less prone to neuronal damage from status epilepticus; epileptic animals, animals pretreated with AEDs and young animals are all resistant to chemoconvulsant-induced neuronal damage [41–46]. Thus, young age, AEDs and prior history of epilepsy may all confer neuroprotection.

What is the relationship of this neuronal damage to the subsequent morbidity of status epilepticus? It appears that the neuronal damage that occurs during status epilepticus is not necessary for epileptogenesis [47,48]. Indeed, damaging the hippocampus through severe hypoxic injury seems to inhibit epileptogenesis [49]. The neuronal damage probably more closely relates to other pathologies post status epilepticus such as memory and behavioural problems [47,50].

The main epileptogenic changes following status epilepticus have yet to be clearly defined. Changes have been reported in intrinsic properties of neurones [51], rate of neurogenesis [52], receptor function [53], inhibitory interneurones [54], synaptic arrangements [55] and the extracellular space. All of these could be epileptogenic; however, it has been difficult to identify one critical or necessary process.

Drug pharmacokinetics and pharmacodynamics

In the rational drug treatment of status epilepticus, an understanding of the pharmacokinetics of acutely administered drugs is needed. In particular, it is important to realize three fundamental points: (1) the pharmacokinetics of a drug administered acutely may greatly differ from that of the drug administered chronically; (2) the intracerebral distribution of a drug during a seizure may differ from that in the non-seizure state; and (3) the longer seizures continue the more difficult they are to treat.

Acute drug pharmacokinetics

Fast drug absorption is essential in the treatment of status epilepticus, and thus almost all drugs need to be administered intravenously. Paraldehyde and midazolam, however, may be given intramuscularly, and diazepam and paraldehyde rectally. Other drugs are less commonly given rectally, and midazolam is given by buccal instillation.

In order to act rapidly, the drugs need to cross the blood–brain barrier readily. Drugs achieve this either by being lipid soluble or by having an active transport mechanism. Thus, the drugs that are effective in status epilepticus usually have a high lipid solubility. Thus, they have usually a large volume of distribution.

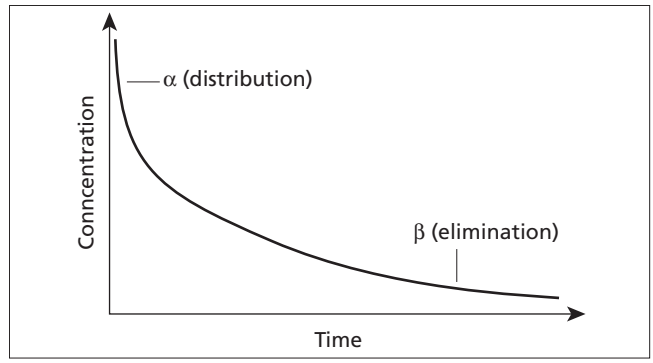

Fig. 18.1 Concentration–time profile of acutely administered drugs showing two phases: a rapid distribution phase (α), in which drug is distributed from the blood compartment to fat and muscle, and a slower elimination phase (β). From ref. 1.

During intravenous (i.v.) administration, a drug directly enters the central compartment (blood and extracellular fluid of highly perfused organs) from where it is distributed to peripheral compartments, in particular fat and muscle. Since most of the drugs with which we are concerned are highly lipid soluble, they are rapidly redistributed into the peripheral compartment from the central compartment. This leads to an initial drop in plasma concentrations, and the rapid fall is measured as the distribution half-life. The drug may be eliminated from the central compartment through renal excretion, hepatic metabolism (the major route of elimination for the majority of AEDs) or exhalation, and the elimination half-life is the measure of this process. The AEDs used in status epilepticus often have a much shorter distribution half-life than elimination half-life (Fig. 18.1). For highly lipid-bound drugs following acute administration, there is a rapid initial fall in plasma levels and brain levels (Fig. 18.1), and thus loss of effect. This has led to the practice of repeat boluses and infusions in order to maintain adequate plasma levels. However, with persistent administration there is accumulation of the drug within the peripheral compartment (saturation), and this results in two important effects [1,56]: (1) higher peak and trough levels with subsequent boluses or with continued infusions; and (2) clearance of the drug from the central compartment becomes dependent on the elimination half-life and therefore it occurs much more slowly (Fig. 18.2). This results suddenly in higher and more persistent drug levels than was the case before saturation occurred.

These two effects are potentially dangerous, and some of the mortality and morbidity of status epilepticus is due to injudicious use of repeated boluses or continuous infusions of lipid-soluble drugs.

Kinetics of drugs during seizures

Seizures (especially convulsive seizures) can affect both peripheral and central pharmacokinetics of drugs. During convulsive seizures, there is a fall in the pH of the blood, resulting in a change in the degree of ionization (and thus lipid solubility) of drugs in plasma. This will affect the distribution half-lives, the ability to cross the blood–brain barrier and the protein binding. In addition, the pH in blood decreases to a greater degree than in the brain; this pH gradient facilitates the movement of a weakly acid

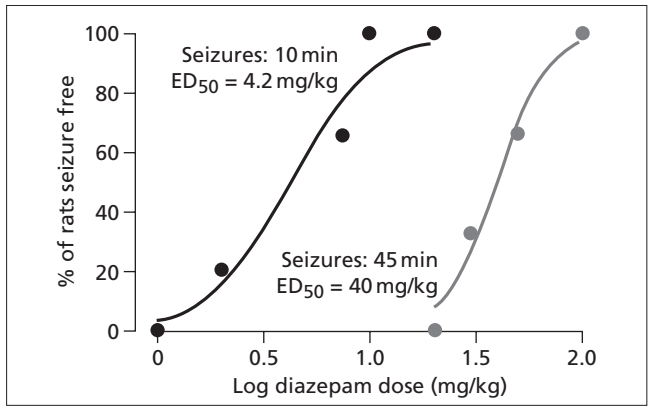

Fig. 18.2 Diazepam was effective in controlling brief (10 min) seizures but lost potency after prolonged (45 min) seizures in a lithium–pilocarpine rat model of status epilepticus. From ref. 58.

drug from blood to brain. This effect can be seen, for instance, with phenobarbital [57]. Other peripheral pharmacokinetic effects are also apparent during status epilepticus. These may result from increased blood flow to muscle, and hepatic and renal compromise (often resulting in a prolongation of the elimination half-life of anticonvulsant drugs). In addition to these peripheral effects, there is also a direct effect of status epilepticus on the brain compartment. There is a breakdown in the blood–brain barrier during convulsive seizures, which again results in more effective brain penetration of anticonvulsant drugs. During seizures there is increased blood flow to seizing brain; thus drugs in which the cortical blood flow determines the rate at which the drug crosses the blood–brain barrier (e.g. phenobarbital) may concentrate in foci of seizure activity in the brain.

Drug responsiveness

As status epilepticus progresses, it becomes more difficult to treat, probably largely because of changes in brain receptors with continued seizure activity [58–62]. Many of the treatments that are successful in the initial stages are ineffective later. Indeed, the potency of benzodiazepines decreases as status epilepticus progresses (Fig. 18.2) [59]; the decrease in their potency is associated with a decrease in the sensitivity of γ-aminobutyric acid (GABA) receptors to benzodiazepines [59]. Acute changes during the episode of status epilepticus must be responsible for the changing responsiveness and, as mentioned above, many neurochemical and neurophysiological changes do occur – often very rapidly. The down-regulation of the benzodiazepine-sensitive $GABA_A$ receptors is probably largely due to seizure-induced changes in the trafficking of receptors from the membrane surface [60,61].

Serial seizures (premonitory phase)

It has been noted that the development of status epilepticus is preceded by an increasing frequency of seizures (a premonitory phase) [1]. Furthermore, as the animal data mentioned above suggests, treatment at this early stage has a much higher chance of success than treatment of established status epilepticus [62]. Treatment at this stage also prevents neuronal damage. Serial seizures and prolonged seizures do not, however, necessarily result in status epilepticus, and in one study of seizures lasting 10–29 min, half the seizures terminated without treatment (whether some of the other episodes that were treated would have terminated without treatment is unknown) [63]. Similarly, a study of new-onset seizures in children found that half the children had seizures lasting longer than 5 min, and 92% of the seizures stopped spontaneously; indeed, approximately three-quarters of the seizures lasting longer than 5 min stopped spontaneously [64]. This introduces two notes of caution: first, that status epilepticus is not an inevitable consequence of prolonged seizures and, second, that treatment studies based on seizures that last less than 30 min may overestimate treatment effects due to spontaneous seizure cessation.

Randomized controlled studies have established the efficacy of oral and rectal diazepam and buccal midazolam in the treatment of serial seizures [65–68]. Most of these studies, however, consider episodes in patient groups (often institutionalized) who have a history of serial seizures but who do not go into status epilepticus. Furthermore, these studies often include many seizure clusters in a few patients. Thus, most of these studies do not directly address the prevention of status epilepticus. However, in a large pragmatic study, buccal midazolam demonstrated superiority over diazepam in a randomized controlled study when given in the emergency room to children [68]. The success rate of either drug was lower than that observed in other studies, perhaps due to their late use (in the emergency room rather than prior to admission), further emphasizing the benefit of early treatment. Buccal midazolam should therefore be preferred to rectal diazepam in children; trial data for buccal midazolam in adults are lacking.

With more prolonged seizures (>10 min) in the community, i.v. diazepam and i.v. lorazepam have been shown to be more effective than placebo at preventing the evolution to, or continuation of, status epilepticus when administered by paramedics [69]. In this study, although not statistically significant, lorazepam had a more impressive effect than diazepam. Interestingly, early treatment in this study did not significantly affect eventual outcome, but this may have been because of the lack of sufficient power in the study to detect such differences (there was a trend to better outcomes for those given active treatment by paramedics) [69].

Rectal paraldehyde has been proposed as an alternative, especially in children. Paraldehyde is, however, difficult to use and administer, and its use should perhaps be reserved for those in whom a rectal benzodiazepine has failed [70].

Tonic–clonic status epilepticus

Diagnosis

Non-epileptic attacks are frequently prolonged and can be confused with status epilepticus. In an audit of patients transferred to a specialist neurological intensive care unit for further treatment of their status epilepticus, approximately half the patients transferred were not in status epilepticus, and were either in pseudostatus or in drug-induced coma (usually secondary to large

amounts of emergency antiepileptic status medication) [71]. The inadequacy of diagnosis from most referring centres was partly due to absent or insufficient EEG services available at those centres. As has been found in another study [72], many patients with pseudostatus had a previous diagnosis of epilepsy that may have confounded the diagnosis. Pseudostatus is often misdiagnosed as true status epilepticus and is often refractory to initial therapy (leading to general anaesthesia and mechanical ventilation) [1,71,72]. Failure by admitting doctors to recognize the possibility of pseudostatus was common. It should thus be emphasized that pseudostatus must be considered if an episode of status epilepticus does not respond promptly to initial therapy (especially if the seizures are in any way atypical).

EEG patterns have also been proposed to be a means of staging the status epilepticus. From experimental models, a progression of EEG changes has been suggested from discrete seizures, to merging seizures, to continuous seizure activity and then eventually periodic lateralized epileptiform discharges (PLEDs) or bilateral periodic epileptiform discharges (BPEDs) [73]. This progression has been proposed to mirror increasing drug resistance and a worsening prognosis [62]. In humans, this clear EEG sequence is not usually found [74]. Although patients with PLEDs generally fare less well, outcome is probably more related to age and aetiology than to any specific ictal pattern [74].

Medical management and complications

Convulsive status epilepticus is a medical emergency because of the significant potential for excitotoxic cerebral damage, other forms of cerebral damage and associated medical complications. The effects of convulsive status epilepticus can be divided into early and late stages. In the early phase, cerebral autoregulation and homeostasis are largely preserved. The initial consequence of a prolonged convulsion is a massive release of plasma catecholamines [75], which results in an increase in heart rate, blood pressure and plasma glucose. During this stage, cardiac arrhythmias are frequently seen, and may be fatal [76]. Cerebral blood flow is greatly increased and thus glucose delivery to active cerebral tissue is maintained [77]. As the seizure continues, there is a steady rise in the core body temperature, and prolonged hyperthermia above 40°C can cause cerebral damage and has a poorer prognosis [78,79]. Acidosis also commonly occurs, and in one series 25% of the patients had an arterial pH below 7.0 [80]. This acidosis is mainly the result of lactic acid production, but there is also a rise in carbon dioxide tension that can, in itself, result in life-threatening narcosis [80]. The acidosis can increase the likelihood of life-threatening cardiac arrhythmias and hypotension and, in conjunction with the cardiovascular compromise, may result in severe pulmonary oedema [81].

The status epilepticus may then enter a second late phase in which cerebral and systemic protective measures progressively fail. The main characteristics of this phase are a fall in blood pressure, a loss of cerebral autoregulation, resulting in the dependence of cerebral blood flow on systemic blood pressure, and hypoglycaemia due to the exhaustion of glycogen stores and the increased neurogenic insulin secretion [75,82,83]. Intracranial pressure may rise precipitously in status epilepticus. The combined effects of systemic hypotension and intracranial hypertension can result in a compromised cerebral circulation and cerebral oedema [84], particularly in children. Further complications may occur, including rhabdomyolysis, leading to acute tubular necrosis, hyperkalaemia and hyponatraemia [85]. Hepatic compromise is not uncommon, and rarely there may be disseminated intravascular coagulation with its subsequent complications [86]. Because of these medical complications, status epilepticus that has lasted an hour or more (and sometimes less) should be managed in the intensive care unit, where there is adequate monitoring and treatment of these potential complications.

Thus, for the new patient presenting as an emergency in status epilepticus, it is helpful to plan therapy in a series of progressive phases – this scheme is taken from Shorvon [1].

First stage (0–10 min)

Oxygen and cardiorespiratory resuscitation

It is first essential to assess cardiorespiratory function, to secure the airway and to resuscitate where necessary. Oxygen should always be administered, as hypoxia is often unexpectedly severe.

Second stage (1–60 min)

Monitoring

Regular neurological observations and measurements of pulse, blood pressure, electrocardiography and temperature should be initiated. Metabolic abnormalities may cause status epilepticus, or develop during its course, and biochemical, blood gas, pH, clotting and haematological measures should be monitored.

Emergency anticonvulsant therapy

This should be started (see below).

Intravenous lines

These should be set up for fluid replacement and drug administration [preferably with 0.9% sodium chloride (normal or physiological saline) rather than 5% glucose solutions]. Drugs should not be mixed and, if two AEDs are needed (e.g. phenytoin and diazepam), two i.v. lines should be sited. The lines should be in large veins, as many AEDs cause phlebitis and thrombosis at the site of infusion. Arterial lines must never be used for drug administration.

Emergency investigations

Blood should be drawn for the emergency measurement of blood gases, sugar, renal and liver function, calcium and magnesium levels, full haematological screen (including platelets), blood clotting measures and anticonvulsant levels. Fifty millilitres of serum should also be saved for future analysis, especially if the cause of the status epilepticus is uncertain. Other investigations depend on the clinical circumstances.

Intravenous glucose and thiamine

Fifty millilitres of a 50% glucose solution should be given immediately by i.v. injection if hypoglycaemia is suspected. If there is a history of alcoholism, or other compromised nutritional states, 250 mg of thiamine (e.g. as the high-potency i.v. formulation of Pabrinex, 10 mL of which contains 250 mg) should also be given

intravenously. This is particularly important if glucose has been administered, as a glucose infusion increases the risk of Wernicke's encephalopathy in susceptible patients. Intravenous high-dosage thiamine should be given slowly (e.g. 10 mL of high-potency Pabrinex over 10 min), with facilities for treating the anaphylaxis, which is a potentially serious side-effect of Pabrinex infusions. Routine glucose administration in non-hypoglycaemic patients should be avoided as there is some evidence that this can aggravate neuronal damage.

Acidosis
If acidosis is severe, the administration of bicarbonate has been advocated in the hope of preventing shock, and mitigating the effects of hypotension and low cerebral blood flow. In most cases, however, this is unnecessary and more effective is the rapid control of respiration and abolition of motor seizure activity.

Third stage (0–60/90 min)

Establish aetiology
The causes of status epilepticus differ with age, and in the presence or absence of established epilepsy. The investigations required depend on clinical circumstances. Computed tomography or magnetic resonance imaging and cerebrospinal fluid examination are often necessary; the latter should be carried out only with facilities for resuscitation available, as intracranial pressure is often elevated in status epilepticus.

If the status epilepticus has been precipitated by drug withdrawal, the immediate restitution of the withdrawn drug, even at lower doses, will usually rapidly terminate the status epilepticus. Pyridoxine should also be given intravenously to children under the age of 3 years who have a prior history of epilepsy and to all neonates.

Physiological changes and medical complications
The physiological changes of uncompensated status epilepticus, listed above, may need specific therapy. Active treatment is most commonly required for hypoxia, hypotension, raised intracranial pressure, pulmonary oedema and hypertension, cardiac arrhythmias, cardiac failure, lactic acidosis, hyperpyrexia, hypoglycaemia, electrolyte disturbance, acute hepatic or renal failure, rhabdomyolysis or disseminated intravascular coagulation.

Pressor therapy
Dopamine is the most commonly used pressor agent, given by continuous i.v. infusion. The dose should be titrated to the desired haemodynamic and renal responses (usually initially between 2 and 5 μg/kg/min, but this can be increased to over 20 μg/kg/min in severe hypotension). Dopamine should be given into a large vein as extravasation causes tissue necrosis. Electrocardiographic monitoring is required, as conduction defects may occur, and particular care is needed in dosing in the presence of cardiac failure.

Fourth stage (30–90 min)

Intensive care
If seizures are continuing in spite of the measures taken above, the patient must be transferred to an intensive care environment, and the usual measures instituted.

Intensive care monitoring
In severe established status epilepticus, intensive monitoring may be required, including intra-arterial blood pressure, oximetry, central venous pressure and pulmonary artery pressure monitoring.

Although magnesium is effective at preventing eclampsia, there is no evidence to suggest that increasing magnesium serum concentrations to supranormal levels has any benefit in status epilepticus. Indeed, such a policy can result in motor paralysis, difficulty in detecting clinical seizure activity and hypotension [87]. However, serum magnesium can be low in alcoholics and patients with acquired immune deficiency syndrome (AIDS) [88,89], and in these patients i.v. loading with 2–4 g of magnesium sulphate over 20 min may help with seizure control and prevention of arrhythmias.

Seizure and EEG monitoring
In prolonged status epilepticus, or in comatose ventilated patients, motor activity can be barely visible. In this situation, continuous EEG monitoring using a full EEG or a cerebral function monitor is necessary, and at the very least intermittent daily EEGs should be recorded. The latter must be calibrated individually, and then can register both burst suppression and seizure activity. Burst suppression provides an arbitrary physiological target for the titration of barbiturate or anaesthetic therapy. Drug dosing is commonly set at a level that will produce burst suppression with interburst intervals of between 2 and 30 s.

Intracranial pressure monitoring and cerebral oedema
Continuous intracranial pressure monitoring is advisable, especially in children, in the presence of persisting, severe or progressive elevated intracranial pressure. The need for active therapy is usually determined by the underlying cause rather than the status epilepticus. Intermittent positive-pressure ventilation, high-dose corticosteroid therapy (4 mg dexamethasone every 6 h), or mannitol infusion may be used (the last is usually reserved for temporary respite for patients in danger of tentorial coning). Neurosurgical decompression is occasionally required.

Long-term anticonvulsant therapy
Long-term, maintenance, anticonvulsant therapy must be given in tandem with emergency treatment. The choice of drug depends on previous therapy, the type of epilepsy and the clinical setting. If phenytoin or phenobarbital has been used in emergency treatment, maintenance doses can be continued orally (through a nasogastric tube) guided by serum level monitoring. Other maintenance AEDs can be started also by giving oral loading doses.

Drug treatment

The doses of drugs commonly used in status epilepticus are contained in Table 18.2. There have been eight randomized studies of i.v. drug treatment in status epilepticus [90–97]. These studies are beset by methodological problems. They use different definitions of status epilepticus, most do not take adequate precautions to exclude patients with pseudostatus epilepticus, and they use different doses of drugs. Also, there are problems of rapid randomization and of defining outcome. These studies compared lidocaine against placebo [94], lorazepam against diazepam [90,92], phenobarbital against diazepam and phenytoin [93],

Table 18.2 Drugs used in the pre-anaesthetic management of status epilepticus.

Drug	Route	Adult dose	Paediatric dose
Diazepam at 2–5 mg/min[a]	i.v. bolus Rectal administration	10–20 mg at 2–5 mg/min[a] 10–30 mg[a]	0.25–0.5 mg/kg 0.5–0.75 mg/kg[a]
Midazolam	i.m. or rectally i.v. bolus i.v. infusion	5–10 mg[a] 0.1–0.3 mg/kg at 4 mg/min[a] 0.05–0.4 mg/kg/h	0.15–0.3 mg/kg[a]
Paraldehyde	Rectally or i.m. i.v.	5–10 mL (approx 1 g/mL) in equal volume of water[a] 5–10 mL/h as a 5% solution in 5% dextrose	0.07–0.35 mL/kg[a]
Chlormethiazole	i.v. infusion of 0.8% solution	40–100 mL at 5–15 mL/min, then 0.5–20 mL/min	0.1 mL/kg/min increasing every 2–4 h
Clonazepam	i.v. bolus	1–2 mg at 2 mg/min[a]	250–500 mg
Fosphenytoin	i.v. bolus	15–20 mg PE/kg at 150 mg PE/min	
Lignocaine	i.v. bolus i.v. infusion	1.5–2.0 mg/kg at 50 mg/min[a] 3–4 mg/kg/h	
Lorazepam	Rectally i.v. bolus	0.05–0.1 mg/kg 0.07 mg/kg (usually 4 mg)a	 0.1 mg/kg
Phenytoin	i.v. bolus/infusion	15–20 mg/kg at 50 mg/min	20 mg/kg at 25 mg/min
Phenobarbital	i.v. bolus	10–20 mg/kg at 100 mg/min	15–20 mg/kg
Valproate	i.v. bolus	15–30 mg/kg	20–40 mg/kg

After ref. 148.
[a]May be repeated.
i.m., intramuscular; i.v., intravenous; PE, phenytoin equivalent.

intramuscular (i.m.) midazolam against i.v. diazepam [91], four different i.v. treatment regimes (lorazepam, phenytoin alone, diazepam and phenytoin, and phenobarbital) [95], valproate against phenytoin [96] and valproate against i.v. diazepam in refractory status epilepticus [97].

Certain conclusions can be drawn from these studies: (a) lidocaine is effective in the treatment of status epilepticus [94]; (b) lorazepam and diazepam are equally effective, although more patients required additional AEDs if given diazepam [90,92]; (c) lorazepam is more effective than phenytoin alone [95]; (d) i.m. midazolam is as effective as initial i.v. diazepam and may be an alternative if i.v. access is difficult in children [91]; (e) phenobarbital alone is as effective as other regimens [93,95]; (f) lorazepam is faster to administer than other drugs; and (g) no particular drug or drug combination has significantly more side-effects including respiratory depression (importantly phenytoin alone was not significantly superior to regimens containing benzodiazepines) [95]. The studies of valproate are unfortunately difficult to interpret. In one study, patients were randomized to valproate or phenytoin alone (an inferior treatment) [96]. This study was underpowered and there was no significant difference between the two treatment arms (the study incorrectly reports one-sided *t*-tests). The other study compared i.v. diazepam infusion against i.v. valproate in status epilepticus refractory to benzodiazepine and phenytoin loading [97]. There was no significant difference between the two treatment arms. Both these studies were inconclusive and used non-standard or inferior comparators, but it appears that high doses of valproate can be effective. Overall, drug choice is perhaps not as important as having a protocol so that satisfactory doses of reasonable drugs are given rapidly; indeed, retrospective studies have found that approximately 70% of patients in status epilepticus are given inadequate doses of antiepileptic medication [71,98].

A protocol for the drug treatment of tonic–clonic status epilepticus

It seems sensible to stage treatment, with less intensive initial therapy requiring less support.

Stage of early status epilepticus

Benzodiazepines are widely accepted as the drugs of choice for initial therapy (see Table 18.2). Of these, i.v. lorazepam is now generally preferred over diazepam as first-line therapy in established status epilepticus. The disadvantage of diazepam is its short redistribution half-life (less than 1 h) and large volume of distribution (1–2 L/kg) [99]. These properties mean that serum and brain concentrations rapidly fall after initial i.v. dosing, leading to potentially high rates of seizure recurrence. Within 2 h of successful treatment with diazepam, over half the patients with status epilepticus relapse [100]. Repeat boluses of diazepam can lead to significant accumulation, prolongation of action and progressively greater peak levels [101]. This may result in cardiorespiratory arrest, and so cannot be recommended. Clonazepam shares many of the pharmacokinetic features of diazepam. It has a similarly rapid brain penetration, short distribution half-life and long elimination half-life. Lorazepam, on the other hand, has a lesser volume of distribution and is less lipid soluble. It enters the brain more slowly, taking up to 30 min to reach peak levels, although therapeutic levels are reached within a few minutes. Its distribution half-life is much longer (2–3 h), and its elimination half-life is shorter (approximately 10–12 h). Its effects, therefore, are longer lasting than are those of diazepam, and for this reason lorazepam is the benzodiazepine of choice in status epilepticus [90,98,99]. Lorazepam should be given as a bolus that can be repeated once after 10 min, at which time phenytoin should be administered. Lidocaine as a bolus followed by an infusion has

Table 18.3 A protocol for the intravenous (i.v.) antiepileptic drug treatment of convulsive status epilepticus (SE) in adults.

Stage of early SE
Lorazepam 4 mg i.v. bolus (can be repeated once)
If seizures continue after 30 min → stage of established SE

Stage of established SE
Phenobarbital i.v. infusion of 10 mg/kg at a rate of 100 mg/min, or
Phenytoin i.v. infusion of 15 mg/kg at a rate of 50 mg/min, or
Fosphenytoin i.v. infusion of 15 mg PE/kg at a rate of 100 mg PE/min
If seizures continue after 30/60 min → stage of refractory SE

Stage of refractory SE
General anaesthesia should be induced with either:
Propofol: i.v. bolus of 2 mg/kg, repeated if necessary, and then followed by a continuous infusion of 5–10 mg/kg/h initially reducing to a dose sufficient to maintain a burst suppression pattern on the EEG (usually 1–3 mg/kg/h)
When seizures have been controlled for 12 h, the drug dosage should be slowly reduced over a further 12 h
or
Thiopental: i.v. bolus of 100–250 mg given over 20 s with further 50-mg boluses every 2–3 min until seizures are controlled, followed by a continuous i.v. infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 3–5 mg/kg/h)
When seizures have been controlled for 12 h, the drug dosage should be slowly reduced over a further 12 h
or
Midazolam: i.v. bolus of 0.1–0.3 mg/kg at a rate not exceeding 4 mg/min initially, followed by a continuous i.v. infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 0.05–0.4 mg/kg/h)
When seizures have been controlled for 12 h, the drug dosage should be slowly reduced over a further 12 h
If seizures recur, the general anaesthetic agent should be given again for a further 12 h, and then withdrawal attempted again. This cycle may need to be repeated until seizure control is achieved

From ref. 148.

Table 18.4 Anaesthetics for refractory status epilepticus.

Drug	Adult dose	Comments
Midazolam	0.1–0.3 mg/kg at 4 mg/min bolus followed by infusion at 0.05–0.4 mg/kg/h	Elimination half-life of 1.5 h, but accumulates with prolonged use Tolerance and rebound seizures can be problematic
Thiopentone	100–250 mg bolus over 20 s then further 50 mg boluses every 2–3 min until seizures are controlled. Then infusion to maintain burst suppression (3–5 mg/kg/h)	Complicated by hypotension. It has saturable pharmacokinetics, and a strong tendency to accumulate. Metabolized to pentobarbital. It can also cause pancreatitis, hepatic disturbance and hypersensitivity reaction
Pentobarbital	10–20 mg/kg at 25 mg/min then 0.5–1 mg/kg/h increasing to 1–3 mg/kg/h	As above
Propofol	2 mg/kg then 5–10 mg/kg/h	Large volume of distribution and short half-life. Rapid recovery. Can be complicated by lipaemia, acidosis and rhabdomyolysis especially in children. Rebound seizures with abrupt withdrawal

From ref. 148.

been recommended as an alternative to benzodiazepines in those in whom respiratory depression is a concern [102], but is not now widely used.

Stage of established status epilepticus

If initial benzodiazepine therapy is ineffective, then the patient can be considered to be in established status epilepticus. Phenobarbital or phenytoin (or fosphenytoin) is the drug of choice in this situation (Table 18.3). Phenobarbital is easier to use, and possibly more effective, but phenytoin may be associated with a lower risk of respiratory depression. Controlled studies have not, however, been carried out, and the relative merits of the two therapies are unclear. Intravenous valproate or levetiracetam have also been proposed as alternatives.

Phenytoin is relatively insoluble in water, and its parenteral formulation has a high pH; consequently, it has a number of side-effects related to its physicochemical properties. It may crystallize and precipitate in solutions; it may cause thrombophlebitis (particularly with extravasation); its vehicle, propylene glycol, can cause hypotension; and phenytoin is poorly and erratically absorbed after i.m. injection. Fosphenytoin (3-phosphoryloxymethyl phenytoin disodium) is a water-soluble phenytoin prodrug which has some advantages relating to tolerability over phenytoin [103]. Fosphenytoin is itself inactive, but is metabolized to phenytoin with a half-life of 8–15 min [103]. It can be administered 2–3 times faster than phenytoin and achieves similar mean serum concentrations, although there is considerable scatter of levels. Cardiac monitoring is still required with fosphenytoin, and the dosing units of the drug are confusing and have caused problems in practice in inexperienced emergency units. There are no controlled trials of fosphenytoin in status epilepticus, and it is not clear if the potential tolerability advantages of fosphenytoin overcome the potential variability in phenytoin levels and the difficulties in dosage, translate in practice into a better outcome than that achieved by phenytoin.

Stage of refractory status epilepticus

In most cases of convulsive status epilepticus (over 80%), therapy with benzodiazepine and phenobarbital or phenytoin will control the seizures rapidly. If the seizures are continuing, however, there is a risk of physiological compromise, neuronal damage and progressive drug resistance. This is the stage of refractory status epilepticus, and transfer to an intensive care unit is required [104]. In many emergency situations (e.g. postoperative status epilepticus, severe or complicated convulsive status epilepticus, patients already in intensive care), anaesthesia should be introduced earlier.

The prognosis of status epilepticus at this stage is less good; in one meta-analysis, the mortality at this stage was estimated to be as high as 48%, with only 29% returning to their premorbid functional baseline [105], although the methodology of this meta-analysis has been open to severe criticism, and the actual mortality in normal practice must be considerably lower than this. The mortality is greater in older patients, those with longer seizure duration, those in a poorer medical condition and those with acute brain injury.

Anaesthesia can be induced by barbiturate or non-barbiturate drugs (Table 18.4). A number of anaesthetics have been recommended [104,106]. The most commonly used anaesthetics are the i.v. barbiturates thiopentone or pentobarbital, the i.v. non-barbiturate infusional anaesthetic propofol or continuous midazolam infusion [104,106]. There have been no randomized controlled studies comparing these treatment options. The aforementioned meta-analysis suggests that there is no difference between these anaesthetics in terms of mortality, but that pentobarbitone was perhaps more effective than midazolam at the expense of greater hypotension [106]. These data, however, need to be interpreted with caution, as the studies compared were non-randomized, had different outcome measures and were subject to considerable reporting bias (the reports are mostly retrospective). Propofol and midazolam have pharmacokinetic advantages over the barbiturates, which readily accumulate. In addition to anaesthesia, it is important that oral AED treatment should continue (usually given by nasogastric tube) and failure to do so will result in seizure relapse when the emergency therapy is withdrawn.

It is imperative at this stage to monitor the EEG, as drug-induced coma can occur with little outward sign of convulsions, yet have ongoing electrographic epileptic activity [106,107]. This exposes the patient to excitotoxic seizure-induced cerebral damage. In addition, patients with prolonged convulsive status epilepticus can enter a stage of subtle generalized convulsive status epilepticus characterized by profound coma, bilateral EEG ictal discharges and only subtle motor activity, regardless of the presence or absence of sedating drugs or paralysing agents [108].

The electrographic endpoint for anaesthetic titration is controversial as there are sparse published data on the subject. The titration of the dose of anaesthetic agents in their use in status is commonly based upon burst suppression on the EEG or cerebral function monitor (CFM) with inter-burst intervals of 2–30 s as an acceptable endpoint [109–111]. Burst suppression supposedly represents disconnection of cerebral grey matter from underlying white matter. Burst suppression can be difficult to achieve, because the degree of anaesthesia required commonly leads to hypotension. Aiming for a more realistic endpoint such as seizure suppression, although more difficult to define, may be more acceptable [71]. EEG monitoring should either be continuous or be repeated regularly.

There are case reports of the successful use of newer drugs (such as oral topiramate and i.v./oral levetiracetam) and steroids in refractory status epilepticus; unfortunately, trials of these are still lacking [112].

Once the patient has been free of seizures for 12–24 h, and provided that there are adequate plasma levels of concomitant antiepileptic medication, then the anaesthetic can be slowly tapered. If seizures recur, the anaesthetic should be reinstated. If one anaesthetic agent is ineffective then it should be replaced by another. There are some data to suggest that those who are loaded with phenobarbital do better than those who are not [12]. In severe cases, anaesthesia may be required for weeks or even months, with many cycles of attempted anaesthetic withdrawal and reinstatement. Eventual recovery occurs in many patients, even after very prolonged episodes, and the process of maintaining a patient under anaesthetic for weeks or months requires great skill, in view of the attendant risks. The ultimate outcome is worse the longer the status continues, but even after very prolonged attacks, a complete recovery can occur. Much depends on the underlying cause – and the ultimate prognosis is more dependent on this than on the duration of seizures.

The above schema is for a typical case, but obviously there are situations in which management will vary considerably. For instance, status epilepticus in the immediate post-neurosurgery or post-head injury situation should be managed by immediate anaesthesia. Similarly, status epilepticus in patients with pre-existing epilepsy due to drug withdrawal should be treated with immediate reinstatement of the withdrawn drug, parenterally if possible. Status in infants and young children can also require a different approach, outlined elsewhere.

Non-convulsive status epilepticus

The advent of more widely accessible EEG and, in particular, the availability of EEG on intensive care units has led to the recognition that non-convulsive status epilepticus (NCSE) is a much more common condition than previously recognized. Indeed, indirect estimates for the incidence of NCSE have been as high as 14–24 per 100 000 population per year (the majority of these are NCSE in the setting of learning difficulties) [6]. Population studies have demonstrated that NCSE accounts for at least one-third of all cases of status epilepticus [9]. NCSE comprises different syndromes, which require different treatment (Table 18.1) [113]. Here, we consider the therapy of typical absence status epilepticus, CPSE, NCSE in coma and specific forms of status epilepticus in patients with learning difficulties, including tonic status epilepticus and atypical absence status epilepticus.

Diagnosis

The diagnosis of NCSE is critically dependent on EEG. In patients with a previous diagnosis of epilepsy, any prolonged change in personality, prolonged postictal confusion (greater than 30 min) or recent-onset psychosis should be investigated with EEG as these can all be presentations of NCSE [114–116]. If progressive developmental delay occurs in the setting of epilepsy, then a sleep EEG should be considered to identify status epilepticus during slow-wave sleep. In non-comatose patients with no history of epilepsy, NCSE can present as confusion or personality change, but almost invariably in the setting of a metabolic derangement, encephalitis or other acute precipitant. Rarely, NCSE can present as autism, and if suspicions are raised (usually a fluctuating course) then EEG is indicated [117,118].

Non-convulsive status epilepticus can result from convulsive status epilepticus, and is an important, treatable cause of persistent coma following convulsive status epilepticus [114,119]. This, and status epilepticus with subtle manifestations such as twitching of the limbs or facial muscles or nystagmoid eye jerking, which can result from hypoxic brain damage, are often collectively referred to as subtle motor status epilepticus [108]. Up to 8% of patients in coma who have no outward signs of seizure activity are in NCSE, thus emphasizing the importance of EEG in the investigation of comatose patients [120]. Similarly, NCSE is underdiagnosed in the confused elderly, in whom the confusion is frequently blamed on other causes [121,122].

Although EEG interpretation is usually straightforward, with regular repetitive discharges occurring in some patients in a cyclical fashion, difficulties can occur in differentiating NCSE from an encephalopathy of other cause [123]. Triphasic waves due to metabolic encephalopathies (particularly hepatic or hyperammonaemic) can be frequent and occasionally sharpened, leading to confusion. Thus, definitions of NCSE should include either (a) unequivocal electrographic seizure activity; (b) periodic epileptiform discharges or rhythmic discharge with clinical seizure activity; or (c) rhythmic discharge with either clinical or electrographic response to treatment [123]. Although these definitions are helpful, difficulties can still arise; triphasic waves can respond to treatment with benzodiazepines, and thus response to treatment is not a definitive indication of an epileptic cause [124]. There is also uncertainty about the relevance of PLEDs [125]. This is most notable following severe encephalitis or hypoxic injury in which discharges can occur with such periodicity so as to be confused with periodic discharges seen following prolonged status epilepticus. Some have argued that such discharges represent ongoing seizure activity, and should be treated thus. The general consensus, however, is that a multitude of aetiologies can underlie PLEDs, and that they should be treated as epileptic only if there is other evidence of ictal activity [125].

Table 18.5 Treatment of different types of non-convulsive status epilepticus (NCSE).

Type	Treatment choice	Other drugs that can be used
Typical absence status epilepticus	i.v. or oral benzodiazepines	Acetazolamide, valproate or chlormethiazole
Complex partial status epilepticus	Oral clobazam	i.v. lorazepam and phenytoin (fosphenytoin) or phenobarbital
Atypical absence status epilepticus	Oral valproate	Oral benzodiazepines (with caution), lamotrigine, topiramate
Tonic status epilepticus	Oral lamotrigine	Methylphenidate, steroids
Myoclonic status epilepticus in coma	Barbiturate anaesthesia (for short trial period)	Steroids, midazolam
Other forms of myoclonic status epilepticus	Oral valproate, benzodiazepines	Levetiracetam
Epilepsia partialis continua	Any oral anticonvulsant	Steroids, immunosuppression
NCSE in the aftermath of tonic–clonic seizures	i.v. benzodiazepines	i.v. phenytoin or phenobarbital
Subtle status epilepticus	Anaesthesia	Steroids

Medical management

Typical absence status epilepticus

This term should be reserved for prolonged absence attacks with continuous or discontinuous 3-Hz spike and wave occurring in patients with primary generalized epilepsy [6]. There are borderline cases also, in which the EEG can include irregular spike–wave, prolonged bursts of spike activity, sharp wave or poly-spike and wave, and it is not clear how to classify these cases.

There is also a category of absence status epilepticus which occurs *de novo* in late adult life [6,126,127] (*de novo* absence status epilepticus of late onset). This often follows drug or alcohol withdrawal and there may or may not be a history of idiopathic generalized epilepsy [6,128].

There is no evidence that absence status induces neuronal damage, and thus aggressive treatment is not warranted [6,128]. Treatment can either be i.v. or oral (Table 18.5). Absence status epilepticus responds rapidly to i.v. benzodiazepines; there is no good evidence to favour one benzodiazepine over another. Sodium valproate is one of the alternatives.

Complex partial status epilepticus

Complex partial status epilepticus (CPSE) has to be differentiated from other forms of NCSE, from postictal states and from other neurological and psychiatric conditions. EEG may be helpful, but the scalp EEG changes can be non-specific and the diagnosis has to be largely clinical [1,31]. The definition as 'a prolonged epileptic episode in which focal fluctuating or frequently recurring electrographic epileptic discharges, arising in temporal or extratemporal regions, result in a confusional state with variable clinical symptoms' [1] emphasizes that complex partial status epilepticus can originate in any cortical region and can fluctuate in a cyclical fashion [6]. The differentiation of CPSE from generalized NCSE can be difficult, as rapid generalization can occur despite an initial focus that may only become apparent after treatment [30,129].

How aggressively CPSE needs to be treated depends upon (a) the prognosis of the condition and (b) if treatment improves the prognosis. As in all epilepsies, the prognosis relates partly to the prognosis of the underlying aetiology and any concomitant medical conditions. Indeed, CPSE in someone with epilepsy is a more benign condition than complex status epilepticus resulting from an acute cerebral event, and should perhaps be treated thus [35]. There is no good evidence that aggressive treatment improves prognosis in this condition; it is important to note that i.v. medication can result in hypotension, respiratory depression and occasionally cardiorespiratory arrest. Indeed, in one series of NCSE in the elderly, aggressive treatment carried a worse prognosis than no treatment [122]. At present, early recognition of the condition and treatment with oral or rectal benzodiazepines can be effective. Valproate may be an alternative, as i.v. valproate is well tolerated with little respiratory or cardiac depression; trials are urgently needed in this area. In patients who have repetitive attacks of CPSE (a common occurrence), oral clobazam over a period of 2–3 days, given early at home, can usually abort the status epilepticus, and such strategies should be discussed with the patient and carers [130,131]. Early recognition is a critical goal, as the delay in treatment comes not from therapeutic strategy, but from failure to diagnose the condition in the first place. For more persistent or resistant CPSE, i.v. therapy should perhaps be used (see Table 18.5), and lorazepam followed by phenytoin (or fosphenytoin) are the drugs of choice [132]. In contrast to

absence status epilepticus, the response to benzodiazepines can be disappointing, and often there is a resolution of the electrographic status epilepticus without concomitant clinical improvement (possibly due to postictal effects) [35]. Whether general anaesthesia is ever justified remains a matter for speculation. Since most CPSE is self-terminating, usually without any serious neurological sequelae, then such aggressive therapy should, in most instances, be avoided. Treatment of the underlying cause (e.g. encephalitis or metabolic derangement) is, of course, paramount.

Atypical absence status epilepticus

Atypical absence status epilepticus is a form of absence status epilepticus associated with the epileptic encephalopathies such as Lennox–Gastaut syndrome [1]. This entity can be difficult to diagnose, but should be considered if there is a change in behaviour, personality, cognition or increased confusion in a patient with one of these epilepsies. The episodes can be prolonged (going on for hours, days or even longer) and the patient may drift in and out of atypical absence status without a clear onset or offset. The EEG characteristics are usually that of continuous or frequent slow (<2.5 Hz) spike and wave. The EEG changes during these periods of absence status can be subtle, and rather similar to the baseline EEG. This condition is usually poorly responsive to i.v. benzodiazepines, which should, in any case, be given cautiously, as they can induce tonic status epilepticus in susceptible patients [133]. Oral rather than i.v. treatment is usually more appropriate, and the drugs of choice are valproate, lamotrigine, clonazepam, clobazam and topiramate (see Table 18.5). Sedating medication, carbamazepine and vigabatrin have been reported to worsen atypical absences.

Tonic status epilepticus

Tonic status epilepticus is not uncommon in patients with syndromes such as Lennox–Gastaut. Tonic status epilepticus can also rarely occur in the setting of normal premorbid intelligence [134]. The tonic seizures may not necessarily be clinically apparent; the EEG, however, demonstrates bursts of paroxysmal, generalized fast discharges [134,135]. Tonic status epilepticus is poorly responsive to conventional treatment. It can be worsened with benzodiazepines, which should be used with care [133]. Sedating medication can worsen all seizure types in Lennox–Gastaut syndrome, and thus should be avoided. Conversely, stimulants such as methylphenidate can be effective. There has also been a case report of the effective termination of tonic status epilepticus with oral lamotrigine [136]. In Lennox–Gastaut syndrome, both adrenocorticotropic hormone (ACTH) and corticosteroids are helpful in the emergency treatment of status epilepticus of all types.

Subtle status epilepticus

This is a clinical and EEG situation similar to that of myoclonic status epilepticus in coma (see below), which can occur in the late stage of convulsive status epilepticus, if untreated, and in this situation is known as subtle status epilepticus [137]. In contrast to the situation in myoclonic status epilepticus in coma, this undoubtedly represents seizure activity and should be treated aggressively with deep anaesthesia and concomitant AEDs (see Table 18.5).

Non-convulsive status epilepticus in the aftermath of tonic–clonic seizures

Non-convulsive status epilepticus can occur in the aftermath of convulsive seizures, in which there may be prolonged confusion with minimal or no motor activity. The EEG shows ongoing electrical activity [114,119]. The recommended treatment is with i.v. benzodiazepines.

Epilepsia partialis continua

This can be considered the status equivalent of simple partial motor seizures, and can be defined as regular or irregular clonic muscular twitching affecting a limited part of the body, occurring for a minimum of 1 h, and recurring at intervals of no more than 10 s [138]. It needs to be differentiated from myoclonic dystonia and brainstem myoclonus. Diagnosis can be difficult; the EEG may show focal abnormalities, but can be normal [138,139]. Epilepsia partialis continua can result from structural abnormalities such as stroke, trauma, cerebral infarction, cerebral abscess, neuronal migration disorders and vascular malformation [138–141]. In approximately 50% of cases, the magnetic resonance imaging scan is normal [139]. Epilepsia partialis continua can be associated with a variety of encephalitides, commonly Rasmussen's encephalitis, but also subacute panencephalitis and Creutzfeldt–Jakob disease [139,141]. It is also not uncommon in the autoimmune encephalopathies. Metabolic causes have also been described, including, importantly, hyponatraemia and hyperglycaemia, although the majority of such patients also have a focal cortical lesion [142]. Treatment is best targeted at the underlying cause. AEDs may prevent seizure spread into complex partial and secondary generalized seizures, but are usually only partially effective in treating the epilepsia partialis continua [139]. Oral corticosteroid therapy and immunosuppression can be of benefit to patients with chronic inflammatory (e.g. Rasmussen's encephalitis) or autoimmune conditions, and nimodipine has been reported to have been successful in two cases of epilepsia partialis continua following an acute cerebral event [143]. Neurosurgical resection should be considered in refractory cases.

Myoclonic status epilepticus in coma

This diagnosis is made in patients who have suffered severe brain injury (for instance, cerebral anoxia following cardiac arrest) who are in deep coma, sometimes with subtle myoclonic twitching, in whom the EEG shows PLEDs or BPEDs, periodic discharges and encephalopathic triphasic patterns or burst suppression patterns [144]. This situation is not uncommon and is seen in up to 8% of patients in coma with no clinical evidence of seizure activity [120]. This is often an agonal event and the prognosis is usually extremely poor, although survival can occur especially if the initial insult was primarily hypoxia related [145]. Survivors are usually left with Lance–Adams-type action myoclonus, which in itself can have a good prognosis [146]. Whether the EEG changes represent electrographic status epilepticus is contentious, and our view is that these usually simply indicate underlying widespread cortical damage or dysfunction. To what extent this myoclonic status epilepticus in coma should be treated is a matter of contention. It is our practice to treat aggressively for 12 h with anaesthesia, but if this is not effective in controlling the EEG therapy should be withdrawn [147].

Other forms of myoclonic status epilepticus

Myoclonic status in the progressive myoclonic epilepsies and in primary generalized epilepsy do not usually require i.v. therapy, although if needed, an i.v. benzodiazepine can be given. The preferred therapy is with oral valproate, clonazepam or piracetam.

Drugs most commonly used in status epilepticus

Diazepam

Diazepam is useful in the premonitory or early stages of status. There is extensive clinical experience in adults, children and the newborn; the drug has well-proven efficacy in many types of status, a rapid onset of action, and well-studied pharmacology and pharmacokinetics. It can be given by rectal administration, and the rectal tubule is a convenient rectal preparation. Diazepam has two important disadvantages, however, which limit its usefulness in status. First, although it has a rapid onset of action, it is highly lipid soluble and thus has a short duration of action after a single injection. This means that there is a strong tendency for seizures to relapse after initial control. Secondly, diazepam accumulates on repeated injections or after continuous infusion, and this accumulation carries a high risk of sudden respiratory depression, sedation and hypotension. Furthermore, in occasional patients, very low doses of diazepam cause severe respiratory depression. Other disadvantages are its dependency on hepatic metabolism and the formation of an active metabolite, which can complicate prolonged therapy. Diazepam has a tendency to precipitate from concentrated solutions and to interact with other drugs, and is absorbed onto plastic on prolonged contact.

Usual preparations

Intravenous formulation

Diazepam solution, 2-mL ampoule containing 5 mg/mL, or diazepam emulsion (Diazemuls®), 1-mL ampoule containing 5 mg/mL.

Rectal formulation

A 2.5-mL rectal tube (Stesolid® containing 2 mg/mL) or, alternatively, the same solution utilized for i.v. administration (2-mL ampoule containing 5 mg/mL).

Usual dosage

Intravenous bolus (undiluted) 10–20 mg (adults) or 0.25–0.5 mg/kg (children), at a rate not exceeding 2–5 mg/min. The bolus dosing can be repeated. Rectal administration 10–30 mg (adults) or 0.5–0.75 mg/kg (children), and this can be repeated.

Fosphenytoin

Fosphenytoin is a prodrug of phenytoin. It is converted in the plasma into phenytoin by widely distributed phosphatase enzymes. The half-life of conversion is about 15 min, and conversion is not affected by age, hepatic status or the presence of other drugs. Fosphenytoin is water soluble and prepared in a Tris buffer; it thus causes less thrombophlebitis when given intravenously. It can also be administered intramuscularly. Fosphenytoin itself is inert, and its action in status is entirely due to the derived phenytoin. When fosphenytoin is infused at 100–150 mg phenytoin equivalents (PEs)/min, the rate at which free phenytoin levels are reached in the serum is similar to that achieved by a phenytoin infusion of 50 mg/min (15 mg PE of fosphenytoin is the same as 15 mg of phenytoin). These are mean results and there is considerable scatter, the clinical consequences of which are not known. Fosphenytoin can therefore be administered three times faster than phenytoin, with equivalent risks of hypotension, cardiac arrhythmias and respiratory depression. Its rate of antiepileptic action is also similar. The dosing (in units of PEs) is confusing and has been reported to have been misunderstood in the emergency situation. The lower incidence of local side-effects is a potential advantage over phenytoin, but in other ways the two drugs are equivalent, and fosphenytoin is more expensive.

Usual preparation

Fosphenytoin is formulated in a Tris buffer at physiological pH. Phials of 50 mg PE are available for mixture with dextrose or saline.

Usual dosage

Fosphenytoin is given at a dose of 15 mg PE/kg at a rate of 100–150 mg PE/min (an average adult dose of 1000 mg PE in 10 min).

Lorazepam

Lorazepam is the drug of choice in the early stage of status, given by i.v. bolus injection. A single injection is highly effective, and the drug has a longer initial duration of action and a smaller risk of cardiorespiratory depression than diazepam. There is little risk of drug accumulation, and also a lower risk of hypotension. The main disadvantage of lorazepam is a stronger tendency for tolerance to develop, the drug being usually effective for about 12 h only. It is thus usable only as initial therapy, and longer-term maintenance AEDs must be given in addition. There is a large clinical experience in adults, children and the newborn, with well-proven efficacy in tonic–clonic and partial status, and the pharmacology and pharmacokinetics of the drug are well characterized. Lorazepam is a stable compound which is not likely to precipitate in solution, and is relatively unaffected by hepatic or renal disease. It has the disadvantage of not being available in many countries.

Usual preparation

A 1-mL ampoule containing 4 mg/mL for i.v. injection.

Usual dosage

Intravenous bolus of 0.07 mg/kg (usually 4 mg), repeated after 10 min if necessary (adults); bolus of 0.1 mg/kg (children). The rate of injection is not crucial.

Midazolam

Midazolam is another benzodiazepine which can be used in the premonitory or early stages of status. It is a water-soluble compound, the ring structure of which closes when in contact with serum to convert it into a highly lipophilic structure. Its water solubility provides one major advantage over diazepam, in that it can be rapidly absorbed by i.m. injection or by intranasal or buccal administration. It is therefore useful in situations in which i.v. administration is difficult or ill-advised. Blinded comparisons

with diazepam after i.m. and buccal administration show it to be equivalent in efficacy and speed of action. Although there is a danger of accumulation on prolonged or repeated therapy, this tendency is less than with diazepam. There is, however, only limited published experience in adults or children with status. Occasionally, severe cardiorespiratory depression occurs after intramuscular administration, and other adverse effects include hypotension, apnoea, sedation and thrombophlebitis. Like diazepam, the drug is short acting, and there is a strong tendency for seizures to relapse after initial control. Its half-life is prolonged in hepatic disease or in the elderly. There are also encouraging reports of the use of i.v. infusions of midazolam as an anaesthetic in the refractory stage of status, and midazolam is the only benzodiazepine which should be used as a continuous infusion. With more experience, i.v. midazolam may become the drug of choice for anaesthesia in refractory status.

Usual preparation

A 5-mL ampoule containing 2 mg/mL midazolam hydrochloride.

Usual dosage

Intramuscularly or rectally 5–10 mg (adults); 0.15–0.3 mg/kg (children). This can be repeated once after 15 min. An i.v. bolus of 0.1–0.3 mg/kg may be given at a rate not to exceed 4 mg/min, which can be repeated once after 15 min. An i.v. infusion can be given at a rate of 0.05–0.4 mg/kg/h. Buccal instillation of 10 mg can be given by a syringe and catheter in children or adults.

Phenobarbital

Phenobarbital is one of the drugs of choice in the stage of established status. It is a reliable AED, with well-proven effectiveness in tonic–clonic and partial status, and there is extensive clinical experience in adults, children and in neonates. Phenobarbital has a stronger anticonvulsant action than other barbiturates and an additional potential cerebral protective action. It has a rapid onset and long-lasting action, and can be administered much faster than can phenytoin. Its safety at high doses has been established, and the drug can be continued as chronic therapy. The disadvantages of the drug relate to prolonged use, where because of the long elimination half-life, there is a risk of drug accumulation and inevitable sedation, respiratory depression and hypotension. Marked autoinduction may also occur. It is also a drug not used much in long-term therapy in epilepsy, and when given in status epilepticus will need a long withdrawal period once the episode of status epilepticus is over.

Usual preparation

A 1-mL ampoule containing phenobarbital sodium 200 mg/mL in propylene glycol 90% and water for injection 10%.

Usual dosage

The i.v. loading dose in adults is 10 mg/kg at rate of 100 mg/min (usual adult dose 600–800 mg), followed by maintenance dose of 1–4 mg/kg (adults). For neonates and children, the i.v. loading dose of 15–20 mg/kg is followed by a maintenance dose of 3–4 mg/kg. Higher doses can be given, with monitoring of blood concentrations.

Phenytoin

Phenytoin is a drug of choice and a highly effective medication for the stage of established status. Extensive clinical experience has been gained in adults, children and neonates, and phenytoin has proven efficacy in tonic–clonic and partial status. The drug has a prolonged action, with a relatively small risk of respiratory or cerebral depression and no tendency for tachyphylaxis. Its main disadvantage is the time necessary to infuse the drug and its delayed onset of action. However, the phenytoin prodrug fosphenytoin (see above) can be administered more quickly. The pharmacokinetics of phenytoin are problematic, with Michaelis–Menten kinetics at conventional dosages and wide variation between individuals. Toxic side-effects include cardiac rhythm disturbances, thrombophlebitis and hypotension. The risk of cardiac side-effects is greatly increased if the recommended rate of injection is exceeded, and cardiac monitoring is advisable during phenytoin infusion. There is a risk of precipitation if phenytoin is diluted in other solutions than 0.9% saline or if mixed with other drugs.

Usual preparations

A 5-mL ampoule containing 250 mg stabilized in propylene glycol, ethanol and water (alternatives exist, e.g. phenytoin in a Tris buffer or in infusion bottles containing 750 mg in 500 mL of osmotic saline).

Usual dosage

In adults, a 15–18 mg/kg i.v. infusion can be given via the side arm of a drip or preferably directly via an infusion pump at a rate not exceeding 50 mg/min (20 mg/min in the elderly). In children, a 20 mg/kg i.v. infusion is usually given, at a rate not exceeding 25 mg/min. The drug should never be given by i.m. injection as absorption is erratic and extremely slow.

Propofol

Propofol is the anaesthetic agent of choice for non-barbiturate infusional anaesthesia in status. It is an excellent anaesthetic with very good pharmacokinetic properties. In status, it has a very rapid onset of action and rapid recovery. There are few haemodynamic side-effects, and the drug has been used at all ages. There is, however, only limited published experience of its use in status, or indeed of prolonged infusions. Unlike isoflurane, it is metabolized in the liver and affected by severe hepatic disease. As with all anaesthetics, its use requires assisted ventilation, intensive care and intensive care monitoring. A particular risk is the propofol infusion syndrome, which is a term used to describe the occurrence of hyperkalemia, lipaemia, metabolic acidosis, myocardial failure, renal failure and rhabdomyolysis. It occurs usually on long-term infusion (>48 h) but has been reported even after only 5 h of infusion. It is much more common in young children (and indeed for this reason the use of propofol is relatively contraindicated in children). The syndrome is often fatal. It may be caused by drug-induced impairment of oxidation of fatty acid chains and inhibition of oxidative phosphorylation in the mitochondria, especially in the presence of high catecholamine and cortisol levels. Involuntary movements (without EEG change) can occur, and should not be confused with seizure activity. Rebound seizures are a problem when it is discontinued too rapidly, and a decremental rate of 1 mg/kg every 2 h is recommended when the drug is to be withdrawn.

Usual preparation
A 20-mL ampoule containing 10 mg/mL (i.e. 200 mg) as an emulsion.

Usual dosage
A 2 mg/kg bolus, repeated if necessary, and then followed by a continuous infusion of 5–10 mg/kg/h initially, reducing to 1–3 mg/kg/h. When seizures have been controlled for 12 h, drug dosages should be slowly tapered over 12 h.

Thiopentone/pentobarbital
Thiopentone is, in most countries, the usual choice for barbiturate anaesthesia. It is a highly effective AED, with additional potential cerebral protective action. It reduces intracranial pressure and cerebral blood flow, has a very rapid onset of action, and there is wide experience of its use. The drug has a number of pharmacokinetic disadvantages including saturable kinetics, a strong tendency to accumulate and a prolonged recovery time after anaesthesia is withdrawn. Indeed, severe sedation commonly lasts for days after a thiopental infusion, because of its tendency to accumulate and its slow clearance. Serum concentration monitoring of the parent drug and its active metabolite (pentobarbital) is advisable on prolonged therapy. There is often some tachyphylaxis to its sedative and, to a lesser extent, its anticonvulsant properties. Respiratory depression and sedation is inevitable, and hypotension is common. Other less common side-effects include pancreatitis, hepatic dysfunction and spasm at the injection site. Full intensive care facilities with artificial ventilatory support and intensive EEG and cardiovascular monitoring are needed. It can react with co-medication, and with plastic giving sets, and is unstable when exposed to air. Autoinduction occurs, and hepatic disease prolongs its elimination.

Usual preparations
Injection of thiopentone sodium 2.5 g diluted in 100 mL, and 5 g in 200 mL diluent, to make 100 mL and 200 mL of a 2.5% solution. Thiopentone sodium is also available as 500-mg and 1-g phials to make 2.5% solutions.

Usual dosage
A bolus of 100–250 mg i.v. given over 20 s, with further 50-mg boluses every 2–3 min until seizures are controlled, followed by a continuous i.v. infusion to maintain a burst suppression pattern on the EEG (usually 3–5 mg/kg/h). The dose should be lowered if systolic blood pressure falls below 90 mmHg despite cardiovascular support. Thiopentone should be slowly withdrawn 12 h after the last seizure.

Valproate
There is a long history of the use of valproate in status epilepticus because early on it was available as an i.v. formulation. However, only recently have randomized trials demonstrated potential as a treatment in status epilepticus, although these trials are inconclusive and used inferior or inappropriate comparators. The theoretical advantages of valproate are a low incidence of respiratory and cardiac depression (there are potentially major advantages), but other potential side-effects such as prolonged bleeding time, hepatic dysfunction, pancreatitis and hyperammonaemia have not been adequately assessed in large studies. Valproate should be avoided in patients with hepatic or mitochondrial disease.

Usual preparations
Injection of thiopentone sodium 2.5 g diluted in 100 mL, and 5 g in 200 mL diluent, to make 100 mL and 200 mL of a 2.5% solution. Thiopentone sodium is also available as 500-mg and 1-g phials to make 2.5% solutions.

Usual dosage
A bolus of 100–250 mg i.v. given over 20 s, with further 50-mg boluses every 2–3 min until seizures are controlled, followed by a continuous i.v. infusion to maintain a burst suppression pattern on the EEG (usually 3–5 mg/kg/h). The dose should be lowered if systolic blood pressure falls below 90 mmHg despite cardiovascular support. Thiopentone should be slowly withdrawn 12 h after the last seizure.

Introduction: the importance of prevention

The treatment of epilepsy has been focused on the treatment of seizures since epilepsy was first recognized as a disorder of the brain. This is in contrast to most other topic areas in medicine, in which the prevention of the disease is the focus of research and treatments, rather than simply the amelioration of symptoms. In recent years, the attention of scientists and clinicians has shifted somewhat to the investigation of the process of epileptogenesis and, to a more limited extent, towards the development of strategies to prevent epilepsy in those clearly at risk. This is particularly important for epilepsy as, at the present time, our ability to actually 'cure' someone who has already developed epilepsy is quite limited. Therefore, once an individual develops epilepsy, it is likely to be a condition that will persist throughout life. Even for those whose seizures are controlled with medication, it is uncommon to have no side-effects from the treatment. Moreover, individuals with epilepsy have problems beyond the seizures themselves (e.g. depression, cognitive impairment, endocrine dysfunction), which may remain unaffected by antiepileptic drugs (AEDs). Thus, prevention of this entire spectrum of the disorder is much more preferable than trying to treat the symptoms in a piecemeal, and often ineffective, manner.

Who is most at risk?

Identification of those at risk has not been a problem in many areas. There are a number of well-known risk factors with fairly predictable probabilities. Brain 'injury' is a category of risks that can be divided into different subgroups. One can examine traumatic brain injury, which will be the main thrust of this chapter, or can include several other 'injuries', such as neurosurgical procedures, stroke, status epilepticus, infections (both meningitis and encephalitis), the presence of mass lesions, and even chronic neurodegenerative diseases. In addition, since this chapter is focused on prevention, one can examine the known risks associated with primary genetic disorders, both those that are manifest by epileptogenic structural lesions, such as tuberous sclerosis (TS), or those commonly considered as 'channelopathies', such as the families of primary generalized epilepsies. These are conditions that can be identified before the development of epilepsy, and thus, at least theoretically, would be amenable to a prevention strategy.

One of the authors (Dichter) has proposed that we identify a new syndrome, the *RED syndrome*, i.e. the syndrome of risk of epilepsy development. Once we recognize this syndrome, we can identify individuals who clearly have the RED syndrome, such as those with moderate or severe traumatic brain injury (TBI), or young children with TS, and recognize that they need treatment for the RED syndrome in order to prevent the progression to epilepsy. Of course, we first need to develop appropriate treatments, but until we, as a community, agree on the nature of the problem, it is unlikely that we will find appropriate solutions.

What are the risks? Among the most well-characterized risks is TBI. Moderate to severe TBI, with either blood in or around the brain, or a penetrating brain injury, carries a risk of ~30% in the civilian population and as high as 50% in military populations [1–4]. Less severe TBI is associated with a lower risk, but it is only with very mild TBI that the risk is below 3–5%. Spontaneous intracerebral haemorrhage, without associated TBI, is associated with a 8–13% risk [5,6] of developing epilepsy over 5 years. The risk after ischaemic stroke has been more difficult to quantify, possibly because ischaemic strokes can occur in many different parts of the brain, some of which are clearly epileptogenic, whereas others have a very low risk (e.g. brainstem strokes). Most estimates would put the risk at somewhere between 5% and 25%, depending on the type of ischaemic stroke, its location and the duration of the follow-up studies [7,8], although others suggest a risk as low as 3% [9]. Interestingly, a large number of stroke intervention clinical trials have been implemented over the last 25 years, with probably tens of thousands of patients enrolled. As far as can be determined, none of these trials has followed patients long enough to determine what the short-, intermediate- and long-term risks for subsequent development of epilepsy might be in this well-characterized population.

After an episode of status epilepticus, the risk of subsequent epilepsy probably approaches 50% [10]. In this population, it is

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

difficult to separate those who might already have developed epilepsy, and for whom the episode of status was their 'first' seizure, from those who developed status for some other reason and then went on to develop chronic epilepsy. In addition, it is not uncommon for an individual who presents in status to be diagnosed with 'encephalitis' based on a few cells and high protein in the cerebrospinal fluid (CSF), both of which might be a consequence of the prolonged seizures rather than evidence of an infectious process. Of interest, it is well established that normal animals who experience a bout of prolonged status epilepticus will develop brain injury and epilepsy over time, so it is quite plausible that otherwise 'normal' humans who develop, for whatever reason, a bout of prolonged seizures may develop chronic epilepsy as a result.

In children with febrile seizures, it is commonly believed that isolated, brief, generalized seizures in the presence of high fevers or ascending fevers represent a benign condition and are not a significant risk factor for subsequent development of epilepsy. On the other hand, focal seizures, prolonged or repetitive seizures, or a combination thereof, are associated with significant risks of subsequent epilepsy, which may be as high as 50% for a child with prolonged focal seizures [11]. A major question associated with these data is whether a child who experiences this kind of 'febrile' seizure had a pre-existing epileptogenic lesion that was 'exposed' by the high fever, or whether the prolonged complex febrile seizure was, in itself, the cause of the subsequent epilepsy. An ongoing study, FEBSTAT [12], is currently under way to image such children soon after their first seizures and then follow them for several years to investigate the possible underlying pathophysiological nature of the problem.

Individuals undergoing craniotomies for any reason are at risk for developing epilepsy. Although it is difficult to separate the risk of seizures caused by a neurosurgical procedure from the risk associated with the reason for the procedure, over 20% of adults develop unprovoked seizures within 2 years of a supratentorial craniotomy. Several antiepileptogenesis clinical trials have been conducted in this situation [13–17]. Most have had relatively small numbers of cases with specific indications for surgery, but the seizure rates in these subgroups give an indication of subgroups with particularly high or low risk, e.g. over 35% chance of unprovoked seizures in those with surgery for arteriovenous malformation, aneurysm in the middle cerebral artery circulation or brain metastases. Scheduled supratentorial neurosurgery provides an unusual opportunity for testing agents that may prevent epilepsy. As was done by Shaw and colleagues [15,17,18], the study treatment can be started prior to scheduled surgery so drug concentrations are already at desired levels before the surgery begins.

Another category of 'brain injury' that is often neglected when discussing risk factors and possible epilepsy prevention is the progressive injuries that occur as a result of chronic neurodegenerative diseases. The incidence of new-onset epilepsy is significantly increased in the population over age 65 [19]. In fact, the incidence in the ageing group is even higher than in young children. The aetiology of epilepsy in this cohort is not completely understood, but cerebrovascular disease, even 'silent', may well be a major cause. However, even after relatively exhaustive examination, in about half the cases, no clear aetiology can be identified. It is well established that individuals with Alzheimer's disease have a higher incidence of epilepsy than their age-matched peers [20,21]. The more clearly identified seizures tend to occur relatively later in the course of the disease, although in familial Alzheimer's disease cases, seizures may present much earlier. Interestingly, Alzheimer's disease patients, even early in the course of their disease, often show fluctuations in their cognitive functions that are not inconsistent with possible partial seizures. A recent study of transgenic mice with an Alzheimer's disease phenotype produced by the expression of a human amyloid mutation demonstrates that these mice exhibit frequent partial seizures, recorded with electrodes implanted into the brains, with a clinical phenotype consisting only of brief staring spells [22]. Extrapolation of these findings to human patients could suggest that some of the variable cognitive performance exhibited by Alzheimer's disease patients might be the result of unrecognized partial seizures.

The presence of mass lesions in or around the brain is another 'risk factor' for epilepsy. Meningiomas, gliomas, tubers and arteriovenous malformations are often accompanied by partial seizures and, in fact, may present as seizures. Identification of these risk factors before seizures develop often occurs because of other neurological symptoms, and it would be possible to treat these individuals to prevent the later development of seizures if such a treatment were available.

Finally, one needs to recognize that even individuals with primary generalized epilepsy that clearly results from a genetic cause almost always develop their seizures well after birth and, thus, would be candidates for a preventative strategy. It is thought that most of these genetically determined epilepsies are a result of a 'channelopathy', which lowers seizure threshold in an anatomically diffuse manner. However, it is possible that treatment before seizures begin could prevent their onset and subsequent consequences of the seizures themselves.

Although the focus of this chapter will remain on the possible treatment of post-traumatic epilepsy, we will continue to discuss possible prevention strategies for other major epilepsy risks. It is possible, if not likely, that if a strategy would work in one form of acquired epilepsy, it might be useful in others as well.

When discussing risk factors for epilepsy, the individual's age and genetic background must be considered as major modifying variables. The consequences of seizures, or brain injuries, in very young children are often significantly different than in older children or adults. For example, bacterial meningitis in young children may result in hippocampal damage, whereas similar infections in older individuals may produce predominantly neocortical damage. In the experimental animal literature, the effects of status epilepticus on very young subjects are often very different than the effects in adult animals, with the young brains being much more resistant to structural damage. Similarly, even febrile seizures in very young animals may have different consequences from similar seizures in older animals. The absence of overt structural damage, however, does not mean the absence of significant neurological deficits, as the young animals may show increased vulnerability to later stresses than their peers. Thus, even when 'damage' is not apparent from an early 'insult', prophylactic measures may be warranted to prevent subsequent epilepsy.

Animal models of epileptogenesis and antiepileptogenesis

Status epilepticus

The most commonly used brain 'insult' to study chronic epileptogenesis has been experimentally induced status epilepticus. Administration of drugs such as pilocarpine or kainic acid will produce focal and generalized seizures in essentially every mammalian species sampled. Similarly, prolonged repetitive brain stimulation can also induce self-sustaining status epilepticus. The status produces widespread damage to neocortex, hippocampus, parahippocampal structures and multiple other areas of forebrain. Depending on the species and strain used, most animals will develop spontaneous seizures within days or weeks of the status. This situation is analogous to human patients who develop chronic epilepsy after an episode of prolonged status epilepticus. Many changes have been identified in the status-injured brain, but the exact mechanisms by which any of these alterations in anatomy, physiology and gene expression produces the chronic epileptic state remain unknown. Numerous attempts have been made to prevent the epileptogenesis in this model but none have succeeded completely. If the convulsive status is blocked by pretreatment of the animals, brain damage can be eliminated and epilepsy does not develop. The degree of damage is dependent on the duration of the status, and administration of drugs that abort the status relatively quickly, such as phenobarbital or other anaesthetics, can reduce the damage and either delay or eliminate the chronic epilepsy. No treatments administered after the status is over have been successful in preventing epilepsy [23,24], although it may be possible to lessen the severity [25]. A variety of AEDs have been tested in this paradigm without success [24].

Kindling

Another commonly used model of epileptogenesis is kindling. Repeated electrical stimulation of the brain with brief trains of stimuli which are not strong enough to evoke seizures but which do evoke afterdischarges (i.e. synchronous EEG spikes lasting beyond the period of stimulation) are applied to a specific area of the brain (e.g. amygdala, hippocampus). Over time, the afterdischarges increase in duration, then begin to spread to other brain regions, and eventually result in generalized seizures. If the process is continued, the animals will eventually develop chronic epilepsy. This form of epilepsy induction results in much less damage to the brain, but is manifest by a variety of changes in local circuits and gene expression. The exact cause of the epilepsy remains unknown, however. Numerous attempts have been made to block the kindling process with AEDs and other medications. In general, if the afterdischarges can be blocked, the kindling process may be blocked. Among the drugs tested, phenobarbital, topiramate and levetiracetam have shown some activity in blocking the kindling process [23,26].

Traumatic brain injury

To date, most experimental studies of TBI have focused on minimizing the damage from the TBI or enhancing a functional recovery. More recent work in a few laboratories has focused on the process of epileptogenesis after brain injury [27]. Injury to neocortex with a controlled lateral percussion has been shown to result in secondary injury to limbic structures, including hippocampus, and has also been linked to increased excitability in hippocampus [28]. More recent work has demonstrated that after some forms of experimental TBI, focal seizures develop around the area of injury. Over time (days to weeks), these seizures can become larger, spread to nearby and distant areas of cortex and become more behaviourally apparent [29,30]. Few data are available about the possible prevention of these seizures after the TBI.

Other forms of 'injury'

For many years, it has been known that if cortex is injured by undercutting its white matter, it becomes hyperexcitable. A number of changes have been identified in these regions that may contribute to the hyperexcitability. Recently, it has been demonstrated that if the undercut cortex is treated with drugs that block action potentials for a critical period after the lesion, the hyperexcitability does not develop [31,32]. Translating these findings into treatments that might be applicable to larger injured area of brain is currently being pursued.

Dysplasias and tumours

As mentioned above, structural lesions in cortex can be very epileptogenic and may be identified before the epilepsy develops. In a transgenic model of tuberous sclerosis, the administration of rapamycin, a drug that acts specifically on the molecular pathway involved in TS, can prevent the development of cortical tubers and can also prevent the development of epilepsy [33].

Primary genetic epilepsy

Many rodent models of primary generalized epilepsy are known. In general, the seizures in these animals respond to many of the same agents that are used to treat similar seizures in humans. Recently, it has been demonstrated that treatment prior to the development of either the EEG trait (spike-and-wave discharges) or the seizures in one form of primary genetic epilepsy results in the prevention of both, as well as the prevention of other, downstream, molecular changes that occur as a consequence of the seizures [34]. These experimental results, along with those from the undercut cortex and TS mouse cited above, can be interpreted as 'proof of principle' experiments demonstrating that epilepsy prevention may be both possible and feasible.

Biomarkers for epileptogenesis

For both experimental studies and human clinical trials, biomarkers that track with the process of epileptogenesis would be extremely useful. Currently, a number of laboratories are investigating biomarkers in TBI, but these are focused on determining the presence and extent of damage to the CNS rather than on the process of epileptogenesis. The main emphasis on biomarkers for epileptogenesis is focused on electrophysiological and imaging biomarkers. Animal data suggest that the presence of EEG spikes, and possibly high-frequency oscillations, may accompany the process of epileptogenesis, and be present before the seizures [35,36]. In human patients, very few data exist on this point. Similarly, researchers are trying to identify specific magnetic resonance imaging (MRI) changes that may accompany

epileptogenesis, specifically hippocampal atrophy and circuit alterations [37].

Is neuroprotection equal to antiepileptogenesis?

As mentioned above, if one can prevent the damage from a brain injury such as occurs after status epilepticus, one can often prevent the subsequent appearance of epilepsy. What is less clear, however, is the extent that partial protection of the brain will also lower the incidence or severity of epilepsy. There are some experimental data that support both sides of this conclusion, but it seems clear that only partial protection is not sufficient to block epileptogenesis reliably.

Human studies of antiepileptogenesis

Over 40 clinical trials have been conducted with a goal of preventing seizures or epilepsy. Almost all have evaluated drugs that are used to treat epilepsy or to suppress seizures. A meta-analysis of the trials with different drugs and different risk factors has been performed [38]. It is helpful to consider trials for provoked seizures separately from those for unprovoked or epileptic seizures. It is also helpful to differentiate treatments that suppress seizures from those that alter the process that causes the brain to generate seizures. Most drug treatments for established epilepsy are of the former variety. When they are at a sufficient concentration, seizures are reduced or eliminated. When the drug is stopped, the seizures return without apparent alteration to the underlying process. Antiepileptogenic treatments, on the other hand, alter the process so that seizures do not occur (or their onset is delayed), even when no seizure-suppressing treatment is present.

Provoked seizures

Provoked seizures occur during or soon after an acute insult. Febrile seizures are the most common provoked seizures. Alcohol-related seizures, contrast media-associated seizures, seizures due to metabolic derangements or infections, and seizures soon after an insult such as a TBI, stroke, aneurysm rupture, or craniotomy are other examples of provoked seizures. In the latter cases, there is no clear demarcation when the 'provocation' ends. Most authors have considered seizures within a week of the insult to be provoked and ones which occur later to be unprovoked or epileptic. The former are often called 'early seizures' and the latter are called 'late seizures'. In virtually every trial to prevent provoked seizures, the therapy tested is itself one that can suppress seizures and it is continued during the period of evaluation. Thus, these trials cannot separate a seizure-suppressive treatment from one which is antiepileptogenic.

The results of meta-analyses of these trials are presented in Figure 19.1. Fourteen trials evaluated five treatments to prevent febrile seizures in children at high risk. Continuous phenobarbital decreased the number of children with additional febrile seizures by about half. Continuous valproate and diazepam, given when a fever is noticed, have results that are promising but unproven, with an effect that is not significantly decreased from that with placebo but with an estimated decrease of at least 25%. Phenobarbital given during a fever or continuous phenytoin had less encouraging results. Phenytoin decreased early seizures after TBI by about two-thirds and carbamazepine decreased them by about 60%. Phenobarbital and the combination of phenobarbital and phenytoin was promising but unproven. Phenytoin similarly decreased early seizures significantly after supratentorial craniotomy and carbamazepine was promising but unproven. Phenobarbital decreased seizures associated with acute cerebral malaria by about two-thirds, and looks promising but unproven for perinatal asphyxia, early seizures after TBI, and early seizures after surgery for brain tumours. Diazepam reduced contrast media-associated seizures by about 90%. Lorazepam decreased alcohol-related seizures by a similar amount, while valproate and phenytoin are promising but unproven for alcohol-related seizures.

All of the above results are based on only clinically reported seizures. Continuous EEG monitoring during the first week after seizures indicates that subclinical seizures are very common and may not be suppressed by standard administration of phenytoin [39,40].

Prevention of epileptic seizures

Traumatic brain injury

Late seizures after TBI have been best studied for the prevention of unprovoked seizures. The initial study conducted by one of the authors (Temkin) at the University of Washington is illustrative of the designs used for the TBI trials [41]. For that study, people whose injury presented at least a 20% risk of unprovoked seizures were randomized to active treatment or identical-appearing placebo and loaded with study drug within 24 h of injury. The initial dose was chosen to produce concentrations within the therapeutic range for treatment of epilepsy. Drug concentrations were monitored at least three times per week in the intensive care unit (ICU), weekly in acute care, and at scheduled visits, and the dose adjusted to keep concentrations within the therapeutic range for the active drug and to maintain masking of placebo. Lorazepam was allowed to treat early seizures, but the participants were supposed to remain on their assigned treatments until either their first unprovoked seizure or one year after injury. Subjects were followed until 2 years after injury so that a seizure-suppressive effect could be separated from an antiepileptogenic effect. Results of the study were that phenytoin reduced early clinical seizures as reported above, but unprovoked seizures were not reduced at all, even during the period of treatment. A total of 27.5% of participants assigned to phenytoin and 21.1% of those assigned to placebo had at least one unprovoked seizure by 2 years. Because not even a suppressive effect was seen, the planned analysis looking for an antiepileptogenic effect (comparing time to first seizure with 18 months after injury) was not reported. A second study at the University of Washington evaluated valproate [42]. The design was similar, but participants in the control arm received 1 week of phenytoin followed by placebo to 6 months after injury. Those assigned to valproate received active drug for either 1 or 6 months and then placebo until 6 months after injury. The results were again disappointing, with a non-significant increase in the late seizure rate with valproate.

The results of the meta-analyses are no more encouraging (see Fig. 19.1). The University of Washington study is the only one to evaluate valproate. Overall, phenytoin was associated with a

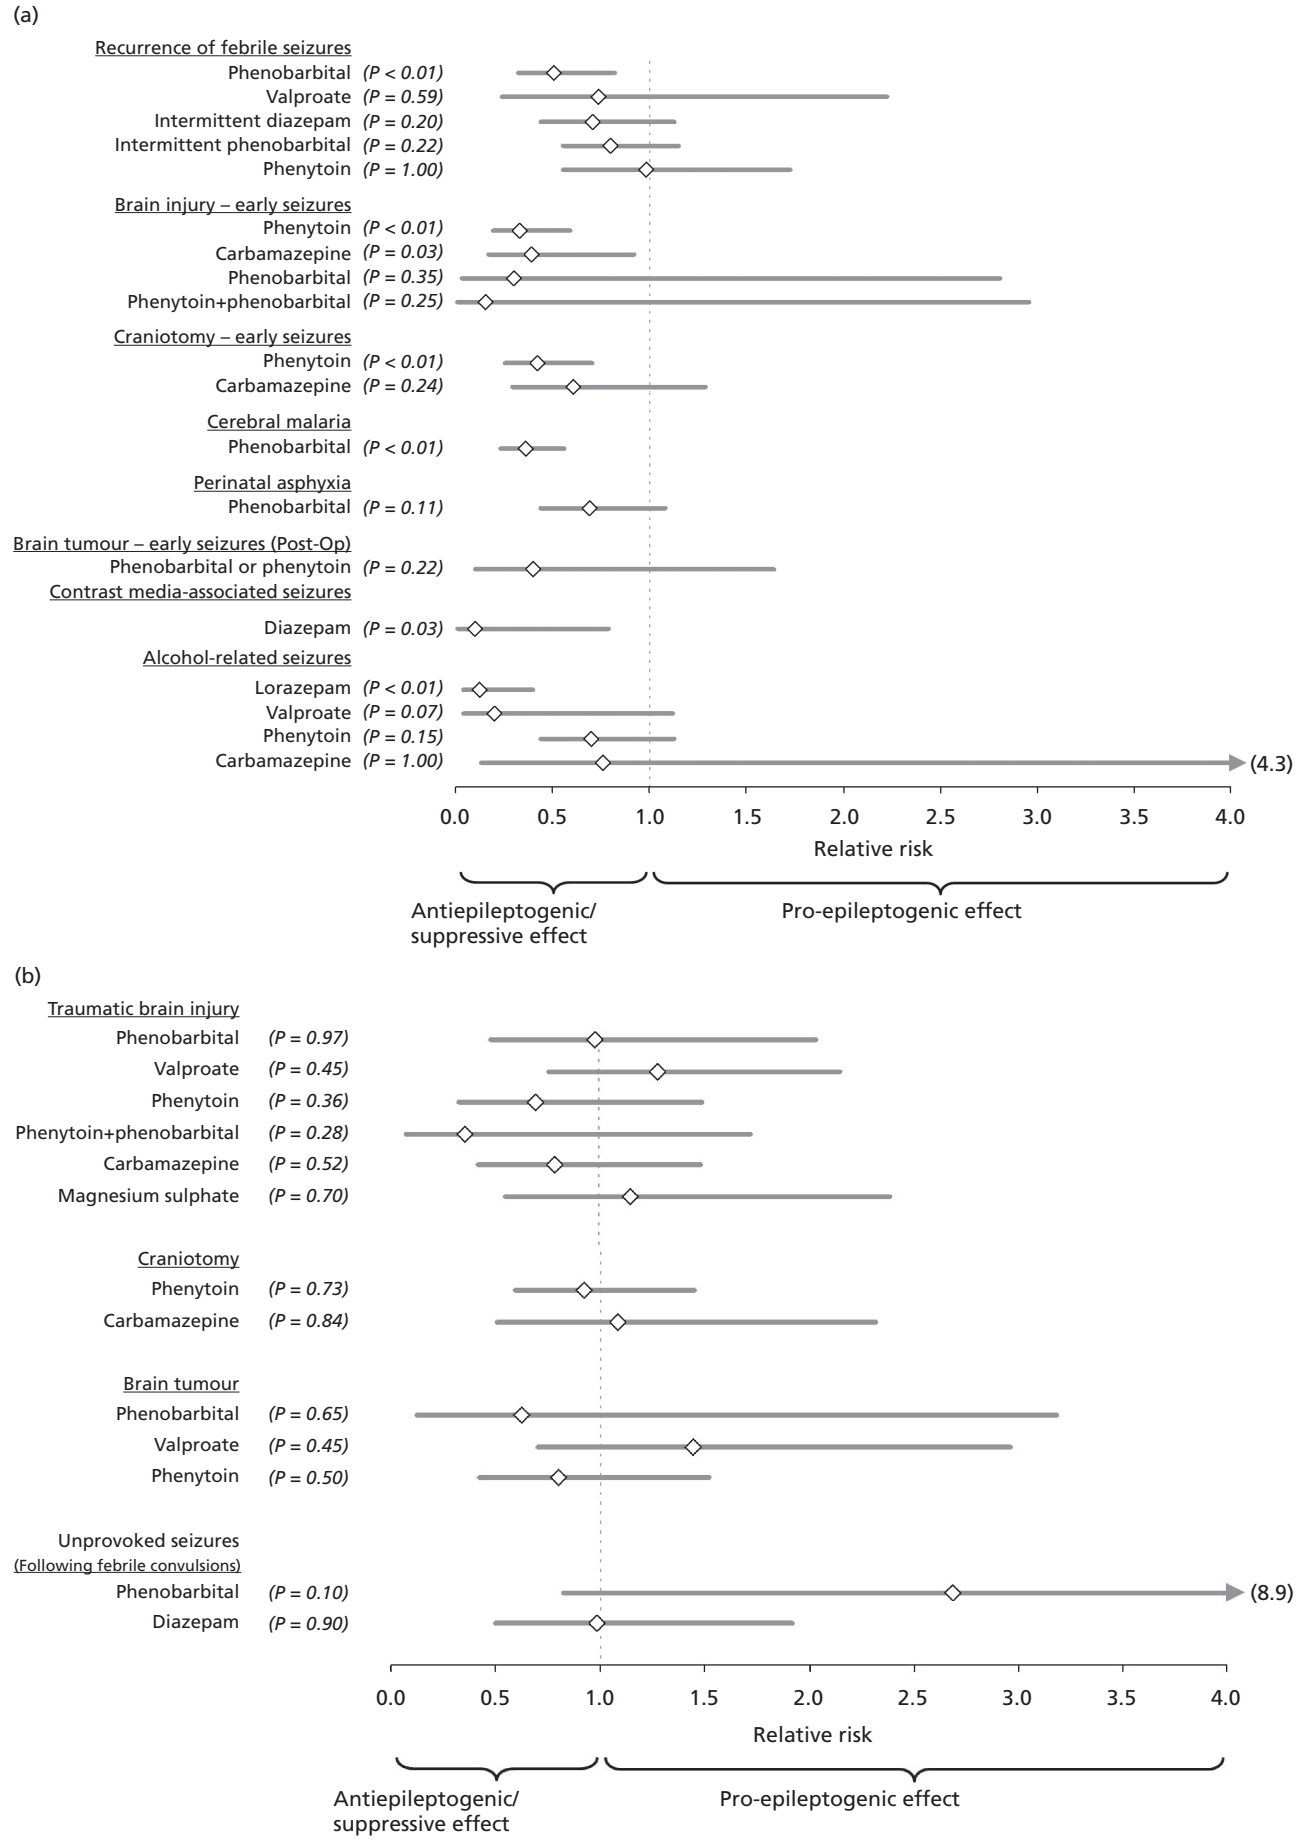

Fig. 19.1 (a) Meta-analyses of studies to prevent provoked seizures. For each condition and drug, the diamond marks the overall relative risk estimate from all studies combined. The line extends to the ends of the 95% confidence interval. A relative risk of 1, representing no treatment effect, is marked by the dashed vertical line. (b) Meta-analyses of studies to prevent epileptic seizures. Results are presented as in part (a). Adapted from ref. 38, with permission.

promising but unproven 30% reduction in late seizures after TBI, but this is driven by a single study with methodological problems (no masking, no placebo and treatment assigned depending on the date rather than by randomization). If only randomized studies are included, phenytoin was associated with a non-significant, 8% *increase* in the number of cases with unprovoked seizures, and the randomized studies in aggregate are compatible with no more than a 24% decrease in the fraction of cases with late seizures. Neither phenobarbital alone nor carbamazepine look promising. The combination of phenobarbital and phenytoin, while having a reduction of two-thirds in the rate of unprovoked seizures, is based on a single study that was stopped early, so even such a large reduction is far from statistically significant ($P > 0.25$). The single study of a drug not generally considered to suppress seizures evaluated magnesium sulphate beginning within 8 h of injury and continuing for 5 days by continuous infusion. Neither early nor late seizures were reduced [43].

Craniotomy

Studies of late seizures after craniotomy are equally disappointing. Neither phenytoin nor carbamazepine shows anywhere near a significantly positive effect, even though the treatment was begun several days before the surgery.

Brain tumours

In studies attempting to prevent seizures in patients with brain tumours, valproate and phenytoin did not look promising, while the 40% reduction with phenobarbital was from a study that was so small that even that reduction was not close to statistical significance ($P = 0.65$).

Febrile seizures

Several studies evaluating diazepam and continuous and intermittent phenobarbital for prevention of febrile seizures followed their cases for years after treatment stopped to see if the treatment affected epileptogenesis. The number of unprovoked seizures was small and there was no suggestion of an antiepileptogenic effect.

Febrile status epilepticus

Children with prolonged and/or complicated seizures associated with fever are at high risk for developing chronic epilepsy. The exact risk is unknown, as is the question of whether such children had a prior neurological abnormality which was exacerbated by the febrile illness and was the true underlying basis for the episode of status. Recently, a co-operative epidemiological study (FEBSTAT) was developed to study children with new-onset status epilepticus associated with fever, but without other obvious cause, to determine the nature of the brain injury sustained by these children, their true risk for developing chronic epilepsy, and to attempt to identify possible biomarkers associated with the development of epilepsy after febrile status [12]. One long-term goal of this study is to try to intervene in those children at high risk so as to prevent the development of epilepsy.

Dysplasias

Although the focus of this chapter is on the prevention of epilepsy after injuries to the brain, it is worth briefly considering other epilepsy prophylaxis studies as well. Individuals with tuberous sclerosis, especially those with intracranial tubers, are at very high risk for developing epilepsy. These individuals can often be identified by family history. Recent laboratory experiments have demonstrated that transgenic mice with the *TS1* mutation will also develop seizures and that the seizures can be prevented by treatment with rapamycin [33]. Unfortunately, the mice require permanent treatment to prevent the seizures. If treatment is stopped the seizures may start. Recently, a pilot clinical trial was initiated to treat children with this mutation with rapamycin to try to prevent epilepsy. Long-term efficacy and safety will need to be carefully established before such treatment becomes acceptable in human patients. However, if this trial is successful, it will be the first demonstration of a prophylactic treatment preventing or even postponing epilepsy in humans.

Limitations of the clinical trials performed to date

The trials performed to date, while disappointing with respect to affecting epileptogenesis, cannot rule out the possibility that these drugs might have an effect. Most studies were small, and even combining their results through meta-analysis cannot rule out a modest effect in all cases and even a substantial effect in many. The doses used were based on what is usual for treating epilepsy and may not be the correct dose for affecting epileptogenesis. Even in the case of early seizures, in which several drugs suppressed clinical seizures, we do not generally know if electrical seizures were also suppressed. Most studies could begin treatment out to 24 h after the insult and that might be too long to affect the process, although the study of planned craniotomy that started treatment prior to surgery showed no more encouraging results. After participants were discharged from the hospital, studies could not ensure compliance. The University of Washington studies measured serum concentrations at scheduled visits and they generally reflected the level of compliance reported by the participants, but that does not ensure that the drugs were taken as consistently between visits. The closest to random serum concentrations were obtained when a participant came into the emergency department because of a seizure. Of the nine patients in whom this occurred, seven had concentrations in the desired range.

Studies that have been carried out have not been based on extensive preclinical work. Although it seems reasonable that a drug that suppresses seizures might prevent them from developing, this has not been demonstrated for any of the AEDs evaluated to date. Dose, critical time window and necessary duration have also not been evaluated in preclinical models. Magnesium was evaluated based on its general neuroprotective effect in the laboratory and its ability to prevent seizures in women with pre-eclampsia, not on a demonstrated antiepileptogenic effect in the laboratory. With the recent development of post-traumatic seizure models, one might expect more knowledge about what is happening in the clinically silent period between the injury and the clinical expression of seizures. This in turn could allow treatments that target specific parts of the process and might truly be antiepileptogenic. If the effects are borne out in clinical trials, these could provide the treatments for those with RED syndrome.

Treatment of post-traumatic epilepsy

Pharmacological treatment of seizures

Seizures developing after TBI are localization-related partial seizures and are treated the same as partial seizures, without, or with, secondary generalization, due to any other cause. There is no evidence that any of the AEDs that are effective in treating partial seizures are more or less effective for post-traumatic epilepsy (PTE). However, there are some special issues that should be considered when choosing among the many available AEDs. Patients with TBI often have problems beyond their seizures, including cognitive, motor and psychological problems resulting from the TBI. These factors must be considered when choosing a first AED. For example, if an AED that may have cognitive side-effects, such as topiramate, is chosen, it is important to carefully monitor the patient for additional cognitive difficulties that could be related to the drug as opposed to the brain injury. Similarly, with medications that may have behavioural side-effects, such as levetiracetam, zonisamide or phenobarbital, careful monitoring of the patient's behaviour after addition of the drug needs attention. In addition, individuals with moderate to severe brain injury may have a compromised level of consciousness; thus, sedating medications should be avoided. In general, all available AEDs have potential side-effects, even if in a small minority of patients, and these may be exacerbated in an individual with significant pre-existing morbidity due to the TBI.

Of particular concern in this group of patients is the issue of non-convulsive seizures. Individuals with TBI may have cognitive and behavioural changes due to the TBI. In addition, however, if such individuals develop non-convulsive partial seizures, the major clinical manifestations of which are periodic decreases in cognitive function or periodic behaviour changes, these seizures may not be recognized and will go untreated. This is particularly problematic in this patient population because these unrecognized seizures can add significantly to the patient's disabilities while being potentially treatable. Even physicians might not recognize the symptoms as being caused by non-convulsive complex partial seizures. What makes this issue even more difficult is that the background EEG may be abnormal but this is attributed to the effects of the TBI itself and even prolonged EEGs may not demonstrate the seizures if they are occurring deep in the brain and are not conducted to the surface of the neocortex. Comprehensive epilepsy centres with large presurgical evaluation programmes commonly see patients whose seizures are only noted on depth electrodes and are not detected in scalp recordings. When such non-convulsive seizures are suspected, a short trial of antiepileptic medication may be the only way to make a correct diagnosis and help the patient. Moreover, increased education of patients, family members, other care providers and all of the medical professionals who deal with TBI patients should be developed to ensure that such paroxysmal changes in cognitive function or behaviour are recognized as potential complex partial seizures.

Surgical treatment of intractable seizures after traumatic brain injury

Individuals with uncontrollable partial seizures may be candidates for ablative surgery for seizure control. Those with a well-localized seizure focus that exists in an area of brain that can be safely removed are the best candidates for epilepsy surgery. This may apply specifically to individuals that sustain unilateral temporal lobe damage, either directly or secondary to the hypoxia and hypotension that may accompany severe trauma. Unfortunately, most individuals with moderate to severe TBI who develop PTE have multifocal brain lesions, many of which could be epileptogenic. It is possible that careful studies will be able to localize the source of the seizures to a region that can be removed safely, but, in general, this is likely to be much more difficult than localization of seizure foci from other causes. In addition, the presence of extensive, multifocal brain injuries will make it more difficult to determine whether removal of any specific epileptogenic region can be performed without leaving the patient with additional deficits. Thus, although epilepsy surgery is sometimes a viable option for achieving seizure control after TBI, it requires a careful case-by-case evaluation and a recognition of the complications inherent in this group of patients.

Recommendations

Currently, administration of phenytoin for 1 week is recommended for treatment after TBI to suppress early clinical seizures. There is good evidence, however, that phenytoin does not reduce the risk of subsequent chronic epilepsy. Despite this, many neurologists and neurosurgeons maintain their patients on phenytoin. More recently, there has been a tendency to utilize several of the newer AEDs for prophylaxis, especially levetiracetam because of its ease of use, but there are no data to indicate that levetiracetam is as efficacious as phenytoin for preventing early seizures, nor if it is useful for preventing chronic epilepsy. It is clear that more well-designed clinical trials are needed to establish whether newer AEDs are as effective, or more effective, in preventing early seizures. Study of levetiracetam after TBI is currently in the pilot/planning phase. Because phenytoin may be more effective in suppressing clinical seizures than electrographic seizures, these studies need to be carried out with long-term EEG monitoring, at least during the first week after TBI. It must also be mentioned that there is suggestive evidence that treatment with some AEDs after stroke or TBI may retard recovery from the injury [44,45]. This was not seen in the controlled trials of phenytoin after TBI, however [46]. Future studies of epilepsy prevention need to consider this when examining outcomes.

Experimental animal research suggests that small localized seizures may occur early after TBI and that these seizures may not be seen with scalp recordings. It is not clear if suppression of such seizures would lead to an antiepileptogenic outcome, but this is a reasonable hypothesis. In addition, other experimental studies have suggested that the early appearance of interictal spike discharges, or high-frequency oscillations, may also act as biomarkers of the process of epileptogenesis. Each of these phenomena would be much more likely to be identified with chronic EEG recording from intracranial electrodes. Currently, such recordings are not a part of our clinical repertoire, but it is possible that in the future it will be desirable to consider such recordings, if they can be accomplished in a safe and minimally invasive manner, as part of a routine seizure prophylaxis protocol.

Similarly, although we can identify potentially epileptogenic lesions by brain imaging, the development of specific imaging biomarkers for the process of epileptogenesis after TBI or other brain insults has not yet been established. This is another area in which non-invasive investigations may allow us to identify those at highest risk and tailor new therapies accordingly.

As the process of epileptogenesis, whether after TBI or any other injurious process, is better understood from a mechanistic perspective, it is hoped that specific therapies can be directed against the critical processes to prevent the development of chronic epilepsy. Such new therapies may be quite different from conventional antiseizure therapies and could, for example, involve temporary interference with specific gene expression patterns that occur after injury. This is the dream of much of current epilepsy research. However, even if such strategies can be developed in the laboratory, it will still require careful clinical protocols, with relatively long-term follow-ups, to demonstrate their effectiveness and safety in human patients. Designing such clinical trials and establishing the infrastructure for their implementation is one of the major challenges in contemporary clinical investigation in epilepsy.

20 Management of Medical Co-morbidity Associated with Epilepsy

Gagandeep Singh
Dayanand Medical College and Hospital, Ludhiana, India

Introduction

Co-morbidity is a term that refers to the occurrence of one or more additional disease(s) in an individual with an index disease (herein, epilepsy) [1]. Although not necessarily the case, the index and co-morbid disorder(s) may have some bearing on the incidence, course and treatment of the other. Physicians involved in specialized epilepsy care frequently encounter co-morbidity. The association between epilepsy and several psychiatric disorders is well known and is an example of co-morbidity (this topic is reviewed in Chapter 21 and is not considered further here). Multimorbidity, on the other hand, is a term referring to the concurrent occurrence of several chronic disorders generally requiring treatment in an individual, commonly used in the context of general practice. The occurrence of seizures requiring treatment in an elderly individual with cardiac disease, prostatism, and mild age-related renal impairment is an example of multimorbidity. Physicians involved in specialist epilepsy practice frequently encounter co-morbidity, while primary care physicians involved in epilepsy care in the community have to deal with multimorbidity, epilepsy being one of the many components. Both co-morbidity and multimorbidity are commonly encountered in the treatment of epilepsy. However, in comparison with psychiatric disorders, the medical (or somatic) co-morbidity of epilepsy is less well appreciated. From the epidemiological standpoint, an increased mortality due to cardiovascular disorders, pulmonary disorders as well as certain cancers has been noted in people with epilepsy [2,3]. Limited data also exist on the incidence and nature of somatic disorders experienced by people with epilepsy during their lifetime. These data suggest that the prevalence rates of cardiovascular disorders, infections, pulmonary disease and gastrointestinal haemorrhage are increased in this population [4]. Reviewed here are aspects of the medical co-morbidity of epilepsy that are important from the clinical standpoint. Several disorders are considered, including hepatic and renal impairment, infectious disorders, connective tissue diseases and pulmonary and cardiac disorders.

Relevant to the co-morbidity of these disorders with epilepsy is the modification of the treatment of the latter imposed by these medical conditions. Furthermore, several medical disorders may arise during the course of epilepsy as a consequence of its treatment (e.g. disorders of bone). The prevention, recognition and treatment of these disorders are an integral component of comprehensive epilepsy care.

Bone health in epilepsy

Although the effects of epilepsy and its treatment on bone structure and function have been investigated for many years, the clinical implications of this interaction have been appreciated only very recently. Two skeletal disorders (i.e. osteomalacia and osteoporosis) are noteworthy in consideration of the impact of epilepsy and antiepileptic drugs (AEDs) on bone health. Osteomalacia is a disorder in which mineralization of the bone is selectively impaired, most often due to deficiency of vitamin D, and osteoporosis refers to generalized loss of bone mass with profound decline in microarchitectural organization leading to a propensity to bone fractures. Although the two disorders do not directly fall within the scope of epileptological practice, a growing recognition of the frequency of occurrence of both osteomalacia and osteoporosis in people with epilepsy demand of the epileptologist the necessary skills to be able to screen and counsel about bone health.

Overview of bone physiology and biochemistry

The bone comprises mineral made up for the most part by calcium and collagenous matrix. Predictably, therefore, disorders of calcium homeostasis affect bone structure and function. The metabolism of calcium in the human body is rather complex and is regulated by two hormonal factors: vitamin D and parathyroid hormone (Fig. 20.1). Vitamin D is acquired from diet and through the skin as a result of sunlight exposure. Accordingly, exposure to sunlight and dietary items such as cereals and fish oils are the principal sources of body stores of this vitamin. In the human body, vitamin precursors acquired through skin and diet are first hydroxylated in the liver to 25-hydroxyvitamin D_3, which is the measurable fraction of the vitamin in plasma. The 25-hydroxyvitamin D_3 is subsequently hydroxylated again in the kidney. The final product, 1,25-dihydroxyvitamin D_3, is the active form of the vitamin as it mediates absorption of calcium in the gut and mobilization of calcium from the bone in addition to exerting a negative feedback control over the secretion of parathyroid hormone by the parathyroid glands. The parathyroid hormone itself induces the mobilization of calcium from the bone.

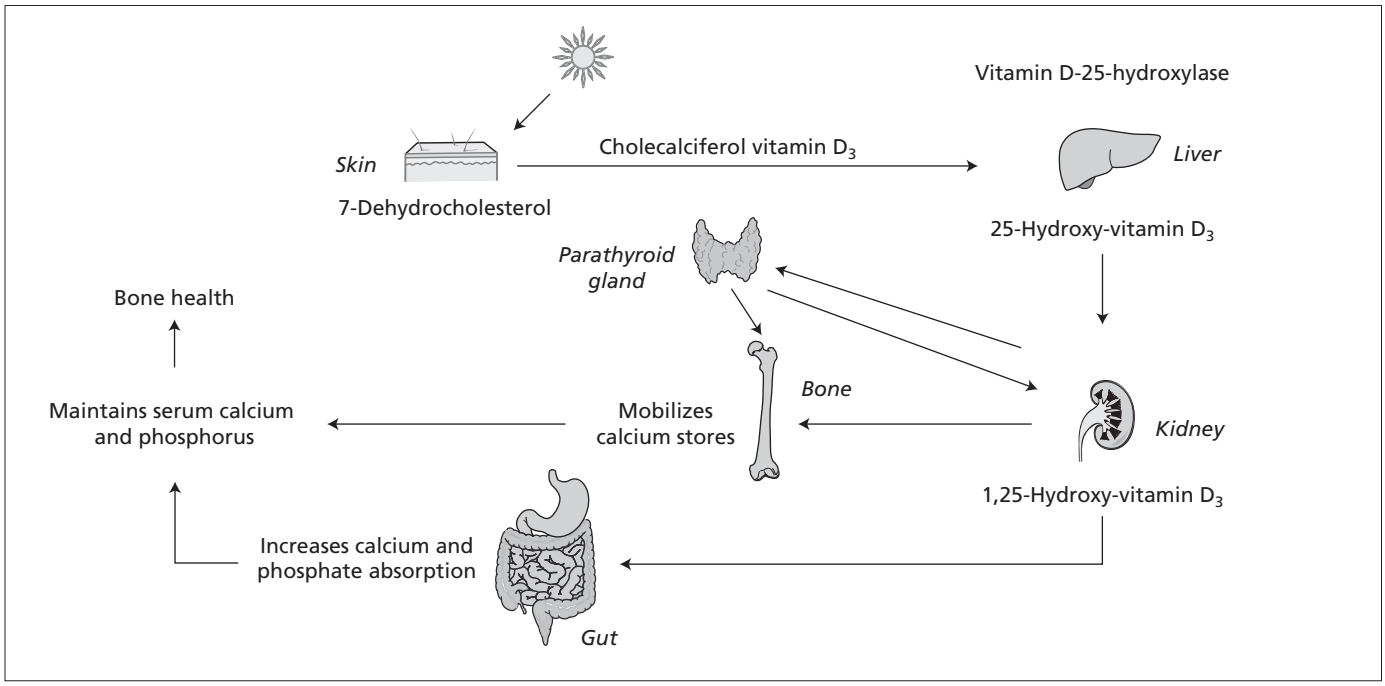

Fig. 20.1 Calcium metabolism pathways in the human body.

Across the span of the human life cycle, there is a period of intense accrual of bone mineral up to the age of 20–30 years, followed thereafter by first a plateau phase and then a gradual decline in bone mineral density. In women, bone loss increases in the postmenopausal period owing to oestrogen deficiency. At any given age, bone mineral density is a function of the peak bone mass accrued in the early period of life and the rate of bone loss. Peak bone mass is determined primarily by genetic factors but also by environmental variables such as nutritional intake and physical exercise (specifically, weight-bearing exercise). On the other hand, bone loss is the result of oestrogen deficiency in the postmenopausal period (in women) and is influenced by physical activity and, to a small extent, by contemporaneous calcium and vitamin D intake. Also influential in this context are several medications (e.g. glucocorticoids and AEDs), alcohol and cigarette smoking, all of which hasten the process of bone loss. The end result is a progressive reduction in bone strength and eventually frailty (or non-traumatic) fractures. The hip, vertebral bodies and wrist are the common sites of frailty fractures. The consequences of such fractures (frailty fractures) include increased mortality and long-term morbidity (due to chronic back pain and immobility), and these fractures pose a social and tremendous economic burden.

Fracture and osteoporosis risk in people with epilepsy

The risk of developing any fracture is two to three times higher in people with epilepsy than in the general population [5]. Of all fracture sites, the risk appears maximally elevated for the hip and vertebral bodies. Fractures in people with epilepsy may be related to the strain experienced by bones during generalized tonic–clonic seizures, falls during generalized seizures and accidents during generalized and complex partial seizures. An increased risk of frailty fractures has also been reported and can be attributed to reduced bone mineral density in people with epilepsy (Table 20.1) [6]. In some early studies, insufficient ambulation directly due to epilepsy and its associated neurological handicaps, poor nutritional status and inadequate exposure to sunlight (leading to vitamin D deficiency) in institutionalized people with epilepsy were cited as reasons for reduced bone strength. However, bone mineral deficits have also been documented in ambulatory as well as outpatient populations of epilepsy, and it is now thought that AED therapy is an important factor in the development of bone mineral deficits [7,8]. The most consistent adverse effects on bone metabolism have been found with the enzyme-inducing AEDs (phenytoin, phenobarbital and primidone). Evidence of impaired bone metabolism with carbamazepine is somewhat conflicting [9,10; reviewed in ref. 11]. Valproic acid treatment is also associated with reduced bone mineral density and this effect appears to be independent of vitamin D-related mechanisms [9,12]. The effects on bone metabolism of the newer AEDs have not been extensively studied but preliminary data do not reveal any consistent effect on various parameters of bone health [13–15].

Compromised bone health not only occurs in adults but has also been documented in children with epilepsy, in whom a poor accrual rather than accelerated loss of bone mineral is believed to be responsible for inadequate bone mass [11,16,17]. Poor bone accrual in childhood may lead to rickets or osteomalacia or simply to inadequate height and growth progress. Moreover, reduced peak bone mass due to poor accrual in

Table 20.1 Putative factors and mechanisms associated with increased fracture risk in people with epilepsy.

Seizure-associated fractures
Bone strain during generalized tonic–clonic seizures
Fractures during falls associated with generalized seizures or AED toxicity
Fractures associated with accidents during generalized and complex partial seizures
Frailty fractures associated with reduced bone mineral density
Increased metabolism of vitamin D in liver by enzyme-inducing AEDs (phenytoin, carbamazepine, phenobarbital, primidone and, to some extent, topiramate and oxcarbazepine
Direct toxic effect on bone (phenytoin-sodium)
Increased bone resorption (valproic acid)
Impaired gut absorption of calcium (due to vitamin D deficiency and direct effect of phenytoin)
Increased catabolism of oestrogens due to enzyme-inducing AEDs
Vitamin K deficiency in users of enzyme-inducing AEDs
Renal tubular dysfunction associated with valproic acid use
Elevated homocysteine levels leading to poor bone collagen formation
Deficient vitamin B_{12} and folate levels leading to poor bone collagen synthesis
Up-regulation of 24,25-hydroxylase in renal tissue, promoting the conversion of 1,25-dihydroxy-vitamin D_3 to inactive compounds by phenobarbital, phenytoin and carbamazepine
Sedentary lifestyle of people with epilepsy predisposing to osteoporosis
Poor sunlight exposure in institutionalized people with epilepsy leading to vitamin D deficiency
Poor nutritional status of people with epilepsy leading to vitamin D deficiency
Altered smoking and alcohol habits in people with epilepsy

AED, antiepileptic drug.
From refs. 5, 6, 9, 12, 20, 147, 148 and 149.

early life increases the risk of developing osteoporosis in later life.

Screening for bone health in people with epilepsy

At present, the dual-energy X-ray absorptiometry (DEXA) scan is the most widely used and reasonably reliable screening method for assessment of bone health. The test measures bone mineral density at selected sites and for the purpose of analysis compares the index bone density to the peak bone density of a young adult of the same gender to generate a T-score. A T-score >1 standard deviation (SD) below the comparator signifies osteopenia and >2.5 SD suggests osteoporosis. The DEXA scan is indicated routinely in postmenopausal women, those with premature ovarian failure, hyper- or hypoparathyroidism, those requiring long-term (>3 months) glucocorticoid treatment and those with radiological evidence of osteoporosis in the vertebrae and prior frailty fracture [18]. There are no standard recommendations regarding the estimation of bone mineral density in people with epilepsy. Some authors recommend that a DEXA scan be undertaken in all people with epilepsy of greater than 2–5 years' duration, those who are receiving enzyme-inducing AEDs, those with symptomatic epilepsy and those commencing treatment in the postmenopausal period [19,20]. The UK National Institute for Health and Clinical Excellence (NICE) recommends estimation of serum calcium, phosphorus, alkaline phosphatase and 25-hydroxyvitamin D_3 every 2–5 years in those adults with epilepsy on enzyme-inducing AEDs. In addition, people with epilepsy should be screened for additional risk factors for osteoporosis as the presence of these may compound the risk of osteoporosis and frailty fractures. The risk factors include age >65 years, postmenopausal status in women, prior frailty fracture, corticosteroid therapy, low body weight and thyroid, parathyroid and gonadal disorders. Screening procedures for bone health in children with epilepsy are uncertain.

Prevention and treatment of bone loss in people with epilepsy

Several aspects of prevention and treatment should be considered in optimizing bone health status of people with epilepsy. Adherence to weight-bearing exercise protocols and avoidance of cigarette smoking and excessive alcohol intake are general measures that need to be followed. Recommendations for supplementary intake of calcium and vitamin D should be based on calculation of daily dietary intake of these items. The required intake of calcium is 1200 mg/day and of vitamin D is 800 IU/day. It is not clear if people using enzyme-inducing AEDs require higher doses of vitamin D due to increased catabolism of the vitamin. However, if vitamin D_3 levels remain in the subnormal range despite routine supplementation, higher doses of the vitamin may be used. In those in whom bone mineral density is in the osteoporotic range (i.e. T-score <–2.5 SD), a range of treatment options are available including bisphosphonate agents, strontium and calcitonin. The advice of an endocrinologist should be sought in such situations. In all people with epilepsy in whom bone mineral density is in the impaired range, a review of medications in order to choose an AED that does not adversely impact bone health should be considered.

Organ impairment

Seizures and epilepsy can occur concomitantly with organ (e.g. hepatic, renal or endocrine) dysfunction and may or may not be related to the latter. At times, the organ impairment may involve multiple systems (multiorgan dysfunction). The presence of concomitant organ failure in epilepsy has the following implications in the management of epilepsy:

1 Seizures may occur due to organ (e.g. renal) dysfunction or as a manifestation of a disorder that affects the brain as well as the body organ.

2 Organ impairment may have an effect on the treatment of seizures and epilepsy.

3 Organ dysfunction may occur as a complication of epilepsy or its treatment.

4 The occurrence of epilepsy may impact the treatment of the organ disorder.

The first of the issues is considered elsewhere, and the remaining three are reviewed in subsequent sections of this chapter. Relevant in this context are the altered pharmacokinetics as well as pharmacological responsiveness to medications used in the treatment of both seizures and epilepsy as well as organ dysfunction as a result of drug disease and drug–drug interactions. Drug–drug interactions are described in detail elsewhere in this volume (Chapter 28) and are considered only briefly here.

Overview of AED pharmacokinetics in hepatic and renal disease

Antiepileptic drug metabolism occurs largely in the liver, while AED elimination usually takes place in either the liver or the kidney or both. The liver and kidney are also involved in synthesis and regulation of plasma proteins and many AEDs are extensively protein bound. Hence, both hepatic and renal dysfunctions affect AED pharmacokinetics through a variety of mechanisms.

The determination of AED dosages in liver disease depends upon the estimation of residual hepatic function. However, no single clinical or laboratory parameter can be utilized as a measure of the estimate of available hepatic function. Hence, dosage considerations are based on clinical assessment of the response to AED (i.e. degree of seizure control) and side-effects (chiefly, neurological side-effects, which are dose dependent), supplemented by total and free drug levels whenever available. The Child–Pugh system of grading liver disease may be used to estimate the degree of impairment in chronic liver disease (Table 20.2) [21]. However, there is limited experience with its use in predicting dosages for those newer AEDs for which estimation of serum levels is not an option [22,23].

The liver extracts drugs from the portal circulation following their absorption through the gastrointestinal mucosa. In addition, it is involved in the metabolism and elimination of many drugs and is the site of synthesis of plasma proteins. Hence, on many accounts, it crucially controls the pharmacokinetics of several drugs including both conventional and many of the newer AEDs. An initial step comprises the extraction of the drug from the portal circulation (the first-pass effect). For most AEDs, the hepatic extraction ratio, which is a measure of the first-pass effect, is reasonably low. A further step is drug metabolism and elimination, which is accomplished in the liver through two sets of reactions (for most but not all AEDs metabolized in the liver), known as the phase I and phase II metabolic reactions. The former comprise mainly oxidation reactions and are involved in altering the functional status (from active to inactive or vice versa) of the drug molecule. The phase I reactions are most vulnerable to impaired hepatocyte function. Since oxidative enzymes in the liver are saturable, the metabolism of drugs through these reactions is limited by the hepatic enzymatic capacity (capacity-limited metabolism, e.g. phenytoin). Phase II reactions involve conjugation and are important for drug excretion.

Table 20.2 Child and Pugh's classification of chronic liver disease.

Measure	One score	Two scores	Three scores
Serum total bilirubin (mg/dL)	<2	2–3	>3
Serum albumin (mg/L)	>35	28–35	<28
Prothrombin time (international normalized ratio)	<1.7	1.71–2.20	>2.20
Ascites	None	Suppressed with medication	Refractory
Hepatic encephalopathy	None	Grade I–II	Grade III–IV

Class A, score of 5–6; class B, score of 7–9; class C, score >10.
Source: [21].

The disorders of liver are several, but from the standpoint of AED prescribing may be divided into acute hepatic necrosis (due to toxins and viral hepatitis) and chronic liver disease (i.e. cirrhosis) (Table 20.3). On the basis of the limited data available, it may be inferred that acute liver insults (e.g. viral hepatitis) do not significantly alter the pharmacokinetics of AEDs [24,25]. Dosage adjustments are, however, often required in cirrhosis due mainly to changes in the proportion of the AED metabolized and eliminated in the liver and in the degree of protein binding. As all available AEDs have low hepatic extraction ratios, this is not normally a factor to consider. The conventional AEDs, including phenytoin, valproate, carbamazepine, phenobarbital and primidone, are metabolized chiefly in the liver. Of the newer AEDs, tiagabine and lamotrigine are metabolized almost exclusively in the liver, and oxcarbazepine, felbamate, topiramate, zonisamide and levetiracetam are partially metabolized in the liver and partially excreted unchanged in the urine. Gabapentin and vigabatrin are excreted unchanged by the kidney [26]. The degree of protein binding is high for certain AEDs including phenytoin, valproate, carbamazepine and tiagabine. In many liver disorders, impaired synthesis of albumin and protein binding by excess circulating bilirubin results in a reduced fraction of the protein-bound drug and elevated free levels of the drug. Hence, estimation of free drug levels of some drugs may be preferable in chronic liver disease.

In renal impairment, reduced glomerular filtration and tubular secretion can result in decreased drug elimination. In addition,

Table 20.3 Practical considerations in the management of epilepsy and seizures in hepatic dysfunction.

Institution of long-term AED treatment in individuals with pre-existing chronic liver disease
The use of valproate and felbamate (and possibly carbamazepine, phenytoin and lamotrigine) is to be avoided
The use of gabapentin appears safe
Levetiracetam and topiramate appear safe in mild chronic liver disease but dose reduction must be considered in Child's C hepatic impairment
Use slower titrations and lower maintenance doses if possible
Dosage considerations should be guided by free AED concentrations whenever available
Occurrence of acute hepatic dysfunction in individuals on AED treatment
Ongoing treatment with valproate to be stopped and the agent should be replaced with an alternative AED
Establish if the hepatic failure is related to AED. If related to AED, the drug should be stopped and replaced with an alternative (Note: AED-induced acute hepatic failure is rare in comparison with other causes of acute hepatic failure)
Dosage modification is often not required for AEDs except in severe hepatic failure, in which case it should be guided by clinical response and free-AED concentrations
Acute seizure control in acute hepatic failure (e.g. due to viral hepatitis or alcohol)
The use of benzodiazepines for seizure control is to be avoided. Midazolam may be used if required, in view of its short duration of action
Phenytoin (in loading dose), phenobarbital, gabapentin and levetiracetam may be administered to control repetitive seizures or status epilepticus or to prevent recurrent seizures

AED, antiepileptic drug.

Table 20.4 Dosage adjustments for newer AEDs in patients with reduced kidney function.

AED	Total daily dose (GFR, ml/min)				Estimated loss during haemodialysis	Supplementary dose after haemodialysis
	60–89	30–59	15–29	<15		
Gabapentin	400–600 mg thrice daily	200–300 mg twice daily	200–300 mg/day	100–150 mg/day or 300 mg every other day	NA	125–250 mg
Levetiracetam	500–1000 mg twice daily	250–750 mg twice daily	250–500 mg twice daily	250–500 mg twice daily	50%	250–500 mg
Topiramate	100–200 mg twice daily	50–100 mg twice daily	50–100 mg twice daily	50–100 mg twice daily	50%	50–100 mg
Zonisamide	100–400 mg	100–400 mg	Insufficient data; use with caution		50%	Supplement 50% dose if seizure occurs after haemodialysis
Oxcarbazepine	300–600 mg twice daily	300–600 mg twice daily	50% of original dose	Insufficient data; use with caution	NA	NA
Felbamate	1200–3600 mg	Insufficient data; reduce dose by 50%			NA	NA
Lamotrigine	100–500 mg	Insufficient data; may benefit from decreased dose			NA	NA
Tiagabine	32–56 mg	No dose adjustment necessary			NA	Not required

NA, data not available.

both quantitative (e.g. protein loss in nephrotic syndrome) and qualitative changes in plasma proteins occur in renal disorders. Uraemic toxins may compete with AEDs in order to bind to plasma proteins, chiefly albumin. The net effect is reduced protein binding and hence increased free drug levels in the plasma. Oral bioavailability of drugs is also compromised as a result of poor gastrointestinal absorption in uraemia. Finally, hepatic metabolism and elimination of AEDs is also altered in uraemia. The overall effect of renal impairment on AED pharmacokinetics is therefore complex and unpredictable. However, in clinical practice, dosage considerations are most often made based on the fraction of the active drug that is eliminated by the kidney (Table 20.4) and functional renal status. Estimation of the functional renal status involves calculation of creatinine clearance from the serum creatinine concentration using the following formula: creatinine clearance = (140 – age in years) × weight in kg/72 × serum creatinine.

Since the apparent volume of distribution of AEDs is presumed to be unaffected in renal impairment, the loading dose of AED when required remains the same as in healthy subjects. Maintenance doses, however, need to be adjusted according to creatinine clearance for AEDs eliminated through the renal route (Table 20.4) by either reducing the dose of the drug dispensed or increasing the time interval between dose administrations. Furthermore, both acute renal failure and end-stage renal disease due to chronic renal failure obligate the use of extracorporeal techniques (haemodialysis, continuous or intermittent peritoneal dialysis, haemofiltration and haemoperfusion) in order to remove uraemic and extraneous toxins, which may also lead to loss of AED from the body. Removal of a drug during dialysis depends on several factors including the molecular weight, degree of protein binding and water solubility of the drug and is hence different for each of the several available AEDs. For certain AEDs, consideration of dialysis-related drug loss entails the administration of supplemental doses in the immediate post-dialysis period (see Table 20.4).

Pharmacokinetic data regarding individual AEDs in renal impairment have been reviewed recently [27] and are summarized in Table 20.4. Dosage guidelines in impaired renal function based on creatinine clearance are available. For those renally excreted AEDs that are targets for the cytochrome P450 (CYP450) enzyme system (e.g. topiramate and felbamate), the proportion of the drug that is metabolized in the liver is increased when enzyme-inducing AEDs are concomitantly administered [28,29]. This effectively decreases plasma concentrations of the target drugs. Hence, dosage adjustments may not be required for these drugs when administered concomitantly with enzyme-inducing AEDs in the setting of renal failure.

Hepatic and renal impairment due to epilepsy and its treatment

Either hepatic or renal impairment may develop during the course of epilepsy or its treatment. There is a considerable body of literature available on hepatic disorders developing during the course and treatment of epilepsy. In comparison, renal impairment is less common [30,31]. Relevant to the finding of hepatic impairment during the course of epilepsy is the concern whether the clinical or laboratory abnormalities indicating hepatic dysfunction are the result of AED toxicity. The finding of otherwise asymptomatic elevation of serum transaminases [aspartate aminotransferase (AST) and alanine aminotransferase (ALT)], γ-glutamyl transferase (GGT) and alkaline phosphatase (ALP) up to two to three times of the upper limit of normal is common with chronic treatment with enzyme-inducing AEDs including phenytoin, carbamazepine, phenobarbital, primidone, topiramate and oxcarbazepine, owing to induction of hepatic microsomal enzyme systems [32]. This finding does not constitute an indication for further investigation or drug or dose modification but requires that baseline liver function parameters be estimated prior to commencement of treatment with enzyme-inducing AEDs. There appears to be no role for the routine monitoring of liver function tests during treatment with any of the AEDs. The ele-

vated ALP in the plasma during prolonged treatment with phenytoin may be of skeletal rather than hepatic origin [33]. Elevation of arterial or venous blood ammonia levels is frequent in individuals on treatment with valproate and the mild elevation usually encountered is of no clinical significance [34]. Hence, routine monitoring of arterial or venous blood ammonia levels during valproate therapy is generally not recommended. However, if unexplained encephalopathy develops following commencement of valproate therapy, estimation of ammonia levels should be undertaken in consideration of the likelihood of hyperammonaemic encephalopathy.

As a class of drugs, AEDs are the third most common cause of serious drug-induced hypersensitivity reactions affecting the liver in clinical practice [35]. Overall, however, the incidence of hypersensitivity is low. Clinically significant hepatic damage due to hypersensitivity has been commonly reported with valproate, phenytoin, felbamate and probably carbamazepine and lamotrigine, but there are only anecdotal descriptions of liver disease developing due to other AEDs. Hepatic dysfunction due to AEDs is a type B reaction; that is, it is idiosyncratic, unpredictable and not dose related, and occurs in (genetically) susceptible individuals [36]. From the mechanistic standpoint, the idiosyncrasy may be either immunoallergic (e.g. with phenytoin, carbamazepine and lamotrigine) or metabolic (with valproate). Phenytoin-induced hepatic dysfunction typically occurs in the setting of generalized hypersensitivity reactions and hence is accompanied by fever, skin rash, lymphadenopathy, nephritis and peripheral blood eosinophilia [37]. The onset of hepatic dysfunction is within 1–6 weeks of commencement of phenytoin therapy. Hypersensitivity features such as eosinophilia appear to be less common with carbamazepine than with phenytoin [37]. The production of the reactive metabolites' arene oxides has been shown to be critically involved in hepatic reactions to both AEDs. These metabolites are detoxified by the enzyme arene epoxide hydrolase to non-toxic excretory products. In susceptible individuals, however, a deficiency of this enzyme leads to an accumulation of arene oxides, which cause hepatic injury [38]. On the other hand, valproate causes hepatic dysfunction owing to its peculiar metabolic degradation in predisposed individuals (see below). Valproate mainly undergoes glucuronidation (phase II reaction) in the liver. However, 20% of its hepatic metabolism occurs by oxidation (phase I reaction), which takes place both in the mitochondria and in the endoplasmic reticulum [39]. Normally, mitochondrial oxidation (known as beta-oxidation) of valproate dominates over cytosolic oxidation (also known as omega-oxidation) and involves carnitine as a carrier molecule leading to the formation of the metabolic product, 2-en-valproic acid. In predisposed individuals or in the setting of carnitine deficiency, cytosolic oxidation occurs preferentially leading to the formation of 4-en-valproic acid [40]. The latter has been linked to hepatic injury as well as hyperammonaemia in as much as it causes microvesicular steatosis, a histological hallmark of valproate-induced liver injury.

The incidence of clinically significant hepatic dysfunction with phenytoin is estimated to be 1 in 100 000 persons exposed. The risk of valproate-induced hepatotoxicity is generally low, about 1 in 37 000 in exposed children younger than 2 years of age and even less in adults [41,42]. However, among the group of selected high-risk individuals, the incidence may be as high as 1 in 500 [42]. The risk of valproate hepatotoxicity is highest among children younger than 2 years of age on AED polytherapy and with underlying mental retardation and developmental delay indicative of organic brain disease or inborn errors of metabolism. Intercurrent infections have also been identified as a risk factor in some studies [43]. The toxic hepatitis manifests within 2–3 months of commencement of valproate therapy with non-specific clinical features including lethargy, anorexia, nausea, vomiting and jaundice. Serum levels of AST, ALT, ALP and GGT are elevated several times above the upper limit of normal. Hyperammonaemia is also noted, though when detected as an isolated finding is not indicative of underlying toxic hepatitis.

Although the finding of serious hepatic dysfunction during AED treatment should certainly arouse suspicion of AED-induced damage, intercurrent infectious and alcoholic hepatitis are probably more common. Thus, viral studies should constitute part of the standard workup of hepatitis developing during AED treatment. The settings for both phenytoin- and valproate-induced hepatitis are, however, fairly characteristic and should be easily recognized by the treating physician. The management comprises promptly discontinuing the offending AED and instituting appropriate liver-specific supportive treatment. The use of carnitine in valproate-induced hepatitis is appealing in view of its role in the mitochondrial oxidation of valproate. A consensus panel recommended its use in valproate-induced toxic hepatitis as well as primary carnitine deficiency [44]. The routine co-administration of carnitine with valproate treatment in order to prevent hepatotoxicity is, however, not justified [39].

Epilepsy and thyroid disease

Abnormalities in thyroid function tests have been shown to occur during treatment with several AEDs, including carbamazepine and valproate [45–47]. However, the reported abnormalities lack consistency across published literature. Most studies suggest subclinical hypothyroidism due to carbamazepine and valproate. Apparently, the abnormalities revert upon withdrawal of the AED. The effects have been variously attributed to the enzyme-inducing effects of carbamazepine, an immunological mechanism or also an effect of the AEDs on the hypothalamic centres regulating thyroid function. Although the clinical implications of the thyroid function abnormalities due to AEDs remain uncertain, the effect may be significant in individuals with pre-existing thyroid disorders. In such individuals, an AED without demonstrated effects on thyroid function may be preferred. Data regarding the effect of newer AEDs on thyroid function are extremely limited.

Multiorgan dysfunction

The management of seizures in individuals with multiorgan dysfunction, often in the intensive care unit, is a complicated issue. While it is imperative to rapidly control seizures, the potential consequences of treatment of seizures on the already compromised function of various organs need to be carefully considered. The AEDs may interact with, or simply add to, the complications produced by the complex therapeutic regimen administered for the multiorgan dysfunction. Furthermore, since patients with multiorgan dysfunction are on multiple classes of drugs, the interaction of a particular drug with AEDs may be influenced by the administration of other medications and hence become compli-

cated and unpredictable. In addition, multiorgan dysfunction in the intensive care unit is often complicated by hypotension, systemic acidosis and hypoproteinaemia. In the presence of hypotension, parenterally administered phenytoin, fosphenytoin, phenobarbital, pentothal, midazolam and propofol should be either given with caution or avoided. Continuous electrocardiographic and haemodynamic monitoring is warranted during the administration of these agents. As far as is known, intravenous valproate and levetiracetam are safe in the presence of hypotension. In the presence of acidosis, certain AEDs that may worsen acidosis, for instance topiramate, propofol and lorazepam (due to the excepient, propylene glycol) in high doses, should be avoided [48–50]. If hypoproteinaemia is associated, the estimations of total drug concentrations in the serum of highly protein-bound AEDs, although widely available, do not accurately reflect free AED concentrations. As a result, total drug concentrations may be normal but free drug levels may be elevated, potentially leading to drug toxicity. Hence, estimation of free drug levels is recommended. Finally, since AEDs are eliminated either through the renal or hepatic route, the combined occurrence of renal and hepatic failure invariably leads to drug accumulation and toxicity. Hence dosage considerations are extremely complicated and should be guided by vigilant observation of the clinical response (i.e. seizure control) and side-effects and frequent monitoring of the free AED concentrations.

Organ transplantation

There is a high incidence of new-onset seizures in kidney, liver and cardiac transplant recipients [51,52]. Diagnostic evaluation of new-onset seizures is somewhat specialized and involves considerations other than the common causes of new-onset seizures in the general population. In addition, individuals with prior epilepsy may happen to be candidates for transplant procedures. A major concern in transplant recipients is related to the administration of immunosuppressive agents, including ciclosporin and tacrolimus. Toxicity due to ciclosporin can result in seizures as one of the features of the reversible posterior leucoencephalopathy syndrome (other features of this condition include hypertension, cortical blindness and mutism). Magnetic resonance imaging (MRI) reveals posterior dominant hyperintensities that do not show up on diffusion-weighted imaging, suggesting that these represent vasogenic oedema. High ciclosporin levels in the serum, in addition to hypomagnesaemia and hypocholesterolaemia, provide laboratory support for the diagnosis of this condition. Tacrolimus can also cause seizures, though imaging abnormalities due to tacrolimus intoxication are more often diffuse rather than posterior [53]. The management of seizures associated with toxicity of immunosuppressive agents toxicity consists in lowering blood pressure, omitting the agents and then modifying their dose according to serum concentrations.

Many of the immunosuppressive agents used in the post-transplant period have a narrow therapeutic index and exhibit considerable inter-individual variation in their pharmacokinetics. Ciclosporin, tacrolimus, sirolimus and glucocorticoids are metabolized by the hepatic CYP enzyme systems and hence are susceptible to the inducing effects of the enzyme-inducing AEDs. Carbamazepine, phenytoin and oxcarbazepine reduce blood levels of ciclosporin, tacrolimus and glucocorticoids, thereby compromising their efficacy and fuelling concerns about their potential to cause transplant rejection [54,55]. There is experimental evidence that ciclosporin may also interact with AEDs through its effect on the P-glycoprotein group of drug transporters [56] but the clinical significance of this interaction is unclear. Newer AEDs that have no effect on the hepatic CYP system may be used, although experience with their use in transplant recipients is extremely limited. Levetiracetam holds promise, though there are concerns about an increased risk of infections during its use that may be relevant to the transplant population [57]. The other immunosuppressive agents – mycophenolate mofetil, OKT3 and azathioprine – do not appear to have any significant interaction with AEDs [52].

Cancer and epilepsy/seizures

Both epilepsy and cancer are common disorders and can occur by chance in a proportion of the general population. However, seizures and epilepsy may occur for the first time in people with cancer and their occurrence should lead to consideration of causes that are considerably different from those in the general population [58]. Conversely, the occurrence of cancer in people with epilepsy raises the possibility that the former is, at least in part, due to the carcinogenic potential of AEDs, lifestyle factors associated with epilepsy (e.g. smoking and alcohol ingestion) or a shared biological predisposition to cancer and epilepsy [59]. A common clinical issue is the variety of pharmacokinetic interactions between AEDs and anti-cancer medication which can alter cancer treatment and hence prognosis. Finally, the occurrence of cancer may modify the treatment and prognosis of epilepsy in some instances.

The true incidence of new-onset seizures in people with cancer is not known. Limited data available from specialist cancer centres suggest that seizures occur in nearly 15% of the selected population [60,61]. There appear to be some differences between adults and children with regard to the incidence and aetiology of seizures [61,62]. In children with cancer, there is a high frequency of seizures associated with the use of high-dose myelo-ablative treatment (busulphan) offered for the treatment of childhood leukaemia. In adults with solid cancers, intracranial (parenchymal or uncommonly leptomeningeal) metastasis may frequently be the cause of seizures. Hence, the occurrence of seizures should prompt imaging studies with gadolinium-enhanced MRI to rule out brain metastasis. Anti-cancer drug-induced seizures and metabolic disturbances are the other common causes of seizures in individuals with cancer. Indeed, seizures constitute a dose-limiting toxicity of several anti-cancer agents. Their occurrence is dose dependent and hence, in clinical oncological practice, seizures are encountered due to inadvertent overdosing, the administration of high doses of anti-cancer agents (e.g. busulphan and chlorambucil) as a component of myelo-ablative treatment in preparation for bone marrow transplantation or in the presence of renal or hepatic failure wherein routine doses may lead to toxicity.

The treatment of seizures and epilepsy in people with cancer requires several special considerations. Seizures provoked by drugs and metabolic disturbances do not require long-term AED treatment. In the treatment of acute seizures, a drug with a rapid

onset of action and parenteral formulation is preferred. Parenteral lorazepam (0.05 mg/kg, intravenous) may be administered slowly in order to terminate repetitive or prolonged seizures. Brief and isolated seizures due to drugs or metabolic disturbances do not require treatment. In other situations, if AEDs are required, a loading dose may be administered by the parenteral route as the absorption of oral AEDs is erratic and compromised due to the damaging effects of anti-cancer agents on the gastrointestinal mucosa. Parenteral formulations are available for phenytoin, phenobarbital, valproate and levetiracetam.

Oral benzodiazepines (lorazepam or clonazepam) are routinely administered prophylactically before and until 24 h after high-dose busulphan, given as myelo-ablative treatment prior to bone marrow transplantation in view of the high incidence of seizures associated with this treatment [63].

Many conventional AEDs (phenytoin, phenobarbital, primidone and carbamazepine) are potent inducers and some of the newer AEDs (topiramate and oxcarbazepine in higher doses) are mild inducers of hepatic microsomal enzyme systems and several anti-cancer agents are metabolized to active or inactive products in the liver. As a result, the enzyme-inducing AEDs may induce the metabolism of several anti-cancer agents (including methotrexate, busulphan, vincristine, tenopuside, paclitaxel, irinotecan and topotecan) [64,59]. The clinical implications of the interactions between enzyme-inducing AEDs and several anti-cancer agents are uncertain. On the basis of pharmacokinetic data, up to 1.5 times higher doses of the anti-cancer agents (e.g. paclitaxel) are recommended when given concomitantly with enzyme-inducing AEDs [65,66]. Besides, in dose-determining (phase I) trials of novel anti-cancer agents, higher maximally tolerated doses of the agents are employed in conjunction with enzyme-inducing AEDs [67]. Finally, there is the possibility that the administration of hepatic enzyme-inducing AEDs may adversely impact cancer survival and remission rates by producing subtherapeutic levels of anti-cancer agents due to induction of their metabolism and, hence, an insufficient cytotoxic effect on cancer cells [68].

The spectrum of adverse effects to AEDs as well as anti-cancer agents is also altered by their concomitant administration. For instance, a high incidence of anticonvulsant hypersensitivity syndrome has been reported with phenytoin use in conjunction with cranial irradiation for metastatic brain tumours [69]. Haematological toxicity due to cisplatin is enhanced when used in conjunction with valproate due to compounding of the potential of both agents to cause thrombocytopenia and increased levels of former as a consequence of valproate-induced hepatic enzyme inhibition [70].

Newer AEDs that do not induce hepatic microsomal enzyme systems (e.g. gabapentin and levetiracetam) may be the preferred AEDs for seizure control in individuals with cancer. Clinical experience with these newer AEDs is now growing and, hopefully, therapeutic strategies for seizure control based on their use will soon emerge [71]. Conventionally, surgical treatment for intractable epilepsy is often disregarded in individuals with cancer owing to their limited survival. However, with the prospects of lasting remission in several cancers, particularly childhood leukaemia, surgical treatment becomes an appealing option in the management of intractable epilepsy in individuals with cancer [72].

Infections and epilepsy

A number of infectious disorders involving the central nervous system (CNS) may cause seizures and epilepsy and, conversely, infectious disorders can occur during the course of chronic epilepsy.

Acute CNS infections are the cause of both acute symptomatic as well as unprovoked seizures. In community-based samples, the incidence of acute symptomatic seizures due to CNS infections is 5.2 in 100 000 person-years [73]. CNS infections may account for as many as 15% of new-onset acute symptomatic seizures. The 20-year risk of unprovoked seizures after an acute CNS infection episode varies between 2.4% and 22% [74]. The risk depends on the nature of the infection, its site and severity. It is high, for instance, following severe herpes simplex encephalitis because of the involvement of the highly epileptogenic mesial temporal cortices, but may be much lower in mild cases. The risk is also increased with the occurrence of early seizures during the acute CNS infection episode and particularly so with the occurrence of status epilepticus [74,75]. In community-based samples of newly diagnosed epilepsy, CNS infections may be responsible for at least 3% of all cases [76]. The figures quoted here are largely derived from the Rochester community in the USA. The incidence and attributable risk is different in other parts of the world because of disparity in the incidence and pattern of CNS infections throughout the world [77].

The incidence, course and outcome of epilepsy following an acute CNS infection episode have not been systematically studied. On the basis of limited data derived from highly specialized epilepsy centres, it may be inferred that both acute bacterial meningitis and viral encephalitis constitute antecedent illnesses for the development of intractable mesial temporal lobe epilepsy with underlying hippocampal sclerosis [78]. In addition, neocortical epilepsy occurs frequently following viral encephalitis but not after bacterial meningitis [79]. Regardless of the nature of the antecedent illness, the prognosis of surgical cure is good in cases in which unilateral mesial temporal sclerosis is demonstrated on MRI [80].

Human immunodeficiency virus infection and seizures

Seizures are common in human immunodeficiency virus (HIV) infection, though their precise frequency varies according to the source population. They typically occur in the later stages of HIV infection. However, on occasion, they may constitute the presenting manifestation of HIV infection [81]. A variety of opportunistic infections such as toxoplasmosis and CNS tuberculosis and primary CNS lymphoma may be the cause of seizures in HIV-seropositive individuals. Other conditions, for example progressive multifocal leucoencephalopathy, cryptococcal meningitis, drugs and metabolic disturbances, may also rarely cause seizures. In about half of HIV-infected individuals, no additional cause for seizures can be identified. In these individuals, the primary HIV infection itself is considered to be the cause of seizures [82]. Regardless of the cause, recurrence rates after new-onset seizures in HIV infection are high. Hence, long-term AED treatment is advocated except when reversible metabolic derangements are identified to be the cause of seizures.

Since HIV-infected individuals have multiple co-morbidities and are often on several medications for the treatment of primary HIV infection as well as for the prophylaxis and treatment of several opportunistic infections, several drug–drug and disease–drug interactions should be carefully considered in making the choice of AED. Gastrointestinal disorders occur frequently in HIV infection and these may impair the absorption of AEDs across the gastrointestinal mucosa. Hypoalbuminaemia in HIV infection may alter protein binding of several AEDs and hypergammaglobulinaemia may signify altered immune status, leading to an increased frequency of allergic reactions to many AEDs [83]. Of the antiretroviral agents, the class of drugs known as protease inhibitors is metabolized by hepatic CYP3A4 and is hence a target for enzyme induction by the enzyme-inducing AEDs including phenobarbital, phenytoin and carbamazepine. The result of these drug interactions is a reduction in plasma concentrations of the antiretroviral agents, potentially leading to increased viral replication and the emergence of drug resistance [83]. An interaction between valproate and zidovudine as a result of hepatic microsomal enzyme inhibition by the former has also been reported [84]. In addition, valproate has been found to stimulate HIV replication *in vitro* [85]. Although the effect has not been replicated *in vivo*, caution is still advised in the use of valproate in HIV-infected individuals [86]. Newer non-enzyme AEDs such as levetiracetam and gabapentin hold promise in view of their inconsequential enzyme-inducing ability and low levels of protein binding. At present, however, clinical experience with their use is extremely limited and their availability in the majority of the regions where HIV infection is most widely prevalent is unpredictable.

Cysticercosis and epilepsy

Infestation of the brain parenchyma by the larval stage of the pork tapeworm, *Taenia solium*, is the main cause of late-onset epilepsy in much of the developing world [87]. Several epidemiological studies in Central and South America have established that roughly one-third of all epilepsies in the community may be attributable to cysticercosis [88]. In addition, the parasitic infestation has been documented in large numbers in parts of South and South-East Asia and sub-Saharan Africa.

Seizures are the most common presenting manifestation of brain parenchymal infestation with cysticerci [89]. Presumably, these occur as a manifestation of host brain parenchymal inflammatory response to degenerating cysticerci. Hence, the majority of the seizures appear to be provoked by brain inflammation and the long-term prognosis for seizure control is generally good [90,91]. However, there may be a subgroup of individuals in whom seizure remission may be difficult to achieve [92]. Factors that have been identified with an increased risk of seizure relapse include persisting brain cysticercal lesions and residual calcific lesions. In addition, an association with mesial temporal sclerosis has been suggested but it remains to be seen if this association is causal [93].

Treatment of cysticercosis comprises the administration of anthelminthic agents (including albendazole and praziquantel), corticosteroids and AEDs. Albendazole (15 mg/kg/day) is most frequently used for varying periods, usually 7–28 days. Benefits of anthelminthic treatment have been demonstrated in the form of superior rates of cyst resolution as well as improved seizure control over short periods of time (usually a few months) in several small, placebo-controlled trials [94,95]. In addition, treatment with a short course (2 weeks) of corticosteroids alone, as well as in combination with anthelminthic agents, has been shown to improve seizure control over 6–9 months [96]. AEDs are administered to all individuals presenting with seizures. Data emerging from observational studies suggest that AEDs should be administered until such a time as imaging shows no active or inflammatory degenerating parenchymal cysticercal lesions [97].

In the subgroup of those with solitary cysticercus granuloma that usually resolves over 3–6 months following initial presentation with seizures, AEDs can be withdrawn after complete resolution is demonstrated on imaging studies [92]. A slight increase in frequency of seizures has been noted during the course of anthelminthic treatment owing to brain parenchymal inflammation provoked by the anthelminthic agent-induced degeneration of the cysticerci [94]. Therapeutic considerations also include potential drug–drug interactions between anthelminthic agents and AEDs (in particular, the enzyme-inducing AEDs). Significant reductions in the maximal plasma concentration and area under concentration–time curve of the active metabolite of albendazole (i.e. albendazole sulphoxide) has been demonstrated with concomitant administration of phenytoin, phenobarbital and carbamazepine) [98].

Tuberculosis and epilepsy

Seizures may occur in CNS tuberculosis for a variety of reasons. These include the presence of brain parenchymal tuberculoma or cortical infarcts due to vasculitis; the use of antitubercular agents such as isoniazid; metabolic disturbances such as hyponatraemia as a result of salt wasting; or inappropriate antidiuretic hormone secretion. Early seizures are fairly common in tubercular meningitis, but late seizures are less common [99,100]. The frequency of late seizures may be underestimated, as there are very few long-term follow-up studies of tubercular meningitis and none have specifically reported rates of epilepsy.

Drug interactions between antitubercular agents and enzyme-inducing AEDs need to be considered in the treatment of tubercular meningitis. Isoniazid induces the metabolism of several AEDs and, on the other hand, rifampicin inhibits the metabolism of many AEDs [101]. The combined administration of the two antitubercular agents (i.e. rifampicin and isoniazid), both of which are standard components of virtually every antitubercular regimen, can produce unpredictable responses. There are also concerns that AEDs may predispose to isoniazid-induced hepatitis, a common adverse effect of antitubercular treatment [102]. Finally, hepatitis complicating antitubercular therapy may precipitate AED toxicity due to impaired hepatic clearance of the latter [103].

Connective tissue disorders

Seizures and/or epilepsy may occur in several connective tissue disorders but have been most characteristically reported in systemic lupus erythematosus (SLE). These occur in 10–15% of hospital-based populations of SLE [104,105]. Diverse

mechanisms may underlie the occurrence of seizures in SLE, including antineuronal antibodies, vascular infarctions, metabolic disturbances and complicating CNS infections. Not infrequent is the occurrence of posterior reversible leucoencephalopathy syndrome in SLE, perhaps due to hypertensive crises complicating the disease [106]. Typically, the occurrence of seizures correlates with disease activity. Correlation has also been noted with other neuropsychiatric presentations of SLE and the demonstration of antiphospholipid antibodies in sera of individuals with SLE [104,105]. In case–control studies of people with epilepsy, however, no association with antiphospholipid antibodies has been noted [107].

The incidence of late unprovoked seizures (or epilepsy) appears to be fairly low in SLE. Effective immunological treatment of the active disease appears to have a favourable impact on seizure control, though long-term AED treatment may be required in many cases. Although chloroquin is known to cause seizures, its administration has not been associated with an increased risk for seizures in SLE. If long-term AED is required, one of the newer, non-enzyme-inducing AEDs may be the preferred option, as patients with SLE may require multiple classes of medications (e.g. corticosteroids, the levels of which are reduced by concomitant administration of enzyme-inducing AEDs).

Pulmonary and respiratory disease

Neurogenic pulmonary oedema is a rare complication of seizures and status epilepticus but is noteworthy as it may be one of the mechanisms by which sudden death occurs in epilepsy (SUDEP) [108]. It occurs within a few hours of the seizure and may present with dyspnoea, breathing difficulty and haemoptysis, leading to cardiovascular collapse. A surge in circulating sympathomimetic amines coincident to the seizure discharge leads to increased vasomotor tone and hence left ventricular failure and an increased pulmonary vascular permeability. Management comprises intensive cardiopulmonary support.

The administration of the bronchodilator agent theophylline in pulmonary airway disease can result in seizures. Seizures attributable to theophylline usually occur in extremes of age and in the context of overdosage but have also been reported with serum levels of theophylline that are within the therapeutic range [109]. Caution is recommended during the administration of theophylline in individuals with known epilepsy.

Obstructive sleep apnoea represents a significant co-morbidity in people with epilepsy. The exact incidence of sleep apnoea in populations with epilepsy has not been determined. However, based on studies of highly selected populations of epilepsy, it has been suggested that sleep apnoea is frequent in people with epilepsy. The converse (i.e. an altered incidence of epilepsy in individuals with sleep apnoea) need not necessarily be the case [110,111]. The high frequency of sleep apnoea among people with epilepsy may be due to a depressive effect of nocturnal seizures and AEDs on airway muscular tone and weight gain associated with some of the AEDs. In individuals with co-morbid epilepsy and obstructive sleep apnoea, the treatment of sleep apnoea with continuous positive airway pressure (CPAP) ventilation has been shown to improve seizure control [112,113]. Evidence for the reverse (i.e. improvement in sleep apnoea with treatment of epilepsy) has also been presented [114].

An interesting related disorder is sleep-disordered breathing with compromised airflow in step with the stimulation-on periods during vagus nerve stimulation [115]. The degree of air flow impairment is usually mild but may be of significance in subjects with pre-existing obstructive sleep apnoea. Therefore, ideally, candidates for vagus nerve stimulation should be screened for obstructive sleep apnoea prior to implantation. Clinically significant sleep-disordered breathing during vagus nerve stimulation usually responds to reduction of stimulation intensity of current and increasing the duration of off-periods. Rarely, CPAP ventilation may be required [115].

Cardiac disease

A bidirectional cause–effect relationship exists between cardiac disorders and epilepsy; cardiac disorders may cause epilepsy and, conversely, epilepsy or its treatment may potentially result in cardiac disorders. Two types of cardiac disorders (i.e. cardiac arrhythmias and ischaemic cardiovascular disease) are discussed in detail below. In addition, hypotension is a well-known adverse effect of intravenously administered phenytoin and fosphenytoin [116,117]. In the case of phenytoin, hypotension is frequently encountered when rates of infusion are in excess of 50 mg/min or in critically ill (e.g. severe sepsis) patients [118]. The manufacturer's product insert advises caution in the intravenous administration of phenytoin in the presence of hypotension. Phenytoin-induced hypotension usually responds to fluid administration, pressor agents, elevation of the foot end of the patient and reducing the rate of infusion.

Cardiac arrhythmias

The exact incidence of cardiac arrhythmias in epilepsy is not known. Available reports are mostly of studies in highly selected populations of epilepsy and hence may represent an overestimate. Nonetheless, these reports are significant as cardiac arrhythmias may account in part for SUDEP in people with epilepsy. A variety of potentially life-threatening cardiac arrhythmias have been described in epilepsy, including cardiac asystole, sinus node arrest, atrioventricular conduction defects, supraventricular tachycardia, ventricular tachycardia and ventricular fibrillation [116,119–121]. These have been documented both during seizures (in particular, complex partial seizures) and in the interictal period [122–124]. The most common cardiac rhythm disorder during complex partial seizures, however, is sinus tachycardia, as is commonly noted in electrocardiographic recordings made during seizures in epilepsy monitoring units. Ictal asystole has been seldom documented [124]. QT interval abnormalities have been documented during interictal epileptiform discharges [125]. Although poorly researched, QT interval prolongation may also occur as a consequence of AED (such as carbamazepine and phenytoin) administration [126–128]. The QT interval abnormalities may predispose to lethal ventricular tachycardias and have been proposed to underlie a proportion of cases of SUDEP.

There are many factors influencing the occurrence of cardiac rhythm disorders in epilepsy. Arrhythmias linked to ictal events

and interictal discharges may be attributable to activation of the amygdala through its connections with the sympathetic centres in the hypothalamus [129]. An intense sympathetic discharge during seizures may be the basis of ictal tachycardia, while excessive parasympathetic discharge may lead to ictal asystole. A common genetic basis of cardiac rhythm disorders and epilepsy has been suggested, referring to potassium and sodium ion channel disorders that may underlie both certain forms of epilepsy as well as the inherited long QT syndromes [130,131]. Structural cardiac abnormalities, including mild fibrosis of the cardiac conduction system, have been described in autopsy studies of SUDEP, but the cause and significance of these appear uncertain [132]. AEDs have been implicated in the generation of arrhythmias. Atrioventricular conduction defects are a recognized complication of carbamazepine, phenytoin and fosphenytoin administration and usually revert following withdrawal of the drug. In addition, reduced variability of heart rate and lengthening of the QT interval have been reported with the use of carbamazepine and phenytoin in some studies but have not been substantiated in others. Barbiturates and most of the newer AEDs appear not to cause cardiac conduction defects or QT interval prolongation [133]. Finally, uncommon cardiac disorders such as the inherited long QT syndromes, which often lack overt cardiac symptoms, may masquerade as epilepsy [134]. Key differentiating features of these conditions include the occurrence of syncopal episodes without seizures, precipitation by exercise and a family history of sudden death.

A baseline electrocardiogram should be ordered prior to commencement of AED treatment, with attention directed to existing cardiac conduction and QT interval abnormalities. In the presence of cardiac conduction defects and possibly also QT prolongation, carbamazepine and phenytoin are best avoided. Barbiturates, valproate and most of the newer AEDs appear to be safe in these situations. If, during treatment with carbamazepine or phenytoin, cardiac conduction defects are detected, then these drugs should be withdrawn and replaced with alternative AEDs. The documentation of ictal asystole or tachyarrhythmia in refractory epilepsy may require insertion of a cardiac pacemaker or automatic implantable cardiac defibrillator [135].

Ischaemic cardiovascular disease

Although early studies suggested that the risk of ischaemic cardiovascular disease was decreased in people with epilepsy, a small number of recent studies have refuted this contention and have demonstrated an increased prevalence of cardiovascular disorders in people with epilepsy [2,4,136]. If the risk of cardiovascular disease were increased in epilepsy, this could be due to lifestyle factors – for instance obesity, altered smoking and drinking habits and sedentary lifestyle – all of which are more common in people with epilepsy [137–139]. In addition, the administration of AEDs may contribute to an increased cardiovascular morbidity through their effect on homocysteine levels and serum lipid composition. Elevations of serum homocysteine levels have been consistently documented during administration of the enzyme-inducing AEDs, including phenytoin, carabamazepine and phenobarbital [140]. The literature regarding the effect of valproate is inconsistent and regarding newer AEDs is scanty [141]. The amino acid homocysteine is closely linked to other amino acids, including cysteine and methionine. Deficiencies of the vitamins B_{12} and B_6 and folic acid lead to increased levels of homocysteine. Elevated levels are associated with an increased risk of ischaemic heart disease, stroke, peripheral vascular disease and venous thrombosis in a graded manner [142]. The degree of elevation of homocysteine levels by the enzyme-inducing AEDs is mild in comparison with some of the genetic disorders responsible for hyperhomocysteinaemia. In addition, the elevated levels during treatment with enzyme-inducing AEDs are accompanied by reduced levels of serum or erythrocyte folate and serum vitamin B_{12}, and pyridoxal phosphate (vitamin B_6). Hence, correction of the accompanying deficiencies by vitamin supplementation may sound an appealing strategy to lower homocysteine levels. However, folic acid or other vitamin supplementation has not been shown to confer a reduced risk of cardiovascular disease in the general population and hence cannot be recommended in people using AEDs [143,144]. Besides the effect of enzyme-inducing AEDs on serum homocysteine levels, there are also concerns about their effect on serum lipid composition. About three-quarters of the cholesterol in the human body is endogenously synthesized, primarily in the liver. As a result, the enzyme-inducing AEDs may step up the hepatic synthesis of cholesterol, thereby increasing the risk of cardiovascular and cerebrovascular events. Longitudinal studies in users of enzyme-inducing AEDs have not, however, demonstrated any consistent effect of the AEDs on the lipid profiles [145,146]. The routine monitoring of serum lipid composition is not recommended in people with epilepsy. Individuals with epilepsy who are on enzyme-inducing AEDs should follow the recommendations regarding monitoring and control of serum lipids as for the general population.

21 Psychiatric Features of Epilepsy and their Management

Brent Elliott, Meriem Amarouche and Simon D. Shorvon

National Hospital for Neurology and Neurosurgery, London, UK

Epilepsy was for many years classified as and considered a 'psychiatric disease', no doubt because of the frequent association of seizures with psychiatric symptoms. In recent times, the physical basis of epilepsy has been emphasized and the psychological and psychiatric features conceptualized as 'co-morbidities'. That there is a close and intimate relationship between the physical and the psychiatric features of epilepsy, however, cannot be denied, and to what extent they are an integral part of the condition or a co-morbidity is arguable. The management of the psychiatric symptoms of epilepsy forms a very important part of modern clinical practice. In this chapter, these psychiatric symptoms are considered under the same broad headings used in conventional psychiatry. However, as will be emphasized, the psychiatric presentations in epilepsy often differ from those encountered in the functional psychiatric disorders.

Affective and anxiety disorders

Affective and anxiety disorders are the most common psychiatric disorders occurring in people with epilepsy. These International Statistical Classification of Diseases and Related Health Problems, 10th revision (ICD-10) [1], or *Diagnostic and Statistical Manual of Mental Disorders*, 4th edn (DSM-IV) [2], categories include manic, depressive, dysthymic, cyclothymic and bipolar affective disorders within the affective subgroup and generalized anxiety disorder (GAD), panic disorder and obsessive–compulsive disorder (OCD) among the anxiety disorders. Many patients with epilepsy, furthermore, suffer from atypical affective disorders which fail to meet established diagnostic criteria. Examples include the interictal dysphoric disorder and the abnormal affective and psychotic states brought about due to a reduction in or abolition of seizures (i.e. forced normalization) or due to the adverse effects of antiepileptic drugs (AEDs).

Not only are these disorders important to diagnose and treat in their own right but their presence also has implications for the treatment of the epilepsy itself. Hitiris *et al*. [3], for example, have shown that pharmacoresistance, in a large cohort followed for over 20 years, was associated with prior or current psychiatric co-morbidity and intermittent recreational drug use. Anhoury *et al*. [4] found that 'patients with a preoperative psychiatric history and de novo psychiatric symptomatology had a poorer surgical outcome in terms of seizure frequency', and Kanner *et al*. [5] noted that a lifetime history of depression is a predictor of failure to reach post-surgical (anterior temporal lobe) seizure outcome, free of auras and disabling seizures.

Prevalence of affective disorders in epilepsy

Estimates of the incidence and prevalence of affective disorders in epilepsy vary widely. Lifetime prevalence for a major depressive episode in the general population ranges between 3.7% and 6.7%. In patients with epilepsy, rates range from 11% (current depression) to 62% (lifetime-to-date depressive disorder) with an estimated mean of 30% across studies [6,7]. Prevalence may be lower (3–9%) in patients with good seizure control [8]. Anxiety disorders are also more frequent in this population and have been reported in 10–25% [7]. Mixed anxiety and depressive disorders have been reported to occur in 8.5% [9].

The prevalence of bipolar symptoms and past diagnoses of bipolar I or II disorder among patients with epilepsy was investigated by Ettinger *et al*. [10]. They found bipolar symptoms to be present in 12.2%; almost half of these 'screen-positive' patients were subsequently diagnosed with bipolar disorder.

The 'bidirectional relationship' between epilepsy and depression

Much research recently has addressed the issue of whether or not the relationship between epilepsy and depression is 'bidirectional'. This is not a new idea. Twenty-six centuries ago, Hippocrates wrote 'melancholics ordinarily become epileptics, and epileptics melancholics' [11]. In 1901, Sir William Gowers wrote that 'Suicide although not a certainty is often a probable indication of a morbid family tendency and some weight must be given to it as an indication of a disposition to a disease of which epilepsy may be the result even when it has an immediate exciting cause' [12].

Recent work supports this view. The main findings are:

- Adults with late-onset epilepsy (>54 years) are 3.7 times more likely to have a history of depression than are control subjects [13].
- Those with new-onset epilepsy are seven times more likely to have a history of depression than control subjects and the risk may be even higher (as much as 17-fold) in those with focal epilepsy [14].

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

- Children with new-onset epilepsy are four times more likely to have had a depressive episode prior to the first seizure [15].
- Adults and children over 10 years of age with a first unprovoked seizure or newly diagnosed epilepsy were found in one study to be five times more likely to have a history of attempted suicide [16].

Depressive symptoms associated with seizures

The occurrence of preictal affective symptoms has received relatively little attention in the literature. It is, nevertheless, clear that many patients with focal seizures do report prodromal states of depression, irritability or anxiety occurring hours to days before a seizure.

Simple or complex partial seizures affecting limbic structures have been associated with the production of numerous affective (fear, anger, depression, sexual excitement) symptoms, many of which have been recorded using intracranial stereoelectroencephalography (SEEG) techniques in patients during seizures [17] or by electrical stimulation of depth electrodes [18]. Ictal fear or panic is brief, lasting less than 30 s. It occurs out of context to concurrent events and may be seen in both temporal and extratemporal epilepsy, although it is more common in the former [19]. It can be severe, and can be confused diagnostically with primary panic attacks, which are also common in patients with epilepsy [20]. Ictal depression may range from mild feelings of sadness to profound hopelessness and despair. The potential for induction, by high-frequency electrical activation, of a depressive state was well demonstrated by Bejjani *et al*. [21], who induced a transient period of acute depression within 5 s of stimulating the left substantia nigra using deep brain stimulation (DBS) in a 65-year-old woman with a 30-year history of Parkinson's disease. This state resolved quickly with termination of the stimulation, but during this episode she started to cry and felt guilt, uselessness and hopelessness, and commented, 'I no longer wish to live, see anything, hear anything . . . I'm fed up with life . . . I'm disgusted with life . . . I don't want to live any more.'

A variety of postictal affective symptoms can occur following individual seizures or clusters of seizures. Kanner *et al*. [22] examined 100 consecutive patients with refractory epilepsy during the postictal period and found that symptoms of depression occurred in 43%, anxiety in 45%, hypomania in 22%, and active and passive suicidal thoughts in 8% and 13%, respectively. There was a significant association between a prior history of depression and symptoms of hopelessness, suicidal ideation, self-deprecation and guilt, and the median duration for most symptoms was 24 h.

Affective disorders in epilepsy

According to ICD-10, the main features of a depressive episode include: (1) lowered mood; (2) reduced energy and concentration; (3) diminished capacity for enjoyment, or interest; (4) marked tiredness after minimal effort; (5) disturbed sleep (hypersomnia or insomnia); (6) reduced appetite and weight loss (DSM-IV specifies a change of 5% of body weight over a 1-month period in the absence of dieting); (7) self-esteem and self-confidence are almost always reduced and, even in the mild form, some ideas of guilt or worthlessness are often present; (8) the lowered mood varies little from day to day and is unresponsive to circumstances; (9) 'somatic' symptoms may be present and include early-morning waking, diurnal variation in mood (worst in morning), psychomotor retardation/agitation and loss of libido; (10) recurrent thoughts of death and suicide are common with an increase in severity of the depression; (11) in severe forms there may be delusions, hallucinations and stupor. DSM-IV specifies that five or more symptoms should be present nearly every day over the same 2-week period and represent a change from previous functioning; at least one of the symptoms must be either low mood or loss of interest and pleasure anhedonia. Whilst depressive episodes which fulfil these criteria do occur frequently in patients with epilepsy, this is not always the case and a range of atypical affective disorders may also occur.

Atypical affective disorders in epilepsy

A significant proportion of depressive disorders in epilepsy fail to conform to current diagnostic criteria [23]. In a review of 97 patients with epilepsy whose depression was severe enough to warrant pharmacological treatment, Kanner *et al*. [24] found that in only 29% were the DSM-IV criteria for a major depressive disorder met.

The most common 'atypical' affective disorder in epilepsy is a chronic intermittent interictal dysphoric syndrome. A symptom complex similar to this was first described in 1923 by Emil Kraepelin, who used the term *Verstimmungszustand* to emphasize the periodicity of the dysphoric mood changes seen in these patients, along with irritability and outbursts of aggressive behaviour [25]. These dysphoric states were felt to occur 'very frequently with utter disgust of life and suicidal bent' [26]. The key symptoms included (1) irritability, (2) low mood, (3) insomnia, (4) anxiety and (5) occasional euphoria, and could last anything from a few hours up to a couple of days, at frequencies varying between every few days and every few months. This concept has since been elaborated upon by Blumer, who listed six key symptoms: (1) depressive mood, (2) anergia, (3) pain, (4) insomnia, (5) labile affective symptoms (fear, anxiety) and (6) 'specific' symptoms, which included paroxysmal irritability and euphoria [27]. A recent incarnation of this disorder is the 'dysthymic-like disorder of epilepsy' (DLDE) [9]. The difference between this and a DSM-IV diagnosis of dysthymic disorder lies in the disorder's duration and severity. Whilst several features are held in common (e.g. low mood, anhedonia, poor concentration, guilt, recurrent thoughts of death, a sense of worthlessness, weight loss/gain, insomnia/hypersomnia and psychomotor retardation/agitation), the former diagnosis is characterized by symptom-free periods of 1 to several days' duration, thus precluding a DSM-IV diagnosis. In the study by Kanner *et al*., 71% of their patients with both epilepsy and depression manifested symptoms of DLDE [24]. Anhedonia was the most disabling symptom in around half of these patients, and was significantly associated with a history of major depression. In the remainder, irritability and poor frustration tolerance were the key features.

Recently, Mula *et al*. [25] investigated whether or not this interictal dysphoric disorder is (a) a robust concept and (b) specific to epilepsy. They found that whilst the construct appeared to be robust, the specificity was lacking, and that the disorder can also be seen in other central nervous system (CNS) disorders such as migraine. This notwithstanding, clinical

experience suggests that this disorder is particularly associated with epilepsy.

Generalized anxiety disorder

In ICD-10, GAD refers to 'anxiety that is generalized and persistent but not restricted to, or even strongly predominating in, any particular environmental circumstances (i.e. it is "free-floating")'. DSM-IV specifies that the symptoms must be present more days than not for a period of at least 6 months. The main symptoms include (1) persistent nervousness, (2) trembling, (3) muscular tension, (4) sweating, (5) lightheadedness, (6) palpitations, (7) dizziness and (8) epigastric discomfort. It is often co-morbid with other medical or psychiatric conditions: in a study by Kessler, up to 90% of patients with GAD showed concomitant symptoms of depression, dysthymia, somatization, bipolar disorder or substance abuse [28].

In the general population, the lifetime prevalence of generalized anxiety disorder is 5.1%, with a 12-month prevalence measured at 3.1% [28]. In patients with epilepsy, anxiety symptoms have been reported in up to 66% [29], and Cramer *et al*. found that 48% of their series reported symptoms of anxiety which were rated as moderate in 16% and severe in 7% [30]. Most recently, Schöndienst and Reuber examined 77 patients with medically refractory epilepsy and reported that 12% met the DSM-IV criteria for the diagnosis of GAD [20].

Panic disorder

The essential features of panic disorder as defined by ICD-10 are 'recurrent attacks of severe anxiety (panic), which are not restricted to any particular situation or set of circumstances and are therefore unpredictable'. DSM-IV specifies that there should be at least one attack per week for a period of at least 1 month. It should not be diagnosed in the presence of a co-morbid depressive disorder.

Episodes of interictal panic are more protracted than those seen in the ictal phase, usually lasting from 5 to 20 min but sometimes persisting for several hours. The feeling of fear or panic is very intense ('feeling of impending doom') and associated with a range of autonomic symptoms (tachycardia, blood pressure fluctuation, diffuse diaphoresis and shortness of breath). There may be anticipatory anxiety due to a fear of further attacks and avoidance behaviours may result and significantly limit independence and quality of life. Beyenburg *et al*. [31] estimated that patients with epilepsy were six times more likely to suffer from panic disorder than the general population, with point prevalence estimates ranging between 5% and 30% [32]. It is important to differentiate true panic attacks from partial seizures, which sometimes can have similar symptoms.

Obsessive–compulsive disorder

According to ICD-10, there are two key features of OCD:

1 Recurrent obsessional thoughts are ideas, images or impulses that repeatedly enter the patient's mind in a stereotyped form. These are recognized as the patient's own thoughts, but are felt to be distressing and are usually resisted.

2 Compulsive acts or rituals are stereotyped repetitive behaviours which are not enjoyable and do not result in the completion of useful tasks. Their function is to prevent some objectively unlikely event, often involving harm to or caused by the patient. Resisting the compulsive act usually leads to an immediate increase in anxiety.

Monaco *et al*. [33] compared the prevalence of OCD in 62 patients with temporal lobe epilepsy (TLE), 20 patients with idiopathic generalized epilepsy (IGE) and 82 healthy control subjects. Nine of the TLE patients, none of the IGE patients, and only one of the controls had a diagnosis of OCD. Patients with TLE and OCD differed significantly with respect to a history of depression when compared with patients with TLE without OCD and a recent study comparing the obsessive–compulsive themes in patients with TLE and Tourette's syndrome concluded that the former tend to focus on existential thoughts whereas the latter present themes related to sexuality and impulsiveness [34]. TLE surgery may cause *de novo* OCD [35,36]; however, several authors have also reported complete remission or improvement of OCD following surgery for TLE [37,38].

Suicide in epilepsy

Suicide accounts for about 1.5% of deaths worldwide [39], yet the suicide rate in epilepsy would appear to be much higher. One meta-analysis by Harris and Barraclough [40] found that suicide accounted for for 181 out of 2196 deaths (8%) in epileptic subjects. Others, however, argue that the true rate is lower. More recently several very large cohorts have been followed up for many thousands of patient-years in Denmark, the UK and Sweden, which demonstrate statistically significant standardized mortality ratios of between 3 and 5.5 [41–43]. It has been stated that the lifetime prevalence of suicidal ideation is roughly twice as high among patients with epilepsy as among the general population [44].

Suicide in epilepsy is a rare event and studies need to retain large numbers of people for long periods of time in order to detect statistically significant differences in suicide between epileptic and non-epileptic populations. Two studies, one in the Netherlands [45] and one in Scotland [46], found increased standardized incidence ratios of 2.1 and 1.7 of suicide in patients with epilepsy, but the differences were not statistically significant. World Health Organization (WHO) prevalence figures for suicide vary from country to country and, whilst it is clear that patients with epilepsy in Denmark are more likely to die by suicide (which has a higher baseline prevalence of suicide), these figures may not apply elsewhere [41].

Several risk factors for suicide in epilepsy have been highlighted in the literature and these can be summarized as follows:

1 The highest relative risk (RR) would seem to occur in the first 6 months after diagnosis (RR 5.35), particularly in those with co-morbid psychiatric disease (RR 29.2), even after adjusting for socioeconomic factors (RR 13.7) [41].

2 Use of antipsychotic drugs increases risk 10-fold [47].

3 Early-onset epilepsy (<18 years vs. >29 years) and having any seizure compared with being seizure free in the past year carry respective relative risks of 16.0 and 2.0 [47].

4 TLE has been associated with a 25-fold increase in risk, and for surgically treated patients this may be even higher [40].

5 Of 193 patients followed up after temporal lobectomy for 5–24 years, 9 out of 37 deaths were by suicide. If six further deaths which occurred in unclear circumstances are included, the suicide rate became 50 times that expected [48].

Diagnosis of depression in epilepsy

Ordinarily, the diagnosis of depression is made on the basis of a patient meeting criteria for a depressive syndrome as per ICD-10 or DSM-IV; however, as the above discussion highlights, there are depressive syndromes in epilepsy which do not meet standardized operational criteria. Furthermore, the diagnosis of depression in this particular patient group is complicated by the fact that many patients do not complain of mood problems (or are rarely asked) and the problems with sleep, appetite, libido, cognition or memory can be interpreted as side-effects of antiepileptic drugs. Feelings of guilt and a circadian pattern of symptom severity are rare in epilepsy [23].

Gilliam *et al*. have attempted to address the difficulties in diagnosis by developing and validating the Neurological Disorders Depression Inventory for Epilepsy (NDDI-E) [49]. This instrument attempts to minimize the confounding effects of adverse events caused by antiepileptic drugs or cognitive problems associated with epilepsy. It includes items relating to core depressive symptoms such as anhedonia, guilt, the feeling that nothing one does is right and that one would be better off dead, and takes only 3 min to complete. It has been validated in patients with epilepsy and a score of ≥15 has a specificity of 90% and sensitivity of 81% for a diagnosis of major depression.

Other potentially useful rating scales include the Beck Depression Inventory (BDI-II) [50], which is a 21-item self-rated screening instrument that takes about 5 min to complete and has also been validated in epilepsy. Scores over 20 indicate moderate to severe depression. Suicidality can be assessed using the suicidality module of the Mini International Neuropsychiatric Interview (MINI) [51].

Treatment of depression in epilepsy

In a random survey of 135 neurologists, Gilliam reports that 82% did not routinely screen epilepsy patients for depression in their outpatient clinics [52]. Others have pointed out that as many as 60% of patients with epilepsy and depression were symptomatic for more than 1 year before any treatment was suggested [24], a finding supported by Wiegartz *et al*. [53], who noted that one-quarter of their patients with partial seizures reported symptoms of minor depressive disorder (dysthymia and depressive disorder not otherwise specified), but none had received treatment.

This could be in part due to the concern that the antidepressant drugs can increase seizure frequency. Tricyclic antidepressants (TCAs) can certainly lower seizure threshold (particularly at higher doses; see below) but the incidence of seizures in people without epilepsy treated with selective serotonin reuptake inhibitor (SSRI), noradrenergic and specific serotonergic (NaSS) and serotonin–noradrenaline reuptake inhibitor (SNRI) antidepressants is actually significantly lower than would be expected in the general population (citalopram, <0.3%; sertraline, 0.0%; fluoxetine, 0.2%; duloxetine, 0.0%; mirtazepine, 0.04%; venlafaxine, 0.1%) with the exception of bupropion IR [54]. Serotonin has been shown to inhibit epileptiform activity in rat hippocampal CA1 neurones via 5-hydroxytryptamine 1A ($5HT_{1A}$) receptor activation, and depresses excitatory postsynaptic potentials in a concentration-dependent manner [55]. Fluoxetine [56] and citalopram [57,58] have been reported to produce antiepileptic effects in open-label studies of non-depressed epileptic patients, reducing seizure frequency by as much as 35–64%, and it may be that seizures which occur after starting SSRIs are merely reflecting the increased risk of seizures associated with the depressive disorder [9]. Assuming the incidence of unprovoked seizures in the general population is 60 per 100 000 patient exposure years [(PEY) the cumulative time in years that a patient is exposed to a drug or placebo], the reported incidence of seizures of 1116.7 per 100 000 PEY in patients treated with placebo in antidepressant clinical trials reviewed by Alper *et al*. is a figure which is approximately 19 times the rate seen in the general population [54].

Tricyclic (particularly high dose) and tetracyclic antidepressants are felt to pose a greater level of risk, and it is recommended in some guidelines that these agents should be avoided altogether if at all possible. However, Blumer and Altshuler [59] treated about 200 depressive epilepsy patients over a period of 20 months, initially with imipramine or amitriptyline at daily doses of less than 150 mg/day. Twenty-two non-responders were then treated in combination with paroxetine 10–50 mg (an SSRI). Fifteen had a complete remission and four a partial response of their depressive symptoms. Only three were refractory to this regimen and there was no exacerbation in seizures. Bupropion (contraindicated in epilepsy, according to manufacturer's prescribing information), clomipramine, amoxapine and maprotiline pose the highest risk of worsening seizures and should be avoided in epilepsy given the wide variety of alternatives available.

Another possible risk is that antidepressant use can 'switch' the depressive into a manic state in patients with hitherto undiagnosed bipolar disorder presenting with depression as the index episode. There are certain features in the history that should act as a red flag for this possibility and would warrant specialist referral before initiating antidepressant therapy: (1) prepubertal, adolescent or postpartum onset; (2) a hypersomnic/psychomotor retarded or catatonic psychotic episode; (3) positive family history for bipolar disorder or consecutive generation mood disorder; and (4) an episode of pharmacologically induced hypomania [60]. In general, the risk of switching is thought to be lower with SSRIs than with tricyclic antidepressants.

Pharmacokinetic interactions between antidepressants and antiepileptic drugs

Carbamazepine, phenytoin, primidone and barbiturates are potent inducers of the cytochrome P450 (CYP) enzymes at regular doses, as are oxcarbazepine and topiramate at higher doses [9]. Several of these enzymes are involved in the metabolism of tricyclic antidepressants and all SSRIs and SNRIs. The drugs affected include amitriptyline, nortriptyline, doxepine, clomipramine, mianserin, nomifensine, bupropion and, to a lesser extent, citalopram and paroxetine. The doses of these antidepressants will often need to be increased when used alongside these agents. The newer AEDs (e.g. gabapentin, lamotrigine, tiagabine, levetiracetam and zonisamide) do not have this effect [9].

Valproate is a broad-spectrum inhibitor of drug metabolism and has been associated with a 50–60% elevation in plasma amitriptyline and nortriptyline concentrations. Valproate also increases concentrations of clomipramine and paroxetine. Certain SSRIs also inhibit CYP enzymes: fluoxetine and fluvoxamine are mild to moderate inhibitors of CYP 3A4, the primary enzyme involved in carbamazepine metabolism. Neither paroxetine nor

sertraline affects plasma concentrations of carbamazepine or phenytoin, but sertraline doses of between 25 and 100 mg have been associated with both valproate and lamotrigine toxicity. There are several reports of plasma phenytoin concentrations increasing to toxic levels after initiation with fluoxetine, probably due to CYP 2C9 inhibition [61]. Phenytoin levels can also rise with co-medication with trazodone, viloxazine and imipramine. Evidence for interaction is often conflicting, and doses may need adjustment depending on levels. Citalopram, mirtazepine and venlafaxine have the least impact on CYP enzyme [9].

Pharmacodynamic interactions

The following points relate to the pharmacodynamic effects of antidepressant medication as used in general psychiatric practice (i.e. in patients without epilepsy). Whilst these findings are not specific to patients with epilepsy, the same general principles are felt to apply. On initiation of therapy with antidepressant drugs, common symptoms include a temporary worsening of anxiety and agitation, which usually passes after the first week or two. In very anxious patients, low-dose short-term benzodiazepine cover (e.g. diazepam 2 mg three times a day) may be given, and normal starting doses may be halved. Gastrointestinal symptoms such as abdominal cramps, nausea and diarrhoea are also seen. Hypertension should be examined for in patients taking venlafaxine, particularly at higher doses, and this medication should be avoided in patients at risk of cardiac arrhythmia. A variety of sexual disturbances may occur and should be asked about, as they reduce compliance. Hyponatraemia can occur with most SSRIs and is often seen in the older patient group. Co-medication with oxcarbazepine, carbamazepine or diuretics will exacerbate this. Mirtazepine is less likely to cause hyponatraemia, or sexual side-effects, but often causes sedation and weight gain. The SSRIs and SNRI venlafaxine should be taken in the morning as evening use can lead to initial insomnia. Fluoxetine is often said to have an 'activating' effect and may be useful in fatigued or lethargic patients, and those with psychomotor retardation. It also has the added benefit of being one of the few antidepressants that does not cause significant weight gain, a particular problem in patients taking AEDs that also induce weight gain, such as valproate, gabapentin and pregabalin. In the UK it is the only antidepressant currently licensed for use in children and adolescents under 18 years of age. Its other benefit is that the main active metabolite, norfluoxetine, has a half-life of 4–16 days, and in patients who regularly forget to take their medication this can often help to prevent SSRI discontinuation symptoms emerging. The latter are an effect common to all SSRIs, and symptoms include headache, rebound insomnia, increased anxiety, flu-like symptoms and electric shock-like sensations. These can best be avoided by gradual dose reduction rather than precipitate discontinuation. All patients started on SSRIs should also be warned of the possibility of an increase in suicidal thoughts and behaviours following drug initiation, and this should be asked about in the subsequent review.

Antidepressant trials in epilepsy

In view of the specific issues relating to depression in epilepsy, there is a clear need for well-conducted, controlled studies, but few such studies have been carried out. In one of the few published controlled studies, Robertson and Trimble [62] randomized 42 patients with epilepsy and depression to amitriptyline 75 mg, nomifensine or placebo. After 6 weeks, there were no between-group differences, perhaps because of the low dosages. On follow-up, 26 non-responders were openly treated with higher doses (150 mg/day) and, after a further 6 weeks, 17 patients entered remission from their depressive symptoms. Specchio *et al*. [58], in an open-label uncontrolled study, were able to show a marked improvement in depression in 39 patients treated with citalopram 20 mg/day. Kuhn *et al*. [63] analysed *post hoc* data from 2 years of treatment of 75 inpatients with major depression and TLE. They compared citalopram, mirtazepine and reboxetine, finding these drugs equally efficacious. There were no serious adverse events or drug interactions.

There are no controlled data available on the treatment of DLDE. In one open trial, however, complete symptom remission was achieved in 57% of patients treated with sertraline [24]. The mechanism of action of antidepressants in DLDE probably differs from that in other depressive disorders; the drugs are rapidly effective at low doses and are effective for anxiety, fears, irritability, insomnia, anergia, atypical pains, low mood and euphoric mood.

A practical protocol for the treatment of depression in epilepsy

There is a Cochrane review regarding antidepressants in epilepsy, but this is currently at the protocol stage, and the best current advice can be taken from the guidelines for the use of antidepressants in non-epileptic patients, with some modifications taking into account considerations mentioned above.

The largest clinical antidepressant trial to date, the National Institute of Mental Health (NIMH) STAR-D (sequenced treatment alternatives to relieve depression) trial [64], was recently completed. The trial protocol consisted of patients sequentially moving through four treatment levels depending on whether or not they responded to a particular antidepressant or combination of antidepressants. The purpose of the trial was to determine the effectiveness of different treatments for people with major depressive disorder who did not respond to the initial antidepressant treatment choice.

In treatment level 1, all patients received citalopram. One-third entered remission and a further 10–15% showed a clinically significant response. Those who did not respond were switched to treatment level 2, in which the citalopram was either (a) changed to sertraline, venlafaxine or cognitive behavioural therapy (CBT) or (b) augmented with buspirone or bupropion (both contraindicated in epilepsy) or CBT. Twenty-five per cent of the patients treated within level 2 eventually became symptom free. Level 3 treatment included mirtazepine or nortriptyline, and, in level 4, antidepressant drug combinations, such as mirtazepine plus venlafaxine, were used.

Whilst this trial was not carried out in patients with epilepsy (in whom bupropion is contraindicated and nortriptyline best avoided), a simple and evidence-based pathway for the treatment of depression in epilepsy (based on the other factors discussed above) would be to start treatment with citalopram, and then if remission of symptoms is not achieved progress through sertraline, mirtazepine and venlafaxine. Recommended starting doses, usual treatment dose and maximum doses as observed in routine psychiatric practice are outlined in Table 21.1.

Table 21.1 Commonly used antidepressants and antipsychotics: doses, receptor binding and other effects.

Antidepressant/ antipsychotic	Starting dose/timing	Usual treatment dose	Maximum dose	Pharmacology	Adverse/other effects
Citalopram	10–20 mg, morning (use 10 mg if very anxious ± panic)	20–40 mg	60 mg	H_1, inhibits CYP 2D6	Inconsistent effect at lower doses Effective in the elderly
Sertraline	50 mg, morning	50–100 mg	200 mg	SRI, DRI, sigma 1 binding	Good for atypical/psychotic (delusional) depression
Fluoxetine	20 mg morning	20–40 mg	60 mg	SRI, NRI, $5HT_{2C}$ antagonist. Inhibits CYP 2D6/3A4	Energizing and fatigue-reducing effect
Mirtazepine	15 mg, night	30 mg	45 mg	α_2, H_1, $5HT_{3/2A/2C}$	No significant sexual dysfunction Weight gain Sleep restoring Less nausea/gastrointestinal problems Anxiolytic
Venlafaxine XL	75 mg, morning	150 mg	225 mg	SRI, NRI	Extended-release version reduces side-effects, particularly nausea May be linked to more robust and longer remission rates Metabolized by CYP 2D6
Risperidone	2 mg	4–6 mg	16 mg (doses >8 mg are rarely used)	$5HT_{2A}$, D_2, α_1, α_2, $5HT_7$	EPSE at higher doses, hyperprolactinaemia, hypertriglyceridaemia, insulin resistance, HONK Less weight gain than olanzapine and clozapine Higher doses may be required due to enzyme induction by carbamazepine/phenytoin (CYP 3A4)
Olanzapine	5 mg	5–15 mg	20 mg	mACh, $5HT_{2A}$, $D_{1–4}$, $\alpha_{1/2}$, H_1, $5HT_{3/6}$, 5HT-C	Weight gain, sedation (less than clozapine) Poses definite cardiometabolic, dyslipidaemia and diabetes risks EPSEs not common Enzyme induction possible with carbamazepine (CYP 1A2)
Quetiapine	25–100 mg (depending on age)	400–600 mg	750–800 mg	D_2, $5HT_{2A/1A/2C}$, H_1, α_1, α_2, M_1	Virtually no EPSE No hyperprolactinaemia Sedation Intermediate to high risk of dyslipidaemia/insulin resistance
Amisulpiride	200 mg	400–800 mg	1200 mg	D_3. Possible D_2 partial agonist	Low EPS May cause dose-dependent QTc prolongation Can increase prolactin
Clozapine	12.5 mg	300–700 mg (adjusted according to plasma level and response)	900 mg	$D_{1–4}$, $5HT_{2A/C}$, α1/2, H,1 mACh, $5HT_{3/6/7}$	Weight gain, sedation, hypersalivation, constipation, bowel obstruction, agranulocytosis, myocarditis, seizures Sudden hyperosmolar syndrome/diabetic ketoacidosis High cardiometabolic risk Reduces suicide risk Cannot be combined with carbamazepine or lamotrigine because of risk of agranulocytosis Needs slow introduction with EEG monitoring Specialist monitoring registration

CYP, cytochrome P450; EPSE, extrapyramidal side-effects; HONK, hyperosmotic non-ketotic acidosis.

Cognitive behavioural therapy

It is likely that affective disorders respond better to a combination of pharmacotherapy and psychological therapy than to either modality alone. CBT usually involves 12–16 sessions with a specially trained psychologist or psychiatrist, during which patients' unhelpful beliefs about themselves and the world they interact with are explored. The behaviours which result from these beliefs act to reinforce the depressed state. In the therapy these views are challenged, alternative possibilities explored and a more helpful set of attitudes and beliefs encouraged.

Electroconvulsive therapy

Epilepsy is not a contraindication to electroconvulsive therapy (ECT), and in fact there is good evidence that ECT actually increases

seizure threshold. However, the use of ECT has declined significantly in routine clinical psychiatric practice but it is still employed (albeit rarely) in patients with severe depression, treatment-resistant mania and, on a very occasional basis, in psychosis.

Deep brain stimulation for treatment-resistant depression

Up to 20% of patients with epilepsy and depression fail to respond to pharmacological or psychotherapeutic interventions and may then require a trial of ECT. Despite this, some patients remain severely depressed. Several studies have demonstrated consistent involvement of the subgenual cingulate (BA25) as an area metabolically overactive in treatment-resistant depression whilst a decrease in BA25 activity has been associated with clinical response to antidepressant treatments. Mayberg *et al.* [65] tested the hypothesis that chronic stimulation to modulate Cg25 (subgenual cingulate) grey matter and interconnected frontal and subcortical regions could reverse this pathological metabolic overactivity and produce clinical benefits in patients with treatment-resistant depression. The regional cerebral blood flow (CBF) changes [using positron emission tomography (PET)] in these treatment-resistant depression patients can be seen at baseline and after 3 and 6 months of continuous deep brain stimulation (Plate 21.1). Whether these approaches would be beneficial in epilepsy and depression has not been demonstrated.

FDA guidance on suicide risk associated with antiepileptic drugs

On 31 January 2008, the US Food and Drug Administration (FDA) issued an alert regarding suicide risk in patients taking antiepileptic drugs. This warning derives from the fact that in March 2005 the FDA sent letters to sponsors of antiepileptic drugs requesting that they submit data from placebo-controlled trials for the FDA to review the possible association of suicidality events and antiepileptic drugs. In all, 199 placebo-controlled trials with a total of 27 863 patients in the drug arms and 16 029 patients in the placebo arms were submitted. Only one-third of these trials were included in the main analysis because trials without reports of suicidality were excluded [66].

The primary endpoint of the study was suicidal behaviour and ideation and this included (1) completed suicide, (2) suicide attempt, (3) preparatory acts towards imminent suicidal behaviour and (4) suicidal ideation. The secondary endpoints were (a) suicidal behaviour (completed suicide, suicide attempt, preparatory acts) and (b) suicidal ideation (suicidal ideation only). The results can be seen in Table 21.2.

There were four completed suicides in the treatment group, a rate of about 1 in 7000. Suicidal behaviour or ideation occurred in 1 in 270 of the drug-treated group compared with 1 in 416 of the placebo group. The overall number needed to harm was 2 per 1000 and the odds ratio was significant at 1.8. In subanalyses for each individual drug, carbamazepine and valproate appeared to reduce suicidal behaviour and ideation events, although this effect was not significant; nevertheless, the alert currently includes the entire class of antiepileptic drugs. In November 2007, the sponsor of lamotrigine submitted three additional placebo-controlled trials, which were not part of the primary analysis. In these three trials there were nine suicidal behaviour or ideation events, only one of which occurred in the drug arm, with the other eight occurring in the placebo arm. The overall odds ratio decreased to 1.55 but remained significant (1.09–2.21). The alert raises significant concerns that patients might stop their antiepileptic drugs, placing them at higher risk of accidental injury and sudden unexpected death in epilepsy (SUDEP). Unfortunately, in our opinion, the points above reduce the validity of the data. Data on suicide need to be collected in a prospective and systematic way and, given the complexity of the relationship between epilepsy, depression and suicide, this meta-analysis is insufficiently robust to be of much value [66].

Table 21.2 Results from the Food and Drug Administration analysis in suicidal behaviour and ideation associated with antiepileptic drug use.

Primary endpoint: suicidal behaviour and ideation	Number	Number of completed suicides (ratio)	Suicidal behaviour or ideation (ratio)	Odds ratio
Drug arm	27 863	4 (1/6966)	0.37% (1/270)	1.8 (1.24–2.66)[a]
Placebo arm	16 029	0	0.24% (1/416)	
Secondary endpoints				
Suicidal behaviour	–	–	–	2.92 [1.44–6.47]
Suicidal ideation	–	–	–	1.45 [0.93–2.30]

[a] Odds ratio prior to additional lamotrigine data.

The psychoses of epilepsy

The psychoses of epilepsy have been the subject of considerable research over the past century. Much of this has been carried out by psychiatrists, whose approach has been to examine these phenomena through the empirical prism of descriptive psychopathology (i.e. without reference to causality) in order to determine to what extent the psychoses of epilepsy are similar to, or differ from, those seen in the 'functional psychoses'. The approach often taken by neurologists has been more biological, linking the symptoms to electrophysiological activity or seizure occurrence. The 'gold standard' investigation of this approach is intracranial stereo-EEG.

There are also strikingly divergent views regarding the causation of affective and psychotic states in patients with epilepsy. Some have emphasized an apparent biological antagonism between affective/psychotic symptoms and ongoing seizures, as described below in the section on forced normalization and which incidentally led von Meduna to introduce iatrogenic convulsions to treat schizophrenia. Others, for instance Slater, postulate a positive link between epilepsy and schizophrenia, an observation elaborated upon subsequently by findings from SEEG. This is a very complex area. One clinical approach has been to subdivide these disorders into ictal, postictal and interictal types, even if at the electrophysiological level these distinctions are less clear. Furthermore, some psychosis in epilepsy may be due to ongoing non-convulsive complex partial (limbic) status epilepticus, some is AED related and some may reflect other changes in neurophysiological activity.

Ictal psychosis (complex partial status epilepticus)

Complex partial status epilepticus is an epileptic condition which provides one of the clearest examples of the propensity of epilepsy to cause prolonged or persisting hallucinatory states. A detailed exploration of this area is beyond the scope of this chapter; however, the reader is referred to a detailed review of the available SEEG data correlating psychotic symptoms with limbic epileptic discharges [67,68]. Psychiatric features include inaccessibility, delusions, illusions, visual or auditory hallucinations, ideas of reference, paranoia, thought disorder and often a rather curious but characteristic perseverative obsessive insistence on oppositions (such as black/white, good/bad, right/left). The hallucinatory experiences often have religious content. The attacks typically last hours, but can be much more prolonged (occasionally continuing for months or years). The attacks are usually self-limiting, and the symptoms frequently fluctuate or 'cycle' [69].

Postictal psychosis

The concept of postictal psychosis can be dated back to the work of Jackson [70] on 'temporary mental disorders after epileptic paroxysms'. Despite this, and the fact that it is the most frequent psychotic condition seen in patients with epilepsy, it did not become the focus of attention until more recently [71,72]. There continues to be no universally agreed definition, although that used by Kanemoto *et al.* [73], including any psychotic episode occurring within 7 days of the last generalized tonic–clonic seizure or cluster of complex partial seizures, is useful.

Common findings among the different case series include (1) delay between the onset of psychiatric symptoms and the time of last seizure; (2) relatively short duration of psychosis; (3) affect-laden symptomatology; (4) the clustering of symptoms into delusional and affective-like psychoses; (5) an increase in the frequency of secondary generalized tonic–clonic seizures preceding the onset of postictal psychosis; (6) the onset of postictal psychosis after a long duration of epilepsy (for a mean period of more than 10 years); and (7) a prompt response to low-dose antipsychotics or benzodiazepines [74].

The phenomenology of postictal psychosis has also been extensively addressed. Most episodes occur in patients between 30 and 40 years of age, and in 86% they follow a clear increase in generalized seizure frequency. The lucid interval can last between 1 and 6 days (mean 2.5) in 75%, following which hallucinations (mainly auditory) are found in about one-third and delusions (mainly persecutory) in one-quarter. One study found that patients fulfilled present state examination (PSE) criteria for schizophrenic psychosis in four, manic/mixed affective psychoses in three and paranoid psychoses in four. They found the psychopathology to be identical to that found in the functional psychoses. Mood was markedly abnormal (elevated, depressed or both) in three-quarters, one-half had paranoid delusions and both auditory and visual hallucinations were common. Hypomania and religiosity following temporal lobe seizures has also been noted and patients appear more likely to experience grandiose and religious delusions in the presence of elevated mood and a feeling of mystic fusion of the body with the universe [68,75].

The other interesting point to raise is that it is likely that at least some cases of apparently 'postictal psychosis' are not in fact 'postictal' at all but are due to ongoing seizure activity – and thus can be categorized as cases of non-convulsive status epilepticus [67,68,76,77]. This has led Oshima *et al.* [78] to suggest that postictal psychosis should be subdivided into two types: first, a nuclear type representing the established clinical picture as described by Kanner above and occurring as an indirect after-effect of seizure activity and, second, an atypical peri-ictal type, occurring as a direct manifestation of limbic epileptic discharges (i.e. complex partial status).

The interictal psychosis of epilepsy

Definition

As Sachdev [79] has pointed out in his review on epileptic psychoses, most studies have lacked a precise definition of either 'psychosis' or 'epilepsy'. Definitions for interictal psychosis need to exclude peri-ictal psychosis, allow for the subcategories of drug induced and the possibility of 'alternative' psychosis, and be present in the absence of seizure discharges. They are frequent and clinically more significant than the peri-ictal psychoses in terms of severity and duration.

Prevalence

There is a great deal of variance in prevalence estimates for psychosis in epilepsy. Reported prevalence rates range from 4.3% and 6% in IGE and TLE groups, respectively [80], to 40.2% and 44% for those with 'centrencephalic' epilepsy and 'psychomotor' epilepsy, respectively [81]. In a later review by Sengoku *et al.* [82], more intermediate rates (19.4% and 15.2% in the IGE and TLE groups, respectively) were reported, and these correspond well with recent work by Filho *et al.* [83], who reported psychotic disorders in 15.8% of 85 patients with TLE plus mesial temporal sclerosis.

Relationship to epilepsy subtype

Throughout the twentieth centrury, there have been numerous attempts made to assign different psychiatric features to the different types of epilepsy. Several studies have not found significant differences [81], and more recent attempts to relate psychopathology to epilepsy localization have also been equivocal [84]. In one of the largest population-based studies to date, Qin *et al.* [85] found that people with a history of epilepsy were two to three times more likely to develop schizophrenia or schizophrenia-like psychosis than people who had never had epilepsy again. They did not find a difference according to the type of epilepsy.

Nevertheless, there is a strong clinical impression that patients with epilepsy involving limbic structures may be particularly vulnerable to psychotic disorders and the view that patients with TLE are particularly prone to psychosis is widely held. Stevens [86] sums up what are still contemporary views: 'It would be correct to say that nearly two thirds of all the adult epileptics studied who were known to have had psychotic episodes which required hospitalisation also had a diagnosis of psychomotor temporal epilepsy.'

Psychopathology in interictal psychosis: comparison with primary psychoses

In the 1950s, Hill and Pond observed that whilst patients with psychosis in epilepsy could experience positive symptoms

(delusions and hallucinations), they tended to remain 'warm and appropriate' and the course of illness lacked the usual deterioration of personality seen in schizophrenia [87]. Slater *et al*. [88] agreed but added that 'the delusions and hallucinations of patients with the psychosis of epilepsy are empathiseable' (i.e. the patient remains in our world). Other key features are the absence of negative symptoms and better premorbid function [88,89]. Interictal manic or bipolar presentations are considered rare. Notable exceptions include Flor-Henry's [90] series, in which an affective psychosis occurred in 40% of patients, and the prevalence rate of 70% for depressive psychosis reported by Fenton [91].

By way of contrast, Mendez *et al*. [92] found that 'the schizophrenia of epilepsy appears to conform to the usual schizophrenic categories' and Perez and Trimble [89] found that 46% of their epilepsy group had nuclear schizophrenia symptoms almost indistinguishable from those seen in patients with schizophrenia.

To summarize, it would seem that the key differences lie in a preservation of affect, fewer negative symptoms and arguably greater insight, whilst the greatest similarities can be seen in positive symptomatology (i.e. that of thought disorder, delusions and hallucinations). Nevertheless, these differences have not been consistently found, and the similarities of the two conditions are much greater than any differences. An interesting point about the interictal psychosis of epilepsy is that it develops almost always only after the epilepsy has been present for many years (usually after a decade or so of seizures) and almost always in patients in whom epilepsy control has been poor.

Forced normalization

Chronic interictal psychoses also seems to be more common than at the beginning of the last century [9]. One explanation advanced for this phenomenon is that it arises as an undesirable result of modern AEDs suppressing epileptic or neurophysiological activity. It has been suggested that the epileptic and psychiatric components of psychomotor epilepsy might be physiologically antithetical [93,94].

'Forced normalization' is a term coined by Landolt [95], who noted that in occasional patients the electroencephalogram (EEG) became 'normalized' each time the patient's mood became dysphoric, and there appeared to be an alternating pattern of interictal psychosis and seizures. This led Landolt to define forced normalization as 'the phenomenon characterized by the fact that, with the recurrence of psychotic states, the EEG becomes more normal, or entirely normal, as compared with previous and subsequent EEG findings' [96]. More recently, the concept has been loosened to refer to almost any psychiatric disorder occurring in patients whose seizure frequency is reduced (disregarding the EEG altogether), and elaborate explanatory theories have been derived from doubtful evidence. One criticism of the original concept, and particularly of the loose extrapolation to include seizures as well as EEG change, is that the reverse situation is much more commonly observed in clinical practice – where psychotic behaviour is increased at times of seizure exacerbation or worsening EEG change. In the eyes of most epileptologists, the concept of forced normalization is of dubious validity and little practical importance, except perhaps in very occasional circumstances. Furthermore, the scalp EEG is a notoriously insensitive tool at detecting epileptic activity in medial limbic structures and a normal scalp EEG is by no means a reliable predictor of quiescent epilepsy.

Psychosis and temporal lobe surgery

When temporal lobectomy was first introduced in the 1950s, it had been hoped that it would alleviate the psychosis of epilepsy as well as seizures; indeed, psychosis was seen as a positive indication. However, it was rapidly recognized that temporal lobectomy also often made psychosis worse. The literature in this area is extensive but the main themes are as follows: some patients can be cured of their psychosis following surgery (although relapse is probably common) [97,98]; more commonly, however, the psychosis can be exacerbated by surgery [99]; and *de novo* psychosis can also occur after epilepsy surgery – in perhaps 5% or more of cases [98–101]. Matsuura [102] found *de novo* interictal psychosis in about 4% of cases, and in two-thirds complete seizure remission following surgery had not been achieved, In two of Shaw's series [101] there was a close temporal link between the recurrence of seizures postoperatively and the first appearance of psychotic symptoms. One of the significant risk factors included bilateral preoperative EEG abnormalities. Right-sided resections appear to be associated with an increased vulnerability to developing psychosis postoperatively [100,102,103]. The data are not entirely consistent, however, and it is clear also that psychosis can follow both left- and right-sided operations [68].

Therapy of psychosis in epilepsy

Pre-ictal, ictal and postictal hallucinations are best treated by controlling the ictus, and thus by AEDs. In cases where postictal psychosis is thought to be due to ongoing limbic status epilepticus, acute therapy with benzodiazepines is usually advised, sometimes with additional antipsychotic therapy (see below) if the psychosis is florid. Clobazam is a common AED choice given orally at 20–30 mg/day over several days. The postictal psychosis of epilepsy has also been shown clearly to respond to ECT [104], although it is hardly ever necessary to resort to this in current practice. It is important to ensure that patients are nursed with the appropriate level of supervision in a contained environment and protected from causing harm to themselves or others.

In patients with chronic interictal psychosis, antipsychotic drug therapy is needed in most cases. In general, modern atypical antipsychotic drugs, such as risperidone, olanzapine, amisulpiride, sulpiride and quetiapine, in relatively low doses, are sufficient to control symptoms, although on occasion combinations of antipsychotic drugs (e.g. amisulpiride and olanzapine) or clozapine may be required in particularly treatment-resistant cases. Recommended starting doses, usual treatment dose and maximum doses as observed in routine psychiatric practice are outlined in Table 21.1.

Treatment is complicated by the fact that almost all available antipsychotics are mildly epileptogenic, with seizure incidence rates (in patients who previously had not had seizures) ranging from approximately 0.1% to approximately 1.5% (the incidence of the first unprovoked seizure in the general population is 0.07 to 0.09) [105]. EEG changes seem to occur in about 7% of patients treated with antipsychotic drugs, but in most cases are of little clinical consequence [106]. In one recent review, seizure incidence for the different atypical antipsychotics was given as

0.3% for risperidone and 0.9% for olanzapine and quetiapine. Another study found that a set of all antipsychotics (olanzapine, quetiapine, clozapine, risperidone, ziprasidone and aripiprazole) was not significantly associated with an increased risk of seizures after the removal of both olanzapine and clozapine from the group [54]. The risk with clozapine increased in a dose-dependent manner from 1.0% with low doses (<300 mg/day) to 2.7% with moderate doses and 4.4% with high-dose (600–900 mg/day) treatment [107]. Pacia and Devinski [108], in a postmarketing study of more than 5000 patients on clozapine, showed a lower rate (1.3%) with no dose dependency, and when Langosch and Trimble [109] treated six patients with epilepsy and severe psychosis with clozapine, none showed an increase and in three there was a substantial reduction in seizure frequency.

The fear of eliciting additional seizures has led to an exaggerated sense of caution in antipsychotic drug use. In patients comedicated with AEDs (as is almost always the case in patients with epilepsy and psychosis) the risk of an increase in seizures is low. However, this risk can be a particular issue for those who are seizure free, in whom the recurrence of seizures has a generally greater impact.

Further problems associated with antipsychotic drug treatment in patients with epilepsy include (a) variation in the individually inherited seizure threshold (for a thorough review see ref. 90); (b) side-effects, in particular sedation, weight gain, worsening of glycaemic control, haematotoxicity and hepatotoxicity, some of which can be moderated by careful dose titration; and (c) a relative lack of studies investigating the efficacy of antipsychotic drugs in the psychoses of epilepsy (a 2006 Cochrane review protocol of this area was able to identify only one randomized controlled trial that met their inclusion criteria). In addition, pharmacokinetic interactions may result from common metabolism via CYP isoenzymes. Carbamazepine and other enzyme-inducing AEDs lower concentrations of haloperidol, chlorpromazine, clozapine, olanzapine, risperidone and quetiapine. These interactions can be very marked (by to 50% on occasions) and clinically important. Valproate has few interactions, and the antipsychotics do not generally affect AED concentrations.

Personality and organic mental disorders

The personality changes of epilepsy have been examined, broadly speaking, in three different ways: (1) the epileptic personality; (2) DSM-IV Axis-II personality disorders; and (3) the organic mental disorders (OMDs) described by the Lindqvist and Malmgren scheme.

The epileptic personality

The first psychoanalytic theorists focused on the 'epileptic personality', which was said to comprise such features as impulsivity, egocentricity and affective viscosity. Later, neurologists such as Gastaut *et al*. [110] confirmed these observations, recorded hyposexuality, hypoactivity and aggressiveness in addition, and noted that this stereotypic symptom complex was the antithesis of the behaviours seen in the Kluver–Bucy syndrome. Waxman and Geschwind [111] later coined the term 'interictal behaviour syndrome' (also known as the 'Gastaut–Geschwind syndrome) to describe a distinct subset of behaviours associated with TLE. These included:

1 viscosity – defined as the tendency to prolong interpersonal encounters, and often associated with circumstantial and pedantic speech;
2 religiosity – there is some evidence that patients with TLE, in particular, experience this personality trait, and differ from patients with extratemporal epilepsies or controls in this regard and sudden religious conversions associated with increased seizure activity have also been reported [112,113];
3 hypergraphia – a tendency towards extensive and sometimes compulsive writing with a striking preoccupation for detail;
4 hyposexuality, including decreased libido and impotence in about half of TLE patients without gender bias [112], although Fenwick *et al*. [114] did not find any significant difference in hyposexuality related to type of epilepsy or seizure frequency; and
5 aggression.

The Kluver–Bucy syndrome occurs as a consequence of bilateral anterior temporal destructive lesions and comprises oral exploratory behaviour, hypersexuality and decreased aggression. It may be seen in patients with TLE who have had a unilateral temporal lobectomy and who then suffer compromise of the contralateral temporal lobe due to a brain injury, cerebrovascular disease or other pathology.

DSM-IV Axis-II personality disorders

The general diagnostic criteria for a personality disorder, according to DSM-IV, specify an 'enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual's culture'. This may be manifested as follows: (1) in the patient's way of seeing him/herself, other people or events; (2) the range, intensity, lability and appropriateness of affectivity; (3) impulse control; and (4) interpersonal functioning. These patterns should be enduring, inflexible and pervasive across a broad range of personal and social situations, lead to significant distress or impairment of function, be stable and of long duration, and should not occur secondary to another mental disorder or to the effects of drug use or a general medical condition.

In patients with epilepsy, the prevalence of Axis-II personality disorders ranges from 18% to 61% across studies, with a mean of 31% [112]. Koch-Stoecker [115] found that, of 100 patients who underwent anterior temporal lobectomy, 14% were subsequently hospitalized for psychiatric complications postoperatively, all of whom exhibited a preoperative Axis-II disorder. None of their patients with only an Axis-I disorder were hospitalized. Derry *et al*. [116] found that patients high in preoperative (anterior temporal lobectomy) neuroticism exhibited significantly worse postoperative psychosocial adjustment and quality of life.

The 'organic mental disorders' (OMD) of Lindqvist and Malmgren

The OMD classification of Lindqvist and Malmgren (the LM scheme) is one of the least studied and least well known of the current classification systems of psychiatric disorder in epilepsy. This is due, in part, to the fact that the concept was originally

detailed in a book published in Swedish in 1991 and there has been only one related article in English [117]. Nevertheless, the syndromes described 'ring true' to many neurologists working with patients who have epilepsy, and it is worth reviewing here.

The LM scheme is the result of the collaboration of a psychiatrist (Göran Lindqvist) and a philosopher/physician (Helge Malmgren). It was developed in Sweden in the early 1990s, and is principally based on the personal experience of the two authors and organized according to logical and semantic considerations [117,118]. The authors base the postulate of their classification upon the existence of a 'level between observable symptoms and distal aetiology' and argue that this level might explain the variety and complexity of mental disorders which occur secondary to somatic disease. As little is known about the processes that link somatic aetiologies and mental symptoms, they can only be introduced as theories, hence the term 'hypothetical pathogenetic processes' (HPPs) [117]. Accordingly, the authors divide OMDs into six basic categories: (1) astheno-emotional disorder (AED); (2) emotional–motivational blunting disorder (EMD); (3) somnolence–sopor–coma disorder (SSCD); (4) confusional disorder (CD); (5) hallucination–coenestopathy–depersonalization disorder (HCDD); and (6) Korsakoff's amnestic disorder (KAD). The typical clinical manifestation, course and main aetiologies of each are summarized in Table 21.3.

Each disorder can occur separately or together with one or more other OMD, and all six disorders may be seen in epilepsy. However, three are more specific to this disorder: the astheno-emotional disorder, the EMD and the HCDD [117,119]. The number of studies using the LM scheme in the assessment of OMD in patients with intractable epilepsy is, unfortunately, small, and the study conducted by Malmgren in 2002 remains the best example of the usefulness and efficacy of this classification [119]. In this study, Malmgren followed up, both pre- and postoperatively, a series of 70 patients: 54 underwent temporal and 16 underwent extratemporal resections. When presurgical evaluation was carried out on all patients, 38.6% of patients were reported to have an OMD, of which astheno-emotional disorder (22.9%) and EMD (15.7%) were the most common. Postoperatively, 60.9% of patients showed an OMD at some time, the most common diagnosis again being the astheno-emotional disorder in both temporal and extratemporal lobe resections (49.1% and 50%, respectively). The frequency of EMD was significantly higher in the extratemporal resection group (37.5% compared with 9.4% in patients with temporal lobe resections). The correlation between pre- and post-surgical psychiatric morbidity was also analysed. Patients with preoperative anxiety–depressive disorders (ADs) as well as pre- and/or post-surgical astheno-emotional disorder were significantly more likely to develop an AD postoperatively than patients with no such history. This risk was also reported to be higher for patients with

Table 21.3 The organic mental disorders [123].

OMDs	Typical manifestations	Course	Causes	Equivalents	
				DSM-III or DSM-III-R	ICD-10
AED	Primary symptoms: *Mild to moderate forms:* Concentration difficulties (specifically problems with upholding sustained attention) Mental fatigability Secondary memory disturbances (affecting short-term memory as well as storing to, and retrieval from, long-term memory) Emotional lability Irritability *Severe forms* (in addition to the above symptoms): Slowed and impoverished associations Reduced ability to apprehend complex facts Destruction of stored long-term memory traces Psychogenic, secondary symptoms Lowered self-esteem Feelings of uncertainty Anxiety Depressive reactions (even severe depressions) Psychosomatic complications including headache Paranoid reactions	In organic cases, the prognosis depends both on the underlying aetiology, the degree of severity of the astheno-emotional disorder, and also on the patient's age Mild and moderately severe cases in young patients: usually heal completely when the underlying somatic aetiology is eliminated Severe cases: prognosis often unfavourable	Mild astheno-emotional disorder can be either organic or psychogenic. Moderately severe cases are usually of organic origin, and the severe forms always have an organic underlying aetiology Can be due to all kinds of localized organic brain diseases or injuries: traumatic injuries, tumours, infections, degenerative and vascular diseases	Dementia (severe, pure astheno-emotional disorder) Organic personality disorder (moderately severe forms with prominent emotional symptoms) Organic mental syndrome not otherwise specified (DSM-III-R) and atypical or mixed organic brain syndrome (DSM-III) for mild astheno-emotional disorder	Dementia Organic amnestic syndrome Organic personality disorder Organic emotionally labile [asthenic] disorder Neurasthenia Unspecified mental disorder Post-concussional syndrome Mild cognitive disorder

Table 21.3 *Continued*

OMDs	Typical manifestations	Course	Causes	Equivalents	
				DSM-III or DSM-III-R	ICD-10
EMD	Emotional shallowness: lack of feelings and consideration for other people, including family members Motivational blunting: general or restricted to particular fields such as personal hygiene or professional ambitions Alteration of cognitive function: capacity of abstraction, foresight, planning, and self-criticism Behavioural disorders: often barely noticeable, some patients may be 'extremely inactive, unspontaneous' while others are 'thoughtless, unrestrained, economically rash, promiscuous' or even show 'a criminal behaviour'	Variable according to the underlying aetiology. The EMD can progressively worsen (cerebral gliomas), be stationary without any improvement (serious brain injury), or, in the majority of cases, spontaneously heal	Usually due to frontal lobe damage, and often referred to as 'frontal lobe syndrome'. It is also described in injuries to limbic structures, thalamus and hypothalamus, as well as severe endocrinopathies	Organic personality disorders for mild, moderately severe and a number of more severe cases; dementia for severe cases	Dementia Organic personality disorder Organic emotionally labile [asthenic] disorder
SSCD	Severe forms: coma of varying depth Moderately severe forms: psychomotoric dampening with a general impairment of most cognitive, emotional and motivational performances, as well as an increased tendency to fall asleep Mild forms: slight, unspecific and usually hard-to-diagnose symptoms		May be the result of toxic influences on the brain, raised intracranial pressure or a number of clinical situations such as pituitary adenoma with suprasellar extension	Delirium Dementia (severe cases)	Dementia Delirium
CD	Pathognomonic sign: incoherence in thought and speech Other symptoms: disorientation, anxiety, hallucinations and illusions	Usually acute	Common complication of diffuse or localized mechanical or chemical brain injury Often psychogenic	Delirium for organic aetiologies Brief reactive psychosis for psychogenic cases	Dementia Delirium
HCDD	Fully blown cases: visual hallucinations or visuoperceptual disturbances, coenestopathies, and feelings of depersonalization and/or derealization. Auditory hallucinations do not occur. In most cases, only one or two symptoms mentioned above are present	Evolution usually towards spontaneous remission even if the underlying aetiology remains unchanged	Intoxications (especially with hallucinogens), migraine, endocrinological diseases, brain traumas, dysfunction of the hypothalamus and/or the temporal lobes (e.g. temporal lobe epilepsy) Psychogenic	Organic hallucinosis	Dementia Organic delusional disorder Organic hallucinosis Acute psychotic disorders
KAD	Fully developed: combination of retrograde amnesia, short-term memory impairment, disorientation and confabulation	Variable according to the underlying aetiology. Can be chronic and stationary (alcoholic dementia), subchronic and gradually healing (moderately severe post-traumatic amnesia) or transient (transient global amnesia)	Bilateral lesions, or dysfunction of the limbic system, the hypothalamus or certain parts of the thalamus	Amnestic syndrome for pure cases of KAD Dementia for patients with KAD and additional cognitive deficits	Dementia Organic amnesic syndrome

AED, astheno-emotional disorder; CD, confusional disorder; EMD, emotional–motivational blunting disorder; HCDD, hallucination–coenestopathy–depersonalization disorder; KAD, Korsakoff's amnestic disorder; SSCD, somnolence–sopor–coma disorder.

a presurgical astheno-emotional disorder than those who *de novo* developed this disorder after the surgery. Laterality or site of resection, histopathology and seizure outcome were not significantly correlated to pre- and/or post-surgical diagnoses of astheno-emotional disorder. One year after the resective surgery, the prevalence of the astheno-emotional disorder was equivalent to the preoperative degree [119].

These disorders are likely to be missed unless specifically enquired about because they are not considered separately in the two main diagnostic classification schemes (ICD-10 and DSM-IV). Although each disorder, as described by Lindqvist and Malmgren, has one or several approximate equivalents in both DSM-IV and ICD-10 (see Table 27.3), the diagnosis does not map easily across schemes. Neither DSM-IV nor ICD-10 recognizes the astheno-emotional disorder, the components of which are lost under a variety of disparate diagnoses such as neurasthenia and dementia.

Mental and behavioural disorders secondary to antiepileptic drug use

Antiepileptic drugs have been associated with numerous psychiatric adverse events (PAEs), including, for example, (1) barbiturates with depression and attention deficit–hyperactivity disorder in children; (2) phenytoin with toxic schizophreniform psychoses; (3) valproate with acute and chronic encephalopathies; (4) vigabatrin, topiramate and other drugs with depression and alternative psychoses [120]; and (5) levetiracetam with irritability, aggressivity and psychosis.

An attempt has been made to determine the risk of PAEs according to mechanisms of action of the AEDs [e.g. γ-aminobutyric acid (GABA)-ergic or antiglutamatergic] [121], but this schema can only partly explain the PAEs. Mula *et al*. [122] tested the hypothesis that some patients are generally more prone to developing psychopathology during AED therapy, irrespective of the mechanism of action of the drug. They investigated the occurrence of PAE with topiramate and levetiracetam in the same population of patients with epilepsy. They found that patients on topiramate tended to have well-defined DSM-IV clinical pictures (in particular depression associated with rapid dose titration), whereas those on levetiracetam experienced more subsyndromal behavioural changes (aggressive behaviour and emotional lability). Most interesting was the fact that a subgroup of patients appeared prone to developing PAEs regardless of the particular AED used. Significant risk factors included (1) a history of drug-resistant epilepsy; (2) febrile convulsions (suggesting that early limbic injury predisposes to psychiatric vulnerability that can be triggered by AEDs); and (3) previous and familial psychiatric history [122].

22 Management of Side-effects of Antiepileptic Drugs

Gaetano Zaccara, Fabrizio Balestrieri and Aldo Ragazzoni

Piero Palagi Hospital, Florence, Italy

In epilepsy treatment, the management of adverse effects of antiepileptic drugs (AEDs) is of crucial importance, requiring knowledge of risk factors and strategies for prevention and early identification. The treatment of adverse effects can require drug reduction or discontinuation and/or specific measures. All steps depend on the establishment of a therapeutic alliance with active patient involvement. After a drug is selected for use, the benefits and risks should be discussed with the patient. The nature of adverse effects should be explained and this can minimize the risk and consequences of many unwanted complications.

Antiepileptic drug-induced adverse effects may be roughly divided into two broad classes: type A (pharmacology related) and type B (idiosyncratic adverse effects). This said, some adverse effects do not fit easily into either category.

Type A adverse effects are predictable, dose dependent, usually observed at the beginning of a treatment or after a dose increase, and explained by the known pharmacological properties of individual agents [1]. These effects, which generally involve the central nervous system (CNS), are usually reversible upon dosage adjustment and rarely require discontinuation of therapy.

Type B adverse effects occur sporadically and unpredictably, and their pathogenesis is the consequence of an abnormal, often immunological, reaction [2]. These can be caused by allergic or direct cytotoxic mechanisms or may be the consequence of effects apparently unrelated to the known mechanisms of action of the offending drug. This last phenomenon is sometimes known as 'off-target pharmacology'.

The identification of adverse effects

Type A, dose-dependent adverse effects, which are relatively frequent, are generally identified during the prelicensing clinical development of a drug. However, the rates of detection are clearly influenced by the method of detection, which varies from spontaneous reporting to the use of checklists [3].

Analysis of double-blind, placebo-controlled studies may be the only way to identify a causal relationship between the experimental drug and some of the most frequently observed treatment-emergent CNS adverse effects (Table 22.1). The incidence of a particular adverse event can be estimated by subtracting the rate on the placebo arm from the rate in the active treatment arm [4].

Treatment with AEDs has also been associated with some chronic adverse effects (e.g. weight gain, reduction in bone mineral density, gingival hyperplasia, etc.) which cannot be identified in double-blind studies because of their limited duration. Long-term and observational studies are the only way to appreciate the frequency and characteristics of these complications.

The most severe type B idiosyncratic reactions occur rarely – in approximately 1 of 30 000–50 000 exposures for most AEDs [5]. Hence, information on their occurrence can only be acquired through drug surveillance programmes, such as spontaneous reports to regulatory authorities [2].

Adverse effects of antiepileptic drugs

Here, a general overview of AED tolerability will be given, and detail of individual drugs is given in the relevant chapters devoted to each specific drug. Teratogenesis is discussed in Chapter 25.

Central nervous system adverse effects

The majority of adverse effects exerted by AEDs involve the CNS. Such side-effects are relatively frequent and more commonly observed at the onset of a treatment or after a dose increase. They are usually promptly reversible after dose reduction. Some CNS adverse effects are more rarely observed and more idiosyncratic in nature.

Disturbances of vigilance and cognitive abilities

Somnolence is the most frequent adverse effect induced by traditional AEDs. It is more frequently observed in patients treated with phenobarbital or primidone than in patients treated with carbamazepine and phenytoin [6]. Somnolence is also reported during treatment with valproate [7,8].

Several new AEDs have sedative properties (see Table 22.1). Felbamate has stimulant-like properties [9]. Somnolence, which can be observed during treatment with this drug, can also be caused by inhibition of metabolism of associated AEDs.

The negative impact of antiepileptic treatment on cognitive functions is a particularly concerning effect, which may not be easily detected and can have important consequences. It has been recognized since the 1990s, for instance, that there is a drug-induced depression of cognitive performance in children treated with phenobarbital for febrile seizures, which may outlast the administration of the drug by several months [10].

	Dizziness	0.06	0.00–0.12

From ref. 4.

All adverse effects which were found to be significantly associated with the experimental AED are reported in the table above. Meta-analysis of all double-blind, placebo-controlled studies performed in adults. Risk difference was calculated using the random effect model. Due to heterogeneity of analysed studies, no comparisons between AEDs are possible.

[a] No meta-analysis was performed for oxcarbazepine and tiagabine and risk differences (95% confidence interval) were calculated for each drug from only one study in each case.

Studies performed with traditional AEDs show that many AEDs can cause negative cognitive effects, when compared with no treatment in cross-over studies conducted in healthy volunteers. The effect of phenytoin, carbamazepine and valproate is relatively small and there is little difference between the three drugs. However, phenobarbital, and also other drugs used in polypharmacy, have been shown to have a greater negative impact on cognition [11].

In general, the newer AEDs exhibit only weak effects on cognition. Topiramate is an exception, and this drug carries the risk of a significant negative effect on attention and also a specific effect on verbal function and language [11].

Disturbances of brainstem and vestibulocerebellar system

Many drugs cause brainstem and/or cerebellar dysfunction. This causes subjective and objective disorders of balance and gait (ataxia, incoordination, dizziness and vertigo) and disturbances of the oculomotor system (diplopia, oscillopsia and nystagmus).

Ataxia and nystagmus are typical manifestations of acute phenytoin and carbamazepine toxicity, and are usually dose related [12]. Although both phenytoin and carbamazepine can produce cerebellar and brainstem dysfunction, there are clinically relevant differences in the drug effects. Carbamazepine usually causes intermittent diplopia and ataxia [12] correlated with fluctuations of serum drug concentrations. Phenytoin-induced ataxia is not intermittent and insidiously and progressively worsens, sometimes over months. The phenytoin-induced ataxia is usually reversible and dose related [12], but can sometimes persist after drug withdrawal. Purkinje cell degeneration and astrocytic changes have been observed in patients who had prolonged intoxication with this drug [13].

Barbiturates, and in particular phenobarbital, seem to have a different spectrum of neurotoxicity, with sedation usually appearing as the first symptom [12]. Among traditional AEDs, sodium valproate is considered to have the least effects on vestibulocerebellar structures [8].

Among the newer AEDs, ataxia is significantly associated mainly with lamotrigine, oxcarbazepine and pregabalin therapy (see Table 22.1).

Disturbances of basal ganglia and other motor central nervous system structures

Antiepileptic drugs are also associated with other motor adverse effects. These can be dose-dependent effects or can have an idiosyncratic nature, being unpredictable and with a rare occurrence at low dosages [2].

Tremor is frequently observed during treatment with valproate [14]. The co-medication of lamotrigine and valproate seems to worsen this adverse effect. Tremor may also be induced by tiagabine [15].

Valproate can also cause a reversible parkinsonian syndrome, which usually appears a few days after the beginning of a treatment with the drug [8]. This syndrome may also have an insidious onset and become clearly detectable only after many years.

Several cases are reported in the literature [16] of dyskinesias induced by phenytoin. Choreoathetosis is the most common manifestation and orofacial dyskinesia, dystonia and ballism are less frequent. Sporadic cases have also been signalled of dyskinesias during treatment with several other AEDs [12].

Tics have been sporadically described during carbamazepine and lamotrigine treatment and, exceptionally, during treatment with phenobarbital and phenytoin [12].

Non-epileptic myoclonus may appear in the course of valproate encephalopathy [17], and can be caused by some new AEDs such as gabapentin and pregabalin, mainly in patients with brain damage [18].

Encephalopathies

Encephalopathies can be observed during intoxication with several AEDs. High phenytoin blood levels, for instance, can

result in ataxia, nystagmus, mental slowing to the level of stupor and coma, and an increase of seizure frequency [12].

Valproate-induced toxic encephalopathy is an example of an idiosyncratic CNS reaction. This is characterized by disturbances of consciousness ranging from a confusional state up to stupor and coma, asterixis and EEG slowing [17]. Exceptional cases of a vigabatrin-induced encephalopathy with stupor, confusion and EEG slowing have been described [19]. A hyponatraemic encephalopathy characterized by mental changes up to coma and EEG slowing has occasionally been signalled during treatment with oxcarbazepine [20].

Psychiatric disturbances

The incidence of depression and psychosis in patients with epilepsy has been repeatedly found to be higher than the expected rate in the overall population. Depression occurs in about 30% of epileptic patients, anxiety disorders in 10–25% and psychosis in 2–7% [21]. Such disturbances often have a multifactorial origin. AEDs, as well as other treatments used in epilepsy, may exert variable psychotropic effects, which can be negative as well as positive (see Chapter 21).

Treatment with drugs with prominent γ-aminobutyric acid (GABA)-ergic properties (barbiturates, vigabatrin, tiagabine) and also topiramate, which has several mechanisms of actions, has been more frequently associated with depression. It has been shown that in patients with a long history of barbiturate therapy there is also a higher prevalence of major depressive disorder and of suicidal ideation [21].

In double-blind studies, an increased prevalence of depression has been observed in patients treated with vigabatrin (12.1% of patients treated with the active drug versus 3.5% of patients treated with placebo), tiagabine (3% versus 1%) and zonisamide (7.4% versus 3%). Topiramate and levetiracetam can also cause depression in some patients [21]. Recently, an analysis of all double-blind, placebo-controlled studies, performed with 11 AEDs for treatment of epilepsy as well as psychiatric disorders and other conditions, has revealed a significantly increased risk of suicidal behaviour and suicidal ideation in patients treated with the active drug in respect to patients treated with placebo. This observation has led to an Food and Drug Administration (FDA) warning [22].

Insomnia, nervousness and depression have been reported in clinical studies of patients treated with felbamate [9].

Detrimental effects on the behaviour of learning-disabled patients with epilepsy have been signalled during treatment with lamotrigine. This has been characterized as a 'release phenomenon', and considered a consequence of a positive effect of the drug on cognition without sedative properties [11]. In similar types of patients, levetiracetam has been associated with aggressive behaviour [23].

Psychosis is a generally rare but well-recognized complication of traditional AED therapy, and especially with ethosuximide. This complication often appears in the context of a significant improvement of seizure frequency and/or improvement of EEG abnormalities, and has been equated to forced normalization [24]. Psychoses have also been reported among patients treated with the newer AEDs such as felbamate, vigabatrin, levetiracetam, lamotrigine, tiagabine, topiramate, zonisamide and gabapentin [25].

Metabolic adverse effects

Megaloblastic anaemia, probably caused by folate and/or vitamin B12 deficiencies, has been described during treatment with phenobarbital, phenytoin or both. Vitamin K deficiency may lead to coagulation defects in neonates of mothers treated with enzyme inducers phenobarbital and phenytoin. Rickets and osteoporosis are the consequence of treatment with phenobarbital and phenytoin, and possibly also carbamazepine and valproate. Vitamin D deficiency, caused by drug-induced increased metabolism by enzyme-inducing AEDs, may partially explain these complications [26].

A dose-dependent thrombocytopenia can often be observed during treatment with valproate [8].

Several studies have demonstrated that enzyme-inducing AEDs are associated with elevations of lipoproteins and also homocysteine, which are risk factors for atherosclerosis [27].

Renal stones are a well-recognized concern with the use of topiramate and zonisamide. They are more common in men and are probably the consequence of the inhibition of the enzyme carbonic anhydrase, which results in increased urinary pH.

Inhibition of carbonic anhydrase may also lead to a reversible metabolic acidosis and, consequently, to a central hyperventilation syndrome, which is primarily observed in children treated with topiramate. Oligohidrosis and hyperthermia have been reported in patients treated with zonisamide and, less frequently, with topiramate [28].

Finally, several AEDs, with different and yet unknown mechanisms, can cause weight changes. Four AEDs – gabapentin, vigabatrin, pregabalin and valproate – and, possibly, carbamazepine cause weight gain. Obesity is an independent risk factor for diabetes and metabolic syndrome, coronary heart disease and hypertension.

Three drugs – felbamate, topiramate and zonisamide – commonly cause weight loss as a consequence of appetite suppression. In general, lamotrigine, levetiracetam and phenytoin do not have any effect on body weight [29].

Adverse effects on other organs or tissues

Several AEDs, particularly among the traditional medicaments, cause adverse effects in the endocrine system or other organs or tissues, often through the agency of endogenous metabolites. In some cases, these adverse effects may be considered as a consequence of known drug properties, and are dose dependent. For example, they can be the consequence of enzymatic induction in the case of phenobarbital, phenytoin or carbamazepine, or inhibition in the case of valproate, of cytochrome P450 (CYP) enzymes, which metabolize not only the AEDs but also other exogenous (vitamins) or endogenous (hormones, etc.) molecules. In many other cases, the mechanisms underlying these complications are not known.

Endocrine effects

Mild modifications of thyroid hormones of uncertain clinical significance can be observed during treatment with phenytoin, carbamazepine and valproate [27]. Carbamazepine, and more often oxcarbazepine, cause hyponatraemia and water retention. [30]. In some patients with prediabetes, insulin secretion may

From ref. 2.

For some of the reactions reported, information is insufficient to draw definitive conclusions about causality. (*) indicates that the specified reaction has been reported for that drug; (†) identifies reactions associated with a warning box in the US prescribing information monographs; and (–) indicates that the reaction has not been reported based on the sources of information stated above.

SJS, Stevens–Johnson syndrome; TEN, toxic epidermal necrolysis.

be impaired by phenytoin and result in an abnormal glucose tolerance test.

Several studies show that carbamazepine, and to a lesser extent phenobarbital and phenytoin, can induce the metabolism of sex hormones, which might be a possible explanation for the hyposexuality experienced by some epileptic male patients. In women, treatment with valproate has been associated with polycystic ovary syndrome, which could be, partly at least, the consequence of drug-induced obesity and hyperinsulinaemia [8].

Connective tissue and cosmetic effects

Thickening of subcutaneous tissue, hirsutism, acne, hyperpigmentation, gingival hyperplasia and other unaesthetic features can be frequently observed in some epileptic patients who receive long-term phenytoin therapy. Other effects of AEDs on connective tissue include barbiturate-induced Dupuytren's contracture and shoulder–hand syndrome [27]. Thinning of hair, alopecia and curling of the regrown hair sometimes occurs with valproate treatment [8].

Other adverse effects

Carbamazepine has been occasionally implicated, particularly in older patients, in the production of a number of cardiovascular abnormalities, including conduction defects, congestive heart failure and hypertension.

Vigabatrin causes a specific bilateral concentric visual field constriction, which can be severe. This occurred in 31% of patients who had received vigabatrin for less than 4 years [31].

In rare cases, topiramate can induce ocular reactions, including acute secondary angle-closure glaucoma, acute bilateral myopia and suprachoroidal effusions [32].

Idiosyncratic cytotoxic or immunological adverse effects

Idiosyncratic adverse effects may involve various organs and tissues. A selection of the most important idiosyncratic reactions associated with AEDs is reported in Table 22.2.

Cutaneous reactions

Cutaneous manifestations are the most common of the idiosyncratic reactions caused by AEDs. They range from very benign mild skin rash to potentially life-threatening dermatological diseases.

Skin rashes, usually morbilliform or maculopapular in appearance, typically occur between day 5 and week 8 after the start of therapy. These are relatively common on therapy with phenobarbital, phenytoin and carbamazepine, with a frequency ranging from 5% to 15% [33]. Oxcarbazepine, the keto analogue of carbamazepine, is associated with a lower incidence of hypersensitivity reactions than carbamazepine. Lamotrigine can also cause this adverse effect. The incidence of rash is consistently higher when lamotrigine is added to valproate than when it is added to enzyme-inducing AEDs (19.5% versus 6.7%, respectively) [34]. Skin rashes may result from therapy with other AEDs, but their frequency is generally lower than that observed with the aromatic AEDs.

Drug-related rash with eosinophilia and systemic symptoms (DRESS), previously known as anticonvulsant hypersensitivity syndrome, is a severe acute drug reaction characterized by fever, skin eruption, eosinophilia, atypical lymphocytosis, arthralgia, lymphadenopathy and multiorgan involvement [35]. This complication is observed most frequently with phenytoin (2.3–4.5 cases per 10 000 exposures) and carbamazepine (1.0–4.1 cases per

10 000 exposures) [36]. Cases have also been reported with lamotrigine [34].

Stevens–Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN; Lyell's syndrome) are bullous reactions accompanied by mucosal involvement and skin detachment. It has been suggested that the risk of SJS and TEN during the first 2 months of therapy is between 1 and 10 per 10 000 new users of carbamazepine, lamotrigine, phenytoin and phenobarbital, and consistently lower for valproate [2]. The recently described relationship of carbamazepine-induced SJS with a specific human leucocyte antigen (HLA) type in the Han Chinese is discussed below.

Haematological reactions

Aplastic anaemia occurs in the general population, with an incidence of 2–6 cases per million [37], and is the most serious drug-induced blood dyscrasia. The AED with the highest potential for causing this affection is felbamate, with a risk of 1 in 5000 or 1 in 10 000 [37]. Rare cases of aplastic anaemia have also been associated with carbamazepine, phenytoin, ethosuximide and valproate [2]. The incidence of carbamazepine-induced aplastic anaemia has been estimated at between 1 in 50 000 and 1 in 200 000 exposed patients [2].

Selective suppression of bone marrow cells may lead to agranulocytosis and pure cell aplasia, which are rarely observed during treatment with AEDs [2].

Pseudo-lymphoma syndrome is a rare condition, which may be part of DRESS syndrome spectrum, and has been associated mainly with phenytoin, although it can occur with other AEDs, particularly those with an aromatic structure [2].

Sporadic cases of thrombocytopenia, probably immune mediated, have been reported with carbamazepine, lamotrigine, phenytoin, felbamate, primidone and tiagabine [2]. Valproate-induced thrombocytopenia should not be considered as immune mediated.

Reactions affecting the liver and pancreas

Drug-induced liver toxicity may be caused by immune-mediated mechanisms or by direct cytotoxic damage. Aromatic AEDs have been recognized as a cause of severe immune-mediated hepatitis, which may be part of the spectrum of DRESS, or it may occur in isolation [38]. The exact incidence of liver toxicity associated with the aromatic AEDs is unknown, although for carbamazepine the risk has been estimated at 16 cases per 100 000 treatment years [2]. Rare cases have also been described of severe lamotrigine-induced liver toxicity [2], sometimes in association with multisystem organ failure and disseminated intravascular coagulation.

Valproate and felbamate are associated with the greatest risk of potential liver toxicity. The pathogenic mechanism of valproate-induced hepatotoxicity is probably characterized by a direct toxic action of valproate and/or its metabolites [39], and differs substantially from those associated with liver toxicity caused by aromatic AEDs. The incidence of fatal valproate-induced hepatotoxicity varies in relation to age and associated therapy. The highest risk (1:500) is in children younger than 2 years on polytherapy. In older patients, the risk has been estimated at 1:12 000 with polytherapy and 1:37 000 with monotherapy [39]. However, in recent years, the overall incidence of valproate-induced fatal liver toxicity seems to have decreased.

The mechanism of this drug-induced liver toxicity due to felbamate is not clearly understood, but may depend on the formation of reactive toxic metabolites [40]. There is evidence that aldehydes generated from felbamate can induce liver damage via a direct cytotoxic mechanism [40]. Immune-mediated mechanisms, however, may also be involved. The risk of fatal hepatic failure due to felbamate is estimated at approximately 1 per 26 000 to 34 000 exposures [2].

Pancreatitis is a rare complication of valproate therapy. This condition can develop at any time, but most commonly occurs during the first year of treatment or after an increase in dosage. Age below 20 years, polytherapy, chronic encephalopathy and haemodialysis are possible risk factors. Estimated incidence is 1:40 000 [2,8].

Systemic lupus erythematosus

Carbamazepine and, to a lesser extent, phenytoin, ethosuximide, valproate, lamotrigine and other AEDs can rarely induce or activate systemic lupus erythematosus. This drug-induced condition is sometimes not easily differentiated from the idiopathic form of the disorder [2].

Prevention and management of adverse effects

Several measures are important. Before prescribing a drug, the adverse effects profile should be tailored to the individual patient. Once on a medication, steps can be taken that prevent or minimize these complications. At the beginning of therapy and during dose escalations, clinical monitoring for early identification of possible adverse effects should be regularly performed.

Analysis of risk factors

Age

Age is a critical influence on a number of adverse effects. Children are especially predisposed to long-lasting consequences of cognitive and behavioural effects of AEDs [10]. Cognitive alterations, hyperactivity and other conduct disorders are frequently observed in children treated with phenobarbital, although these symptoms may also occur in association with phenytoin, benzodiazepines, gabapentin and vigabatrin [11]. Fragile elderly patients, often with several co-morbidities and treated with many drugs, are also at special risk for development of cognitive and motor adverse effects induced by several AEDs [41].

Differences in drug metabolism may explain why some AED-induced idiosyncratic adverse effects develop more frequently in children [2]. Glucuronide conjugation is reduced while cytochrome-mediated reactions are faster in infants and children than in adults, and this can result in an increased production of reactive metabolites [41]. Lamotrigine-induced serious and non-serious skin rashes [42] occur more frequently in children than in adults. The incidence of SJS in children started on lamotrigine has been estimated to be as high as 1:100, compared with 1:1000 in adults [43].

Young age is also a major risk factor for valproate-induced hepatic injury, for which the highest risk is recorded in infants

below the age of 2 years [39]. This might be due to the higher prevalence of predisposing conditions such as inborn errors of metabolism in infants, as well as pharmacokinetic factors such as accumulation of the toxic metabolite 4-en-valproate, the concentration of which is negatively correlated with age [2].

Idiosyncratic reactions occur at a relatively high frequency also in old age. In a controlled trial in elderly patients with new-onset epilepsy, as many as 19% of those exposed to carbamazepine withdrew in the first 2 weeks because of skin rashes, despite use of a low dose (100 mg/day) [44].

Medical and psychiatric co-morbidities

Concomitant diseases may strongly influence tolerability to several AEDs.

The probability of developing a CNS dose-dependent adverse effect can be influenced by the presence of a structural brain lesion. Brain damage also predisposes to 'off-target pharmacology'. For example, basal ganglia damage and mental retardation are frequently reported in patients with phenytoin-induced choreoathetosis [16].

Psychiatric adverse effects of AEDs are more frequently observed in predisposed patients. It has been suggested that vigabatrin, topiramate and ethosuximide should be avoided in patients with a previous history of psychotic episodes and levetiracetam used only with great caution in this population of subjects [23].

The risk of cytotoxic or allergic idiosyncratic adverse effects is also strongly increased in the presence of several diseases. Rheumatoid arthritis, systemic lupus erythematosus, Hashimoto thyroiditis, panhypogammaglobulinaemia, idiopathic thrombocytopenic purpura, high serum antinuclear antibody titres, and a history of cytopenia or hypersensitivity to other AEDs are considered as risk factors for felbamate-induced aplastic anaemia [2]. Systemic lupus erythematosus, other immune system disorders, corticosteroid therapy and a family history of serious rashes are also risk factors for hypersensitivity reactions to other AEDs [2]. Infectious diseases are also associated with a higher frequency of allergic drug reactions [2]. HIV infection also seems to be a risk factor for hypersensitivity reactions to AEDs. In general, the presence of such risk factors justifies the preferential use of AEDs with a low allergenic potential such as gabapentin, levetiracetam, pregabalin, clobazam, tiagabine, valproate and, possibly, topiramate.

Valproate-induced liver toxicity is another example of an idiosyncratic adverse effect, the frequency of which is greatly increased in patients with specific concomitant affections. Several metabolic disorders, including urea cycle defects, organic acidurias, multiple carboxylase deficiency, mitochondrial or respiratory chain dysfunction, cytochrome aa3 deficiency in muscle, pyruvate carboxylase deficiency and pyruvate dehydrogenase complex deficiency, all predispose to valproate toxicity [2]. Patients with GM1 gangliosidoses type 2, spinocerebellar degeneration, Friedreich ataxia, Lafora body disease, Alpers–Huttenlocher disease and myoclonic epilepsy with ragged red fibre (MERRF) disease are also more susceptible to valproate hepatotoxicity [2].

Associated drugs

It is well known that the frequency of CNS dose-dependent adverse effects is increased by polytherapy. Total drug load, pharmacodynamic and pharmacokinetic interactions are possible explanations. Every effort should be made to reduce the number of concomitant treatments. Patients whose seizures have not responded to an initially prescribed AED are less likely to develop adverse effects by being switched gradually to an alternative drug also given as monotherapy [45].

Co-medication can also influence susceptibility to idiosyncratic reactions. Concomitant treatment with valproate, in particular, increases the risk of lamotrigine-induced hypersensitivity [34]. Enzyme-inducing AEDs increase the incidence of valproate-induced liver toxicity, pancreatitis, hyperammonaemia and encephalopathy [39]. Ketogenic diet is often associated with reduced carnitine stores and may therefore increase the risk of valproate-induced hyperammonaemic encephalopathy and hepatotoxicity [46].

The risk of oxcarbazepine and carbamazepine-induced hyponatraemia and water retention is increased in elderly patients who are also treated with some diuretics or selective serotonin reuptake inhibitor (SSRI) antidepressants.

Genetic factors

More than 40 years ago, patients were identified who were slow metabolizers of phenytoin and therefore particularly susceptible to dose-dependent adverse effects of this drug [12]. Today, it is known that mutations of the gene coding for *CYP2C9*, one of the two P450 isoenzymes which metabolize phenytoin, appear to be responsible for this effect [47].

The occurrence of similar idiosyncratic reactions to AEDs in identical twins and in families suggests a genetically determined predisposition [2], possibly with an autosomal pattern of inheritance. Siblings of patients who had immune-mediated idiosyncratic reactions to aromatic AEDs such as phenytoin, carbamazepine, phenobarbital and primidone have up to a 25% probability of experiencing a similar reaction when exposed to a drug of the same class (cross-reactivity).

The higher incidence of carbamazepine-induced SJS in Chinese compared with white patients also reveals that genetic factors must be involved. It has been recently observed in the Han Chinese population that carbamazepine-induced SJS and TEN, but not carbamazepine-induced maculopapular reactions or DRESS, are strongly associated with the HLA-B*1502 allele [48]. Interestingly, the role of ethnicity in these reactions is emphasized by recent data confirming that an association between carbamazepine-induced SJS and the HLA-B*1502 allele is present in Asians, but not in whites [49]. A genetic test has recently been made available on the market for detection of the HLA-B*1502 allele and the FDA now recommends execution of this test for those patients with ancestry across Asia and South Asia before starting carbamazepine treatment [50].

Strategies for prevention or minimization of adverse effects

Low doses at the beginning of a treatment, slow titration, the search for minimal effective maintenance doses and appropriate posological schemas can greatly reduce the risk of adverse effects [45].

Starting dose and titration rate

The frequency and severity of most adverse effects is influenced by the starting dose and by the speed of dose incrementation. For this reason, care should be taken not to exceed the recommended initial dose and speed of titration of every drug, and indeed in routine practice to start with lower doses and to increase doses more slowly.

Tolerance to CNS adverse effects is common. Gradual titration can prevent such effects by allowing the development of pharmacodynamic tolerance. A slow titration may also minimize CNS adverse effects in practice by permitting early detection of subtle or prodromal signs which thus warn against further dose increase.

There is a common misconception that the idiosyncratic adverse effects are unaffected by dose or titration rate. In fact, some immune-mediated reactions occur only when a critical dose threshold is reached. Several lines of evidence indicate that the risk of allergic reactions decreases when treatment is started at a low dose and is increased gradually, possibly because slow titration may allow desensitization to occur [43]. A relation between starting dose (and titration rate) and the incidence of cutaneous reactions has been particularly demonstrated in therapy with lamotrigine [34], carbamazepine and phenytoin [33]. For example, in lamotrigine monotherapy trials in adults, rash occurred in 6.1% of patients when the dose in the first treatment week was <31 mg/day, and in 20.5% of patients when the dose was between 62.5 and 125 mg/day [34].

Individualization of minimal effective dose of a drug

The prescription of excessively high dosages of AEDs is relatively common [44]. AEDs have a narrow therapeutic ratio, and with these drugs, particularly for toxic effects, dose–response relationships vary greatly from one patient to another. Every effort should be made to identify, wherever possible, the lowest effective dose.

Daily regimens and chrono formulations

Fluctuations of blood levels can be responsible for some intermittent dose-related CNS adverse effects. It has been observed, in patients treated with carbamazepine who complain of intermittent diplopia and ataxia, that these adverse effects can be closely correlated with total and free carbamazepine blood levels [12]. The same applies to tiagabine, an AED with a short half-life, the metabolism of which can be induced and the absorption of which is greatly affected by the relationship of dosing to meals. In such cases, an increase in the number of daily administrations or, in the case of carbamazepine, a controlled-release formulation often improves drug tolerability [51].

Monitoring drug therapy

Proper consumption of therapy should be constantly discussed with the patient. Some patients may occasionally decide to increase the dose of a drug when they experience a seizure. Other patients may take their therapy inconsistently because they may forget one daily dose (it is known that compliance worsens with increasing number of daily doses). In all these cases, higher fluctuations of blood levels of an AED may increase not only probability of seizure recurrence, but also the appearance of some dose-dependent adverse effects.

Monitoring serum drug concentrations

The measurement of blood levels in patients with apparently dose-dependent adverse effects, especially of drugs with a narrow therapeutic index and/or non-linear kinetics such as phenytoin or carbamazepine, is of crucial importance.

However, even though knowledge of AED plasma levels can be useful for seeking the optimal dose of a drug, data can be misleading if misinterpreted. It should be realized that reference therapeutic ranges are only probabilities and that patients with clinical response at serum AED concentrations below the lower limit of these ranges should not have their treatment increased. A measure which can be useful is the identification of the concentration of an AED at which an optimal response is achieved [45]. In other clinical circumstances, for instance when changing doses of concomitant medication or formulations, serum drug monitoring can be useful in preventing seizure recurrence or adverse effects.

Other measures

Other measures for preventing adverse effects include increased water intake in male patients treated with topiramate or zonisamide to avoid kidney stones, or decreased water intake in patients treated with oxcarbazepine who are at risk of hyponatraemia, for instance the elderly or patients taking other drugs which may cause hyponatraemia [28].

Early identification

The key for the early identification of adverse effects is clinical monitoring. Vigilance is important, as is the awareness of patients, doctors and relatives of potential complications and the symptoms that may herald the occurrence of an adverse effect.

Identification of subtle toxicity

Although dose-dependent adverse effects are frequent and have a major impact on a patient's quality of life [52], they are not always easily identified. Subtle motor or cognitive effects can be neglected in the outpatient setting. Some relevant adverse effects (e.g. reduced libido or impaired sexual potency) are less likely to be reported spontaneously, and need to be investigated specifically. In one clinical study, nearly one-third of epileptic patients on treatment with AEDs who were screened with a self-report instrument [the adverse events profile (AEP)] met criteria for drug toxicity. When clinicians, for the evaluation of their patients, could utilize information from this instrument, drug treatment adjustments led to an improvement of drug toxicity score. Interestingly, the quality of life score [52] was significantly inversely correlated with AEP score but was not correlated with seizure frequency (Fig. 22.1). This problem is compounded by the fact that, after a number of months of drug treatment with an AED, some patients forget what normal cognitive and motor functions were like [5].

Neurophysiological examinations (quantitative EEG measurements, posturography, quantitative analysis of ocular movements, etc.) aimed at measuring subtle toxic effects of AEDs on CNS, though of a certain utility as a research tool, have no practical use for clinical monitoring [12]. One exception is the case of visual field examinations, which should be performed before the start of treatment and at regular intervals during treatment with

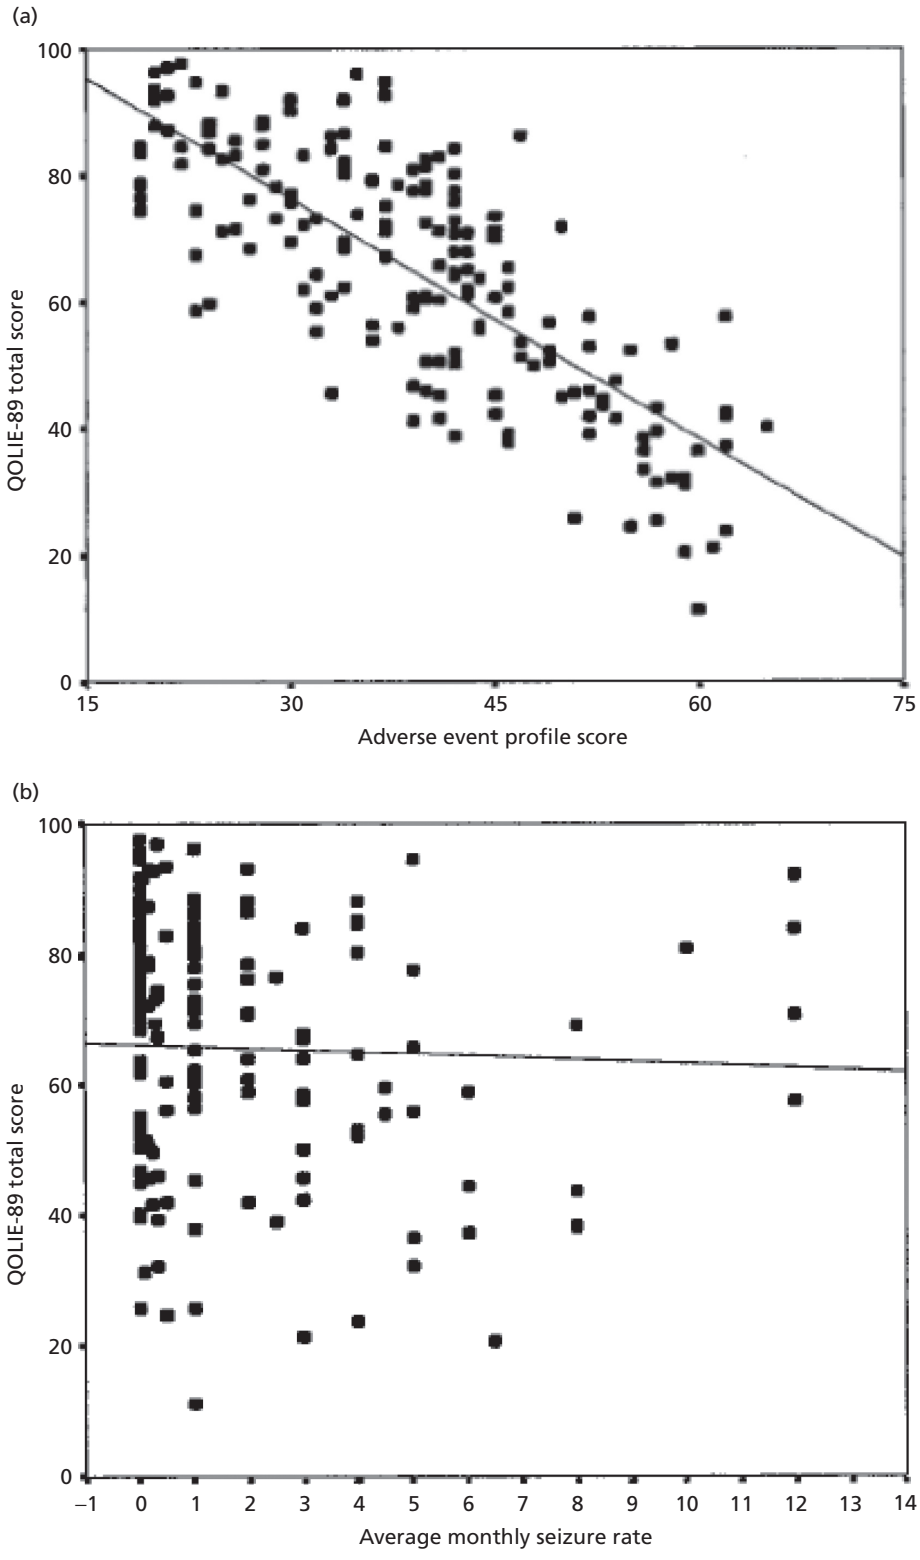

Fig. 22.1 Comparison of baseline Quality of Life in Epilepsy (QOLIE)-89 total score with (a) baseline adverse events profile (AEP) score ($r = –0.76$; $P < 0.001$) and (b) average monthly seizure rates (partial correlation controlling for AEP score; $r = 0.001$; $P = 0.99$; $n = 200$). From ref. 52.

vigabatrin for monitoring of retinal toxicity induced by this drug [31].

Early identification of idiosyncratic reactions

Early identification of idiosyncratic drug reactions may be life saving. It is most important to inform patients and relatives about potential adverse effects and to report warning symptoms or signs.

One issue concerns the utility of laboratory monitoring in the early identification of subclinical allergic or cytotoxic idiosyncratic reaction in asymptomatic patients. Package inserts of several AEDs include recommendations about laboratory

Table 22.4 Management of AED-induced immune-mediated idiosyncratic reactions. Prompt recognition of the reaction and withdrawal of the offending drug are essential management steps.

Most patients need a complete blood count and biochemistry (including thyroid function tests) for the evaluation of internal organ involvement. Such tests should be repeated at 3 months. Additional investigations (e.g. chest radiography, bone marrow or skin biopsy) may be indicated depending on clinical presentation
Patients with drug rash with eosinophilia and systemic symptoms (DRESS) require hospitalization for symptomatic and supportive therapy. Patients with Stevens–Johnson syndrome (SJS) or toxic epidermal necrolysis (TEN) should be preferentially managed in burn units
Treatment with corticosteroids is advisable, controversial or contraindicated, depending on the condition. Other treatments (e.g. immunoglobulins, immunosuppressants, organ transplantation, etc.) should be considered depending on clinical presentation
An appropriate AED should replace the withdrawn AED, to prevent recurrence of seizures and status epilepticus. AEDs expected to be involved in cross-reactivity reactions or to aggravate the underlying pathology should be avoided
Patients with serious hypersensitivity reactions should not be re-challenged. The value of patch tests and *in vitro* tests for assessing causality and predicting risk of recurrence is limited

From ref. 2.

monitoring. However, there is no evidence of any real usefulness of such examinations for prevention of these serious complications [2,5] and several authors [5] have concluded that routine screening is neither cost-effective nor of significant value.

A reasonable approach is to carry out laboratory monitoring (Table 22.3) in the following situations: (1) before starting treatment (or adding a new AED), to establish a baseline against which to interpret any subsequent change in clinical status; (2) in high-risk groups; and (3) in patients with impaired ability to communicate [5]. However, for high-risk drugs, most notably felbamate or valproate (in young children), it would be wise to follow package instructions.

Traditional AEDs can cause a reduction of blood levels of some vitamins. In selected cases it is useful to measure levels of vitamin D, folic acid and vitamin B_{12}.

Treatment

Dose reduction and/or modification of dosing schemas (more frequent daily administrations, higher dose in the evening in the case of sedating drugs), chrono formulations and/or a lower titration speed will be sufficient to avoid or manage several of the most common dose-related adverse effects. In a few cases, specific treatments can be given to alleviate the intensity of some adverse effects, for example the use of propanolol, amantadine and acetazolamide to alleviate valproate-induced tremor.

However, some patients do not tolerate certain treatment-emergent adverse effects even at low doses of an AED, and in this case it is necessary to discontinue the drug. In these situations, it is wise to try a new AED with a different profile of tolerability (e.g. a patient who complains of somnolence during a treatment with levetiracetam might be switched to lamotrigine, which is less sedative). Similar recommendations could be given in the case of rare but not serious adverse effects that are caused by an unusual interaction of the drug with the host organism (e.g. the development of dyskinesia or tics).

The case is different for serious reactions (or reactions potentially evolving into severe conditions) which require immediate discontinuation of the offending agent. In the majority of cases, it is appropriate to substitute another AED considered to be reasonably safe in the specific context. In patients with hypersensitivity reactions to an aromatic AED, other aromatic anticonvulsants should be avoided, and agents with a low allergenic potential, such as benzodiazepines, levetiracetam, gabapentin and pregabalin, are probably safe. Topiramate and valproic acid may also be safe, but they are less suitable for fast titration. Also, valproic acid, being an inhibitor of epoxide hydrolase, may delay the detoxification of residual reactive metabolites.

In patients with early symptoms or also the suspicion of an idiosyncratic reaction, baseline (see Table 22.3) and specialized hematochemical tests should be immediately performed. In patients who develop a hypersensitivity syndrome (hepatitis, pancreatitis, DRESS, etc.) the full gamut of laboratory tests should be carried out to evaluate a possible multi-organ involvement according to the nature of the suspected incipient reaction.

For the management of immune-mediated hypersensitivity reactions, symptomatic and supportive therapy may be indicated based on the clinical presentation. Treatment with corticosteroids is controversial, though most physicians elect to start prednisone at a dose of 1–2 mg/kg if symptoms are severe [2]. Patients with specific organ involvement need to be managed by the appropriate specialist. Patients with SJS and TEN in particular should be managed, preferably in a burns centre, to ensure adequate supportive management in terms of wound care, hydration, nutritional support, and prevention of infection and other complications (Table 22.4).

In selected cases, to avoid the situation whereby a patient is erroneously labelled as 'hypersensitive' to an AED, it is important to make confirmatory tests.

Re-challenge, for diagnostic purposes, remains the only conclusive method to confirm causality, and may be appropriate for certain reactions (e.g. many idiosyncratic effects affecting the CNS) which do not involve immune-mediated hypersensitivity or cytotoxicity. However, re-challenge is not justified in those who have experienced serious reactions [2].

Presently, there are some tests available for diagnosis of immune-mediated hypersensitivity reactions, namely patch and prick tests, and *in vitro* tests such as the lymphocyte transformation test and the lymphocyte assay. While the skin patch test has been proven to be very useful for prediction and diagnosis of some types of hypersensitivity reactions such as allergy to beta-lactam antibiotics, the diagnostic value of this test is yet to be determined for diagnosis of allergic reactions to AEDs. *In vitro* tests are primarily research tools, and their negative and positive predictive values are still unknown [2]. Because of the above considerations, all these tests are rarely conducted. If these tests are performed, results should be interpreted cautiously. In fact, a negative test result does not exclude the possibility of a drug reaction, and in these cases re-challenge should be done only when absolutely necessary and under close medical control [2].

Traditional AEDs have several metabolic effects which, in some cases, mainly during long-term treatment, may lead to some diseases. The most important example is probably the effect on bone mineral density by phenobarbital and phenytoin and, perhaps, by carbamazepine and valproic acid. Rickets and osteoporosis are possible consequences of this metabolic effect. While treatment of choice for rickets is vitamin D, bisphosphonates are used for the treatment of osteoporosis in both children and adults [25]. Megaloblastic anaemia, which can be observed during therapy with phenobarbital and phenytoin, usually responds to folate therapy.

23 Ketogenic Diets

Eric H. Kossoff and Jennifer L. Dorward
Johns Hopkins Hospital, Baltimore, MD, USA

Introduction

The history of the ketogenic diet has been described in great detail in recent reviews [1]. The use of diet manipulation to control seizures has its origins back to biblical times, with descriptions of Jesus curing 'possessed' patients with prayer and fasting. In 1911, Guelpa and Marie [2] reported the use of fasting to improve epilepsy in the French population. Interest in the USA originates with Geyelin [3], who reported at the 1921 American Medical Association convention the successful use of 3 weeks of fasting for 26 patients with severe epilepsy. Much of his protocol was based on the work of Conklin [4], an osteopathic physician from Michigan who treated a 10-year-old boy with the help of a faith healer, Bernarr Macfadden, and a 'water diet'.

Research into the ketogenic diet soon followed as the word of this successful advance in epilepsy spread. Gamble and Howland subsequently investigated the ketogenic diet at the Johns Hopkins Hospital [5]. Early research indicated a potential role of acidosis, dehydration and ketosis [6–8]. Wilder [8], from the Mayo Clinic, first proposed attempting an actual diet in order to maintain children and adults on this therapy for extended periods of time. This ketogenic diet mimicked starvation by providing a regimen of 1 g/kg protein, 10–15 g of carbohydrate and the remaining calories per day as fat [9]. A ratio of fats to carbohydrates and protein of typically either 3:1 or 4:1 was used to maintain ketosis. Calories were based on the basal metabolic rate plus 50%. This is quite similar to the ketogenic diet still in use today, with slightly less insistence on calorie and fluid restriction.

Further reports of efficacy followed [10], especially in children, but were later ignored by the discovery of phenytoin in 1938. As the era of anticonvulsants began, the ketogenic diet was viewed as rigid, expensive and restrictive. A medium-chain triglyceride (MCT) oil-containing diet was developed to make the diet easier to use [11]. A study comparing the classical ketogenic diet, the MCT oil diet and a modified MCT oil diet revealed similar efficacies, with 81% of patients on both diets having a greater than 50% reduction in seizures [12]. This diet allows for more carbohydrates than the classic long-chain triglyceride (LCT) ketogenic diet, and is still widely used in the UK. New research regarding this diet will be discussed later in this chapter. As new anticonvulsants continued to become widely available, many more epileptologists felt the diet was not useful. Although several centres, mostly in the USA, continued to use the diet actively [13], the number of patients treated with the diet became very small.

In 1992, things changed dramatically. A 2-year-old boy named Charlie was admitted to the Johns Hopkins Hospital because of intractable epilepsy [14]. Charlie was started on the ketogenic diet and within weeks had respnded extremely well. As a result, Charlie's father created the Charlie Foundation, which informs patients and physicians about the ketogenic diet and remains very active (www.charliefoundation.org). Since then, many medical centres have started using the ketogenic diet, and several large studies have demonstrated its effectiveness [15–17]. The ketogenic diet is now well established in the medical community for the treatment of childhood (including infantile) epilepsy, and it is reimbursed by insurance companies including Blue Cross and Blue Shield in the USA [18]. Other parent advocacy groups, such as Matthew's Friends in the UK (site.matthewsfriends.org), and collaborative research from individual nations' child epileptologists, have led to the ketogenic diet being available nearly everywhere in the world with the exception of large parts of Central America and Africa [19]. The ketogenic diet (as the modified Atkins diet) has had a recent resurgence for the treatment of adults with epilepsy, now 80 years after it was initially reported in this age group.

The ketogenic diet requires skill and commitment to initiate and to maintain, especially in older children and adolescents. A well-trained team of neurologists and dietitians is needed to initiate and also monitor the ongoing use of the diet. The effects on seizures, in children whose seizures were previously intractable, can be dramatic. The diet requires commitment by the families, and ongoing medical advice and support by the treating team. An international, multicentre consensus statement on the ideal clinical management of the ketogenic diet is now in press [20].

Mechanisms of action

The ketogenic diet mimics the starvation state by utilizing a high-fat, adequate-protein (1 g/kg body weight), low-carbohydrate diet. This diet causes a dramatic shift in metabolism that affects the entire body. The actual mechanism by which the ketogenic diet helps suppress epilepsy remains unclear despite decades of research [21]. Initial research theorized that acidosis, dehydration and hyperlipidaemia reduced seizures, but these hypotheses shifted towards ketosis 20 years ago [1].

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

Ketone bodies (acetoacetate, acetone and β-hydroxybutyrate) are formed in the liver, often preferentially when the body is forced to use stored fats for energy [1]. Long-chain fatty acids are released from adipose tissue in a starvation state, transported via plasma to the liver cytosolic membrane, and then enter mitochondria via the carnitine acyltransferase system [22]. Once inside the mitochondria, fatty acid oxidation converts the fatty acids to acetyl coenzyme A (CoA). Acetyl CoA is then converted to ketone bodies. Medium-chain fatty acids are also converted to acetyl CoA via acyl-CoA synthetase, but are able to bypass the carnitine acyltransferase system.

Ketone bodies are utilized efficiently by the body, and can provide 65% of the brain's energy requirements in starvation states [23]. Ketone bodies are transported into the brain after being synthesized in the liver via a monocarboxylic acid transporter [24]. Once there, they are both metabolized via the tricarboxylic acid cycle into energy and converted into cholesterol, lipids and fatty acids [1]. Elevated levels of ketone bodies also inhibit glucose metabolism in the brain, returning the glucose to the liver for gluconeogenesis as lactate and pyruvate [25].

The exact mechanism by which (or if) elevated ketone bodies in the brain reduce seizures is less clear. Uhlemann and Neims [26] developed the first animal model of the ketogenic diet in 1972. Mice were made ketotic using a diet and were then tested for protection against electroshock- and bicuculline-induced seizures. Ketonaemia protected the mice against both methods of seizure induction, with loss of this protection within 3.5 h of diet discontinuation [26]. In addition, younger mice (16 days old) were able to produce higher ketonaemia and thus longer seizure protection than older mice (40 days old). Other studies of rats have reproduced this protective effect [26,27].

More recent research has attempted to elucidate the mechanisms by which ketone bodies affect seizure thresholds. There has been some suggestion that ketone bodies are structurally similar to γ-aminobutyric acid (GABA) and may act as anticonvulsants in themselves [19,28]. Thio *et al*. [29], however, recently demonstrated that direct application of ketone bodies to rat hippocampus failed to directly affect synaptic transmission.

However, in recent years, the importance of ketosis in the mechanism of action of the ketogenic diet has been questioned

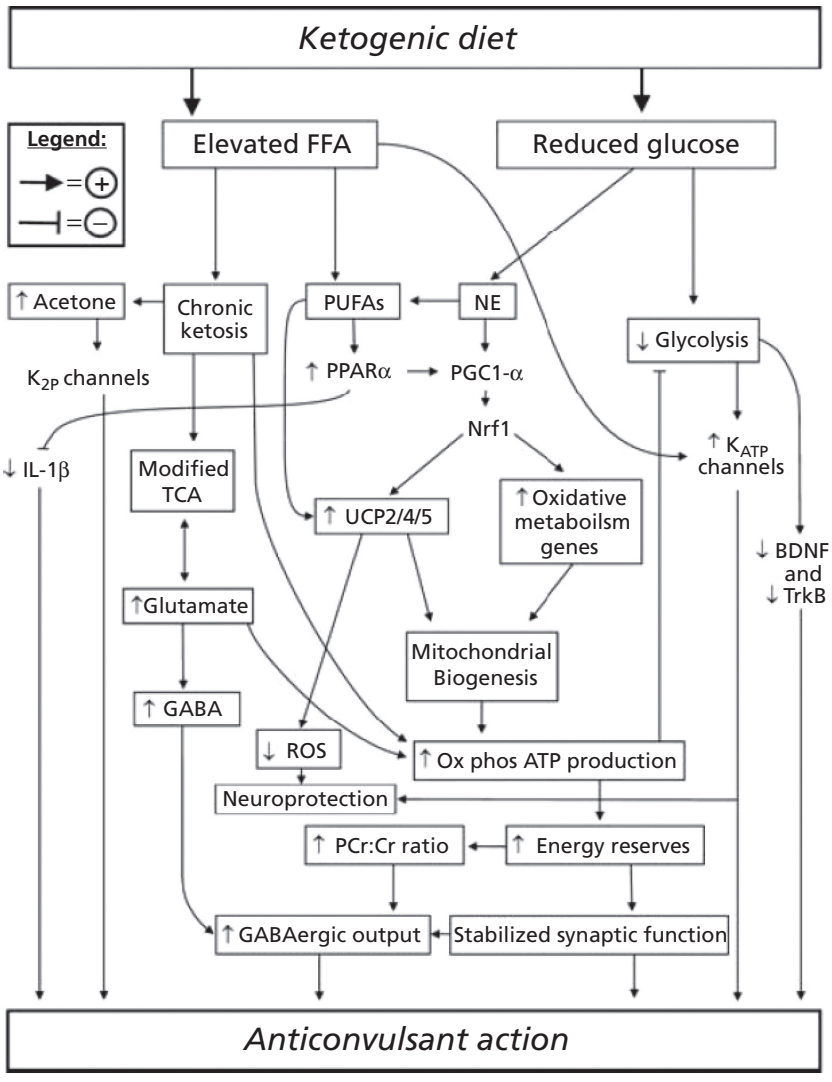

Fig. 23.1 Potential mechanisms of action of the ketogenic diet. Reproduced with permission by *Epilepsia* and Dr Jong Rho [30].

[30]. It may be more accurate to say that ketosis is necessary as a sign of a shift in body metabolism, but may not be sufficient to lead to seizure reduction. Studies of alternative diets such as the low glycaemic index treatment suggest that the efficacy of the diets is related to either glycolysis inhibition or stabilization of serum glucose levels. Genetic studies have also implicated the diet's effects on the mitochondrial processes of oxidative phosphorylation, and suggested that energy production in these cell organelles is the final end-pathway of diet action [31]. Another recent study demonstrated that the ketogenic diet may act via activation of potassium adenosine triphosphate (ATP) channels and a negative feedback effect on glycolysis [32]. Whether these diets work through increased fats, decreased glucose, caloric restriction or several other pathways to achieve this goal is unclear. A summary of potential mechanisms under active investigation is in Figure 23.1.

Seizure outcomes

Many retrospective studies of the ketogenic diet's efficacy have been performed. Initial findings by Peterman in 1925 [33] showed that 95% of children on the ketogenic diet experienced a reduction in seizures of more than 50%. Reports of results from the 1980s also showed efficacy, with 67% of children showing greater than 50% improvement in their seizures [34]. However, these studies were typically retrospective and single centre.

Two prospective uncontrolled studies in 1998 [15,16] brought the ketogenic diet's usefulness for intractable epilepsy to the medical mainstream. A multicentre study from seven sites in the USA enrolled 51 children aged 1–8 years on a 4:1 ketogenic diet [15]. At 3 months, 54% had a greater than 50% reduction in seizures, compared with 55% at 6 months and 40% at 1 year [15]. In addition, side-effects were uncommon, and 47% stayed on the diet to at least 1 year.

Johns Hopkins published its single-centre, prospective experience with 150 children that same year [16]. These children were of similar ages and had intractable epilepsy (mean 410 seizures per month, 6.2 prior anticonvulsants). Efficacy was similar to the multicentre study, with 50% having greater than 50% seizure reduction at 1 year and 27% having greater than 90% seizure reduction. This original 150-patient cohort was subsequently followed for 3–6 years [35]. Of these children, 44% were still more than 50% improved, and 78% of those who remained on the diet for at least 12 months were more than 50% improved.

At the time of writing, nearly 100 prospective and retrospective studies of the ketogenic diet have been completed, many multicentre in design. Results are surprisingly similar between studies, as outlined in a recent meta-analysis [34]. In general, approximately 55–60% of children started on the ketogenic diet will have at least a 50% seizure reduction after 3–6 months of therapy. Between 25% and 30% will show even more improvement, with at least 90% seizure reduction. Approximately 10–15% of all children started on the ketogenic diet will become seizure free, often permanently. This improvement occurs rapidly, often within 2–4 weeks of diet onset [36]. The diet also appears to work more quickly, after a median of 9 days, in those children who are fasted for 24–48 h before the diet is initiated. Considering that these results are noted in a very intractable population, one would hypothesize that the ketogenic diet is a better option for difficult-to-control seizures than medications.

A randomized, controlled study of both the classic (LCT) and MCT diets has been recently completed at Great Ormond Street Hospital in London in a manner to prove this hypothesis [37]. In this study, 145 children were all started on one of the two diets after either a 4-week (active) or 12-week (control) period of continued and unchanged medication therapy, with each child therefore serving as his/her own control. The ketogenic diet was dramatically more likely to result in seizure improvement – the results showed that children receiving the ketogenic the diet experienced 38% fewer seizures than previously, compared with an *increase* in seizures of 37% in the control group ($P < 0.001$) [37]. Five children in the diet group had a > 90% seizure reduction, whereas none in the control group did. There was no difference between the classic and MCT diet in regards to efficacy.

A study has been completed recently in order to address prospectively the efficacy of the ketogenic diet in a double-blind, randomized, placebo-controlled manner at Johns Hopkins Hospital [38]. Children were started on a ketogenic diet but were then given a solution of either placebo (saccharin) or 60 g glucose to take orally daily. After 5 days, each subject was crossed over to restart the ketogenic diet with the alternative solution. EEGs, clinical seizure activity and ketones were monitored to assess efficacy. The study showed a significant reduction in seizures over the total 12-day period, with a median decrease of 34 seizures per day ($P = 0.003$). However, there was no difference between the saccharin and glucose arms in regards to EEG change, and only a trend towards reduced parent-observed seizures ($P = 0.07$). This research did demonstrate, despite the non-significant results, that a double-blinded study of the ketogenic diet can be completed successfully using this unique design.

A possible additional benefit of the ketogenic diet is a reduction in medication costs. In one study [39], 74% of patients had their medications reduced with a cost reduction of 70%. The average estimated cost reduction per child per year was US$530 in this report. It is also important to realize that many parents start the ketogenic diet not only for seizure control but for cognitive improvement as well as medication reduction [40]. Understanding and addressing these parental concerns may lead to better ketogenic diet compliance.

Ketogenic diets and adults

In 1930, the ketogenic diet was perceived as a viable approach to intractable adult epilepsy in a study of 100 adults by Dr Barborka [41]. In this study, patients aged 16–51 years were started on the traditional ketogenic diet and 56% responded. This is surprisingly similar to most studies today in children, yet the diet was seen as less beneficial for adults. In fact, in the discussion, Dr Barborka stated, 'there seems to be no question but that the patient who can be afforded the best opportunity for treatment is the child or young adult . . . whereas older patients . . . are the least likely to be benefited' [41].

The ketogenic diet fell out of favour and was not specifically reported on in adults again until Dr Joseph Sirven and his group from Jefferson Medical Center in Philadelphia first presented their research in abstract form 69 years later [42]. In this study, 11 adults (9 women) were treated with a traditional, 4:1 ratio, ketogenic diet with 55% having a > 50% improvement after 8 months of therapy [42]. Cholesterol increased from a baseline of 208 to 291 mg/dL over the study period.

In 2008, the results of a prospective, open-label trial of the modified Atkins diet in adults was reported [43]. Further details about this 'alternative' ketogenic diet, which induces ketosis with less dietary restrictions, are discussed in the following section. Results were encouraging, with 47% having a > 50% improvement after 3 months using an intent-to-treat analysis [43]. Cholesterol increased slightly, but the median weight loss of 6.8 kg was motivational for most adults who were overweight to start. Further adult studies of the modified Atkins diet are under way.

Alternative ketogenic diets

In 2002, the experience of treating two children at Johns Hopkins led to the creation of an alternative version of the ketogenic diet that has now been studied in a total of 90 children and adults from three countries [43–45]. This diet has been called the 'modified Atkins diet'. The first child was a 7-year-old girl with intractable complex partial seizures who was 1 month away from her scheduled admission for the ketogenic diet. Her parents were counselled to restrict carbohydrates to prepare her for the restrictions of the ketogenic diet. Within 2 days of following the induction phase of the Atkins diet (<20 g/day of carbohydrates), her seizures had stopped, and 1 week later her ketogenic diet admission was cancelled. She remained on the Atkins diet for over 3 years. A second child, age 10 years, had stopped the traditional ketogenic diet 1 year prior due to absence seizure freedom. When his seizures began to recur, his mother started refeeding him the high-fat and low-carbohydrate foods *ad lib* that he had eaten in the past. Ketosis recurred and seizures stopped once again.

These two children led to prospective studies in using the 'modified' Atkins diet, which initially restricts carbohydrates to 10 g/day (15 g/day in adults), encourages high-fat foods, but does not require an admission or fast [44]. Protein, fluids and calories are not limited (in fact, they are encouraged). In both children and adults, results are surprisingly similar, with 47% of patients with intractable epilepsy having at least a 50% reduction in their seizure frequency [43,44]. Ketosis occurs, but generally decreases over several months on this diet, yet does not appear to correlate with efficacy except during the first month only [45]. Side-effects include increased cholesterol and blood urea nitrogen (not creatinine, however) and weight loss [44,45]. Interestingly, in adults, weight loss correlated with seizure control at 3 months [43]. This was not seen in any other time point, with children or in any ketogenic diet study previously. Although still restrictive, the modified Atkins diet appears to work quickly, often within 2 weeks when effective.

A study from Massachusetts General Hospital in 2005 described an even less restrictive diet, the 'low glycaemic index treatment' [46]. This diet restricts carbohydrates to 40–60 g/day, does not restrict fluids or protein, but loosely monitors fat and calories. Unlike the modified Atkins diet, the type of carbohydrates is important in this diet, with only carbohydrates with glycaemic indexes <50 allowed. These carbohydrates include berries and wholegrain breads as opposed to potatoes, white bread and most citrus fruits. Efficacy is also surprisingly good despite an absence of urinary and only low levels of serum ketones [46].

Further studies in both children and adults of both diets are under way. Unanswered questions include long-term efficacy, comparative efficacy versus the ketogenic diet and the use of these diets for new-onset seizures. Both diets may also be of value in developing countries without dietitian resources but with large numbers of children with intractable epilepsy.

Indications for the ketogenic diet

The use of the ketogenic diet is restricted mainly to the treatment of refractory paediatric epilepsies (Table 23.1). There is no question that children who have cognitive or behavioural side-effects from multiple anticonvulsants can show improvement on the ketogenic diet in combination with a reduction in medications [39]. In addition, the ability to exercise control over their child's epilepsy makes the ketogenic diet attractive to many parents [39]. Children with gastrostomy tubes is also a population that is likely to be compliant with improved efficacy over children with solid-food ketogenic diets [47,48]. Some important contraindications to the ketogenic diet are listed in Table 23.1.

Many researchers have sought to identify predictive factors for maximal benefit from the ketogenic diet. Age of the child does not seem to be a factor in predicting effectiveness, with several studies showing no difference in outcome [15,16]. Certainly, infants can tolerate and derive significant benefit from the ketogenic diet if followed carefully [49]. Infants can do extremely well,

Table 23.1 Indications and contraindications of the ketogenic diet.

Indications
Intractable epilepsy (children)
Epilepsy with intolerable anticonvulsant side-effects
Glucose transporter protein deficiency (GLUT1)
Pyruvate decarboxylase deficiency
Suggested indications
Infantile spasms
Myoclonic–astatic epilepsy (Doose syndrome)
Tuberous sclerosis complex
Rett's syndrome
Severe myoclonic epilepsy of infancy (Dravet's syndrome)
Formula-fed infants
Gastrostomy tube-fed children
Certain mitochondrial disorders
Contraindications
Pyruvate carboxylase deficiency
Porphyria
Carnitine deficiency (primary)
Fatty acid oxidation defects

especially as the diet can be provided as a liquid formula using Ross Carbohydrate Free (RCF) formula, Microlipid and polycose. In addition, a commercially available, powder formula, ketogenic diet (KetoCal) is available in premixed 3:1 and 4:1 ratios (Nutricia, North America, and SHS International, Liverpool, UK).

Seizure type and EEG pattern also do not seem to be predictive [15–17]. In the multicentre trial [15], there was no difference in outcome between seizure types, although a small decrease in efficacy was seen for those children with multifocal spikes on EEG at 3 months ($P = 0.04$). A common conception is that children with Lennox–Gastaut-type seizure disorders will have better improvement on the ketogenic diet, but at least one study looking at that issue found no statistically significant difference [16]. Seizure frequency also has not been shown to be predictive [16].

Special indications for the ketogenic diet do exist in paediatric epilepsy. Children with glucose transporter protein deficiency (GLUT1) and pyruvate dehydrogenase deficiency should be treated with the ketogenic diet as first line [50,51]. In both cases, the utilization of alternative sources to glucose for brain metabolism can prevent seizures by providing acetyl CoA directly into the tricarboxylic acid cycle without prior glycolysis.

There are other epilepsy syndromes that appear to respond preferentially to the ketogenic diet. A retrospective study of 23 infants placed on the ketogenic diet for difficult-to-control infantile spasms revealed 38% with greater than 90% seizure reduction at 3 months and 46% at 12 months with greater than 90% seizure reduction [52]. Of these infants, 57% had their medications reduced and the same number had developmental progression, which was correlated with seizure control ($P = 0.03$). Even in this age range, in which some children were as young as 5 months, tolerability was high.

The next logical study, considering the evidence for preferential benefit towards infantile spasms, was recently published in 2008 [53]. In this study, the first specifically of its kind, the ketogenic diet was used as a first-line therapy for infantile spasms. The diet was successful within days in 62% (8 of 13), whereas adrenocorticotropic hormone (ACTH) was of benefit in 90% (18 of 20; $P = 0.06$). In those in whom diet was not able to stop their spasms typically within 2 weeks, other therapies, including ACTH, were helpful in the majority immediately afterwards. Side-effects and the recurrence rate were lower with the ketogenic diet [53].

Other epilepsy conditions that do well on the ketogenic diet include myoclonic–astatic epilepsy (Doose syndrome) [54] and tuberous sclerosis complex [55]. These conditions may also be reasonable to consider for 'early', perhaps first- or second-line therapy, with parental consent.

Calculation of the ketogenic diet

The ketogenic diet is calculated individually for each child; however, there are certain guidelines for deciding on the ratio, calories and fluid requirements. The ratio of fats to carbohydrates and protein is based on the age, size, weight and activity level of the patient. Infants, children younger than 2 years of age and adolescents often receive a 3:1 diet to provide additional protein for growth and increased carbohydrates to improve compliance. Children aged 2–12 will typically be started on a 4:1 diet. During the fine-tuning of the diet to achieve greater efficacy, children may be given anything from a 2.5 to 4.5:1 ratio. Research suggests that a 4:1 ketogenic diet may be more effective; however, a 3:1 diet is better tolerated and is associated with fewer gastrointestinal symptoms [56].

Calories have historically been restricted to 75% of the recommended daily intake for age, but there is little research that supports the need to restrict calories or fluid to achieve seizure control with the ketogenic diet. At our institution, calories are estimated individually, taking into account a 3-day diet record provided by the parents. In addition, anthropometric data including weight for age, height for age, and weight for height or body mass index (BMI) are evaluated, as well as estimated ideal body weights, dietary reference intakes (DRIs), gender, age, activity level and other medical conditions and medications that may alter metabolism. Significantly overweight children may be given only 25–30% of the recommended calories until they approach their ideal body weight; however, a retrospective review of 123 patients found no association between ideal BMI or changes in BMI and efficacy of the ketogenic diet for seizure control [57]. The goal is to provide adequate calories and protein to promote growth along the patient's curve on his or her growth chart. Computer-generated meals are created individually, taking into account the child's food preferences, to increase tolerability.

Fluids are restricted to caffeine- and carbohydrate-free beverages at 80–100% of estimated daily needs. Fluids are unrestricted in children with a family history of renal calculi, infants and all children during times of acute illness. Parents are encouraged to check their child's urine specific gravity weekly to assess the adequacy of fluid provision.

Initiation of the ketogenic diet

Children are fasted for 24 h prior to the initiation of the diet, beginning after the dinner on the day prior to admission. Occasionally, medically complex children will not be fasted (Table 23.2). There are many centres now that do not fast children, and research indicates that there is no difference in efficacy between fasted and non-fasted children [58]; however, the more rapid reduction of seizures that can be seen with earlier ketosis is often very reassuring for family members [59,60].

On day 1 of hospitalization, the child is admitted during the 24-h fast. Fluid intake is encouraged due to the effects of ketosis on thirst. Blood glucose is monitored with finger dextrosticks every 6 h, unless it falls below 40 mg/dL, after which it is checked every 2 h. If the child has symptoms of hypoglycaemia, or the glucose level falls below 25 mg/dL, 30 mL of orange juice is provided and the glucose is checked 1 h later. Even small children tolerate the fast well, with rare symptomatic hypoglycaemia. Daily urine ketones are also checked. Ketosis can begin during the fasting period, and the resultant nausea and vomiting can occasionally require intravenous hydration using non-dextrose-containing fluids.

Anticonvulsant medications are often continued during the fasting and initiation period at their previous doses. All medications are carefully examined for carbohydrate content and

Table 23.2 Ketogenic diet protocol at Johns Hopkins Hospital.

Day prior to admission (Sunday)
Fasting starts the night before admission
Day 1 (Monday)
Admitted to the hospital
Fasting continues until dinner (24 h)
Fluids restricted to 80–100% of estimated needs
Blood glucose monitored every 6 h
Use carbohydrate-free medications when possible
Dinner given as one-third of calculated diet meal as eggnog or ketogenic formula
Parents begin education programme
Day 2 (Tuesday)
Breakfast and lunch given as one-third of diet as eggnog or ketogenic formula
Blood glucose checks discontinued after lunch, if lunch tolerated
Dinner given as two-thirds of calculated diet meal as eggnog or ketogenic formula
Education continues
Day 3 (Wednesday)
Breakfast and lunch given as two-thirds of diet as eggnog or ketogenic formula
Dinner increased to full ketogenic meal (not eggnog)
Education continues
Day 4 (Thursday)
Full ketogenic diet breakfast and lunch given
Education completed
Prescriptions provided for carbohydrate-free anticonvulsants and supplements
Child discharged to home

Table 23.3 Typical day of food for a child on a 4:1 ratio, 1500-calorie ketogenic diet.

Breakfast: eggs with bacon
Egg (28 g)
Cooked bacon (11 g)
36% heavy whipping cream (37 g)
Butter (23 g)
Apple (9 g)
Snack: peanut butter ball
Peanut butter (6 g)
Butter (9 g)
Lunch: tuna salad
Tuna fish (28 g)
Mayonnaise (30 g)
Celery (10 g)
36% heavy whipping cream (36 g)
Lettuce (15 g)
Snack: keto yoghurt
36% heavy whipping cream (18 g)
Sour cream (17 g)
Strawberries (4 g)
Artificial sweetener
Dinner: cheeseburger
Ground beef (22 g)
American cheese (10 g)
Butter (26 g)
Cream (38 g)
Lettuce (10 g)
Green beans (11 g)
Snack: keto custard
36% heavy whipping cream (25 g)
Egg (9 g)
Pure vanilla flavouring

formulations changed when necessary. There is no evidence that anticonvulsant serum levels are altered by ketosis [61].

Fasting continues until dinner on day 1 of the admission, when one-third of the calculated diet is provided as an 'eggnog' or ketogenic formula. A ketogenic eggnog looks and tastes like a milkshake and can be sipped, frozen as ice cream or cooked as scrambled eggs. Excess ketosis at this time, which causes nausea and vomiting, can be relieved with a small amount of orange juice. Once the child begins eating, serum glucose checks are unnecessary and are discontinued.

Breakfast and lunch remain at one-third of the calculated calories as eggnog or formula on day 2, but dinner increases to two-thirds of the usual allowance (still eggnog or formula). On day 3, breakfast and lunch are also increased to two-thirds of allowance, and dinner is then given as the first full ketogenic diet meal (with actual foods provided). On hospital day 4, the child receives a full ketogenic breakfast and lunch and is discharged to home. All children are sent home with prescriptions for urine ketosticks, additional calcium and a sugar-free, fat-soluble vitamin and mineral supplement.

Throughout the 4-day hospital stay at our institution, classes are held with physicians, nurses and dietitians to teach the family about the rationale of the ketogenic diet, calculation of meals, nutrition label reading and management of their children during illnesses. This is just as important to achieving a favourable outcome as the actual logistics of the diet initiation. Examples of typical ketogenic meals are given in Table 23.3.

After discharge, parents are instructed to check urine ketones daily, and the diet is individually adjusted after consultation by telephone or email to maximize seizure control. Another option is to use commercially available blood ketone meters that measure β-hydroxybutyrate levels (range 0–4 mmol/L). The advantages of these meters over urine ketones remains to be determined, but in some cases the urine ketones may measure 'large' (the highest level on urine ketone sticks) at the same time that serum ketones will only be 2 mmol/L. In some cases, additional seizure control was potentially gained when ketosis was pushed higher, to achieve a serum ketone level above 4 mmol/L [62]. Most ketogenic diet centres do not advocate the routine measurement of serum ketones using these meters, however, as the evidence of direct correlation of efficacy to any measure of ketosis remains controversial today.

Serum glucose or electrolytes are not routinely monitored after discharge. Weight is monitored by the parents and reported if significantly changed. Periodic laboratory measures are obtained typically every 3 months in order to monitor for side-effects (lipid profile, electrolytes, anticonvulsant levels, urine calcium/creatinine). Urine alkalinization is accomplished with the use of Polycitra-K for all patients if the urine calcium to creatinine ratio is elevated above 0.2. However, as the use of Polycitra-K resulted

in a threefold reduction in kidney stones, we now currently advocate its empiric use for all children at our centre [63]. Medications may be tapered and discontinued on an individual basis, as one of the most common parental reasons for starting the diet is anticonvulsant reduction. As evidence suggests that it is safe to wean anticonvulsants even during the first 1–2 weeks of the ketogenic diet [64], this goal should be discussed with each family [40]. Children should be seen in clinic every 3 months, with more frequent visits for infants and medically fragile patients.

Handling increased seizures

Parents and physicians not familiar with the ketogenic diet are often very uncomfortable handling increased seizures. Certain basic management options apply to help improve seizure control. Parents are instructed to maintain seizure calendars that include daily ketone levels, medication changes, illness, diet/food changes or other activities that may affect seizure control. First, we always try to ensure that no new medications have been added that might contain carbohydrate (e.g. antibiotics, anticonvulsants). Occasionally, topical ointments and lotions (e.g. sunscreen, hair gels) contain sorbitol, which can be systemically absorbed, especially in very young children. Many food additives are described as 'sugar free' but contain carbohydrate-containing chemicals such as maltodextrin, sorbitol, starch and fructose. Secondly, the family should check urine ketones to ensure adequate ketosis. If ketones are not moderate to large, the child can be fasted with clear liquids for 24 h to improve ketosis rapidly. If there is no known aetiology of increased seizures, carnitine and/or MCT oil may be added. Carnitine is a carrier of fatty acids into the mitochondria for fatty acid oxidation and, although not necessary as a ketogenic diet supplement, serum levels often are reduced with ketogenic diet therapy [65]. MCT oil is more ketogenic than the LCTs that make up the classical ketogenic diet, and is more easily absorbed and transported into the cell than LCTs. Periodic oral or rectal benzodiazepines can be useful for seizure exacerbations as well.

Discontinuation of the ketogenic diet

The issue of when to discontinue the ketogenic diet is a difficult one. In children who are doing well, many parents are appropriately reluctant to discontinue a therapy that has been effective for years and risk restarting the anticonvulsants that were either ineffective in the past or caused side-effects. Because of the potential long-term adverse effects of the diet on lipids and growth, after 2–3 years on the diet there is a temptation to try to discontinue it, recognizing that it can always be restarted if necessary. Evidence suggests that a recent epileptiform EEG, structural brain abnormality on magnetic resonance imaging (MRI) and presence of tuberous sclerosis complex increase the risk of recurrence in seizure-free children who then discontinue the ketogenic diet [66]. As with anticonvulsants, when discontinued it is usual to taper the diet slowly over 2–3 months by gradually lowering the ratio of fat to protein and carbohydrate, then relaxing the weighing of ingredients and, finally, adding new carbohydrate foods over weeks while keeping calories constant.

A recent study of children who discontinued the diet prior to 1 year, in most situations due to inefficacy, determined very surprisingly that nearly 50% of these children had less than half of the seizures they had before starting the diet 3–6 years previously [67]. Several of these children had epilepsy surgery or vagus nerve stimulation implantation, yet even those who did not had a long-term prognosis that was much better than would be expected considering their intractable epilepsy (even to the ketogenic diet). This evidence, although very limited, suggests that the ketogenic diet may be not only anticonvulsant in the acute setting, but anti-*epileptogenic* in the long term. Further studies are under way.

The timing of dietary discontinuation in the child with no perceived seizure reduction has been investigated recently. Nearly 90% of children who improve on the ketogenic diet do so within 1 month, and nearly all by 2 months [36]. Therefore, continuing the ketogenic diet beyond 6 months in a child with no seizure improvement would seem inappropriate. Typically, if a child has been on the ketogenic diet for only several months, he/she can be weaned over 2–3 weeks. If the child is having significant difficulty with the ketogenic diet, he/she can be discontinued immediately, however, without dramatic increase in seizures in most cases.

Side-effects

The ketogenic diet is not without side-effects. As with any medical therapy for seizures, benefits need to be balanced against risks (Table 23.4). Side-effects were recently well summarized in an editorial by Wheless [68].

During the initiation of the ketogenic diet, the fast itself can cause vomiting, dehydration and food refusal. These effects are usually transitory and easily treated; however, if the child has an underlying metabolic disorder, the fast and ketogenic diet can be dangerous. All children, especially infants, need to have a thorough history, physical examination and often screening tests (lactate, pyruvate, carnitine, electrolytes, urine organic acids and serum amino acids) performed prior to initiating the diet. Diseases that could potentially deteriorate on the ketogenic diet include pyruvate carboxylase deficiency, porphyria, primary carnitine deficiency, certain mitochondrial disorders and fatty acid oxidation defects (see Table 23.1) [65].

Some of the more common side-effects include constipation, exacerbation of gastro-oesophageal reflux, acidosis with illnesses,

Table 23.4 Side-effects reported with the ketogenic diet.

Constipation
Exacerbation of gastro-oesophageal reflux
Water-soluble vitamin deficiency (if unsupplemented)
Elevated serum cholesterol, triglycerides, and low-density lipoprotein cholesterol
Renal stones
Growth inhibition
Weight loss
Worsening of acidosis with illnesses
Bone fractures
Vitamin D and selenium deficiency
Cardiomyopathy

growth difficulties, renal stones and hyperlipidaemia. Constipation and gastro-oesophageal reflux disease are common and likely to be secondary to the low-roughage and high-fat component of the ketogenic diet. Both can be treated effectively with increased fluids, stool softeners and laxatives when necessary. The use of MCT oil in the diet can often be helpful for constipation also. Acidosis, not only during the initiation of the diet but also during acute illnesses, is a true concern and needs to be discussed at length with the family. At the time of diet initiation, parents should be taught the signs of acidosis and how to hydrate with non-sugar-containing fluids.

Growth is often of concern for parents, and they need to understand that weight gain may be reduced with the ketogenic diet. A recent review of the diet in 237 children revealed a reduction in the rate of weight gain (more so in children above the average median weight) at 3 months but which then remained constant for up to 3 years [69]. The rate of increase of height remained normal for the first 6 months of the diet but then decreased over the next 18 months, especially in those children above the median to start. There were also significant differences between age groups for height and weight, with younger children growing less well.

Renal stones occur in approximately 6% of patients and tend to be either uric acid or calcium oxalate stones [70–72]. Children with a family history of kidney stones (even calcium stones) may be at higher risk for renal calculi and should be hydrated more aggressively and their urine alkalinized [72]. Renal ultrasound should be performed in any child with haematuria or pain upon urination. Periodic spot urine calcium to creatinine ratios can also help screen for this condition. If the ratio is >0.2, potassium citrate should be started to help alkalinize the urine in children [63]. Lithotripsy, or occasionally surgical removal, can be performed successfully and the diet continued, and renal stones should not be considered a mandatory reason for withdrawal of the diet. Recent evidence suggests that potassium citrate reduces the risk of kidney stones threefold, and we now routinely start all children on this supplement at diet initiation [63]. Although there does not appear to be a higher risk of stones with combination use of topiramate or zonisamide, we suggest that if these drugs are being used in a child on the ketogenic diet, they should be stopped [72].

Hypercholesterolaemia does occur on the ketogenic diet. Sixty per cent of children will have abnormal cholesterol or triglycerides during their treatment with the diet [73]. Abnormal results are less likely in children receiving a formula-only ketogenic diet [74]. The increase in cholesterol may be due to a ketogenic diet-induced decrease in apolipoprotein B (apo B), the major serum carrier of cholesterol [73]. Triglycerides also increased in this study, but then later normalized. The long-term effects of the ketogenic diet on atherosclerosis remain to be determined; however, most children on the ketogenic diet for 6–12 years in one cohort had normal or only slightly elevated total cholesterol and triglycerides [75]. Adjustments to the diet such as additional MCT oil or polyunsaturated fats and decreased ketogenic ratios can be made in children with significantly elevated triglycerides and cholesterol, and were successful 60% of the time [74]. Children should be screened with a serum cholesterol level if physical examination findings (such as cholesterol deposits in skin or retina) or a family history of early atherosclerosis indicates the possibility of familial hypercholesterolaemia.

More uncommon complications attributed in the literature to the diet have been reported [76–79]. They include cardiomyopathy, pancreatitis, bruising and vitamin deficiency. Most were case reports and do not prove that these problems were diet related. Four of five patients reported by Ballaban-Gil [76] had severe hypoproteinaemia, Fanconi's renal tubular acidosis and increased liver function tests potentially in combination with valproate. The correlation of these complications with the ketogenic diet is unclear, but the authors propose a possible additive effect with valproate interfering with carnitine function and fatty acid oxidation. In a study by Best *et al.* [77], prolonged QT interval was discovered in 3 of 20 patients, but this has not been reported elsewhere. No child at our institution has ever had arrhythmias or cardiomyopathy attributable to the ketogenic diet. Increased tendency for bruising was seen in a recent study in 16 of 51 children reported by Berry-Kravis *et al.* [78]. Vitamin deficiency is rare [80]; however, it can be appropriately avoided using supplementation. Routine administration of magnesium, selenium, zinc, vitamin D, vitamin C, B-complex vitamins and additional calcium is recommended.

24 Non-pharmacological, Complementary and Alternative Treatments for Epilepsy

Tom Whitmarsh

Glasgow Homeopathic Hospital, Glasgow, UK

Most general reviews of treatment for epilepsy concentrate entirely on the pharmacological agents on offer. Most of the rest of this book demonstrates this. When non-pharmacological treatments are discussed, these include, almost without exception, only surgical interventions, vagus nerve stimulation and the ketogenic diet. This chapter is concerned with other treatments which have been tried, or which might usefully be further investigated and which continue to be used by a large number of people with epilepsy. One survey of all members of the Epilepsy Federation of Arizona found that 44% had used a non-conventional treatment for their seizures at some time [1]. The authors extrapolated their results and found that, of 24 000 individuals with epilepsy (IWE) in Arizona, probably 10 500 were using or had tried a non-conventional therapy for their seizures. An interesting difference in studies of complementary and alternative medicine (CAM) in general is in the proportion of individuals with epilepsy who avoid telling their physicians about CAM use. In this survey (2003), only 7% of 379 patients with epilepsy said that they would not tell their physician about CAM use. Earlier surveys suggested that up to 40% of people using CAM in the general population omitted to tell their physicians of the use [2]. A more recent survey [3] of 228 IWE in the western USA found that 39% reported using some form of CAM, with 25% reporting use specifically for epilepsy. These studies do bring up the issue of lumping all non-conventional treatments into one category, as if, for example, prayer as a form of CAM is to be considered as in some way similar to acupuncture, which is clearly true only if they are both just considered as 'non-conventional'. The rising tide of concern among patients in the Western world about the side-effects of conventional pharmaceuticals has been considered one reason for the rapid rise in popularity of many forms of unconventional medicine [4]. Nowhere is this concern more likely to be felt than among sufferers of epilepsy, a predominantly youthful population which has to take such agents daily for many years, and their families. Any techniques or treatments which could be applied to reduce the need for conventional medication, in even a small proportion of sufferers, are worth noting by all those who care for people with epilepsy.

Some of these techniques, such as EEG biofeedback, psychotherapy, relaxation and hypnosis, verge on the mainstream, but most of them are more commonly viewed under the CAM banner. CAM refers to 'diagnosis, treatment and/or prevention which complements mainstream medicine by contributing to a common whole, by satisfying a demand not met by orthodoxy, or by diversifying the conceptual frameworks of medicine' [5]. As suggested earlier, there is an unfortunate tendency to lump all non-conventional practices together as 'alternative' and label them all as either 'good' or 'bad', depending on one's preference. Viewed more holistically, there are approaches on both sides of a notional dividing line which bring health benefits to particular individuals. There is little to guide us in knowing in advance which sufferers will benefit from which therapy. It is perhaps one of the tasks of medicine over the next few decades to integrate CAM therapies into treatment pathways, the prime goal being to alleviate suffering and promote health. Some such attempts are available as case reports [6,7]. Some are positive about possible developments in this direction [8] and some are worried [9,10]. It is notable that much of the concern appropriately springs from worries about the possible risks of forgoing conventional treatments (though most IWE use CAM as add-on, complementary therapy to their conventional management) and direct adverse effects of some CAM treatments [9,11]. Herbal interactions with AEDs are another major concern [10], but should be minimized if most IWE tell their physician what they are doing and if the physicians are at least a little knowledgeable about CAM.

This review aims to help answer the questions of what evidence is already available to help in the task of integration and what might be the most promising lines for future research to take.

Experience from the developing world suggests that people with epilepsy are extremely pragmatic in their approach to potential therapies, continuing to use anything which they perceive as helpful and quickly rejecting anything perceived as unhelpful. For example in a neurology outpatient setting in Lagos, Nigeria, it has been found that many people with epilepsy develop a personal care strategy which may combine elements of 'conventional' (pharmaceutical) and 'complementary' (traditional remedies and/or spiritual healing) medicine [12]. Similarly, this approach is widely adopted generally in the developed world [13]. There is, though, evidence of some improvement in public attitudes to epilepsy over time in many countries, and it is interesting to perform cross-cultural comparisons of treatment and perceptions of epilepsy between developed and developing countries. One study compared these factors in 28 IWE in the USA with 29 IWE in Kashmir [14]. Both samples had quite similar attitudes to

The Treatment of Epilepsy, Third Edition Edited by S. Shorvon, E. Perucca and J. Engel
 ISBN: 978-1-405-18383-3

AEDs, though the American group had a greater access to newer drugs and also to non-pharmacological treatments. The two groups both expressed frustration at the societal lack of understanding of their condition and the importance of support from family and friends. On the whole, both groups used alternative treatments in addition to, rather than instead of, conventional therapies, with spiritual practices and prayer being considered most important. A very well-told case of a child with severe generalized seizures born in California after the family had been forcibly resettled from IndoChina shows how important it is for Western-trained physicians to be sensitive to cultural differences in their patients [15]. Even in the UK, non-indigenous communities can maintain a strong belief that epilepsy is just the 'will of God' and 'punishment for sins of a past life' and turn to spiritual practices and traditional healers along with conventional treatment in a desperate search for a 'cure' [16]. These examples suggest that it is vital for those who care for people affected by epilepsy to have at least a basic familiarity with the more commonly used CAM treatments. This should enable appreciation of any safety issues, such as potential drug interactions, enhance the understanding relationship between health professional and patient and even allow the occasional referral for appropriate, effective non-conventional treatments.

There are a number of unconventional and CAM therapeutic approaches that are sometimes helpful in the treatment of epilepsy. There are some studies which help to indicate which individual patients might benefit, but as there has been relatively very little funding of research in CAM and there are few well-established research networks, case reports and individual clinical experience have a strong role. The rise of evidence-based medicine (EBM), and the risk of providers allowing funding only if a treatment comes up to some acceptable standard of EBM, is very much a concern in the CAM therapist community. Since the only acceptable 'evidence' seems to be that from randomized clinical trials and since not many CAM therapies are well supported by this kind of evidence, much of what follows may be felt unacceptable. Certainly, the amount of apparently quite good 'evidence' specifically excluded from Cochrane reviews (as the major publications in EBM) causes a worry that some effective treatments could be increasingly overlooked because they have not come up an evidence standard against which they have never been tried.

Therapies with varying levels of seeming evidence of efficacy in epilepsy include behavioural/psychological therapies such as psychotherapy, cognitive therapy, hypnosis, meditation, EEG biofeedback and relaxation, herbal medicine, low-antigen diets, dietary supplements, music therapy, exercise, homeopathy, acupuncture, transcranial magnetic stimulation and chiropractic therapy.

Psychological/behavioural treatments

Many different therapies which could come under the 'psychological' or 'behavioural' tags have been tried in epilepsy. Much of the literature reports single cases or very small studies, but there are Cochrane reviews of psychological treatments for epilepsy [17] and of behavioural treatments for non-epileptic seizures (NES) [18]. To an extent, these supersede the reviews of Fenwick [19] and Goldstein [20], but they are limited to detailed comment only about randomized controlled trials (RCTs) and some may find the more discursive and 'real life' clinically focused earlier discussions more useful, though Goldstein is a joint author of the Cochrane review. Ramaratnam *et al.* [17], therefore, have to dismiss most of the high-quality work that has been done over the years on EEG biofeedback or relaxation training, as adequate RCTs are not available. Similarly, Brooks *et al.* [18] are only able to include three trials, two of hypnosis and one of 'paradoxical therapy', in a discussion which aims to 'establish the evidence base for treating NES'. The conclusion, of course, has to be that there really is hardly any evidence on strict Cochrane criteria, but this does seem to be a process that takes attention away from possibly helpful treatments. The reader is directed to these authors for further detail, but, broadly, psychotherapy, individual counselling and cognitive behavioural therapy (CBT) may help the psychological problems associated with epilepsy, and there is a suggestion of reduction in seizure frequency with some of these techniques. Operant or classical conditioning is reported to decrease seizure frequency and to be particularly helpful in control of the reflex epilepsies (seizures reliably triggered by a specific sensory stimulus, such as music or strong smells). Cases have also been reported of the beneficial effect of changing arousal levels in response to cues indicative of the onset of a seizure. Such 'countermeasures' are individually designed, according to the seizure cues, and many patients soon discover what action is effective for them to abort a threatened seizure.

Hypnosis

Hypnosis is a technique by which general arousal levels can be changed. It has not been assessed unrelated to other therapies in RCTs, and this is discussed in the Cochrane review of treatment of non-epileptic seizures [18], though there are many case reports. One highly developed programme in an epilepsy centre combined it with aromatherapy and reported on its first 100 patients, concluding that for those individuals who are highly motivated, hypnosis plus aromatherapy had a very helpful, lasting effect [21]. A report on just two patients suggests that it can be effective in control of seizures [22]. An impressive case report gives great detail of the hypnotic processes learned by a woman with Jacksonian seizures due to a benign, but inoperable, frontotemporal tumour. She reduced her seizure frequency from 35 to five per week over the course of hypnotic treatment lasting 16 months [23]. Utility to distinguish 'psychogenic' [non-epileptic events (NEE)] seizures from epileptic events (EE) by the degree of 'hypnotizability' of the subject has been suggested. In one study [24], 60 patients attending a specialist epilepsy centre were evaluated. While undergoing continuous video-EEG monitoring, they completed an inventory designed to measure the degree of hypnotizability [the hypnotic induction profile (HIP)]. An attempt was made to induce the patient's typical events and any event without an EEG correlate was felt to represent an NEE. Results of the hypnotic assessment were compared with the diagnoses of NEE made independently by a neurology team. HIP scores for EE-only patients were significantly lower than for those who had NEE as some or all of their events. The sensitivity of seizure induction in the diagnosis of NEE was 77% and the specificity was 95%. The authors concluded that the HIP along with seizure induction

is a useful technique to aid in the diagnosis of patients with NEE.

Meditation and yoga

In a well-conducted study, 11 adults with drug-resistant epilepsy were taught meditation (of classical Indian word repetition, non-religious type) and followed up for a year of practice (20 min daily) [25]. They were compared with a waiting list control group of nine subjects, well matched for age, duration of illness and seizure type. Both groups received the same professional attention; the control group, however, did not practise meditation. The meditation group showed a reduction in attack frequency and duration after 6 months' practice compared with the 6-month period pretreatment, which became highly significant with a further 6 months' treatment. The meditators also demonstrated normalization of EEG recordings with prolonged treatment, with a reduction in mean spectral intensity of the 0.7–7.7 Hz segment and an increment in intensity of the 8–12 Hz segment. There were no changes in the controls. The authors discuss the rationale for the study in terms of eliciting the 'relaxation response' of Benson [26] and suggest that this might be a common link towards understanding the mode of action of all of these psychological techniques.

Yoga teaches a combination of physical postures, breathing exercises, relaxation and meditation to attain optimal physical and mental health. A number of documented clinical and physiological effects are relevant to epilepsy [27]. There are many different schools of yoga practice, some emphasizing control over the physical body, some control over the breathing and some specifically using meditative practices to calm the mind and achieve 'union of the individual energy ('prana') with the universal energy ('Brahman'). There are a number of methodological issues about the kind of yoga to be used and the diagnoses of participants which have to be overcome [28]. Most of the reports of yoga as treatment for epilepsy have been concerned with the directly meditative forms (specifically Sahaja yoga) and may perhaps be considered along with meditation as an intervention. A Cochrane review of yoga in epilepsy [29] identified five studies, but only considered data from one in detail. Interestingly, one of the excluded studies in this review of 'yoga' is that of meditation considered in detail above, and does not in fact mention yoga at all [25].

The study included by the Cochrane reviewers randomized 32 uncontrolled epileptic patients to three groups [30]. Group I (n = 10) was the yoga group, who practised Sahaja yoga meditation under guidance of an instructor twice daily for 20–30 min for the 6-month duration of the study. Group II (n = 10) practised mimicking exercises in the same environment as group I and were provided with the same attention. Group III (n = 12) was a control group, just being followed up in outpatients.

Four out of 10 patients in the active group became seizure free after 6 months of practice, compared with none out of 22 in the controls. Nine in the active group had more than a 50% reduction in seizure frequency compared with just one among the 22 controls. These differences are significant and suggest that further research in this area is justified, with larger group sizes.

A pilot open-label study of a yoga meditation protocol (YMP) has been performed at a specialist epilepsy centre in south India [31]. Twenty patients with epilepsy on maximal doses of standard antiepileptic drugs (AEDs) (age range 15–47 years, median 27 years) and at least four complex partial seizures in the preceding 3 months were asked to perform the YMP for 20 min twice daily for 3 months. They also attended for a supervised YMP session weekly. At 3 months, a reduction in seizure frequency to <50% of the pretreatment value was apparent in all except one patient. Of the 16 patients who (optionally) carried on the YMP beyond 3 months, 14 continued this response, as did all of the eight patients who elected to carry on for 6 months. Three of these became seizure free. The authors are recruiting for a RCT using sham yoga as a control.

Whether any changes are specific to a form of meditation called yogic, or indeed to any form of deep relaxation, and whether similar effects might be obtained with other, more familiar, physical forms of yoga remains to be elucidated.

It has been argued from a theoretical point of view that, as a rise in brain glutamate and serotonin and the development of 'hypersynchrony' of EEG activity which accompany meditative states are also known to underlie the development of epilepsy, so meditation might be expected to increase attacks in epileptics (a kindling phenomenon) [32]. This view of potential harm from meditating in epileptics has been strongly countered with clinical effectiveness and experiential arguments [33].

EEG and other biofeedback

Biofeedback in general involves the use of electronic displays to collect and show physiological processes to the patient, with the goal of increasing the patient's control over the internal processes and changing them at will. It has been extensively studied in a variety of neurological conditions. For example, thermal biofeedback (in which control of the skin temperature of a finger is learned) and electromyograph (EMG) biofeedback (in which control is learned over the tension in a muscle, such as temporalis) are well established as treatments for migraine and tension-type headache respectively, at least in the USA [34,35]. In EEG biofeedback, also referred to as EEG operant conditioning or neurotherapy, the subject learns to voluntarily control a chosen EEG rhythm which has been associated with suppressing seizure activity and thereby gain control over the seizures themselves. Initial work was done on the 'sensory-motor rhythm' (SMR) over the somato-sensory cortex, and it is this rhythm which has been most studied. Modern protocols use well-developed software with visual displays guided by quantitative EEG analysis. Biofeedback reinforcement of other rhythms such as the alpha rhythm and also the suppression of slow wave and spike activity have also been investigated and found to be effective in some studies. There is much debate in the literature about just which rhythms are likely to be most useful for biofeedback for which conditions.

Sterman and Friar first observed protection against drug-induced seizures in cats following operant conditioning of 11–15 Hz sensorimotor EEG rhythm to produce a sustained increase in the rhythm. They used the technique to successfully treat a 23-year-old woman with a 7-year history of generalized major tonic–clonic seizures of unknown origin, occurring at least twice monthly. The seizures had proved resistant to many drug regimes. With 3 months of twice-weekly biofeedback training enhancing 11–15 Hz activity, she became seizure free [36].

In a comprehensive review of the literature from the first case report in 1972 to 1996, Sterman [37] collected the results on a total of 174 patients with intractable epilepsy treated with sensorimotor EEG operant conditioning, in 18 studies from many different authors. One hundred and forty-two (82%) of those who were otherwise not controlled showed 'clinical improvement', that is reductions in seizure frequency of at least 50%. The average value of reduction of seizure frequency was above 50% and many of the studies reported reductions in seizure severity. Approximately 5% of this difficult subset of epileptic patients experienced complete control of seizures for up to 1 year. Not all studies reported EEG findings, but of those that did, 66% of reported cases (in 13 studies) showed 'EEG improvement'. Most of the studies are of very small groups of under 10 patients and many of them report individual patient characteristics and outcomes, often using the patients as their own controls in pre- versus post-treatment comparisons of frequency and severity. Two larger studies [38,39] report on groups of 23 and 83 patients and find significant beneficial effects on seizure frequency.

Sterman [37] comments that 'the consensus arising (from the studies) is that most epileptic patients who show clinical improvement with EEG biofeedback also show contingency-related EEG changes and a shift towards EEG normalization. However, not all patients who respond to this treatment show EEG changes and a few patients who show EEG changes experience little clinical improvement. In a further, very comprehensive, review of principles underlying neurofeedback [40], he tells us that it is now so well documented that it meets criteria in seizure disorder for 'clinical guidelines' of evidence-based treatments of the American Academy of Child and Adolescent Psychiatry. It is reassuring to read of groups other than the originators publishing experience of this technique [41].

Advocates of EEG biofeedback point to an accumulation of evidence of positive effects in neurophysiological and clinical studies over the past 25 years. They lament the lack of interest in its potential usefulness for a most difficult-to-help group of patients in the wider neurological community and specifically that the technique is still regarded as 'experimental' [37]. Sceptics may acknowledge that there are 'adequate data to suggest that EEG biofeedback can work in some clinical conditions' [42], but clearly, a lot more work needs to be done to satisfy the demands of non-enthusiasts before EEG biofeedback can take its place as a generally available option for people with intractable seizures. For the individual strong-responding patients who have been able to come off all anticonvulsants and return to work [43] or be issued with a driving licence for the first time [36], this view may seem a little narrow.

It is undoubtedly a rather lengthy and expensive treatment in terms of laboratory, technician and patient time, and there is as yet no way of determining in advance which patients will benefit.

One study with skin galvanic biofeedback is considered in the Cochrane review of psychological treatments [44]. This is, of course, a much less complicated procedure than EEG biofeedback. Eighteen patients were randomized to receive either active or placebo skin galvanic skin response biofeedback for three sessions per week for 4 weeks. Seizure frequency was compared in the 3 months before the treatment with the 3 months afterwards. All had AED-refractory epilepsy. Six of 10 in the treatment group had 50% or greater reduction in seizure frequency compared with none of eight in the sham feedback group.

Relaxation

Relaxation has been investigated as a possible treatment for epilepsy in at least four controlled studies. The particular form of relaxation generally used has been progressive muscular relaxation (PMR), as codified by Bernstein and Borkovec [45]. An early report was that of Snyder [46], who recruited 16 patients with mostly 'mixed' seizures. Only four practised relaxation on 15 or more days each month, but of these three reported a decrease in seizure frequency. Rousseau and colleagues performed a controlled study [47] and placed eight subjects into two groups on a sequential, alternating basis. Group I underwent a training session in PMR and were then asked to practise the exercise twice daily for the next 3 weeks. Group II were initially trained in a sham treatment and sat quietly for 20 min twice daily, relaxing as best as they could. Baseline seizure frequency was recorded for the 3 weeks before training and both groups continued to record seizure frequency through the first 3 weeks of the study. At the end of 3 weeks, group II was taught PMR and practised twice daily for the next 3 weeks, recording seizure frequency. There was a significant decrease in seizure frequency after PMR training (by 43–100%) compared with after the sham (0–51%), although two subjects also did well with the sham.

Whitman *et al*. [48] trained 12 patients in PMR who had at least six seizures in an 8-week baseline period and followed them up for 6 months, but did not include a control group. The mean reduction from baseline in seizure frequency at 6 months was 54%. Puskarich *et al*. [49] enrolled 24 subjects with at least six seizures in a baseline period of 8 weeks. They were randomized in alternating blocks of five to a group which received six sessions of training in PMR ($n = 13$) and a control 'quiet sitting' (QS) group ($n = 11$) which attended six times for 30 min of non-directive conversation, followed by 15 min of sitting alone in a reclining chair in a darkened room. This training period lasted 8 weeks. The groups were then followed up for 8 weeks. In the PMR group, 11 subjects had a decreased frequency of seizures from baseline to follow-up ($P < 0.01$), and in the QS group seven had a decrease ($P < 0.05$). The mean decrease in seizure frequency was 29% (from 17.0 at baseline to 12.1 during follow-up) for the PMR group and 3% for the QS group (from 10.3 at baseline to 10.0 during follow-up). Subject numbers and study quality have risen with each new report and there is increasing evidence for a worthwhile effect on seizure frequency of this simple psychological intervention.

There is also evidence that adults with resistant seizures can learn early signs of cortical dysarrhythmias and apply relaxation acutely to inhibit the seizure [50].

Psychiatric interventions

One study reviewed experience with 37 patients with uncontrolled seizures, whose seizures seemed to be precipitated by emotional stress [51]. Each received psychiatric intervention on at least two occasions (range 2–70, median 7.5). The intervention consisted of 'individual and family assessment, followed by the formulation of a treatment strategy geared toward alleviating

possible psychogenic contributions to the patient's seizures'. It should be noted that in an appreciable proportion of these cases, 'hysterical' seizures were rated as being probably (19 of 37) or definitely (3 of 37) present. After 2–36 months' follow-up (median = 6.5 months), 9 of 37 patients became seizure free and 12 additional patients showed a marked improvement (at least two-thirds decrease in seizure frequency). Patients with partial seizures were more likely to respond than those with generalized seizures, and those with non-epileptic ('hysterical') seizures were especially responsive. Hypnotizability and having an intelligence quotient (IQ) within the average range were also positively associated with a favourable outcome.

An analysis of 70 case studies in psychological approaches for prevention of nocturnal seizures encompasses extremely heterogeneous groups of patients and treatments [52]. Its author is unable to draw any firm conclusions, specifically about factors which might predict good response to a particular therapy. Most provocatively, it is suggested that freedom from seizures as a consequence of psychological treatment of epilepsy was most often achieved in these 70 cases when AEDs were withdrawn.

In conclusion, there are a number of psychological/behavioural interventions which have been well studied and considered to be helpful as additional therapy for even the most drug-resistant epileptic patients. Choice of intervention probably depends mostly on local availability and patient preference and motivation, as there are, as yet, few indications of which technique is most likely to be helpful in an individual.

Exercise

There has been a reluctance to allow normal participation by epileptic patients in physical activity and sport, generally due to fear of injury or concern about exercise-induced seizures, although there has generally been a shift in medical opinion away from restricting participation towards encouragement. There appears to be no generalized increase in seizure frequency with physical exercise [53], although there is considerable individual variation. Exercise has been studied as a possible means of reducing seizures in drug-resistant epilepsy. Eriksen *et al.* [54] gave 15 women with drug-resistant epilepsy (median 2.9 seizures per week) physical exercise sessions twice per week for 15 weeks. The exercise sessions lasted 1 h and consisted of a warm-up, 30 min of aerobic dancing, a cool-down, 15 min strength training and 5 min relaxation, all accompanied by music. Seven subjects had a total of 27 seizures during the 30 exercise sessions, mostly during the aerobic dancing or cool-down periods. Self-reported seizure rate was significantly reduced during the 15 weeks of the intervention (from 2.9 seizures/week at baseline to 1.7/week during exercise) and there was also a reduced level of other health complaints, such as muscle pains, sleep problems and fatigue. The positive effects did not, however, last through a follow-up period of 3 months, when most subjects were unable to continue exercise on their own. The authors feel that 15 weeks is not long enough to effect a complete lifestyle change towards regular, hard physical activity. They believe that the benefits of increased fitness, decreased overall health complaints and reduction in total number of seizures more than balance the relatively few seizures during exercise that occurred in half of the subjects. Accordingly, they recommend that physical activity such as aerobic dance can be recommended to epileptic patients, its most important effect being 'the normalization of the life situation for severely affected hypoactive and understimulated epileptic patients'.

Music

That music and different neurological diseases are in some way interconnected in human behaviour has long been appreciated (for a fascinating discourse, see Kaplan [55]). The specific entity of seizures being triggered by music (musicogenic epilepsy) is well recognized, but can it work 'the other way round' – can music be used to treat epilepsy?

The 'Mozart effect' was first reported as an enhancement of spatiotemporal reasoning after listening to Mozart's sonata for two pianos (K448) for 10 min [56]. Later, EEG changes such as enhanced synchrony of the firing pattern of the right frontal and left temporoparietal areas, persisting for 12 min, were demonstrated. In 23 of 29 epileptic patients with focal discharges, there was a significant normalization of the EEG after listening to Mozart's music and one case report describes an 8-year-old girl with Lennox–Gastaut syndrome and intractable, frequent seizures (about two per hour) who achieved a very significant reduction in attacks by the playing of the Mozart sonata for 10 min each hour of her waking time. These studies, and the probability that this effect is not specific to Mozart's music, are considered by Jenkins [57]. A more recent case of gelastic epilepsy in a 56-year-old man responded almost completely to listening to Mozart (not a specific piece of music) for an average of 45 min/day [58]. He had had gelastic fits since shortly after birth and developed tonic–clonic seizures during his mid-thirties. He was found on MRI to have a right hypothalamic hamartoma. He had tried seven AEDs, had Gamma Knife surgery and brachytherapy to the hamartoma, but the seizures did not change in frequency in the long term. Before he began listening to Mozart (which he did spontaneously as he had heard that it might enhance spatiotemporal reasoning) he was having gelastic seizures with intense laughter five or six times each day, as well as secondarily generalized tonic–clonic seizures on average seven times per month. In the 3 months after starting to listen to Mozart regularly, he had no secondary generalized tonic–clonic seizures. He continued to have five gelastic seizures a day, but these showed themselves as just brief, 5–9-s smiles, which could be disguised in the presence of others. The authors felt that 'it would be appropriate to revisit the Mozart effect in those with epilepsy'. It is hard to disagree.

The effect of another form of music – 'medical resonance therapy music' – has been studied in 34 patients in an epilepsy hospital in Minsk, Belarus [59]. This a commercial product (you can buy the CD) of 'harmonic music' by German composer Peter Heubner, which has been available as a 'stress reducer' for 19 years and has been used medically in migraine and other disorders thought of as 'stress related'. Subjects listened to the music daily for 1 h for 6 to 16 sessions. The author claims a 75% reduction in seizure frequency and a significant improvement in psychological state. Unfortunately, the report is very unclear, with no actual numbers of seizures given, only percentage improvements on

undefined scales. The kind of music is not well described, but appears to be a rhythmical, computer-generated creation, designed for therapeutic purposes rather than to be listened to for pleasure. Since there are no formal studies of more conventional music (Mozart K448, for example) with which it can be compared, this study stands as the only one of its type in epilepsy. The field looks ripe for experimentation.

Herbal medicine

A large number of plants are traditionally used throughout the world for the treatment of epilepsy. One review of the literature found around 150 plants or other natural substances from traditional medicines which have been tested for their *in vivo/in vitro* anticonvulsant activities in the last 30 years [60]. The authors felt that 10 of these warrant further study. It should be remembered that many herbal preparations of course have very significant interactions with commonly prescribed conventional drugs [10,61] or may cause seizures as side-effects [62], and use of these preparations should always be specifically enquired about.

One herbal mixture which has been quite extensively studied and which is sometimes recommended as add-on treatment for epilepsy is the Japanese mixture Saiko-keishi-to (SK). This is made up of parts of nine plants. Two other very similar mixtures have been studied, sho-saiko-to and the Chinese chai-hu-keui-chi-tang. These differ only in the relative amounts of the baseline herbs and they all appear to have equivalent effects. One study gave SK to 24 poorly controlled epileptic patients daily for at least 10 months, as add-on treatment, keeping the conventional AED regimes constant. Six became seizure free and 13 improved in seizure frequency or severity [63].

Another study found a greater than 25% reduction in seizure numbers in 8 of 24 patients with drug-resistant partial epilepsy after 8 weeks' daily treatment with SK. There were corresponding cognitive improvements [64]. Neither of these studies was adequately controlled, but the results are suggestive of a useful action of SK in drug-resistant epilepsy and there has been extensive experimental research on the cellular actions of this preparation [65].

Interestingly, it appears that only the crude mixture of plants which is SK possesses activity, at least in *in vitro* models [66]. Attempts to refine the preparation too far in looking for the pharmacologically active agent may prove fruitless. This is very much in line with herbalists the world over, who believe that 'the whole is more that the sum of its parts', holding that plants act synergistically within such mixtures and also that the balance of compounds within a single plant acting in concert is likely to be responsible in large part for its actions [67].

A traditional Chinese medicine (TCM) analysis is given in detail for three cases of different epilepsies by Hijikata *et al.* [68]. A Chinese traditional herbal mixture was used to very good effect as additional treatment (along with AEDs) in reducing seizure frequency in cases of epilepsy and Moyamoya disease, epilepsy with hemiparesis and hemiconvulsions and temporal lobe seizures.

In the Western world, though, the use of cannabis is probably more widespread.

In a telephone study performed from a tertiary care epilepsy centre in Canada [69], 48% of 136 patients had used marijuana at some point in their lives and 21% were active users (i.e. they had used it in the past year). There was no difference in age, sex or employment status of users versus non-users which are factors affecting use in the general population, but there were differences in the groups when considering the duration of the disease (1.6 times more likely to be marijuana users for duration < 10 years versus duration > 5 years) and seizure frequency (eight times more likely to use marijuana with 'frequent seizures'). The authors also asked participants of their knowledge of effects of marijuana in epilepsy and 56 of the 136 participants had heard of marijuana use as a treatment for epilepsy and 57% of these had heard it was beneficial. Of the active users, 12 (43%) stated 'medical reasons' (presumably related to their epilepsy) for use, though none was officially approved. It is probable that people with long-term conditions, not fully treated by conventional methods, are more likely to seek alternatives. It is, though, not impossible that frequent marijuana use leads to more severe and frequent seizures.

The use of cannabis in epilepsy might be a further example of 'synergism'. A brief report [70] tells of comparing the psychoactive ingredient of cannabis, tetrahydrocannabinol (THC), cannabis herb and a cannabis herb extract from which the THC had been removed in 'an *in vitro* model of epilepsy'. All the substances abolished 'epileptiform bursting' in the model (the details of which are, unfortunately, not specified), which suggests that not all of the therapeutic effects of cannabis are due to THC. Perhaps herbs really are more than the sum of their parts.

Dietary measures

Food sensitivity

Oligoantigenic diets and avoidance of foods to which the patient is sensitive appear to be effective in children with epilepsy and migraine, although not in those with epilepsy alone [71]. There is evidence that seizures can be precipitated in some adult subjects by eating certain foods to which they have an allergic or sensitivity response. One study used double-blinded food challenge in a 19-year-old woman with frequent seizures, a history of allergies to dust, pollen and mould, a strong family history of allergies, and an eosinophilia and who discovered by elimination diet to be sensitive to beef. Seizures occurred soon after taking capsules containing beef, but not chicken, and she remained seizure free in the long term by avoiding any beef products, having stopped anticonvulsant medication [72]. Particularly in those epileptic patients who have a strong family or personal history of allergy (asthma, allergic rhinitis or other allergy) or an eosinophilia, it is recommended to look for food sensitivities by means of exclusion diet and phased re-introduction.

Nutritional supplements

Anticonvulsant actions have been claimed in clinical trials for vitamins E and D, the trace elements selenium, manganese and zinc and the amino acid taurine. Vitamin E, in particular, has been used relatively widely [7] for its presumed anticonvulsant

activity. Thiamine and folic acid have been studied with regard to neuropathic and dental side-effects of AEDs. A Cochrane review of these studies [73] and those with vitamins E and D concluded that, in general, the number of participants is rather low and the study quality is not high. There is some evidence that thiamine can help some neuropsychological functions and vitamin D may improve bone mineral content in users of older AEDs, but folic acid does not seem to help with the neuropathy associated with some AEDs (although the number assessed in just one study was very small and the method of assessment was outdated) and only the small study (discussed below) using vitamin E demonstrated a reduction in seizure frequency, although again the numbers included were low and the confidence intervals of results wide.

This trial [74] randomized 24 subjects aged 5–18 years with various types of seizures and at least four seizures per month to receive either 294 mg (400 IU) of vitamin E ($n = 12$) or matching placebo ($n = 12$) daily for 3 months in addition to their usual AEDs. Ten of the patients in the active group were considered 'responders', that is their seizure frequency declined by at least 60%, and the two non-responders were actually non-compliant (by blood levels of vitamin E). There were no responders in the placebo group. This difference in response rate (83% versus 0%) was significant at $P < 0.05$. Blood levels of standard AEDs were not altered during the study and it was concluded that vitamin E may be a useful antiepileptic agent, at least in a paediatric population with drug-resistant epilepsy. Unfortunately, no further studies seem to have been conducted to confirm these promising preliminary results.

A single study [75] supplemented the diet of 23 adult epileptic patients with various seizure types who stayed on their standard AEDs with 4000–16 000 IU of vitamin D daily (9 patients) or placebo (14 patients). Seizure frequency declined by about 30% only whilst taking vitamin D, not on placebo, and the result was discussed in terms of the possible effects of AEDs on calcium and magnesium metabolism. The authors concluded that it might be advisable for all patients taking AEDs to receive prophylactic vitamin D. Again, this result has not been taken forward.

There is some evidence from animal studies that omega-3 fatty acids (omega-3 FAs) may increase seizure thresholds and a study has assessed their effect in refractory epilepsy [76]. This was a 12-week double-blind, placebo-controlled parallel-group study in patients with refractory epilepsy living in a residential facility. Sixty-eight patients were screened and 58 randomized. One in the group randomized to placebo was withdrawn from the trial for clinical reasons unrelated to the trial, and so 30 received active capsules containing fish oils (equivalent total daily dose 1.7 g omega-3 FAs) and 27 received matching placebo capsules containing mixed, non-fish oils. The types of epilepsy syndromes and the AEDs being used are listed and well matched in each group. A significantly greater proportion of patients taking supplements (5/30) compared with those taking placebo (0/27) had at least a 50% reduction in seizures in the first 6 weeks of the trial, but this was not sustained. There were no changes in serum AED concentrations. The authors discuss the loss of apparent efficacy after the first phase of the trial in terms of the dose of omega-3 FAs used and its purity, treatment duration, which may need to be longer, and sample size, in what some might say is not a particularly representative group of IWE in the general population.

Low levels of serum magnesium [77], manganese and zinc [78] have been reported in epileptic patients and supplementation has been reported to be sometimes helpful with seizure control.

Selenium is a widely used antioxidant supplement. Its use in epilepsy is based on findings of low selenium levels in the serum of some patients, and rare case reports suggesting potential clinical usefulness. Four children with intractable seizures since birth were found to have glutathione peroxidase deficiency, probably due to a primary deficiency in two and to defective selenium resorption or transport, as this enzyme has selenium at its active centre [79]. Supplementation with selenium and discontinuation of AEDs led to clinical improvement in all four.

The amino acid taurine has been extensively studied for its anticonvulsant properties. It appears to have only a moderate effect in general, but there are case reports of complete effectiveness in previously severe drug-resistant epilepsies [80].

Naturopathy

Naturopaths use a wide range of techniques in people with epilepsy, with the aim of allowing or stimulating the body to 'heal itself'. Any or all of the therapies discussed in this chapter can be brought to bear on the problem, but this is especially true for dietary, nutritional and homeopathic interventions [81].

Despite the wide range of evidence, there seems to be little current general enthusiasm for utilizing or researching these non-pharmacological, dietary methods of seizure control. Particularly in paediatric epilepsy, however, some of these approaches might bring worthwhile benefit.

Homeopathy

Homoeopathy is a complementary medical system which uses preparations of substances whose effects when administered to healthy subjects produce the manifestations of the disorder seen in the individual patient, so in many ways it looks for analogies between an individual patient and a substance from the natural world. It was developed by Samuel Hahnemann (1755–1843) and is now practised throughout the world [82]. This 'let like heal like' method of prescribing and the use of extremely diluted substances are the most contentious aspects of homeopathy. Large-scale meta-analyses of randomized controlled clinical trials of homeopathy [83–85], provide some evidence of activity over placebo in a wide range of conditions, even though the strength of the evidence is probably low because of the poor methodological quality of the trials. Evidence for activity of homeopathy is considered in detail elsewhere [86,87].

There are five homoeopathic hospitals within the NHS in the UK. There are no clinical trials of homoeopathy as add-on treatment in epilepsy, but there are uncontrolled case series which report improvements in seizure control [88,89]. For example, there is a case report of complete effectiveness of homeopathy in abolishing absence seizures with normalization of the EEG in a 6-year-old girl [90]. The homeopathic approach

lends itself to management of complex cases with extensive psychosocial overlay, although effectiveness in dogs may help those who feel that any effect of homeopathy must be due completely to a strong placebo response towards accepting that there is an action of remedies on the body. Ten dogs with idiopathic epilepsy (one to five tonic–clonic fits per week) were given homeopathic Belladonna 200C and no AEDs [91]. The number of fits reduced to two to three per week during the first 2 weeks after starting therapy and then no fit was reported by the owners in the next 2–8 months. Unfortunately, this is an uncontrolled study, but it helps to begin to generate ideas for future trials.

An individualized prescription is usually made, so that it is not possible to exactly list homeopathic drugs for epilepsy, as each patient will have a different prescription (of one of approximately 2500 available remedies). Experience from the Department of Developmental Neurology, Hospital for Sick Children, Glasgow, suggests that previously uncontrolled epileptic children, with seizures arising from congenital defects, birth injury, infections or other usually intractable causes, can gain improvement at the hands of a skilled homeopathic doctor [92].

Acupuncture

In its oldest form, acupuncture is a part of TCM. In traditional Chinese physiology, energy ('Qi') runs in meridians which are said to course just below the surface of the skin over the whole body. TCM encompasses an enormous range of practices including Chinese herbal medicine, Chinese acupressure and massage, dietary therapy and mind–body exercise such as Qigong and t'ai chi. It is a major established health-care system used by millions of people throughout the world for every medical condition. In TCM acupuncture, the insertion of very fine needles into the meridians at predefined points is held to re-balance blocked or excessive energy flow and so cure symptoms. It has been used for thousands of years as part of TCM treatment of epilepsy [93]. It is complex to learn this sort of approach, and Western scientists have seen the theoretical structure as off-putting.

Good results in long-term reduction of seizures [94,95] and even status epilepticus [96] have been reported, but nearly always in uncontrolled fashion or in retrospective case series. Different forms of acupuncture have been employed, but a lot of the work has been done using electro-acupuncture (i.e. stimulation of the needles by electric impulses or stimulation of the acupuncture points by surface electrodes). One study [95] reports on 98 cases of drug-resistant epilepsy treated with courses of scalp electro-acupuncture, 30 min of electrical stimulation at 2–3.5 Hz through needles placed under the scalp, given daily for 15 days and repeated with a week's break between courses. In this uncontrolled study, 89% of patients experienced a worthwhile reduction in seizure frequency and severity after a mean follow-up of 4 years.

The anticonvulsant action of acupuncture has been demonstrated in animal models and its mechanism investigated. It has been hypothesized that electroacupuncture may act as an antiepileptic via the same possible route as vagus nerve stimulation, through stimulation of the nucleus of the solitary tract [97]. Acupuncture can significantly change levels of some neurotransmitters responsible for inhibition of seizures at specific brain sites [98].

In contrast to the vast Chinese experience, many Western practitioners learn a form of acupuncture which makes fewer therapeutic claims. This 'medical acupuncture' assumes that one day it will be possible to explain all the undoubted clinical effects of acupuncture scientifically. So far, it has been most used and studied in painful conditions with good evidence of efficacy [99]. It is now a widely used therapeutic modality in, for example, physiotherapy departments and pain clinics.

It has been much more difficult to demonstrate the claimed efficacy of TCM acupuncture in systemic illness according to conventionally acceptable scientific methodology. A Cochrane review of acupuncture and epilepsy could find only three trials which met the entry criteria of acupuncture being used against a control condition, despite having no language limitation [100]. The trials were generally small and of poor quality and the review concluded that there is currently no good evidence for the effectiveness of acupuncture in epilepsy. One study, by Kloster *et al.* [101], aimed to show the effectiveness of TCM acupuncture in chronic intractable epilepsy in Norway. The authors recruited 39 patients with partial or generalized epilepsy with a duration of at least 2 years and a seizure frequency of one or more per week. Five withdrew in the 8-week baseline period. For the 8-week treatment period, they were divided into two groups by four-block randomization. One group ($n = 18$) received acupuncture and the second group ($n = 16$) acted as controls. The patients in the acupuncture group were all needled in a standard set of acupuncture points, with the possibility of one or more extra points being treated, chosen according to their TCM diagnosis. Stimulation was applied either manually or electrically (3 Hz, 3–20 mA), and all TCM diagnoses were made and the acupuncture treatments were given by two professors from the Shanghai University of TCM. The control group were given 'sham' acupuncture, that is standardized, bilateral, shallow needling of three points chosen for their minimum expected effect. Treatment time in both groups was 30 min and there were three treatment sessions per week for 7.5 weeks, with a 4-day break in the middle. Assessment of outcome was done weekly by neurologists, blind to the allocation of the subjects.

The groups were comparable in baseline characteristics, although it is a strange omission that details on use of AEDs were not reported. There was a non-significant reduction in seizure frequency in both groups, and an increase in the number of seizure-free weeks, which reached significance in the 'sham' group. There were no EEG changes of significance throughout the study and no factors could be identified which correlated with response to treatment, including age, age at onset of epilepsy, duration of epilepsy, educational level, IQ or TCM diagnosis. A subsequent paper documents the inability to detect an effect of acupuncture on health-related quality of life within this study [102]. The authors concluded that they had been unable to prove a beneficial effect of acupuncture in chronic epilepsy. The trial is certainly the study that conforms closest to the conventional norms of scientific investigation and will no doubt be taken as

convincing evidence against the use of acupuncture, but it can be criticized. The lack of information on baseline AEDs is potentially important, as the two groups could have been imbalanced by this, which is presumably at least as important a factor in 'severity' as frequency of seizures. Moreover, the study was small and the patients had a mean duration of epilepsy of 26–28 years so that the findings may not be representative for more benign epilepsies. Another important problem is the control used. The question of just what is the most appropriate control condition in acupuncture research has been much discussed. Generally, it is accepted that sham acupuncture cannot be considered a placebo, as it has measurable physiological and clinical effects [103]. If the control condition has a positive clinical effect and if the specific effect size of the active intervention is not large, then very large groups would be needed to detect a significant difference between groups. It would therefore be overhasty to conclude that acupuncture does not 'work' in epilepsy, and more research in this area is justified.

Transcranial magnetic stimulation

Transcranial magnetic stimulation (TMS) has been used as a non-invasive way of evaluating, from a neurophysiological point of view, the excitatory and inhibitory functions of the cerebral cortex. It is beginning to be thought of and investigated as a possible non-pharmacological method of treating epilepsy. An excellent review of the field is provided by Tassinari *et al.* [104], but it is notable how little is said about therapeutic use in the review.

One brief report [105] describes an open pilot study in which nine patients with refractory, very frequent partial and secondary generalized seizures were treated with low-frequency, repetitive transcranial magnetic stimulation (rTMS). The subjects had experienced, on average, more than seven seizures per week in the 6 months before the study. rTMS was done on five consecutive days, using a coil placed over the vertex. Five hundred pulses at 0.33 Hz were delivered twice each study day. In the 4 weeks after the study, seizure frequency was reduced from a mean of 10.3/week in the 4 weeks prior to the study, to a mean of 5.8/week. The mean reduction in seizures per week was 36.6% (P = 0.017).

A blinded trial randomized 24 patients with localization-related uncontrolled partial and secondary generalized seizures to active or placebo rTMS stimulation at 1 Hz, delivered for 15 min twice daily for a week [106]. Stimulation was given over the scalp position best representing the ictal focus (determined by EEG). The placebo control patients underwent the same procedure, but the magnetic coil was angled 90 degrees away from the scalp. Weekly seizure frequency was compared for 8 weeks before and after 1 week of rTMS. The effect on seizure frequency was mild and short-lived in the active group compared with the placebo group. The authors try to explain this lack of apparent effect by citing the difference in stimulation frequency to the previous open trial (1 Hz versus 0.33 Hz), only giving 1 week of treatment, which may not be long enough to lead to more than a temporary reduction in seizure frequency, and the likelihood that this study may be too small to show an effect.

Further studies are needed, but rTMS may result in being a non-invasive option to add to AEDs in the control of intractable epilepsy.

Chiropractic treatment

Chiropractic therapy is a form of manipulation of the joints, particularly those of the vertebral column. As originally formulated by Daniel David Palmer, all illness stems from entrapment of spinal nerves by subluxations of the vertebrae and so all illness can be removed by manipulating these vertebral subluxations back into proper alignment. This rather rough view has been gradually replaced with a sophisticated diagnostic system and a steadily growing research base, which largely supports the use of chiropractic treatment in many areas, most (but not all) of which are related to the musculoskeletal system [107,108].

The effects of chiropractic care on the progress of epilepsy in adults remain largely unreported, but Pistolese [108] reviews 17 case reports of children with epilepsy who received chiropractic treatment. Fourteen of these were receiving AEDs that had not been successful in controlling their seizures. 'Upper cervical care to correct vertebral subluxation' was administered to 15 patients, all of whom reported positive outcomes in terms of decreased seizure activity. The critical predictor of a favourable outcome seemed to be the finding of a cervical spine malalignment in chiropractic terms. This is undoubtedly a more subtle phenomenon than most non-chiropractor clinicians are accustomed to detecting. The analysis goes no further than this and the author suggests that further investigations into the potential value of chiropractic care in paediatric epilepsy would be justified. Some of the cases detailed are truly impressive. For example, a 6-year-old girl experiencing 20–25 absence seizures per day had 'upper cervical specific adjustments to correct the atlas subluxation complex', weekly for an (unfortunately) unspecified number of weeks. There was an immediate reduction in attack frequency after the first treatment and by the end of the treatment course she was experiencing one attack per week or fewer.

Alcantara [109] reports on a 21-year-old woman who had epilepsy since childhood and now suffered a generalized tonic–clonic seizure every 3 h, lasting between 10 s and 30 min. Examination revealed very extensive abnormalities (in a chiropractic sense) in the cervical spine, and specific adjustments were administered. The seizure rate dropped to one per day by the fifth treatment session, when the treatment technique was changed. A marked increase in seizure rate followed and in fact she had a seizure during the sixth session. Rapid chiropractic adjustment at the C6–C7 level aborted the seizure immediately. Subsequent examinations showed no evidence of recurrence of the subluxation complex and all seizure activity had ceased. At 12- and 18-month follow-up, she reported minor seizures of short duration about once per month, but had experienced up to 2 months seizure free. Interestingly, in this case, the subject realized that many of her seizures were preceded by neck pain. This is the only report of successful acute treatment of an epileptic seizure by chiropractic manipulation. The authors discuss models of how upper spine malalignment might lower seizure threshold, invoking concepts of seizure triggering by sensory input to the brain

and aberrant sensory impulses from a disordered cervical spine. Again, they call for more research.

These case reports are well written and document apparent beneficial effects of chiropractic care in some patients with epilepsy at least as clearly as many case reports for the psychological treatments mentioned earlier. There are a number of controlled studies demonstrating specific effects of chiropractic care in different clinical conditions against a variety of inventive placebo conditions [110]. Controlled trials may be justified in those patients with epilepsy who have cervical spine disorders demonstrable by chiropractic techniques.

Conclusions

Most of the studies and case reports discussed in this chapter are based on uncontrolled observations, and therefore claims of therapeutic success should be interpreted with caution. In randomized trials, many patients with epilepsy may respond well to placebo, which may be explained by emotional influences on seizure activity and also by the phenomenon of the regression to the mean (i.e. the tendency of patients to seek medical attention during periods of seizure exacerbation, which tend to be naturally followed by a spontaneous decline of seizure frequency towards its average value). While these limitations should be kept in mind, the evidence discussed in this chapter does suggest that some of the non-pharmacological approaches reviewed above may have worthwhile efficacy, and high-quality research should be supported in the more suggestive areas. In particular, there appears to have been a peculiar blindness to the benefits which can be obtained from behavioural techniques such as EEG biofeedback and dietary measures such as oligo-antigenic diets. The patients are already using many of these treatments, sometimes without divulging this fact to their medical attendants, with all that implies. An effective way to select patients and advise them about particular treatments should be the aim.

Love it or loathe it, patients with epilepsy will continue along their pragmatic therapeutic paths. It would be of benefit to all if their caregivers could, if not walk with them, guide them safely.
